NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The author and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the author nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Preface

As the rest of medicine changes, so does neurology. Neurologic diagnosis and treatment has been so vastly altered by modern neuroimaging, molecular biology, and genetics that the original authors of this book, Raymond D Adams and Maurice Victor, would barely recognize the practices of today. Secular interest in neurologic diseases is also expanding because of the large number of problems of the brain, spinal cord, nerves, and muscles that arise with aging and from the treatment and control of other, non-neurologic, diseases. Whereas cancer and heart disease had occupied foremost positions in the minds of individuals within developed societies, Alzheimer, Parkinson, and related diseases are central to the modern conversation about the quality of life. Moreover, the desire to understand the workings of the brain and to gain insights into human behavior has become a preoccupation of the public. At the same time, the manner in which information, both accurate and otherwise, is transmitted about the nervous system and neurologic diseases has changed. Access to information about diseases, accepted treatments, and clinical symptoms and signs, ubiquitously clutters the Internet. Physicians now less frequently seek a comprehensive understanding of a disease or class of diseases, “the whole story” if you will, but instead favor rapid access to single answers to a clinical problem.

For many reasons, particularly the last of these regarding the nature of medical information, writing a textbook on neurology has become a complex enterprise. We have even asked ourselves if there is a role for a textbook in the modern era, especially one written by only three authors. Yet, in identifying the characteristics of the capable clinician, one who is equipped to help patients and play a role in society to the fullest extent possible, we continuously return to the need for careful clinical analysis that is combined with a deep knowledge of disease. These are still the basis for high-quality practice and teaching. Even if the current goals of efficiency and economy in medicine are to be met, neurology is so complex that the confident implementation of a plan of diagnostic or therapeutic action quickly finds itself beyond algorithms, flow charts, and guidelines. The goal of our textbook therefore is to provide neurologic knowledge in an assembled way that transcends facts and information and to present this knowledge in a context that cannot be attained by disembodied details. While the biological bases of neurologic diseases are being discovered rapidly, the major contribution of the clinical neurologist remains, as it is for the whole of medicine: a synthesis of knowing how to listen to the patient, where to find the salient neurologic signs, and what to acquire from laboratory tests and imaging.

There is always a risk of such a book being simply archival. But the dynamic nature of modern neurology

requires more than ever a type of integration among knowledge of clinical neurosciences, traditional neurology, and the expanding scientific literature on disease mechanisms. Only a text that has been thoughtfully constructed for the educated neurologist can fulfill this need and we hope that we have done so in this edition. Furthermore, in appropriate conformity to the methods by which physicians obtain information, McGraw-Hill has made an investment in their Access Medicine website that will highlight our book as well as several other neurology texts. Combined with these books will be sophisticated search functions, teaching curricula for students and residents, and, hopefully in the future, a form of interaction with us, the authors. Another inception has been the addition of color figures and photographs to this edition in order to make the visual material more accessible and appropriate for the web version.

To these ends, we offer the current 10th edition of *Principles of Neurology* to meet the needs of the seasoned as well as the aspiring neurologist, neurosurgeon, internist, psychiatrist, pediatrician, emergency physician, physiatrist, and all clinicians who have need of a comprehensive discussion on neurologic problems. We begin with an explanation of the functioning of the nervous system as it pertains to neurologic disease in the first part of the book, followed by detailed descriptions of the clinical aspects of neurology in its great diversity. In all matters, we have put the patient and relief of suffering from neurologic disease in a central place. The book is meant to be practical without being prescriptive and readable without being too exhaustive. When there is a digression, it has been purposely structured to complete a picture of a particular disease. We have also retained historical aspects of many diseases that are central to the understanding of the specialty and its place in medicine.

By taking an inclusive and yet sensibly chosen clinical approach, we do not eschew or criticize the modern movement to homogenize medicine in order to attain uniformity of practice. We ourselves have witnessed over 35 years the unappealing aspects of idiosyncratic practices, which were based on limited basic information and on a superficial understanding of neurology. Nonetheless, the complexity of neurologic diseases, especially now, puts the practitioner in a position of choosing among many options for diagnosis and treatment that are equivalent, or for which the results are uncertain. Clinical trials abound in neurology and set a direction for clinical practice in large populations, but are difficult to apply to individual patients. The need for a coherent method of clinical work is one reason we have retained authorship rather than editorial management that characterizes many textbooks in other areas of medicine. Limited authorship permits a uniform style of writing and level of exposition across subject matter and chapter headings.

It also allows us to judiciously include our own experiences and opinions when we feel there is something more to say than is evident in published articles. Our comments should be taken as advisory and we have no doubt that our colleagues in practice will develop their own views based on the body of information provided in the book and what is available from many outside sources. To the extent that some of the views we express in the book may be perceived as having a “Boston-centric” outlook, we appeal to the reader’s forbearance. We have neither a proprietary formula for success in neurology nor the answers to many of the big clinical questions. If there is a stylistic aspect that comes through in the book, we hope it is still that neurology must be taken one patient at a time.

We gratefully acknowledge on the following pages several experts in particular fields of neurology whose help was invaluable in revising this edition. We sought their guidance because of the high regard we have for

their clinical skills and experience. If there are concerns regarding specific comments in the book, they are our responsibility.

With this edition, we introduce our colleague Joshua P. Klein, MD, PhD, the chief of the Division of Hospital Neurology in the Department of Neurology at Brigham and Women’s Hospital. Dr. Klein is dually trained in neurology and neuroradiology. He brings a wealth of perspective on imaging and has been a powerful partner in moving the book toward a more modern idiom that recognizes the centrality of neuroimaging in practice. It is a privilege to have him join us to bring the book through the beginning of the current century.

Martin A. Samuels, MD
Joshua P. Klein, MD, PhD

Acknowledgments

The authors gratefully acknowledge the colleagues listed below who gave considerably of their time to assist us with sections of the book. Any oversights in the content of the book are our responsibility. Updating this 10th edition of *Principles of Neurology* would not have been possible without these expert physicians and we extend to them our sincere thanks.

PART

1

THE CLINICAL METHOD OF
NEUROLOGY

This page intentionally left blank

Approach to the Patient with Neurologic Disease

Neurology is regarded by many as one of the most difficult and exacting medical specialties. Students and residents who come to a neurology service for the first time may be intimidated by the complexity of the nervous system through their brief contact with neuroanatomy, neurophysiology, and neuropathology. The ritual they then witness of putting the patient through a series of maneuvers designed to evoke certain mysterious signs is hardly reassuring. In fact, the examination appears to conceal the intellectual processes by which neurologic diagnosis is made. Moreover, the students have had little or no experience with the many special tests used in neurologic diagnosis—such as lumbar puncture, EMG (electromyography), EEG (electroencephalography), CT (computed tomography), MRI (magnetic resonance imaging), and other imaging procedures—nor do they know how to interpret the results of such tests. Neurology textbooks only confirm their fears as they read the detailed accounts of the many unusual diseases of the nervous system.

The authors believe that many of the difficulties in comprehending neurology can be overcome by adhering to the basic principles of the clinical method. Even the experienced neurologist faced with a complex clinical problem depends on this basic approach.

The importance of the clinical method stands out more clearly in the study of neurologic disease than in certain other fields of medicine. In most cases, it consists of an orderly series of steps:

1. The symptoms and signs are secured with as much confidence as possible by history and physical examination.
2. The symptoms and physical signs considered relevant to the problem at hand are interpreted in terms of physiology and anatomy—i.e., one identifies the disorder(s) of function and the anatomic structure(s) that are implicated.
3. These analyses permit the physician to localize the disease process, i.e., to name the part or parts of the nervous system involved. This is the *anatomic*, or *topographic* diagnosis, which often allows the recognition of a characteristic clustering of symptoms and signs, constituting a syndrome. This step is called *syndromic diagnosis* and is sometimes conducted in parallel with anatomic diagnosis.
4. Expert diagnosticians often make successively more accurate estimates of the likely diagnosis, utilizing pieces of the history and findings on the examination to either further refine or exclude specific diseases. Flexibility of thought must be practiced so as to avoid the common pitfall of retaining an initially incorrect impression and selectively ignoring data that would bring it into question. It is perhaps not surprising that the method of successive estimations works well in that evidence from neuroscience reveals that this is the mechanism that the nervous system uses to process information.
5. From the anatomic or syndromic diagnosis and other specific medical data—particularly the mode of onset and speed of evolution of the illness, the involvement of nonneurologic organ systems, the relevant past and family medical histories, and the laboratory findings—one deduces the *pathologic diagnosis* and, when the mechanism and causation of the disease can be determined, the *etiologic diagnosis*. This may include the rapidly increasing number of molecular and genetic etiologies if they have been determined for a particular disorder.
6. Finally, the physician should assess the degree of disability and determine whether it is temporary or permanent (*functional diagnosis*); this is important in managing the patient's illness and judging the potential for restoration of function.

In recent decades, many of these steps have been eclipsed by imaging methods that allow precise localization of a lesion and furthermore often characterize the etiology of disease. Many of the elaborate parts of the examination that were intended to localize lesions are no longer necessary in daily clinical work. Nonetheless, insufficient appreciation of the history and examination and the resulting overdependence on imaging leads to diagnostic errors and has other detrimental consequences. A clinical approach is usually more efficient and far more economical than is resorting to scans. The loss of the personal impact by the physician that is created by listening to a story and observing responses to various maneuvers is regrettable. Images are also replete with spurious or unrelated findings, which elicit unnecessary further testing and needless worry on the part of the patient.

All of these steps are undertaken in the service of effective treatment, an ever-increasing prospect in neurology. As is emphasized repeatedly in later chapters, there is always a premium in the diagnostic process on the discovery of treatable diseases. Even when specific treatment is not available, accurate diagnosis may in its own right function as a therapy, as uncertainty about the cause of a neurologic illness may be more troubling to the patient than the disease itself.

Of course, the solution to a clinical problem need not always be schematized in this way. The clinical method offers a much wider choice in the order and manner by which information is collected and interpreted. In fact, in some cases, adherence to a formal scheme is not necessary at all. In relation to syndromic diagnosis, the clinical picture of Parkinson disease, for example, is usually so characteristic that the nature of the illness is at once apparent. In other cases it is not necessary to carry the clinical analysis beyond the stage of the anatomic diagnosis, which, in itself, may virtually indicate the cause of a disease. For example, when vertigo, cerebellar ataxia, unilateral Horner syndrome, paralysis of a vocal cord, and analgesia of the face occur with acute onset, the cause is an occlusion of the vertebral artery, because all the involved structures lie in the lateral medulla, within the territory of this artery. Thus, the anatomic diagnosis determines and limits the etiologic possibilities. If the signs point to disease of the peripheral nerves, it is usually not necessary to consider the causes of disease of the spinal cord. Some signs themselves are almost specific—e.g., opsoclonus for paraneoplastic cerebellar degeneration and Argyll Robertson pupils for neurosyphilitic or diabetic oculomotor neuropathy. Nonetheless, one is cautious in calling any single sign pathognomonic as exceptions are found regularly.

Ascertaining the cause of a clinical syndrome (etiologic diagnosis) requires knowledge of an entirely different order. Here one must be conversant with the clinical details, including the speed of onset, course, laboratory and imaging characteristics, and natural history of a multiplicity of diseases. Many of these facts are well known and form the substance of later chapters. When confronted with a constellation of clinical features that do not lend themselves to a simple or sequential analysis, one resorts to considering the broad classical division of diseases in all branches of medicine, as summarized in Table 1-1.

Table 1-1

THE MAJOR CATEGORIES OF NEUROLOGIC DISEASE

Infectious
Genetic-congenital
Traumatic
Degenerative
Vascular
Toxic
Metabolic
Inherited
Acquired
Neoplastic
Inflammatory-immune
Psychogenic
Iatrogenic

Irrespective of the intellectual process that one utilizes in solving a particular clinical problem, the fundamental steps in diagnosis always involve the accurate elicitation of symptoms and signs and their correct interpretation in terms of disordered function of the nervous system. Most often when there is uncertainty or disagreement as to diagnosis, it is found later that the symptoms or signs were incorrectly interpreted in the first place. Thus, if a complaint of dizziness is identified as vertigo instead of light-headedness or if partial continuous epilepsy is mistaken for a tremor or choreoathetosis, then the clinical method is derailed from the beginning. Repeated examinations may be necessary to establish the fundamental clinical findings beyond doubt. Hence the aphorism: A second examination is the most helpful diagnostic test in a difficult neurologic case.

PREVALENCE AND INCIDENCE OF NEUROLOGIC DISEASE

To offer the physician the broadest perspective on the relative frequency of neurologic diseases, estimates of their approximate prevalence in the United States, taken from several sources, including the NIH, are given in Table 1-2. Donaghy and colleagues have provided a similar but more extensive listing of the incidence of various neurologic diseases that are likely to be seen by a general physician practicing in the United Kingdom. They note stroke as far and away the most commonly

Table 1-2

RELATIVE PREVALENCE OF THE MAJOR NEUROLOGIC DISORDERS IN THE UNITED STATES

INDIVIDUALS AFFECTED	
<i>Degenerative diseases</i>	
Amyotrophic lateral sclerosis	5 × 10 ⁴
Huntington disease	5 × 10 ⁴
Parkinson disease	5 × 10 ⁶
Alzheimer disease	5 × 10 ⁶
Macular degeneration	5 × 10 ⁷
<i>Autoimmune neurologic diseases</i>	
Multiple sclerosis	4 × 10 ⁵
<i>Stroke, all types</i>	5 × 10 ⁶
<i>Central nervous system trauma</i>	
Head	2 × 10 ⁶
Spinal cord	2.5 × 10 ⁵
<i>Metabolic</i>	
Diabetic retinopathy	2 × 10 ⁶
<i>Headache</i>	3 × 10 ⁷
<i>Epilepsy</i>	3 × 10 ⁶
<i>Back pain</i>	5 × 10 ⁷
<i>Peripheral neuropathy</i>	
Total	2.5 × 10 ⁷
Inherited	1 × 10 ⁴
Diabetic neuropathy	2 × 10 ⁶
<i>Mental retardation</i>	
Severe	1 × 10 ⁶
Moderate	1 × 10 ⁷
<i>Schizophrenia</i>	3 × 10 ⁶
<i>Manic depressive illness</i>	3 × 10 ⁶

Table 1-3

APPROXIMATE ORDER OF INCIDENCE AND PREVALENCE OF NEUROLOGIC CONDITIONS IN A GENERAL PRACTICE IN THE UNITED KINGDOM

INCIDENCE IN GENERAL PRACTICE	PREVALENCE IN THE COMMUNITY
Stroke (all types)	Migraine
Carpal tunnel syndrome	Chronic tension headache
Epilepsy	Stroke
Bell's palsy	Alzheimer disease
Essential tremor	Epilepsy
Parkinson disease	Essential tremor
Brain tumor	Multiple sclerosis
Multiple sclerosis	Chronic fatigue syndrome
Giant cell arteritis	Parkinson disease
Migraine	Unexplained motor symptoms
Unexplained motor symptoms	Neurofibromatosis
Trigeminal neuralgia	Myasthenia gravis

Source: Adapted from Donaghy and colleagues: *Brain's Diseases of the Nervous System*.

encountered condition; those that follow in frequency are listed in Table 1-3. More focused surveys, such as the one conducted by Hirtz and colleagues, give similar rates of prevalence, with migraine, epilepsy, and multiple sclerosis being the most common neurologic disease in the general population (121, 7.1, and 0.9 per 1,000 persons in a year); stroke, traumatic brain injury, and spinal injury occurring in 183, 101, and 4.5 per 100,000 per year; and Alzheimer disease, Parkinson disease, and amyotrophic lateral sclerosis (ALS) among older individuals at rates of 67, 9.5, and 1.6 per 100,000 yearly. Data such as these assist in guiding societal resources to the cure of various conditions, but they are somewhat less helpful in leading the physician to the correct diagnosis except insofar as they emphasize the oft-stated dictum that “common conditions occur commonly” and therefore should be considered a priori to be more likely diagnoses (see further discussion under “Shortcomings of the Clinical Method”).

TAKING THE HISTORY

In neurology, perhaps more than any other specialty, the physician is dependent upon the cooperation of the patient for a reliable history, especially for a description of those symptoms that are unaccompanied by observable signs of disease. If the symptoms are in the sensory sphere, only the patient can tell what he sees, hears, or feels. The first step in the clinical encounter is to enlist the patient's trust and cooperation and make him realize the importance of the history and examination procedure.

The practice of making notes at the bedside or in the office is recommended. Of course, no matter how reliable the history appears to be, verification of the patient's account by a knowledgeable and objective informant is always desirable.

The following points about taking the neurologic history deserve further comment:

1. Special care must be taken to avoid suggesting to the patient the symptoms that one seeks. Errors and inconsistencies in the recorded history are as often the fault of the physician as of the patient. The patient should be discouraged from framing his symptom(s) in terms of a diagnosis that he may have heard; rather, he should be urged to give a description of the symptom—being asked, for example, to choose a word that best describes his pain and to describe precisely what he means by a particular term such as dizziness, imbalance, or vertigo. The patient who is given to highly circumstantial and rambling accounts can be kept on the subject of his illness by directive questions that draw out essential points.
2. The setting in which the illness occurred, its mode of onset and evolution, and its course are of paramount importance. One must attempt to learn precisely how each symptom began and progressed. Often the nature of the disease process can be decided from these data alone, such as in stroke. If such information cannot be supplied by the patient or his family, it may be necessary to judge the course of the illness by what the patient was able to do at different times (e.g., how far he could walk, when he could no longer negotiate stairs or carry on his usual work) or by changes in the clinical findings between successive examinations.
3. In general, one tends to be careless in estimating the mental capacities of patients. Attempts are sometimes made to take histories from patients who are cognitively impaired or so confused that they have no idea why they are in a doctor's office or a hospital. Asking the patient to give his own interpretation of the possible meaning of symptoms may sometimes expose unnatural concern, anxiety, suspiciousness, or even delusional thinking. Young physicians and students also have a natural tendency to “normalize” the patient, often collaborating with a hopeful family in the misperception that no real problem exists. This attempt at sympathy does not serve the patient and may delay the diagnosis of a potentially treatable disease.

THE NEUROLOGIC EXAMINATION

The neurologic examination begins with observations of the patient while the history is being obtained. The manner in which the patient tells the story of his illness may betray confusion or incoherence in thinking, impairment of memory or judgment, or difficulty in comprehending or expressing ideas. A common error is to pass lightly over inconsistencies in history and inaccuracies about dates and symptoms, only to discover later that these flaws in memory were the essential features of the illness. A more extensive examination of attention, memory,

cognitive ability, and language is undertaken if the history or the manner in which it is given indicates the problem lies in those spheres. Otherwise, asking the date and place, repeating words, and simple arithmetic are adequate screening procedures.

One then proceeds from an examination of the cranial nerves including the optic discs, neck, and trunk to the testing of motor, reflex, and sensory functions of the upper and lower limbs. This is followed by an assessment of the function of sphincters and the autonomic nervous system if appropriate and testing for meningeal irritation by examining the suppleness of the neck and spine. Gait and station (standing position) are observed before or after the rest of the examination.

When an abnormal finding is detected, whether cognitive, motor, or sensory, it becomes necessary to analyze the problem in a more elaborate fashion. Details of these sensitive examinations are addressed in appropriate chapters of the book (motor: Chaps. 3, 4, and 5; sensory: Chaps. 8 and 9; and cognitive and language disorders: Chaps. 22 and 23) and cursorily, below.

The neurologic examination is ideally performed and recorded in a relatively uniform manner in order to avoid omissions and facilitate the subsequent analysis of records. Some variation in the order of examination from physician to physician is understandable, but each examiner should establish a consistent pattern. Even when it is impractical to perform the examination in the customary way, as in patients who are unable to cooperate because of age or cognitive deficiency, it is good practice to record the findings in an accustomed and sequential fashion. If certain portions are not performed, this omission should be stated so that those reading the description at a later time are not left wondering whether an abnormality was not previously detected. Some aspects of the complete examination that were performed routinely by neurologists in former years are now infrequently included because they provide limited or duplicative information—among these are tests of olfaction and superficial reflexes but each finding may have a place in special circumstances or to corroborate another sign.

The thoroughness of the neurologic examination must also be governed by the type of clinical problem presented by the patient. To spend a half hour or more testing cerebral, cerebellar, cranial nerve, and sensorimotor function in a patient seeking treatment for a simple compression palsy of an ulnar nerve is pointless and uneconomical. The examination must also be modified according to the condition of the patient. Obviously, many parts of the examination cannot be carried out in a comatose patient; also, infants and small children, as well as patients with psychiatric disease, must be examined in special ways.

Portions of the general physical examination that may be particularly informative in the patient with neurologic disease should be included. For example, examination of the heart rate and blood pressure, as well as carotid and cardiac auscultation, are essential in a patient with stroke. Likewise, the skin can reveal a number of conditions that pertain to congenital, metabolic, and infectious causes of neurologic disease.

EXAMINING PATIENTS WHO PRESENT WITH NEUROLOGIC SYMPTOMS

Numerous guides to the examination of the nervous system are available (see the references at the end of this chapter). For a full account of these methods, the reader is referred to several of the monographs on the subject, including those of Bickerstaff and Spillane, Campbell (DeJong's Neurological Examination), and of the staff members of the Mayo Clinic, each of which approaches the subject from a somewhat different point of view. An inordinately large number of tests of neurologic function have been devised, and it is not proposed to review all of them here. Some are described in subsequent chapters dealing with disorders of mentation, cranial nerves, and motor, sensory, and autonomic functions. Many tests are of doubtful value or are repetitions of simpler tests and thus should not be taught to students of neurology. Merely to perform all of them on one patient would require several hours and, in most instances, would not make the examiner any the wiser. The danger with all clinical tests is to regard them as indicators of a particular disease rather than as ways of uncovering disordered functioning of the nervous system. The following approaches are relatively simple and provide the most useful information.

Testing of Higher Cortical Functions

These functions are tested in detail if the patient's history or behavior has provided a reason to suspect some defect. Broadly speaking, the mental status examination has two main components, although the separation is somewhat artificial: the psychiatric aspects, which incorporate affect, mood, and normality of thought processes and content, and the cognitive aspects, which include the level of consciousness, awareness (attention), language, memory, visuospatial, and other executive abilities.

Questions are first directed toward determining the patient's orientation in time and place and insight into his current medical problem. Attention, speed of response, ability to give relevant answers to simple questions, and the capacity for sustained and coherent mental effort all lend themselves to straightforward observation. There are many useful bedside tests of attention, concentration, memory, and clarity of thinking including repetition of a series of digits in forward and reverse order, serial subtraction of 3s or 7s from 100, and recall of three items of information or a short story after an interval of 3 min. More detailed examination procedures appear in Chaps. 20, 21, 22, and 23. The patient's account of his recent illness, dates of hospitalization, and day-to-day recollection of recent incidents are excellent tests of memory; the narration of the illness and the patient's choice of words (vocabulary) and syntax provide information about language ability and coherence of thinking.

If there is any suggestion of a speech or language disorder, the nature of the patient's spontaneous speech should be noted. In addition, the accuracy of reading, writing, and spelling, executing spoken commands,

repeating words and phrases spoken by the examiner, naming objects and parts of objects, and solving simple logical problems should be assessed.

The ability to carry out commanded tasks (praxis) has great salience in the evaluation of several aspects of cortical function. Bisecting a line, drawing a clock or the floor plan of one's home or a map of one's country, and copying figures are useful tests of visuospatial perception and are indicated in cases of suspected cerebral disease. The testing of language, cognition, and other aspects of higher cerebral function are considered in Chaps. 21, 22, and 23.

Testing of Cranial Nerves

The function of the cranial nerves must be investigated more fully in patients who have neurologic symptoms than in those who do not. If one suspects a lesion in the anterior cranial fossa, the sense of smell should be tested in each nostril; then it should be determined whether odors can be discriminated. Visual fields can be outlined by confrontation testing, ideally by testing each eye separately. If an abnormality is suspected, it should be checked on a perimeter and scotomas sought on the tangent screen or, more accurately, by computerized perimetry. Pupil size and reactivity to light, direct, consensual, and during convergence, the position of the eyelids, and the range of ocular movements should next be observed. Details of these tests and their interpretations are given in Chaps. 12, 13, and 14.

Sensation over the face is tested with a pin and wisp of cotton. Also, the presence or absence of the corneal reflex, direct and consensually, may be determined.

Facial movements should be observed as the patient speaks and smiles, for a slight weakness may be more evident in these circumstances than on movements to command.

The auditory meati and tympanic membranes should be inspected with an otoscope. A high-frequency (512 Hz) tuning fork held next to the ear and on the mastoid discloses hearing loss and distinguishes middle-ear (conductive) from neural deafness. Audiograms and other special tests of auditory and vestibular function are needed if there is any suspicion of disease of the vestibulocochlear nerve or of the cochlear and labyrinthine end organs (see Chap. 15). The vocal cords must be inspected with special instruments in cases of suspected medullary or vagus nerve disease, especially when there is hoarseness. Voluntary pharyngeal elevation and elicited reflexes are meaningful if there is an asymmetrical response; bilateral absence of the gag reflex is seldom significant. Inspection of the tongue, both protruded and at rest, is helpful; atrophy and fasciculations may be seen and weakness detected. Slight deviation of the protruded tongue as a solitary finding can usually be disregarded, but a major deviation represents under action of the hypoglossal nerve and muscle on that side. The pronunciation of words should be noted. The jaw jerk and the snout, buccal, and sucking reflexes should be sought, particularly if there is a question of dysphagia, dysarthria, or dysphonia.

Testing of Motor Function

In the assessment of motor function, the most informative aspects are observations of the speed and strength of movements and of muscle bulk, tone, and coordination and these are considered in the context of the state of tendon reflexes. The maintenance of the supinated arms against gravity is a useful test; the weak arm, tiring first, soon begins to sag, or, in the case of a corticospinal lesion, to resume the more natural pronated position ("pronator drift"). The strength of the legs can be similarly tested with the patient prone and the knees flexed and observing downward drift of the weakened leg. In the supine position at rest, weakness due to an upper motor neuron lesion causes external rotation of the hip.

It is essential to have the limbs exposed and to inspect them for atrophy and fasciculations. Abnormalities of movement and posture as well as tremors may be revealed by observing the limbs at rest and in motion (see Chaps. 4, 5, and 6). This is accomplished by watching the patient maintain the arms outstretched in the prone and supine positions; perform simple tasks, such as alternately touching his nose and the examiner's finger; make rapid alternating movements that necessitate sudden acceleration and deceleration and changes in direction, such as tapping one hand on the other while alternating pronation and supination of the forearm; rapidly touch the thumb to each fingertip; and accomplish simple tasks such as buttoning clothes, opening a safety pin, or handling common tools. Estimates of the strength of leg muscles with the patient in bed are often unreliable; there may seem to be little or no weakness even though the patient cannot arise from a chair or from a kneeling position without help. Running the heel down the front of the shin, alternately touching the examiner's finger with the toe and the opposite knee with the heel, and rhythmically tapping the heel on the shin are the only tests of coordination that need be carried out in bed.

Testing of Reflexes

Testing of the biceps, triceps, supinator-brachioradialis, patellar, Achilles, and cutaneous abdominal and plantar reflexes permits an adequate sampling of reflex activity of the spinal cord. Elicitation of muscle stretch (tendon) reflexes requires that the involved muscles be relaxed; underactive or barely elicitable reflexes can be facilitated by voluntary contraction of other muscles (Jendrassik maneuver).

The plantar response poses some difficulty because several different reactions besides the Babinski response can be evoked by stimulating the sole of the foot along its outer border from heel to toes. These are (1) the normal quick, high-level avoidance response that causes the foot and leg to withdraw; (2) the pathologic slower, spinal flexor nocifensive (protective) reflex (flexion of knee and hip and dorsiflexion of toes and foot, "triple flexion"); Dorsiflexion of the large toe and fanning of the other toes as part of the latter reflex is the well-known Babinski sign (see Chap. 3); (3) plantar grasp reflexes; and (4) support reactions in infants. Avoidance and withdrawal responses interfere with the interpretation of the Babinski sign and

can sometimes be overcome by utilizing one of several alternative stimuli (e.g., squeezing the calf or Achilles tendon, flicking the fourth toe, downward scraping of the shin, lifting the straight leg, and others) or by having the patient scrape his own sole. An absence of the superficial cutaneous reflexes of the abdominal, cremasteric, and other muscles are useful ancillary tests for detecting corticospinal lesions, particularly when unilateral.

Testing of Sensory Function

Because this part of the examination is attainable only through the subjective responses of the patient, it requires considerable patient cooperation. For the same reason, it is subject to overinterpretation and suggestibility. Usually, sensory testing is reserved for the end of the examination and, if the findings are to be reliable, should not be prolonged for more than a few minutes. Each test should be explained briefly; too much discussion with a meticulous, introspective patient encourages the reporting of meaningless minor variations of stimulus intensity.

It is not necessary to examine all areas of the skin surface. A quick survey of the face, neck, arms, trunk, and legs with a pin takes only a few seconds. Usually one is seeking differences between the two sides of the body (it is better to ask whether stimuli on opposite sides of the body feel the same than to ask if they feel different), a level below which sensation is lost, or a zone of relative or absolute analgesia (loss of pain sensibility) or anesthesia (loss of touch sensibility). Regions of sensory deficit can then be tested more carefully and mapped. Moving the stimulus from an area of diminished sensation into a normal area is recommended because it enhances the perception of a difference. The finding of a zone of heightened sensation ("hyperesthesia") calls attention to a disturbance of superficial sensation.

The sense of vibration may be tested by comparing the thresholds at which the patient and examiner lose perception at comparable bony prominences. We suggest recording the number of seconds for which the examiner appreciates vibration at the malleolus, toe, or finger after the patient reports that the fork has stopped buzzing.

Variations in sensory findings from one examination to another reflect differences in technique of examination as well as inconsistencies in the responses of the patient. Sensory testing is considered in greater detail in Chaps. 8 and 9.

Testing of Gait and Stance

The examination is completed by observing the patient arise from a chair, stand and walk. An abnormality of stance or gait may be the most prominent or only neurologic abnormality, as in certain cases of cerebellar or frontal lobe disorder; and an impairment of posture and highly automatic adaptive movements in walking may provide the most definite diagnostic clues in the early stages of diseases such as Parkinson disease. Having the patient walk tandem or on the sides of the soles may bring out a lack of balance or dystonic postures in the hands and trunk. Hopping or standing on one foot may

also betray a lack of balance or weakness. Standing with feet together and eyes closed will bring out disequilibrium due to sensory loss (Romberg test) that is usually attributable to a disorder of the large diameter sensory fibers in the nerves and posterior columns of the spinal cord. Disorders of gait are discussed in Chap. 7.

TESTING THE PATIENT WHO DOES NOT HAVE NEUROLOGIC SYMPTOMS (THE SCREENING NEUROLOGICAL EXAMINATION)

In this situation, brevity is desirable but any test that is undertaken should be done carefully and recorded. Accurate recording of negative data may be useful in relation to some future illness that requires examination. As indicated in Table 1-4, the patient's orientation, insight, judgment, and the integrity of language function are readily assessed in the course of taking the history. With respect to the cranial nerves, the size of the pupils and their reaction to light, ocular movements, visual and auditory acuity, and movements of the face, palate, and tongue should be tested. Observing the bare outstretched arms for atrophy, weakness ("pronator drift"), tremor, or abnormal movements; checking the strength of hand grip and dorsiflexion at the wrist; inquiring about sensory disturbances; and eliciting the biceps, brachioradialis, and triceps reflexes are usually sufficient for the upper limbs. Inspection of the legs while the feet, toes, knees, and hips are actively flexed and extended; elicitation of the patellar, Achilles, and plantar reflexes; testing of vibration and position sense in the fingers and toes; and assessment of coordination by having the patient alternately touch his nose and the examiner's finger and run his heel up and down the front of the opposite leg, and observation of walking complete the essential parts of the neurologic examination.

This entire procedure adds only a few minutes to the physical examination but the routine performance of these few simple tests provides clues to the presence of disease of which the patient is not aware. For example,

Table 1-4

BRIEF NEUROLOGIC EXAMINATION IN THE GENERAL MEDICAL OR SURGICAL PATIENT (PERFORMED IN 5 MIN OR LESS)

1. Orientation, insight into illness, language assessed during taking of the history
2. Size of pupils, reaction to light, visual and auditory acuity
3. Movement of eyes, face, tongue
4. Examination of the outstretched hands for atrophy, pronating or downward drift, tremor, power of grip, and wrist dorsiflexion
5. Biceps, supinator, and triceps tendon reflexes
6. Inspection of the legs during active flexion and extension of the hips, knees, and feet
7. Patellar, Achilles, and plantar reflexes
8. Vibration sensibility in the fingers and toes
9. Finger-to-nose and heel-to-shin testing of coordination
10. Gait

the finding of absent Achilles reflexes and diminished vibratory sense in the feet and legs alerts the physician to the possibility of diabetic or nutritional neuropathy, even when the patient does not report symptoms.

THE COMATOSE PATIENT

Although subject to obvious limitations, careful examination of the stuporous or comatose patient yields considerable information concerning the function of the nervous system. It is remarkable that, with the exception of cognitive function, almost all parts of the nervous system, including the cranial nerves, can be evaluated in the comatose patient. The demonstration of signs of focal cerebral or brainstem disease or of meningeal irritation is useful in the differential diagnosis of diseases that cause stupor and coma. The adaptation of the neurologic examination to the comatose patient is described in Chap. 17.

THE PSYCHIATRIC PATIENT

One is compelled in the examination of psychiatric patients to rely less on the cooperation of the patient and to be unusually critical of their statements and opinions. The depressed patient, for example, may perceive impaired memory or weakness when actually there is neither amnesia nor reduced power, or the sociopath or hysteric may feign paralysis. The opposite is as often true: Psychotic patients may make accurate observations of their symptoms, only to have them ignored because of their mental state. It is well to keep in mind that patients with even the most extreme psychiatric disease are subject to all of the neurologic conditions typical of others their age.

If the patient will speak and cooperate even to a slight degree, much may be learned about the functional integrity of different parts of the nervous system. By the manner in which the patient expresses ideas and responds to spoken or written requests, it is possible to determine whether there are hallucinations or delusions, defective memory, or other recognizable symptoms of brain disease merely by watching and listening to the patient. Ocular movements and visual fields can be tested with fair accuracy by observing the patient's response to a moving stimulus or threat in the visual fields. Cranial nerve, motor, and reflex functions are tested in the usual manner, but it must be remembered that the neurologic examination is never complete unless the patient will speak and cooperate in testing. On occasion, mute and resistive patients judged to be psychotic prove to have some widespread cerebral disease such as hypoxic or hypoglycemic encephalopathy, a brain tumor, a vascular lesion, or extensive demyelinating lesions.

INFANTS AND SMALL CHILDREN

The reader is referred to the special methods of examination described by Andr e-Thomas and colleagues, Volpe

and the staff members of the Mayo Clinic, which are listed in the references and described in Chap. 28. Many of these volumes address the developmental aspects of the child's nervous system, and although some signs may be difficult to obtain because of the age of the patient, they still stand as the best explications of the child's neurologic examination.

THE GENERAL MEDICAL EXAMINATION

The general medical examination often reveals evidence of an underlying systemic disease that has secondarily affected the nervous system. In fact, many of the most serious neurologic problems are of this type. Two common examples will suffice: adenopathy or a lung infiltrate implicates neoplasia or sarcoidosis as the cause of multiple cranial nerve palsies, and the presence of low-grade fever, anemia, a heart murmur, and splenomegaly in a patient with unexplained stroke points to a diagnosis of bacterial endocarditis with embolic occlusion of cerebral arteries. The examination of a patient with stroke is incomplete without a search for hypertension, carotid bruits, heart murmurs, and irregular heart rhythm.

IMPORTANCE OF A WORKING KNOWLEDGE OF NEUROANATOMY, NEUROPHYSIOLOGY, MOLECULAR GENETICS, NEUROIMAGING AND NEUROPATHOLOGY

Once the technique of obtaining reliable clinical data is mastered, students and residents may find themselves handicapped in the interpretation of the findings by a lack of knowledge of the basic sciences of neurology. For this reason, each of the later chapters dealing with the motor system, sensation, special senses, consciousness, memory, and language is introduced by a review of the anatomic and physiologic facts that are necessary for understanding the associated clinical disorders.

At a minimum, physicians should know the anatomy of the corticospinal tract; motor unit (anterior horn cell, nerve, and muscle); basal ganglionic and cerebellar motor connections; main sensory pathways; cranial nerves; hypothalamus and pituitary; reticular formation of brainstem and thalamus; limbic system; areas of cerebral cortex and their major connections; visual, auditory, and autonomic systems; and cerebrospinal fluid pathways. A working knowledge of neurophysiology should include an understanding of neural excitability and nerve impulse propagation, neuromuscular transmission, and contractile process of muscle; spinal reflex activity; central neurotransmission; processes of neuronal excitation, inhibition, and release; and cortical activation and seizure production. The genetics and molecular biology of neurologic disease have assumed increasing importance in the past few decades. The practitioner should be familiar with the terminology

of mendelian and mitochondrial genetics and the main aberrations in the genetic code that give rise to neurologic disease.

The wide availability of imaging offers the possibility of localization and etiologic diagnosis with limited input from the traditional clinical method. At a minimum, the educated neurologist must therefore be very familiar with the optimal imaging technique to disclose each of the multitudes of clinical diseases encountered in practice, the imaging appearance of each, and the risk and pitfalls of imaging.

From a practical diagnostic and therapeutic point of view, we believe the neurologist is helped by a knowledge of pathologic anatomy—i.e., the neuropathologic changes that are produced by disease processes such as infarction, hemorrhage, demyelination, physical trauma, compression, inflammation, neoplasm, and infection, to name the more common ones. Experience with the gross and microscopic appearances of these disease processes greatly enhances one's ability to explain their clinical effects. The ability to visualize the abnormalities of disease on nerve and muscle, brain and spinal cord, meninges, and blood vessels gives one a strong sense of which clinical features to expect of a particular disease and which features are untenable or inconsistent with a particular diagnosis. An additional advantage of being exposed to neuropathology is, of course, that the clinician is able to intelligently evaluate pathologic changes and reports of material obtained by biopsy. For many conditions there is a parallel representation of neuropathology through various imaging techniques. This allows the clinician to deduce the pathology from the imaging appearance.

From the foregoing description of the clinical method, it is evident that the use of laboratory aids, including imaging in the diagnosis of diseases of the nervous system is ideally preceded by rigorous clinical examination. As in all of medicine, laboratory study can be planned intelligently only on the basis of clinical information. To reverse this process is wasteful of medical resources and prone to the discovery of irrelevant information, and in some cases can expose a patient to unnecessary risk.

In the prevention of neurologic disease, however, the clinical method in itself is inadequate; thus, of necessity, one resorts to two other approaches, namely, the use of genetic information and laboratory screening tests. Biochemical screening tests are applicable to an entire population and permit the identification of neurologic diseases in individuals, mainly infants and children, who have yet to show their first symptom; in some diseases, treatment can be instituted before the nervous system has suffered damage. Similarly in adults, screening for atherosclerosis and its underlying metabolic causes is profitable in certain populations as a way of preventing stroke. Genetic information enables the neurologist to arrive at the diagnosis of certain illnesses and to identify patients and relatives at risk of developing certain diseases.

The laboratory methods that are available for neurologic diagnosis are discussed in the next chapter and in Chap. 45, on clinical electrophysiology. The relevant principles of genetic and laboratory screening methods

for the prediction of disease are presented in the discussion of the disease to which they are applicable.

SHORTCOMINGS OF THE CLINICAL METHOD

If one adheres to the clinical method, neurologic diagnosis is greatly simplified. In most cases one can reach an anatomic diagnosis. However, even after the most assiduous application of the clinical method and laboratory procedures, there are numerous patients whose diseases elude diagnosis. In such circumstances we have often been aided by the following perspectives:

As mentioned earlier, when the main sign has been misinterpreted—if a tremor has been taken for ataxia or fatigue for weakness—the clinical method is derailed from the start. Focus the clinical analysis on the principal symptom and signs and avoid being distracted by minor signs and uncertain clinical data.

As the lessons of cognitive psychology have been applied to error analysis in medical diagnosis, several heuristics (rules of thumb) have been identified as both necessary to the diagnostic process and as major pitfalls for the unwary clinician. The advantage of awareness of these heuristics is the opportunity to incorporate corrective strategies when shortcuts are employed. Investigators such as Redelmeier have given the following categories of cognitive mistakes that are common in arriving at a diagnosis:

- The framing effect reflects excessive weighting of specific initial data in the presentation of the problem.
- Anchoring heuristic, in which an initial impression cannot be subsequently adjusted to incorporate new data.
- Availability heuristic, in which experience with recent cases has an undue impact on the diagnosis of the case at hand.
- Representative heuristic refers to the lack of appreciation of the frequency of disease in the population under consideration, a restatement of Bayes theorem.
- Blind obedience, in which there is undue deference to authority or to the results of a laboratory test.

With our colleague Vickery, we have reviewed the workings of these heuristics in neurological diagnosis. Common to all of these cognitive errors is the tendency to come to early closure in diagnosis. Often this is the result of premature fixation on some item in the history or examination, closing the mind to alternative diagnostic considerations (the anchoring effect). The first diagnostic formulation should be regarded as only a testable hypothesis, subject to modification when new items of information are secured (anchoring heuristic). Should the disease be in a stage of transition, time will allow the full picture to emerge and the diagnosis to be clarified.

When several of the main features of a disease in its typical form are lacking, an alternative diagnosis should always be entertained. In general, however, one is more likely to encounter rare manifestations of common diseases than the typical manifestations of rare diseases (a paraphrasing of the representative heuristic).

It is advantageous to base diagnosis on clinical experience with the dominant symptoms and signs and not on statistical analyses of the frequency of clinical phenomena. Nonetheless, implicit in all diagnostic methods is an assessment of the likely causes of a sign or syndrome in the context of the patient's broad demographic characteristics including their sex, age, race, ethnicity, and the geographical circumstances. Moreover, as mentioned earlier, neurologists place a premium on finding treatable illnesses, even if the odds do not favor its presence.

As pointed out by Chimowitz, students tend to err in failing to recognize a disease they have not seen, and experienced clinicians may fail to appreciate a rare variant of a common disease. There is no doubt that some clinicians are more adept than others at solving difficult clinical problems. Their talent is not intuitive, as sometimes is presumed, but is attributable to having paid close attention to the details of their experience with many diseases and having catalogued them for future reference. The unusual case is recorded in memory and can be resurrected when another one like it is encountered. To achieve expert performance in all areas, cognitive, musical, and athletic, a prolonged period of focused attention to the subject and to personal experience is required.

THERAPEUTICS IN NEUROLOGY

Among medical specialties, neurology has traditionally occupied a somewhat anomalous position, in the past being thought of by many as little more than an intellectual exercise concerned with making diagnoses of untreatable diseases. This view of our profession is fallacious, as we have pointed out in a recent review of 200 years of neurological progress (Ropper). There are a growing number of diseases, many medical and others surgical, for which specific therapy is now available; through advances in neuroscience, their number is steadily increasing. Among the most sweeping changes, now that many infectious diseases of the nervous system are being addressed, have been entirely novel medications for stroke, multiple sclerosis, Parkinson disease, migraine, neuropathy, brain tumor and epilepsy. These therapies and the dosages, timing, and manner of administration of particular drugs are considered in later chapters in relation to the description of individual diseases. The neurologist must also be familiar with the proper application of surgical treatment when it is an integral part of the amelioration or cure of disease, as it is for

brain tumor, degenerative and neoplastic diseases of the spine, cerebral aneurysm, extracranial arterial stenosis, and some congenital disease of the brain and spinal cord.

There are, in addition, many diseases in which neurologic function can be restored to a varying degree by appropriate rehabilitation measures or by the judicious use of therapeutic agents. Claims for the effectiveness of a particular therapy based on statistical analysis of large-scale clinical studies must be treated circumspectly. Was the study well conceived as reflected in a clearly stated hypothesis and outcome criteria; was there adherence to the plans for randomization and admission of cases into the study; were the statistical methods appropriate; and were the controls truly comparable? It has been our experience that the original results must be accepted with caution and it is prudent to wait until further studies confirm the benefits that have been claimed.

There are, of course, many instances in which evidence is not available or is not applicable to difficult individual therapeutic decisions. This is in part true because small albeit statistically significant effects may be of little consequence when applied to an individual patient. It goes without saying that data derived from trials must be used in the context of a patient's overall physical and mental condition and age. Furthermore, for many neurologic conditions there is, at the moment, inadequate evidence on which to base treatment. Here, the patient requires a skilled physician to make judgments based on partial or insufficient data. Even deciding actively to wait before committing to an intervention displays wisdom and adheres to the dictum, "first, do no harm". Even when no effective treatment is possible, neurologic diagnosis is more than an intellectual pastime. The first step in the scientific study of any disease process is its identification in the living patient.

In closing this introductory chapter, a comment regarding the extraordinary burden of diseases of the nervous system throughout the world is appropriate. It is not just that conditions such as brain and spinal cord trauma, stroke, epilepsy, mental retardation, mental diseases, and dementia are ubiquitous and account for the majority of illness, second only in some parts of the world to infectious disease, but that these are highly disabling and often chronic in nature, altering in a fundamental way the lives of the affected individuals. Furthermore, more so than in other fields, the promise of cure or amelioration by new techniques such as molecular biology, genetic therapy, and brain-computer interfaces has excited vast interest, for which reason aspects of the current scientific insights are included in appropriate sections.

Imaging, Electrophysiologic, and Laboratory Techniques for Neurologic Diagnosis

The analysis and interpretation of data elicited by a careful history and examination may prove to be adequate for diagnosis. Special laboratory examinations then do no more than corroborate the clinical impression. However, it happens more often that the nature of the disease is not discerned by “case study” alone; the diagnostic possibilities may be reduced to two or three, but the correct one is uncertain. Under these circumstances, one resorts to ancillary examinations. The aim of the neurologist is to arrive at a final diagnosis by artful analysis of the clinical data aided by the least number of laboratory procedures.

Only a few decades ago, the only laboratory tests available to the neurologist were examination of a sample of cerebrospinal fluid, radiography of the skull and spinal column, contrast myelography, pneumoencephalography, and electroencephalography. The physician’s armamentarium has been expanded to include a multitude of neuroimaging modalities, biochemical, and genetic methods. Some of these new methods give the impression of such accuracy that there is a temptation to substitute them for a careful, detailed history and physical examination. Reflecting the limitations of laboratory diagnosis, in a carefully examined series of 86 consecutively hospitalized neurologic patients reported by Chimowitz and colleagues, laboratory findings (including MRI) clarified the clinical diagnosis in 40 patients but failed to do so in the remaining 46. Moreover, it is common in practice for ancillary testing to reveal abnormalities that are of no significance to the problem at hand. Consequently, the physician should always judge the relevance and significance of laboratory data only in the context of clinical findings. Hence the neurologist must be familiar with all laboratory procedures relevant to neurologic disease, their reliability, and their hazards.

What follows is a description of laboratory procedures that have application to a diversity of neurologic diseases. Procedures that are pertinent to a particular symptom complex or category of disease—e.g., audiography to study deafness; electronystagmography (ENG) in cases of vertigo; electromyography (EMG) and nerve conduction studies, as well as nerve and muscle biopsy, where there is neuromuscular disease—are presented in the chapters devoted to these disorders.

LUMBAR PUNCTURE AND EXAMINATION OF CEREBROSPINAL FLUID

The information yielded by examination of the cerebrospinal fluid (CSF) is crucial in the diagnosis of certain neurologic diseases, particularly infectious and inflammatory conditions, subarachnoid hemorrhage, and processes that alter intracranial pressure. Combinations of findings, or formulas, in the CSF generally denote particular classes of disease; these are summarized in Table 2-1.

Indications for Lumbar Puncture

1. To obtain pressure measurements and procure a sample of the CSF for cellular, cytologic, chemical, and bacteriologic examination.
2. To aid in therapy by the administration of spinal anesthetics and occasionally, antibiotics or antitumor agents, or by reduction of CSF pressure.
3. To inject a radiopaque substance, as in myelography, or a radioactive agent, as in radionuclide cisternography.

Lumbar puncture (LP) carries some risks if the CSF pressure is very high (evidenced mainly by headache and papilledema), for it increases the possibility of a fatal cerebellar or transtentorial herniation. The risk is considerable when papilledema is the result of an intracranial mass, but it is much lower in patients with subarachnoid hemorrhage, in hydrocephalus with communication between all the ventricles, or with pseudotumor cerebri, conditions in which repeated LPs may at times be employed as a therapeutic measure. Asymmetric lesions, particularly those near the tentorium or foramen magnum carry a greater risk of herniation precipitated by lumbar puncture. In patients with purulent meningitis, there is also a small risk of herniation, but this is far outweighed by the need for a definitive diagnosis and the institution of appropriate treatment at the earliest moment. With this last exception, LP should generally be preceded by CT or MRI whenever an elevation of intracranial pressure is suspected. If radiologic procedures

Table 2-1

CHARACTERISTIC CSF FORMULAS

CONDITION	CELLS	PROTEIN	GLUCOSE	OTHER FEATURES
Bacterial infection	WBC >50/mm ³ , often greatly increased	100–250 mg%	20–50 mg%; usually lower than half of blood glucose level	Gram stain shows organisms; pressure increased
Viral, fungal, spirochetal infection	WBC 10–100/mm ³	50–200 mg%	Normal or slightly reduced	Special culture techniques required; pressure normal or slightly increased
Tuberculous infection	WBC >25/mm ³	100–1,000 mg%	<50, often markedly reduced	Special culture techniques and PCR may be needed to detect organisms
Subarachnoid hemorrhage	RBC >500/mm ³ ; slight increase in WBC	60–150 mg%	Normal; slightly reduced later	Must be distinguished from traumatic lumbar puncture by presence of xanthochromia of spun sample; greatly increased pressure
Cerebral hemorrhage, trauma	RBC 50–200/mm ³ ; higher if ventricular rupture of blood	50–150 mg%	Normal	Pressure may be elevated
Ischemic stroke	Normal or few WBC	Normal	Normal	Normal pressure unless brain swelling
Multiple sclerosis	Normal or few WBC	Normal or slightly increased	Normal	Increased IgG fraction and oligoclonal bands
Meningeal cancer	WBC 10–100/mm ³	Usually elevated	Normal or depressed	Neoplastic cells in CSF; elevation of certain protein markers (e.g., β_2 -microglobulin)

IgG, immunoglobulin G; PCR, polymerase chain reaction; RBC, red blood cells; WBC, white blood cells.

disclose a mass lesion that is causing displacement of brain tissue toward the tentorial opening or the foramen magnum (the presence of a mass alone is of less concern) and if it is considered essential to have the information yielded by CSF examination, the LP may be performed—with certain precautions. If the pressure proves to be very high—over 400 mm H₂O—one should obtain the smallest necessary sample of fluid and then, according to the suspected disease and patient's condition, administer mannitol or another hyperosmolar agent and ideally, to observe a fall in pressure on the manometer. Dexamethasone or an equivalent corticosteroid may generally also be given in an initial intravenous dose of 10 mg, followed by doses of 4 to 6 mg every 6 h in order to produce a sustained reduction in intracranial pressure. Corticosteroids are particularly useful in situations in which the increased intracranial pressure is caused by vasogenic cerebral edema (e.g., tumor-associated edema).

Cisternal (foramen magnum) puncture and lateral cervical subarachnoid puncture, although safe in the hands of an expert, are too hazardous to entrust to those without experience and do not circumvent the problem of increased intracranial pressure. LP is preferred except in obvious instances of spinal block requiring a sample of cisternal fluid or for myelography above the lesion.

Technique of Lumbar Puncture

Experience teaches the importance of meticulous technique and proper positioning of the patient. LP should be done under locally sterile conditions. Xylocaine is injected in and beneath the skin, which should render the procedure almost painless. Warming of the analgesic by rolling the vial between the palms seems to diminish the burning sensation that accompanies cutaneous infiltration. The patient is positioned on his side,

preferably on the left side for right-handed physicians, with hips and knees flexed, and the head as close to the knees as comfort permits. The patient's hips should be vertical, the back aligned near the edge of the bed, and a pillow placed under the ear. The puncture is usually easiest to perform at the L3-L4 interspace, which corresponds in many individuals to the axial plane of the iliac crests, or at the interspace above or below. In infants and young children, in whom the spinal cord may extend to the level of the L3-L4 interspace, lower levels should be used. Experienced anesthesiologists have suggested that the smallest possible needle be used and that the bevel be oriented in the longitudinal plane of the dural fibers (see below regarding atraumatic needles). It is usually possible to appreciate a palpable "give" as the needle approaches the dura, followed by a subtle "pop" on puncturing the arachnoid membrane. At this point, the trocar should be removed slowly from the needle to avoid sucking a nerve rootlet into the lumen and causing radicular pain. Sciatic pain during the insertion of the needle indicates that it is placed too far laterally. If the flow of CSF slows, the patient's head can be elevated slowly. Occasionally, one resorts to gentle aspiration with a small-bore syringe to overcome the resistance of proteinaceous and viscous CSF. Failure to enter the lumbar subarachnoid space after two or three trials usually can be overcome by performing the puncture with the patient in the sitting position and then helping him to lie on one side for pressure measurements and fluid removal. The "dry tap" is more often the result of an improperly placed needle than of obliteration of the subarachnoid space by a compressive lesion of the cauda equina or by adhesive arachnoiditis. In an obese patient, in whom palpable spinal landmarks cannot be appreciated, or after several unsuccessful attempts in any patient, fluoroscopy can be employed to position the needle.

LP has few serious complications. The most common is headache, estimated to occur in one-third of patients, but in severe form in far fewer. Prolonged or severe post-lumbar puncture headache is usually seen in patients with a history of migraine. The pain is presumably the result of a reduction of CSF pressure from leakage of fluid at the puncture site and tugging on cerebral and dural vessels as the patient assumes the erect posture. Although neither recumbency nor oral fluid administration after LP has been shown to prevent headache, they are often implemented nonetheless. Strupp and colleagues have found that the use of an atraumatic needle almost halved the incidence of headache. Curiously, headaches are twice as frequent after diagnostic LP as they are after spinal anesthesia. Patients who are prone to frequent headaches before LP reportedly have higher rates of headache afterwards, which accords with our experience. Severe headache can be associated with vomiting and mild neck stiffness. Unilateral or bilateral sixth nerve or other cranial nerve palsies occur rarely after lumbar puncture, even at times without headache and rare cases of hearing loss or facial palsy have been reported. The syndrome of low CSF pressure, its treatment by "blood patch," and other complications of lumbar puncture are considered further in Chap. 30.

Bleeding into the spinal meningeal or epidural spaces after lumbar puncture can occur in patients who are taking anticoagulants (generally with an international normalized ratio [INR] >1.4), have low platelet counts (<50,000/mm³), or impaired platelet function (alcoholism, uremia). Treatment is by reversal of the coagulopathy and, in some cases, surgical evacuation of the clot. Purulent meningitis and disc space infections rarely complicate LP as the result of imperfect sterile technique, and the introduction of particulate matter (e.g., talc) or irritant carriers of injected drugs can produce a sterile meningitis.

Examination Procedures For CSF

Once the subarachnoid space has been entered, the pressure and fluctuations with respiration of the CSF are determined, (see below) and samples of fluid are obtained. The gross appearance of the fluid is noted, after which the CSF, in separate tubes, can be examined for (1) number and type of cells and presence of microorganisms by direct observation; (2) protein and glucose content; (3) tumor cells (cytology); (4) presence of oligoclonal bands or content of gamma globulin and other protein fractions, and serologic tests; (5) pigments, lactate, LDH, and substances elaborated by some tumors (e.g., β_2 microglobulin); and (6) bacteria and fungi (by culture), cryptococcal antigen, mycobacteria, the DNA of herpesvirus, cytomegalovirus and other organisms (by polymerase chain reaction), markers or certain infections (e.g., 14-3-3 protein), and viral isolation.

Pressure

With the patient in the lateral decubitus position, the CSF pressure is measured by a manometer attached to the needle in the subarachnoid space. In the normal adult, the opening pressure varies from 100 to 180 mm H₂O, or

8 to 14 mm Hg. In children, the pressure is in the range of 30 to 60 mm H₂O. A pressure above 200 mm H₂O with the patient relaxed and legs straightened reflects increased intracranial pressure. In an adult, a pressure of 50 mm H₂O or below indicates intracranial hypotension, generally caused by leakage of spinal fluid or systemic dehydration. When measured with the needle in the lumbar sac and the patient in a sitting position, the fluid in the manometer rises to the level of the cisterna magna (pressure is approximately double that obtained in the recumbent position). It fails to reach the level of the ventricles because the latter are in a closed system under slight negative pressure, whereas the fluid in the manometer is influenced by atmospheric pressure. Normally, with the needle properly placed in the subarachnoid space, the fluid in the manometer oscillates through a few millimeters in response to the pulse and respiration and rises promptly with coughing, straining, and with jugular vein or abdominal compression. An apparent low pressure can also be the result of a needle aperture that is not fully within the subarachnoid space; this is evidenced by the lack of expected fluctuations in pressure with these maneuvers.

The presence of a spinal subarachnoid block was in the past confirmed by jugular venous compression (Queckenstedt test, which tests for a rapid rise in CSF pressure within a few seconds after application of the pressure on the vein). The maneuver risks worsening of a spinal block or of raised intracranial pressure and is of historical interest.

Gross Appearance and Pigments

Normally, the CSF is clear and colorless. Minor degrees of color change are best detected by comparing test tubes of CSF and water against a white background (by daylight rather than by fluorescent illumination) or by looking down into the tubes from above. (A microhematocrit tube is too narrow for this purpose.) The presence of red blood cells imparts a hazy or ground-glass appearance; at least 200 red blood cells (RBCs) per cubic millimeter (mm³) must be present to detect this change. The presence of 1,000 to 6,000 RBCs per cubic millimeter imparts a hazy pink to red color, depending on the amount of blood; centrifugation of the fluid or allowing it to stand causes sedimentation of the RBCs. Several hundred or more white blood cells (WBCs) in the fluid (pleocytosis) may cause a slight opaque haziness.

A traumatic tap, in which blood from the epidural venous plexus has been introduced into the spinal fluid, may seriously confuse the diagnosis if it is incorrectly interpreted to indicate a preexistent subarachnoid hemorrhage. To distinguish between these two types of "bloody taps," two or three serial samples of fluid should be taken at the time of the LP. With a traumatic tap, there is usually a decreasing number of RBCs in the subsequent tubes. Also with a traumatic tap, the CSF pressure is usually normal, and if a large amount of blood is mixed with the fluid, it will clot or form fibrinous webs. These are not seen with preexistent hemorrhage because the blood has been greatly diluted with CSF and defibrinated by

enzymes in the CSF. In subarachnoid hemorrhage, the RBCs begin to hemolyze within a few hours, imparting a pink-red discoloration (erythrochromia) to the supernatant fluid; if the spinal fluid is sampled more than a day following the hemorrhage, the fluid will have become yellow-brown (xanthochromia). Prompt centrifugation of bloody fluid from a traumatic tap will yield a colorless supernatant; only with large amounts of venous blood (RBC more than 100,000/mm³) will the supernatant fluid be faintly xanthochromic due to contamination with serum bilirubin and lipochromes.

The fluid from a traumatic tap should contain one or two WBCs per 1,000 RBCs assuming that the hematocrit is normal, but in reality this ratio varies widely. With subarachnoid hemorrhage, the proportion of WBCs rises as RBCs hemolyze, sometimes reaching a level of several hundred per cubic millimeter; but the vagaries of this reaction are such that it, too, cannot be relied upon to distinguish traumatic from preexistent bleeding. The same can be said for crenation of RBCs, which occurs in both types of bleeding.

Why red corpuscles undergo rapid hemolysis in the CSF is not clear. It is surely not because of osmotic differences, as the osmolarity of plasma and CSF is essentially the same. Fishman suggested that the low protein content of CSF disequilibrates the red cell membrane in some way.

The pigments that discolor the CSF following subarachnoid hemorrhage are oxyhemoglobin, bilirubin, and methemoglobin. In pure form, these pigments are colored red (orange to orange-yellow with dilution), canary yellow, and brown, respectively. Oxyhemoglobin appears within several hours of hemorrhage, becomes maximal in approximately 36 h, and diminishes over a 7- to 9-day period. Bilirubin begins to appear in 2 to 3 days and increases in amount as the oxyhemoglobin decreases. Methemoglobin appears when blood is loculated or encysted and isolated from the flow of CSF. Spectrophotometric techniques can be used to distinguish the various hemoglobin breakdown products and thus determine the approximate time of bleeding.

Not all xanthochromia of the CSF is caused by hemolysis of RBCs. With severe jaundice, both conjugated and unconjugated bilirubin diffuse into the CSF. The quantity of bilirubin in the CSF ranges from one-tenth to one-hundredth that in the serum. Elevation of CSF protein from any cause results in a faint opacity and xanthochromia, more or less in proportion to the albumin-bound fraction of bilirubin. Only at protein levels greater than 150 mg/100 mL does the coloration become visible to the naked eye. Hypercarotenemia and hemoglobinemia (through hemoglobin breakdown products, particularly oxyhemoglobin) also impart a yellow tint to the CSF, as do blood clots in the subdural or epidural space of the cranium or spinal column. Myoglobin does not enter the CSF because a low renal threshold for this pigment permits rapid clearing from the blood.

Cellularity

During the first month of life, the CSF may contain a small number of mononuclear cells. Beyond this period, the

CSF is normally nearly acellular (i.e., fewer than 5 lymphocytes or other mononuclear cells per cubic millimeter). An elevation of WBCs in the CSF always signifies a reactive process to bacteria or other infectious agents, blood, chemical substances, an immunologic inflammation, a neoplasm, or vasculitis. The WBCs can be counted in an ordinary counting chamber, but their identification requires centrifugation of the fluid and a Wright stain of the sediment or the use of a Millipore filter, cell fixation, and staining. One can then recognize and count differentially neutrophilic and eosinophilic leukocytes (the latter being prominent in Hodgkin disease, some parasitic infections, neurosyphilis, and cholesterol emboli), lymphocytes, plasma cells, mononuclear cells, arachnoid lining cells, macrophages, and tumor cells. Bacteria, fungi, and fragments of echinococci and cysticerci can also be seen in cell-stained or Gram-stained preparations. An India ink preparation is useful in distinguishing between lymphocytes and cryptococci or *Candida*. Acid-fast bacilli will be found in appropriately stained samples. The monographs of den Hartog-Jager and the article of Bigner are older but still excellent references on CSF cytology. Special cell separation and immunostaining techniques permit the recognition of leukemia and lymphoma cell markers, glial fibrillary acidic protein, and other special cellular elements and antigens. These and other specific methods for the examination of cells in the CSF are discussed in the appropriate chapters.

Proteins

In contrast to the high protein content of blood (5,500 to 8,000 mg/dL), that of the lumbar spinal fluid is 45 to 50 mg/dL or less in the adult. The protein content of CSF from the basal cisterns is 10 to 25 mg/dL and that from the ventricles is 5 to 15 mg/dL. This gradient may reflect the fact that CSF proteins leak from the blood plasma through capillary tight junctions, which form the blood-brain and blood-CSF barrier. The spinal fluid is an ultrafiltrate of blood made by the choroid plexus in the lateral and the fourth ventricles in a manner that is analogous to the formation of urine by the glomerulus. The amount of protein in the CSF would then be proportional to the length of time it is in contact with the blood-CSF barrier. Thus shortly after it is formed in the ventricles, the protein is low. More caudally in the basal cisterns, the protein is higher and in the lumbar subarachnoid space it is highest of all. In children, the protein concentration is somewhat lower at each level (<20 mg/dL in the lumbar subarachnoid space). Levels higher than normal indicate a pathologic process in or near the ependyma or meninges—in either the brain, spinal cord, or nerve roots—although the cause of modest elevations of the CSF protein, in the range of 75 mg/dL, frequently remains obscure.

As one would expect, bleeding into the ventricles or subarachnoid space results in spillage not only of RBCs but of serum proteins. If the serum protein concentrations are normal, the CSF protein should increase by about 1 mg per 1,000 RBCs provided that the same tube of CSF is used in determining the cell count and protein content. (The same holds for a traumatic puncture that allows

seepage of venous blood into the CSF at the puncture site.) However, in the case of subarachnoid hemorrhage, caused by the irritating effect of hemolyzed RBC upon the leptomeninges, the CSF protein may be increased by many times this ratio.

The protein content of the CSF in bacterial meningitis, in which choroidal and meningeal perfusion are increased, often reaches 500 mg/dL or more. Viral infections induce a less intense and mainly lymphocytic reaction and a lesser elevation of protein—usually 50 to 100 mg/dL but sometimes up to 200 mg/dL; in some instances of viral meningitis and encephalitis the protein content is normal. Paraventricular tumors, by reducing the blood–CSF barrier, often raise the total protein to over 100 mg/dL. Protein values as high as 500 mg/dL are found in exceptional cases of the Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy. Values in the lumbar CSF of 1,000 mg/dL or more usually indicate a block to CSF flow; the fluid is then deeply yellow and clots readily because of the presence of fibrinogen; a combination called Froin syndrome. Partial CSF blocks by ruptured discs or tumor may elevate the protein to 100 to 200 mg/dL. Low CSF protein values are sometimes found in meningismus (a febrile illness with signs of meningeal irritation but normal CSF), in hyperthyroidism, or in conditions that produce low CSF pressure (e.g., after a recent LP as indicated in Chap. 30).

The quantitative partition of CSF proteins by electrophoretic and immunochemical methods demonstrate the presence of most of the serum proteins with a molecular weight of less than 150 to 200 kDa. The protein fractions that have been identified electrophoretically are prealbumin and albumin as well as α_1 , α_2 , β_1 , β_2 , and gamma globulin fraction, the last of these being accounted for mainly by immunoglobulins (the major immunoglobulin in normal CSF is IgG). The gamma globulin fraction in CSF is approximately 70 percent of that in serum. Table 2-2 gives the quantitative values of the different fractions. Immunoelectrophoretic methods have also demonstrated the presence of glycoproteins, ceruloplasmin, hemopexin, beta-amyloid and tau proteins. Large molecules—such as fibrinogen, IgM, and lipoproteins—are mostly excluded from the CSF unless generated there.

There are other notable differences between the protein fractions of CSF and plasma. The CSF always contains a prealbumin fraction and the plasma does not. Although derived from plasma, this fraction, for an unknown reason, concentrates in the CSF, and its level is greater in ventricular than in lumbar CSF, perhaps because of its concentration by choroidal cells. Also, tau (also identified as β_2 -transferrin) is detected only in the CSF and not in other fluids; its concentration is also higher in the ventricular than in the spinal fluid. The concentration of tau protein and in particular the ratio of tau to beta-amyloid, has found use in the diagnosis of Alzheimer disease, as discussed in Chap. 39. At present only a few of these proteins are known to be associated with specific diseases of the nervous system. The most important is IgG, which may exceed 12 percent of the total CSF protein in diseases such as multiple sclerosis, neurosyphilis, subacute sclerosing panencephalitis and other

Table 2-2

AVERAGE VALUES OF CONSTITUENTS OF NORMAL CSF AND SERUM

	CEREBROSPINAL	
	FLUID	SERUM
Osmolarity	295 mOsm/L	295 mOsm/L
Sodium	138.0 mEq/L	138.0 mEq/L
Potassium	2.8 mEq/L	4.1 mEq/L
Calcium	2.1 mEq/L	4.8 mEq/L
Magnesium	2.3 mEq/L	1.9 mEq/L
Chloride	119 mEq/L	101.0 mEq/L
Bicarbonate	23.0 mEq/L	23.0 mEq/L
Carbon dioxide tension	48 mm Hg	38 mm Hg (arterial)
pH	7.31–7.33	7.41 (arterial)
Nonprotein nitrogen	19.0 mg/dL	27.0 mg/dL
Ammonia	30.0 g/dL	70.0 g/dL
Uric acid	0.24 mg/dL	5.5 mg/dL
Urea	4.7 mmol/L	5.4 mmol/L
Creatinine	1.1 mg/dL	1.8 mg/dL
Phosphorus	1.6 mg/dL	4.0 mg/dL
Total lipid	1.5 mg/dL	750.0 mg/dL
Total cholesterol	0.4 mg/dL	180.0 mg/dL
Cholesterol esters	0.3 mg/dL	126.0 mg/dL
Glucose	60 mg/dL	90.0 mg/dL
Lactate	1.6 mEq/L	1.0 mEq/L
Total protein	15–50 mg/dL	6.5–8.4 g/100 dL
Prealbumin	1–7%	Trace
Albumin	49–73%	56%
Alpha ₁ globulin	3–7%	4%
Alpha ₂ globulin	6–13%	10%
Beta globulin	9–19%	12%
(beta ₁ plus tau)		
Gamma globulin	3–12%	14%

chronic viral meningoencephalitides. The serum IgG is not correspondingly increased, which means that this immune globulin originates in (or perhaps is preferentially transported into) the nervous system. However, an elevation of serum gamma globulin—as occurs in cirrhosis, sarcoidosis, myxedema, and multiple myeloma—will be accompanied by a rise in the CSF globulin. Therefore, in patients with an elevated CSF gamma globulin, it is necessary to determine the electrophoretic pattern of the serum proteins as well. Certain qualitative changes in the CSF immunoglobulin pattern, particularly the demonstration of several discrete (oligoclonal) electrophoretic “bands”, each representing a specific immune globulin, and the ratio of IgG to total protein, are of special diagnostic importance in multiple sclerosis, as discussed in Chap. 36.

The albumin fraction of the CSF increases in a wide variety of central nervous system (CNS) and craniospinal nerve root diseases that increase the permeability of the blood–CSF barrier, but no specific clinical correlations can be drawn. Certain enzymes that originate in the brain, especially the brain-derived fraction of creatine kinase (CK-BB) but also enolase and neopterin, are found in the CSF after stroke, global ischemic hypoxia, or trauma, and have been used as markers of brain damage

in experimental work. Other special markers such as elevation of the 14-3-3 protein, which has some diagnostic significance in prion disease, β_2 -microglobulin in meningeal lymphomatosis, neuron specific enolase in traumatic and other severe brain injuries, and alpha fetoprotein in embryonal tumors of the brain, may be useful in specialized circumstances.

Glucose

The CSF glucose concentration is normally in the range of 45 to 80 mg/dL, i.e., about two-thirds of that in the blood (0.6 to 0.7 of serum concentrations). Higher levels parallel the blood glucose in this proportion; but with marked hyperglycemia, the ratio of CSF to blood glucose is reduced (0.5 to 0.6). With extremely low serum glucose, the ratio becomes higher, approximating 0.85. In general, CSF glucose values below 35 mg/dL are abnormal. After the intravenous injection of glucose, 2 to 4 h are required to reach equilibrium with the CSF; a similar delay follows the lowering of blood glucose. For these reasons, samples of CSF and blood for glucose determinations should ideally be drawn simultaneously in the fasting state or the serum should be obtained a few hours before the puncture but (this is often not practical). Low values of CSF glucose (hypoglycorrhachia) in the presence of pleocytosis usually indicate bacterial, tuberculous, or fungal meningitis, although similar reductions are observed in some patients with widespread neoplastic infiltration of the meninges and occasionally with sarcoidosis, subarachnoid hemorrhage (usually in the first week) and in chemically induced inflammation.

For a long time it was assumed that in meningitis the bacteria lowered the CSF glucose by their active metabolism, but the fact that the glucose remains at a subnormal level for 1 to 2 wk after effective treatment of the meningitis suggests that another mechanism is operative. Theoretically at least, an inhibition of the entry of glucose into the CSF, because of an impairment of the membrane transfer system, can be implicated. As a rule, viral infections of the meninges and brain do not lower the CSF glucose, although low glucose values have been reported in a small number of patients with mumps meningoencephalitis, and rarely in patients with herpes simplex and zoster infections. The almost invariable rise of CSF lactate in purulent meningitis probably suggests that some of the glucose is undergoing anaerobic glycolysis by polymorphonuclear leukocytes and by cells of the meninges and adjacent brain tissue.

Serologic and Virologic Tests

CSF testing for cryptococcal surface antigen has become widely available as a rapid method if this infection is suspected. On occasion, a false-positive reaction is obtained in the presence of high titers of rheumatoid factor or antitreponemal antibodies, but otherwise the test is diagnostically more dependable than the formerly used India ink preparation. The nontreponemal antibody tests of the blood—Venereal Disease Research Laboratories (VDRL) slide flocculation test and rapid plasma reagin (RPR) agglutination test—can also be performed on the

CSF. When positive, these tests are usually diagnostic of neurosyphilis, but false-positive reactions may occur with collagen diseases, malaria, and yaws, or with contamination of the CSF by seropositive blood. Tests that depend on the use of treponemal antigens, including the *Treponema pallidum* immobilization test and the fluorescent treponemal antibody test, are more specific and assist in the interpretation of false-positive RPR and VDRL reactions. The value of CSF examinations in the diagnosis and treatment of neurosyphilis is discussed in Chap. 32, but testing of CSF for treponemal antibodies is no longer routine. Serologic tests for the Lyme spirochete are useful in circumstances of suspected infection of the central nervous system with this agent.

The utility of serum serologic tests for viruses is limited by the time required to obtain results, but they are useful in determining retrospectively the source of meningitis or encephalitis. More rapid tests that use the polymerase chain reaction (PCR) in CSF, which amplifies viral DNA fragments, are now widely available for diagnosis, particularly for herpesviruses, cytomegalovirus, and JC virus. These tests are most useful in the first week of infection, when the virus is being reproduced and its genomic material is most prevalent; after this time, serologic techniques for viral infection are more sensitive. Amplification of DNA by PCR is particularly useful in the rapid detection of tubercle bacilli in the CSF, the conventional culture of which takes several weeks at best., tests for the detection of 14-3-3- protein that reflects the presence of prion agents in the spinal fluid are available and may aid in the diagnosis of the spongiform encephalopathies, but the results have been erratic (Chap. 33).

Changes in Solutes and Other Components

The average osmolality of the CSF (295 mOsm/L) is identical to that of plasma. As the osmolality of the plasma is increased by the intravenous injection of hypertonic solutions such as mannitol or urea, there is a delay of up to several hours in the rise of osmolality of the CSF. It is during this period that the hyperosmolality of the blood maximally dehydrates the brain and decreases the volume of CSF. Table 2-2 lists the CSF and serum levels of sodium, potassium, calcium, and magnesium. Neurologic disease does not alter the CSF concentrations of these constituents in any characteristic way. The low CSF concentration of chloride that occurs in bacterial meningitis is not specific but a reflection of hypochloremia and, to a slight degree, of a greatly elevated CSF protein. Acid-base balance in the CSF is of interest in relation to metabolic acidosis and alkalosis but pH is not routinely measured. Normally, the pH of the CSF is approximately 7.31—i.e., somewhat lower than that of arterial blood, which is 7.41. The PCO_2 in the CSF is in the range of 45 to 49 mm Hg—i.e., higher than in arterial blood (about 40 mm Hg). The bicarbonate levels of the two fluids are about the same, 23 mEq/L. The pH of the CSF is precisely regulated, and it tends to remain relatively unchanged even in the face of severe systemic acidosis and alkalosis. Acid-base changes in the lumbar CSF do not necessarily reflect the presence of similar changes in the brain, nor are the CSF data as accurate an

index of the systemic changes as direct measurements of arterial blood gases.

The ammonia content of the CSF is one-third to one-half that of the arterial blood; it is increased in hepatic encephalopathy, the inherited hyperammonemias, and the Reye syndrome; the concentration corresponds roughly with the severity of the encephalopathy. The uric acid content of CSF is approximately 5 percent of that in serum and varies with changes in the serum level (high in gout, uremia, and meningitis, and low in Wilson disease). The urea concentration in the CSF is slightly lower than that in the serum; in uremia, it rises in parallel with that in the blood. An intravenous injection of urea raises the blood level immediately and the CSF level more slowly, exerting an osmotic dehydrating effect on the central nervous tissues and CSF. All 24 amino acids have been isolated from the CSF. The concentration of amino acids in the CSF is approximately one-third that in plasma. Elevations of glutamine are found in all of the portosystemic encephalopathies including hepatic coma and the Reye syndrome. Concentrations of phenylalanine, histidine, valine, leucine, isoleucine, tyrosine, and homocysteine are increased in the corresponding aminoacidurias.

Many of the enzymes found in serum are known to rise in CSF under conditions of disease, usually in relation to a rise in the CSF protein. None of the enzyme changes has proved to be a specific indicator of neurologic disease with the possible exception of lactic dehydrogenase, especially isoenzymes 4 and 5, which are derived from granulocytes and are elevated in bacterial meningitis but not in aseptic or viral meningitis. Lactic dehydrogenase is also elevated in cases of meningeal tumor infiltration, particularly lymphoma, as is carcinoembryonic antigen; the latter, however, is not elevated in bacterial, viral, or fungal meningitis. As to lipids, the quantities in CSF are small and their measurement is difficult.

The catabolites of the catecholamines can be measured in the CSF. Homovanillic acid (HVA), the major catabolite of dopamine, and 5-hydroxyindoleacetic acid (5-HIAA), the major catabolite of serotonin, are normally present in the spinal fluid; both are five or six times higher in the ventricular than the lumbar CSF. The levels of both catabolites are reduced in patients with idiopathic and drug-induced parkinsonism.

IMAGING TECHNIQUES OF THE SKULL, BRAIN, AND SPINE

A century ago, Harvey Cushing introduced the use of plain x-ray films of the cranium as part of the study of the neurologic patient, but it is has become evident that the yield of useful information from this procedure is relatively small. Even in patients with head injury, where radiography of the skull would seem to be an optimal method of examination, a fracture is found in only 1 of 16 cases, at a cost of thousands of dollars per fracture and a small risk from radiation exposure. Nevertheless plain skull films do demonstrate fractures, changes in contour of the skull, bony erosions and hyperostoses, infection in

paranasal sinuses and mastoids, and changes in the basal foramina. Plain films of the spine are able to demonstrate destructive lesions resulting from degenerative processes as well neoplastic, dysplastic, and infectious diseases. It also detects, fracture dislocations, spondylolistheses, and spinal instability, utilizing images acquired during flexion and extension maneuvers.

Refinements of radiographic techniques have greatly increased the yield of valuable information but without question the most important advances in neuroradiology have come about with the development of CT and MRI.

Computed Tomography

In this procedure, x-radiation is attenuated as it passes successively through the scalp, skull, CSF, cerebral gray and white matter, and blood vessels. The intensity of the exiting radiation relative to the incident radiation is measured, the data are integrated, and two-dimensional images are reconstructed by computer. This major achievement in methodology, attributed to Hounsfield and others, permitted the technologic advance from plain radiographs of the skull to reconstructed images of the cranium and its contents in any plane. The differing densities of bone, CSF, blood, and gray and white matter are distinguishable in the resulting picture with great clarity. One can see hemorrhage, infarcted, contused and edematous brain, abscess, and tumor tissue and also the precise size and position of the ventricles and midline structures. The radiation exposure is not significantly greater than that from plain skull films and comparable to a chest x-ray.

As illustrated in Fig. 2-1A-D, in transverse (axial) section of the brain, one sees the cortex and underlying subcortical white matter, the caudate and lenticular nuclei and the internal capsules and thalami. The position and width of all the major sulci and fissures can be measured, and the optic nerves and medial and lateral rectus muscles stand out clearly in the posterior parts of the orbit. The brainstem, cerebellum, and spinal cord are easily visible in the scan at appropriate levels. The scans are also useful in imaging parts of the body that surround peripheral nerves and plexuses, thereby demonstrating tumors, inflammatory lesions, and hematomas that involve these nerves. Intravenous administration of radio-opaque contrast can be used with CT to visualize regions where the blood-brain barrier has been disrupted from tumors, demyelination and infection.

In imaging of the head, CT has a number of advantages over MRI, the most important being safety when metal may be present in the body and the clarity of blood from the moment of bleeding. Other advantages are its lower cost, broader availability, larger aperture of the machine that reduces patient claustrophobia, shorter examination time, and equivalent or superior visualization of calcium, fat, and bone, particularly of the skull base and vertebrae (Fig. 1D). If constant monitoring and use of life support equipment is required during the imaging procedure, it is accomplished more readily by CT than by MRI. Recent advances in CT technology have greatly increased the speed of the scanning procedure and have

Figure 2-1. Normal axial CT scans of the brain, orbits, and skull base from a young healthy man. *A.* Image through the cerebral hemispheres at the level of the corona radiata. The dense bone of the calvarium is white, and fat-containing subcutaneous tissue is dark. Gray matter appears denser than white matter due to its lower lipid content. *B.* Image at the level of the lenticular nuclei. The caudate and lenticular nuclei are denser than the adjacent internal capsule. CSF within the frontal horns of the lateral ventricles as well as surrounding the slightly calcified pineal body appears dark. *C.* Image through the mid-orbits. The sclera appears as a dense band surrounding the globe. The bright optic nerves are surrounded by dark orbital fat. The medial and lateral rectus muscles lie along the orbital walls and have a fusiform shape. Air within the nasopharynx and paranasal sinuses appears dark. *D.* Image at skull base clearly shows the aerated mastoid air cells as well as the internal auditory canals and inner ear structures.

also made possible the visualization, with great clarity, of the cerebral vasculature (CT angiography; see further on).

CT Contrast Myelography

By injecting 5 to 25 mL of a water-soluble radiopaque contrast through an LP needle and then placing the patient in the Trendelenburg position, the entire spinal subarachnoid space can be visualized with radiography and fluoroscopy (Fig. 2-2A-F). The procedure is almost as harmless as the LP except for cases of complete spinal block, in which high concentrations of contrast near the block can cause pain and regional myoclonus. Iophendylate (Pantopaque), a formerly used fat-soluble dye, is still approved by the FDA but is now employed only in special circumstances (visualizing the upper level of a spinal canal lesion that completely obstructs the flow of water soluble dye). If iophendylate is left in the subarachnoid space, particularly in the presence of blood or inflammatory exudate, it may incite arachnoiditis of the spinal cord and brain.

CT of the vertebral column provides structural images of the spinal canal and intervertebral foramina in three planes. Herniated lumbar and cervical discs, cervical spondylotic bars and bony spurs encroaching on the spinal cord or roots, and spinal cord tumors can be visualized with clarity. MRI provides even sharper visualization of the spinal canal and its contents as well as the vertebrae and intervertebral discs (Fig. 2-2D-F); consequently, it has largely supplanted contrast myelography.

Limitations and Safety of CT

The risks of contrast infusion include allergic reactions and nephropathy, which is most often transient and reversible, but can be more severe in patients with underlying renal dysfunction. Intravenous contrast is generally withheld if the glomerular filtration rate (GFR) is less than 30 mL/min/1.73 m²; with GFR of 30-60, hydration and discontinuation of potentially nephrotoxic medications precedes the administration of contrast, particularly nonsteroidal anti-inflammatory agents, cisplatin containing chemotherapy and aminoglycosides. Infusion is also avoided if there has been exposure to contrast in the previous 72 h.

The primary risk of CT is radiation exposure, and overexposure can have clinical consequences ranging from relatively benign alopecia to leukomalacia and neoplasia. The interested reader should refer to FDA guidelines. Given the need for repeated CT examinations in certain patients, tracking of total radiation exposure is recommended. CT should not be performed during pregnancy unless the mother's health is at imminent risk (i.e., following trauma). The potential harm to a fetus from radiation depends on gestational age and total absorbed dose. It is noteworthy that the fetal radiation dose from maternal cranial CT is lower than from maternal pelvic CT.

Magnetic Resonance Imaging

MRI also provides images in any plane, but it has the great advantage over CT in using nonionizing energy and providing higher resolution views, and improved

contrast between different structures within the nervous system. For visualization of most neurologic lesions, MRI is the preferred procedure.

MRI is accomplished by placing the patient within a powerful magnetic field, causing certain endogenous isotopes (atoms) within the tissues and CSF to be aligned in the longitudinal orientation of the magnetic field. Application of a brief (few milliseconds) radiofrequency (RF) pulse into the field changes the axis of alignment of the atoms. When the RF pulse ceases, the atoms return to their original alignment and the RF energy that was absorbed is then emitted by the isotopes, producing a magnetic signal that is detected by receiver coils. To create contrasting tissue images from these signals, the RF pulse must be repeated many times (a pulse sequence), the signals being measured after the application of each pulse. The scanner stores the signals as a matrix of data, which is subjected to computer analysis and from which two-dimensional images are reconstructed.

Nuclear magnetic resonance can be detected from several endogenous isotopes, but current technology uses mainly signals derived from hydrogen atoms because hydrogen is the most abundant element in tissue and yields the strongest magnetic signal. The image is essentially a map of the hydrogen content of tissue, therefore reflecting largely the water concentration, but influenced also by the physical and chemical environment of the hydrogen atoms. The terms T1- and T2-weighting refer to the time constants for proton relaxation; these may be altered to highlight certain features of tissue structure. In T1-weighted images, CSF appears dark and gray matter is hypointense to white matter. In T2-weighted images, CSF appears bright, and gray matter is hyperintense to white matter. Lesions within the white matter, such as the demyelination of multiple sclerosis, are more easily seen on T2-weighted images, appearing hyperintense against normal white matter (Table 2-3).

Because of the high degree of contrast between white and gray matter, one can identify, on both T1- and T2-weighted images, all discrete nuclear structures (Fig. 2-3A-D). Lesions near the skull base and within the posterior fossa, in particular, are seen with greater clarity on MRI compared to CT, unmarred by signals from adjacent skeletal structures. Each of the products of disintegrated RBCs—oxyhemoglobin, deoxyhemoglobin, methemoglobin, and hemosiderin—can be recognized, enabling one to approximate the age of hemorrhages and to follow their resolution, as discussed in Chaps. 34 and 35. Gradient-echo (GRE), or susceptibility weighted imaging (SWI), is especially sensitive to blood and its breakdown products that appear hypointense. These sequences can reveal lobar microhemorrhages as seen in cerebral amyloid angiopathy.

MRI of the spine provides clear images of the vertebral bodies, intervertebral discs, spinal cord, and cauda equina (Fig. 2-2D-F). Abnormalities such as syringomyelia, herniated discs, tumors, epidural or subdural hemorrhages, areas of demyelination, and abscesses are well delineated.

Additional radiofrequency pulses can be applied to T1- and T2-weighted images in order to selectively suppress signal from fluid or fat. The FLAIR (fluid attenuated inversion recovery) sequence is a T2-weighted sequence

Figure 2-2. CT myelogram and MRI of the lumbosacral spine. Sagittal (A) and axial (B-C) CT images of the lumbosacral spine obtained after the intrathecal administration of radioopaque contrast material. The vertebral bodies are separated by intervertebral discs and the spinous processes are seen posteriorly. Contrast contained within the thecal sac appears white. The conus medullaris terminates at the L2 vertebral level (A-B) and the nerve roots of the cauda equina are clearly seen within the posterior thecal sac (A-C). Sagittal (D) and axial (E-F) T2-weighted MRI of the lumbosacral spine shows hyperintense CSF surrounding the conus medullaris, which terminates at the L1 vertebral level (A-B). The nerve roots of the cauda equina are seen within the posterior thecal sac (A-C). In C and F, traversing nerve roots within the lateral recess of the spinal canal are seen.

Table 2-3

CT AND MRI IMAGING CHARACTERISTICS OF VARIOUS TISSUES

TISSUE	CT GRAY SCALE	MRI T1 SIGNAL	MRI T2 SIGNAL
Brain	Gray	Gray	Gray
Air	Black	Black	Black
CSF	Black	Black	White
Fat	Black	White	Black
Calcium	White	Black	Black
Bone	Very white	Black	Black
Extravasated blood	White	White	Black
Inflammation	Contrast enhancing	Gray, gadolinium enhancing	White
Edema	Dark gray	Gray	White
Tumor	Gray or white and contrast enhancing	Gray or white and gadolinium enhancing	White

in which the bright signal of fluid is suppressed. This is a particularly useful sequence for visualizing lesions located near CSF compartments. Fat-suppression, which can be applied to T1 or T2 sequences, can be used to demonstrate inflammation of the optic nerve, visualize pathologic inflammation within the vertebral bodies, and show thrombus within the false lumen of a cervical dissection.

Diffusion-weighted imaging (DWI) is a technique that measures the free diffusion of water molecules within tissue. Preferential movement of water molecules along a particular direction, for example, parallel to white matter tracts, is referred to as anisotropy (i.e., non-isotropic movement). Many abnormal processes can produce anisotropy as well. In acute ischemic stroke, failure of the sodium-potassium ATPase pump leads to cellular swelling and reduced intercellular space, thus limiting the free movement of water and producing hyperintensity on DWI. This imaging technique reveals the abnormalities of ischemic stroke earlier than standard T1- or T2-weighted MRI, or CT. Pus-filled abscesses and hypercellular tumors can also show DWI hyperintensity, reflecting the limitation of free diffusion of water in these lesions.

Because of the relationship between DWI and T2 signal intensity, true restricted diffusion, appearing hyperintense on the DWI sequence in acute infarction, instead is *hypointense* on a related sequence termed apparent diffusion coefficient, or ADC. If the hyperintense DWI signal is also *hyperintense* on ADC, then diffusion is termed facilitated rather than restricted. This phenomenon is seen when the free movement of water within a tissue becomes more isotropic, as with vasogenic edema. Therefore, the interpretation of DWI signal hyperintensity must be gauged in the context of the ADC signal in the same region.

The administration of gadolinium, a paramagnetic agent that accelerates the process of proton relaxation during the T1 sequence of MRI, permits even sharper

definition and highlights regions surrounding many types of lesions where the blood-brain barrier has been disrupted in the brain, spinal cord, or nerve roots.

Limitations and Safety of MRI

The degree of cooperation in holding still that is required to perform MRI limits its use in young children and in the cognitively impaired. Some form of sedation is required in these individuals and most hospitals have services to safely accomplish conscious sedation for this purpose. Studying a patient who requires a ventilator is also difficult but manageable by using either manual ventilation or nonferromagnetic ventilators (Barnett et al).

The main dangers in the use of MRI are torque, dislodgement or heating of metal clips on blood vessels, of dental devices and other ferromagnetic objects, and of small metal fragments in the orbit, the last of these often acquired unnoticed by operators of machine tools. For this reason it is wise, in appropriate patients, to obtain plain radiographs of the orbits so as to detect metal in these regions. Corneal metal fragments can be removed by an ophthalmic surgeon if an MRI is necessary. The presence of a cardiac pacemaker, defibrillator, or implanted stimulator in the brain or spinal cord is an absolute contraindication to the use of MRI as the magnetic field induces unwanted currents in the device and the wires exiting from it. However, many new implantable medical devices have been developed that do not distort the magnetic field. Most of the newer, weakly ferromagnetic prosthetic heart valves, joint prostheses, intravascular access ports, aneurysm clips, and ventricular shunts and adjustable valves do not represent an untoward risk for magnetic imaging although shunt valves may require resetting. An extensive list of devices that have been tested for their ferromagnetic susceptibility and their safety in the MRI machine can be found at www.mrisafety.com. MRI entails some risk in these situations unless there is direct knowledge of the type of material contained in the device. It should be noted that devices or materials that are deemed safe for 1.0 or 1.5 Tesla scanners may not be compatible with higher magnetic field strength scanners.

Because of the development of cataracts in the fetuses of animals exposed to MRI, there has been hesitation in performing MRI in pregnant patients, especially in the first trimester. However, current data indicate that imaging may be performed provided that the study is medically indicated. In a study of 1,000 pregnant MRI technicians who entered the magnetic field frequently (the magnet remains on between procedures), no adverse effects on the fetus could be discerned (Kanal et al).

In recent years, an additional risk of nephrogenic systemic fibrosis, a severe cutaneous sclerosing disease, has been linked to the administration of gadolinium. Most instances occur in patients with preexisting renal failure, for which reason it has become common to obtain BUN and creatinine measurements before administering gadolinium. The problem had not been appreciated previously in part because of its rarity (the frequency has not been well established) and because of a delay in the appearance of sclerosis in the kidney, of several days to two months.

Figure 2-3. Normal brain MRI. *A.* Axial T2-weighted MRI at the level of the lenticular nuclei. Gray matter appears brighter than white matter. CSF within the ventricles and cortical sulci is very bright. The caudate nuclei, putamen, and thalamus appear brighter than the internal capsule. *B.* Axial T2-weighted MRI at the level of the pons. Subcutaneous fat and calvarial marrow appear bright. CSF within the 4th ventricle and prepontine cistern, endolymph within the cochlea and semicircular canals, and ocular vitreous fluid appears very bright. Signal is absent (i.e., a “flow void”) within the basilar artery. *C.* Midline sagittal T1-weighted MRI of the brain. Note that white matter appears brighter than gray matter and the corpus callosum is well defined. The pons, medulla, and cervicomedullary junction are well delineated, and the pituitary gland is demonstrated with a normal posterior pituitary bright spot. The cerebral aqueduct is seen between the ventral midbrain and the tectum. The clivus and upper cervical vertebrae are noted as well. *D.* Axial T2-weighted fluid attenuated inversion recovery (FLAIR) MRI of the brain at the same level as in *A.* Note that the hyperintense fluid signal from CSF is now suppressed, and the differentiation between brighter gray matter and darker white matter is accentuated.

Many types of MRI image artifacts are known, most having to do with technical aspects of the electronic characteristics of the magnetic field or of the mechanics involved in the imaging procedure (for details, see Morelli). Among the most common and problematic are CSF flow artifacts in the thoracic spinal cord, giving the impression of an intradural mass; distortions of the appearance of structures at the base of the brain from ferromagnetic dental appliances; and lines across the entire image induced by vascular pulsations and patient movement.

The increasing use of MRI and the sensitivity of current machines and computer algorithms have had the unintended effect of revealing a large number of unimportant findings that create undue worry and often trigger a neurologic consultation. However, a surprising number of incidental brain lesions of consequence are also exposed. For example, a large survey of asymptomatic adults who were being followed in the "Rotterdam Study" is in accord with several prior studies in which cerebral aneurysms were found in approximately 2 percent, meningiomas in 1 percent, and a smaller but not insignificant number of vestibular schwannomas and pituitary tumors; the meningiomas, but not the aneurysms, increased in frequency with age. One percent had the Chiari type I malformation, and a similar number had arachnoid cysts. In addition, seven percent of adults older than age 45 years had occult strokes, mostly lacunar. Because this survey was performed without gadolinium infusion, it might be expected that even more small lesions could be revealed (Vernooij et al).

Special Imaging Techniques

Perfusion Imaging

This imaging modality is a contrast-based technique that can be performed with both CT and MRI. Images are rapidly and serially acquired as the contrast transits through the vasculature and parenchyma. A time-intensity curve is produced, from which measurements of cerebral blood flow, cerebral blood volume, and transit time can be derived. Perfusion imaging has provided a means of detecting regions of ischemic tissue, and to monitor the elevated blood volume in certain brain tumors.

Magnetic Resonance Spectroscopy

The tissue concentrations of a variety of cellular metabolites can be determined with the technique of magnetic resonance spectroscopy (MRS). Among these substances, *N*-acetyl aspartate (NAA) is a marker of neuronal integrity, and is decreased in both destructive lesions and in circumstances in which there is a reduction in the density of neurons (e.g., edema or glioma that increases the distance between neurons). Choline (Cho), a marker of membrane turnover, is elevated in some rapidly dividing tumors. Therefore, compared to normal white matter, the spectrogram of a glioma characteristically shows decreased NAA and increased Cho.

Diffusion Tractography

A technique related to DWI, termed diffusion tensor imaging (DTI) integrates measurements of directional

anisotropy to reconstruct fiber tracts in the brain (tractography). This modality detects damage to, or displacement of white matter tracts because of trauma, vascular injury, or tumor, in extraordinary detail. Tractography is also occasionally used in surgical planning to localize critical white matter tracts avoid their inadvertent transection during operations.

Functional Imaging

In the last two decades, several remarkable techniques of functional imaging has been introduced to study activation of regions of cerebral cortex during activities, both mental and physical, carried out by test subjects. The MRI based technique shows the difference between oxy- and deoxy-hemoglobin, reflecting brain oxygen extraction, in two or three dimensions. This blood oxygen level-dependent (BOLD) signal can be extracted from MRI data and used as a surrogate for local cerebral metabolic activity. This technique has also been used in pre-surgical planning in order to avoid damage to eloquent cortex, and in epilepsy to help localize seizure foci.

Positron emission tomography (PET) produces images that reflect the regional concentration of systemically administered radioactive compounds. Positron-emitting isotopes (mainly ^{11}C , ^{18}F , and ^{15}O) are produced in a cyclotron or linear accelerator, injected into the patient, and incorporated into biologically active compounds in the body. The concentration of these tracers in various parts of the brain is determined by an array of radiation detectors and tomographic images are constructed by techniques similar to those used in CT and MRI.

Local patterns of cerebral blood flow, oxygen uptake, and glucose utilization can be measured by PET, and the procedure has proved to be of value in grading primary brain tumors, distinguishing tumor tissue from radiation necrosis, localizing epileptic foci, and, in differentiating types of degenerative diseases. The technique has been applied to specially labeled ligands of beta-amyloid, producing images of the deposition of this protein in Alzheimer disease. No doubt this approach will become increasingly important in the study of degenerative diseases and their response to treatment. The ability of the technique to quantitate neurotransmitters and their receptors also promises to be of importance in the study of Parkinson disease and other degenerative conditions. However, this technology is costly and does not always add to the certainty of diagnosis.

Single-photon emission computed tomography (SPECT), a technique which has evolved from PET, uses isotopes that do not require a cyclotron for their production. Radioligands (usually containing iodine) are incorporated into biologically active compounds, which, as they decay, emit only a single photon. This procedure allows the study of regional cerebral blood flow under conditions of cerebral ischemia and regional degenerative diseases of the cortex or during increased tissue metabolism (e.g., seizures and actively growing tumors). Once injected, the isotope localizes rapidly in the brain, with regional absorption proportional to blood flow, and is then stable for an hour or more. It is thus possible, for

example, to inject the isotope at the time of a seizure, while the patient is undergoing video and electroencephalographic monitoring, and to scan the patient later. The limited anatomic resolution provided by SPECT has reduced its clinical usefulness, but it is more widely available than other functional imaging techniques. PET and SPECT techniques that use I^{23} labeled dopamine, have been recently introduced and offer the possibility of imaging striatal dopamine and assisting in the diagnosis of Parkinson disease (see Chap. 39).

Angiography

This technique has evolved over the past century to the point where it is a safe and valuable method for the diagnosis of aneurysms, vascular malformations, narrowed or occluded arteries and veins, arterial dissections, and angitis. Since the advent of CT and MRI, the use of angiography has practically been limited to the diagnosis of these vascular disorders, and refinements in the former two techniques (magnetic resonance angiography [MRA] and computed tomography angiography [CTA] described further on) promise to reduce or replace conventional x-ray angiography. However, new endovascular procedures for the ablation of aneurysms, arteriovenous malformations, and vascular tumors still may require the incorporation of conventional angiography. Following local anesthesia, a needle is placed in the femoral or brachial artery; a cannula is then threaded through the needle and along the aorta and the arterial branches to be visualized. In this way, a contrast agent is injected to visualize the arch of the aorta, the origins of the carotid and vertebral systems, and the extensions of these systems through the neck and into the cranial cavity and the vasculature in and surrounding the spinal cord. Experienced arteriographers can visualize the cerebral and spinal cord arteries down to about 0.1 mm in lumen diameter (under optimal conditions) and small veins of comparable size. With current refinements of radiologic technique that use digital computer processing it is possible to produce images of the major cervical and intracranial arteries with relatively small amounts of contrast medium introduced through smaller catheters than those used previously.

Angiography is not altogether without risk. High concentrations of the injected contrast may induce vascular spasm and occlusion, and clots may form on the catheter tip and embolize the artery. Overall morbidity from the procedure is approximately 2.5 percent, mainly in the form of worsening of a preexistent vascular lesion or from complications at the site of artery puncture. Occasionally, a cerebral or systemic ischemic lesion is produced, probably the result of either particulate atheromatous material dislodged by the catheter, thrombus formation at or near the catheter tip, or less often, by dissection of the artery by the catheter. The patient may be left hemiplegic, quadriplegic, or blind; for these reasons the procedure should not be undertaken unless it is deemed necessary to obtain a clear diagnosis or in anticipation of surgery that requires a definition of the location of the vessels. A cervical myelopathy is a rare but disastrous complication of vertebral artery contrast injection; the problem is heralded by pain in the

back of the neck immediately after injection. Progressive cord ischemia from an ill-defined vascular process ensues over the following hours. This same complication may occur at other levels of the cord following visceral or spinal angiography.

Magnetic Resonance and Computed Tomographic Angiography

These are noninvasive techniques for visualizing the intracranial and cervical arteries. They can reliably detect intracranial vascular lesions and extracranial arterial stenosis and are supplanting conventional angiography. They approach the radiographic resolution of invasive angiography, but do not engender the risk of selective arterial catheterization (Fig. 2-4). Visualization of the cerebral veins is also possible by CT (Fig. 2-4D).

CT angiography requires contrast administration. In comparison, MR angiography can be performed without contrast, using the "time-of-flight" technique. This data can be reconstructed into an image that reflects flow-related enhancement. The signal obtained from time-of-flight MRA represents flow through the lumen of a vessel, rather than the configuration as obtained by contrast opacification. The use of these and other methods for the investigation of carotid artery disease is discussed further below and in Chap. 34, on cerebral vascular disease.

Ultrasonography

In recent years this technique has been refined to the point where it has become a principal methodology for clinical study of the fetal and neonatal brain and an important ancillary test for evaluating the cerebral vessels in adults. The instrument for this application consists of a transducer capable of converting electrical energy to ultrasound waves of a frequency ranging from 5 to 20 kHz. These are transmitted through the intact skull into the brain. Different tissues have specific acoustic impedances and send echoes back to the transducer, which displays them as waves of variable height or as points of light of varying intensity. In this way, one can obtain images in the neonate of choroid plexuses, ventricles, and central nuclear masses. Usually several coronal and parasagittal views are obtained by placing the transducer over open fontanelles or the child's thin calvarium. Intracerebral and subdural hemorrhages, mass lesions, and congenital defects can readily be visualized.

Similar instruments are used to insonate the basal vessels of the circle of Willis ("transcranial Doppler"), the cervical carotid and vertebral arteries, and the temporal arteries for the study of cerebrovascular disease. Their greatest use is in detecting and estimating the degree of stenosis of the origin of the internal carotid artery. In addition to providing an acoustic image of the vascular structures, the Doppler frequency shift caused by flowing red blood cells creates a display of velocities at each site in a vessel. The two techniques combined have been called "carotid duplex"; they allow an accurate localization of the locus of maximal stenosis as reflected by the highest rates of flow and turbulence. The display scale for the

Figure 2-4. Intracranial and cervical angiography. *A.* Oblique CT angiogram of the neck showing the carotid bifurcation and the cervical segments of the internal and external carotid arteries. Note the slightly dilated carotid bulb at the initial segment of the internal carotid artery. A small focus of calcified atherosclerosis is noted near the origin of the external carotid artery. Note that the external carotid artery has multiple branches within the neck. *B.* Coronal MR angiogram of the neck showing the aortic arch, the origins and cervical courses of the carotid and vertebral arteries, and the vertebrobasilar junction. The sigmoid sinuses and internal jugular veins are faintly visible. *C-D.* Midline sagittal dynamic CT angiography of the head. Bony and soft tissue structures as well as brain parenchyma have been digitally subtracted. The image *C* was acquired during the arterial phase; the carotid and basilar termini and the anterior cerebral arteries are enhanced. Venous phase imaging shows enhancement of the superior and inferior sagittal sinuses, straight sinus, vein of Galen, internal cerebral veins, basal veins of Rosenthal, and the transverse and sigmoid sinuses.

Doppler shift is color coded so as to make the insonated image and flow map easier to view and interpret.

The transcranial Doppler uses a 2-MHz pulsed signal that is able to pass through the calvarial bone in adults and then receives a frequency-shifted signal from the blood flowing in the lumen of the basal vessels. This allows the detection of vascular stenoses and the greatly increased blood flow velocity caused by vasospasm from subarachnoid hemorrhage.

Ultrasound has several advantages, notably that it is noninvasive, harmless (hence can be used repeatedly), convenient because of the portability of the instrument, and inexpensive. More specific applications of this technique are discussed in Chap. 38, on developmental diseases of the nervous system, and in Chap. 34, on stroke. The related technique of echocardiography has also assumed a central role in the evaluation of stroke, as indicated in Chap. 34.

ELECTROENCEPHALOGRAPHY (EEG)

The electroencephalographic examination, for many years a standard laboratory procedure in the study of all forms of cerebral disease, has to a large extent been supplanted by CT and MRI for the purposes of localization of structural lesions. It continues to be an essential part of the assessment of patients with seizures and those suspected of having seizures, as well as in brain death and for the study of sleep (polysomnography). It is also used in evaluating the cerebral effects of many systemic metabolic diseases and in the operating room to monitor cerebral activity in anesthetized patients. For a few diseases, such as subacute spongiform encephalopathy (prion disease), it is a useful confirmatory laboratory test. The technique is described here in some detail, as its general use in neurology cannot suitably be assigned to any other single chapter.

The electroencephalograph records spontaneous electrical activity generated in the cerebral cortex. This activity reflects the electrical currents that flow in the extracellular spaces of the brain that are the summated effects of innumerable excitatory and inhibitory synaptic potentials upon cortical neurons. This spontaneous activity of cortical neurons is highly influenced and synchronized by subcortical structures, particularly the thalamus and high brainstem reticular formation. Afferent impulses from these deep structures are probably responsible for entraining cortical neurons to produce characteristic rhythmic brain-wave patterns, such as alpha rhythm and sleep spindles (see further on).

Electrodes, which are silver or silver-silver chloride discs 0.5 cm in diameter, are attached to the scalp by means of a conductive paste. The electroencephalograph has 8 to 32 or more amplifying units capable of recording from many areas of the scalp at the same time. The amplified brain rhythms are seen as waveforms of brain activity in the frequency range of 0.5 to 30 Hz (cycles per second) on a standard display of that runs at 3 cm/s. In the past, the amplified signals were recorded by a bank of pens but now, a digital format of the rhythms is displayed

on a computer screen and stored electronically. The resulting electroencephalogram (EEG), essentially a voltage-versus-time graph, is a number of simultaneous parallel wavy lines, or "channels" (Fig. 2-5A). Each channel represents the difference in electrical potential between two electrodes (a common or ground electrode may be used as one recording site, but the channel still represents a bipolar recording). The channels are arranged for viewing into standard montages that generally allow comparison of the activity from one region of the cerebral cortex to others, and particularly to the corresponding region of the opposite side. The favored configuration of electrode pairs, or montage, is the "International 10-20" system, which uses 10 electrodes on each side of the cranium and emphasizes contiguous regions of the brain for ease of visual inspection of the record.

Patients are usually examined with their eyes closed and while relaxed in a comfortable chair or bed. Consequently, the ordinary EEG represents the electrocerebral activity that is recorded under restricted circumstances, usually during the waking or sleeping state, from several parts of the cerebral convexities during an almost infinitesimal segment of the person's life.

In addition to the resting record, a number of so-called activating procedures are usually employed. First, the patient is asked to breathe deeply 20 times a minute for 3 min. Hyperventilation, through a mechanism yet to be determined, may activate characteristic seizure patterns or other abnormalities. Second, a powerful strobe light is placed about 15 inches from the patient's eyes and flashed at frequencies of 1 to 20 per second with the patient's eyes open and closed. In a healthy subject, the occipital EEG leads show waves corresponding to each flash of light (photic driving, Fig. 2-5B).

The EEG is recorded after the patient is allowed to fall asleep naturally or occasionally, following the administration of sedative drugs. The drowsy state and the transition to and from deeper stages of sleep can reveal abnormalities.

Many abnormalities associated with sleep are more evident with long-term continuous EEG monitoring (hours to days) as described in Chap. 19. EEG activity can be synchronized with videographically recorded seizure activity in order to characterize the nature of the seizure. EEGs recorded by small digital devices or telemetry from freely moving ambulatory patients are similarly effective in cases of suspected seizure disorders. Chapter 16 discusses these techniques in detail. Chapter 19 contains information on the use of EEG to analyze disorders of sleep (polysomnography).

Certain preparations are necessary if electroencephalography is to be most useful. The patient should not be sedated (except as noted above) and should not have been without food for a long time, for both sedative drugs and relative hypoglycemia may modify the normal EEG pattern and should avoid caffeine if a sleep EEG study is planned. When dealing with patients who are suspected of having epilepsy and are already being treated for it, most physicians prefer to record the EEG while the patient continues to receive antiepileptic medications. During inpatient monitoring, these drugs are

Figure 2-5. A. Normal alpha (8 to 12 per second) activity is present posteriorly (bottom channel). The top channel contains a large blink artifact. Note the striking reduction of the alpha rhythm with eye opening (arrow). B. Photic driving. During stroboscopic stimulation of a normal subject, a visually evoked response is seen posteriorly after each flash of light (signaled on the bottom channel). C. Stroboscopic stimulation at 14 flashes per second (bottom channel) has produced a photoparoxysmal response in this epileptic patient, evidenced by the abnormal spike and slow-wave activity toward the end of the period of stimulation. (*continued*)

often withdrawn for a day or two in order to increase the likelihood of recording a seizure discharge but this requires careful clinical monitoring.

The proper interpretation of EEGs involves the recognition of several characteristic normal and abnormal patterns and background rhythms (in accordance with the age of the patient), the detection of asymmetries and

periodic changes in rhythm, and, importantly, the differentiation of artifacts from genuine abnormalities.

Normal EEG Patterns

The normal record in adults shows slightly asymmetrical 8- to 12-per-second 50-mV sinusoidal *alpha waves* in both

Figure 2-5. (Continued) *D.* An EEG showing focal spike-and-wave discharges over the right frontal region (channels 1 to 3). There were convulsive movements of the left side of the body. *E.* Absence seizures, showing generalized 3-per-second spike-and-wave discharge. The abnormal activity ends abruptly and normal background activity appears. *F.* Large, slow, irregular delta waves are seen in the right frontal region (channels 1 and 2). In this case a glioblastoma was found in the right cerebral hemisphere, but the EEG picture does not differ basically from that produced by a stroke, abscess, or contusion. (continued)

occipital and posterior parietal regions. These waves wax and wane in amplitude spontaneously and are attenuated or suppressed completely with eye opening or mental activity (see Fig. 2-5A). In contrast, the frequency of the alpha rhythm is almost invariant for an individual patient, although the rate slows with aging. Waves faster than 12 Hz and of lower amplitude (10 to 20 mV), called *beta waves*, are normally recorded from the frontal regions symmetrically. If benzodiazepines or other sedating drugs have been administered, an increase in the

fast frequencies is typically observed. When the normal subject falls asleep, the alpha rhythm slows symmetrically and characteristic waveforms consisting of vertex sharp waves and sleep spindles appear (see Fig. 19-1). A small amount of theta (4- to 7-Hz) activity may normally be present over the temporal regions, somewhat more so in persons older than 60 years of age. Delta (1- to 3-Hz) activity is not present in the normal waking adult.

The presence of a photic driving a response indicates that some of the visual pathways are preserved. Spread of

Figure 2-5. (Continued) *G.* Grossly disorganized background activity interrupted by repetitive “pseudoperiodic” discharges consisting of large, sharp waves from all leads about once per second. This pattern is characteristic of Creutzfeldt-Jakob disease. *H.* Advanced hepatic coma. Slow (about 2 per second) waves have replaced the normal activity in all leads. This record demonstrates the triphasic waves often seen in this disorder. *I.* Deep coma following cardiac arrest, showing electrocerebral silence. With the highest amplification, electrocardiogram (ECG) and other artifacts may be seen, so that the record is not truly “flat” or isoelectric. However, no cerebral rhythms are visible. Note the ECG (channel 5).

the occipital response induced by photic stimulation, with the production of abnormal sharp or paroxysmal waves, provides evidence of abnormal cortical excitability (Fig. 2-5B and C). Seizure patterns may be produced during this type of EEG testing, accompanied by gross myoclonic jerks of the face, neck, and limbs (photomyoclonic response), by electrographic seizure activity that outlasts the photic stimulation (photoparoxysmal response), or by or a convulsion (photoconvulsive response). Such effects occur with some regularity during periods of withdrawal from alcohol and other sedative drugs.

Children and adolescents are more sensitive than adults to all the activating procedures mentioned. It is customary for children to develop delta waves (3 to 4 Hz) during the middle and latter parts of a period of hyperventilation. This EEG activity, referred to as “breakdown,” or “buildup,” disappears soon after hyperventilation has stopped. The frequency of the dominant rhythms in infants is normally about 3 Hz, and they are very irregular. With maturation, there is a gradual increase in frequency and regularity of these occipital rhythms; an alpha rhythm appears by age 6 years and

the adult frequency is reached by the age of 10 to 12 years (see Chap. 28 for further discussion of maturation of the brain as expressed in the EEG). The interpretation of records of infants and children require considerable experience because of the wide range of normal patterns at each age period (see Hahn and Tharp). Nevertheless, grossly asymmetrical records or seizure patterns are clearly abnormal in children of any age. Normal patterns in the fetus, from the seventh month onward, have been established. Certain changes in these patterns, as described by Stockard-Pope et al. and by deWeerd, are indicative of a developmental disorder or disease.

Types of Abnormal Recordings

Localized regions of greatly diminished or absent brain waves are seen overlying large area of cerebral infarction, traumatic necrosis, tumor, or extensive clot. In the past, these findings allowed relatively precise localization of the abnormality—but, of course, the nature of the lesion was not disclosed.

Two types of abnormal waves, already mentioned, are of lower frequency and higher amplitude than normal. Waves below 4 Hz with amplitudes from 50 to 350 mV are called *delta waves* (Fig. 2-5F); those with a frequency of 4 to 7 Hz are called *theta waves*. Fast (beta) activity tends to be prominent frontally and usually reflects the effects of sedative drugs or, if focal, an immediately underlying skull defect called a “breach rhythm” (bone normally filters the abundant fast activity of the cortex). Spikes or sharp waves are transient high-voltage waveforms that have a pointed peak at recording speeds and duration of 20 to 70 ms and 70 to 200 ms (Fig. 2-5D). Spikes or sharp waves that occur interictally are referred to as epileptiform discharges.

When a series of abnormal fast and slow waves interrupts a relatively normal background EEG pattern in a paroxysmal fashion, it is suggestive of epilepsy. The electrical discharges associated with absence seizures have a more stereotyped pattern of 3-per-second spike-and-wave complexes that characteristically appear abruptly in all leads of the EEG simultaneously and disappear almost as suddenly at the end of the seizure (Fig. 2-5E).

The most pathologic finding of all is the absence of EEG activity, or “electrocerebral silence” that is a component of brain death. Artifacts of various types should be apparent as the amplifier gains are increased; if not, there is a risk that the leads are not properly connected to the machine or of another technical fault. Acute intoxication with high levels of drugs such as barbiturates can transiently produce this sort of isoelectric EEG (Fig. 2-5I). In the absence of nervous system depressants or extreme degrees of hypothermia, a record that is isoelectric (<2 uV except for artifacts) over all parts of the head is almost always a result of profound cerebral hypoxia or ischemia or of trauma and raised intracranial pressure. Such a patient—without EEG activity, brainstem reflexes, and spontaneous respiratory or muscular activity of any kind—is said to be brain dead as discussed further in Chapter 17.

Neurologic Conditions Causing Abnormal Electroencephalograms

Epilepsy

Epileptic seizures (see Chap. 16) are almost by definition associated with some abnormality in the EEG provided that it is being recorded at the time of the seizure. Rare exceptions are seizure states that originate in deep temporal, medial, or orbital frontal foci, from which the discharge fails to reach the scalp in sufficient amplitude to be seen against the normal background activity of the EEG. Most often, a completely normal EEG during a convulsion indicates a “pseudoseizure” (a psychogenic nonepileptic seizure, or “non-epileptic behavioral event”).

Some of the different types of seizure patterns are shown in Fig. 2-5D and E and are associated with particular clinical syndromes in Chap. 16. The absence, myoclonic, and grand mal EEG patterns correlate closely with the clinical seizure type and may be present in milder form in the EEG during periods between clinically evident seizures (interictally).

Between seizures, a single EEG recording will show a normal pattern in as many as 30 percent of patients with absence seizures and 50 percent of those with generalized tonic-clonic (grand mal) epilepsy (this percentage is less with repeated recordings). Antiepileptic therapy may mask interictal EEG abnormalities but the degree to which this occurs is not known. The records of another 30 to 40 percent of those with epilepsy, although abnormal between seizures, are nonspecifically so; consequently, the diagnosis of epilepsy can be made only by the correct interpretation of clinical data in relation to the EEG abnormality.

Focal Brain Lesions (Brain Tumor, Abscess, Subdural Hematoma, Stroke, and Encephalitis)

In a very high proportion of patients, intracranial mass lesions are associated with focal or localized slow-wave activity (usually delta, as in Fig. 2-5F) or, occasionally, seizure activity. Although the EEG may be diagnostically helpful in cases of brain tumor or abscess, particularly when integrated with the other laboratory and clinical findings, reliance is now placed almost exclusively on CT and MRI.

However, EEG remains of considerable value in the diagnosis of herpes simplex encephalitis in which periodic high-voltage sharp waves and slow-wave complexes at intervals of 1 to 3 per second in the temporal regions are characteristic. The other infectious encephalitides are often associated with sharp or spike activity, particularly if there have been seizures. Figure 2-5G shows the characteristic pattern of almost periodic sharp waves seen in Creutzfeldt-Jakob disease.

The EEG is now little used in the differential diagnosis of stroke, except to distinguish a transient ischemic attack from a seizure. In the past, one practical value was in the ability to differentiate an acute ischemic lesion in the distribution of the middle cerebral artery, which produces a large area of slowing, from lacunar infarction deep in the cerebrum or brainstem, in which the surface EEG is

usually normal despite prominent clinical abnormalities. After 3 to 6 months, in roughly 50 percent of patients with infarction in the territory of the middle cerebral artery, the focal EEG slowing becomes normal. Perhaps half these patients will have had normal EEGs even in the week or two following the stroke. A persistent abnormality is generally associated with a poor prognosis for further recovery. Large lesions of the diencephalon or midbrain produce bilaterally synchronous slow waves, but those of the pons and medulla (i.e., below the mesencephalon) are usually associated with a normal or near-normal EEG pattern despite catastrophic clinical changes.

A brief episode of cerebral concussion in animals is accompanied by a transitory disturbance in the EEG, but in humans this is usually no longer evident by the time a recording can be made. Large cerebral contusions produce focal EEG slowing similar to those described for cerebral infarction. Sharp waves or spikes sometimes emerge as the focal slow-wave abnormality resolves and may precede the occurrence of posttraumatic epilepsy; serial EEGs may be of prognostic value in this regard. During syncope, the EEG is slowed and of reduced amplitude even to the point of becoming "flat." Upon recovery, a number of patterns have been described as discussed further in Chap. 18.

Diseases that Cause Coma and States of Impaired Consciousness

The EEG is abnormal in almost all conditions in which there is impairment of the level of consciousness. There is, for example, a fairly close correspondence between the severity of acute anoxic damage from cardiac arrest and the degree of EEG slowing. The mildest forms are associated with generalized theta activity, intermediate forms with widespread delta waves and the loss of normal background activity, and the most severe forms with "burst suppression," in which brief isoelectric periods are followed by high-voltage sharp and irregular delta activity. The latter pattern usually progresses to the electrocerebral silence of brain death, a condition discussed earlier.

The term alpha coma refers to a unique EEG pattern in which an apparent alpha activity in the 8- to 12-Hz range is distributed widely over the hemispheres rather than in its normal location posteriorly. When analyzed carefully, this background activity, unlike the normal monorhythmic alpha, is found to vary slightly in frequency. This is usually a transitional pattern after global anoxia; less often, alpha coma occurs with large acute pontine lesions. With severe hypothyroidism, the brain waves are normal in configuration but usually of decreased amplitude and frequency.

In altered states of alertness, the more profound the depression of consciousness, in general, the more abnormal and slower the EEG rhythms. In states of deep stupor or coma, the slow (delta) waves are bilateral and of high amplitude and tend to be more conspicuous over the frontal regions (Fig. 2-5H). This pertains in such differing conditions as acute meningitis or encephalitis and disorders that severely alter blood gases, glucose, electrolytes, and water balance; uremia; diabetic coma; and impairment

of consciousness accompanying the large cerebral lesions discussed above. In hepatic coma, the degree of abnormality in the EEG corresponds roughly to the degree of confusion, stupor, or coma. Characteristic of hepatic coma are paroxysms of bilaterally synchronous large, sharp "triphasic waves" (Fig. 2-5H), although such waveforms may also be seen with less regularity in encephalopathies related to renal or pulmonary failure and with acute hydrocephalus (intermittent biphasic frontal slowing is more typical of hydrocephalus).

An EEG may also be of help in the diagnosis of coma that is due to ongoing seizures ("nonconvulsive status epilepticus") or, when the pertinent history is not available and there was an unobserved convulsion. It may also point to an otherwise unexpected cause of coma, such as hepatic encephalopathy, intoxication with barbiturates or other sedative-hypnotic drugs, the effects of diffuse anoxia-ischemia, catatonia, or hysteria (in which the EEG is normal).

Diffuse Degenerative Diseases

Alzheimer disease and other degenerative diseases that cause serious impairment of cerebrocortical function are accompanied by relatively slight degrees of diffuse slow-wave abnormality in the theta (4- to 7-Hz) range; many recordings are normal in the early and midstages of illness. More rapidly progressive disorders—such as subacute sclerosing panencephalitis (SSPE), Creutzfeldt-Jakob disease, and to a lesser extent the cerebral lipidoses—often have, in addition, very characteristic and almost pathognomonic EEG changes consisting of periodic bursts of high-amplitude sharp waves, usually bisynchronous and symmetrical (Fig. 2-5G). In a negative sense, a normal EEG in a patient who is profoundly apathetic is a point in favor of the diagnosis of hysteria, catatonia, or schizophrenia (see below).

Other Diseases of the Cerebrum

Many disorders of the brain cause little or no alteration in the EEG. Multiple sclerosis and other demyelinating diseases are examples, although as many as 50 percent of patients with advanced disease will have an abnormal record of nonspecific type (mild focal or diffuse slowing). Delirium tremens and Wernicke-Korsakoff disease, despite the dramatic nature of the clinical picture, cause little or no change in the EEG. Interestingly, the psychoses (bipolar disorders or schizophrenia), intoxication with hallucinogenic drugs such as lysergic acid diethylamide (LSD), and the majority of cases of mental retardation are associated either with no modification of the normal record or with only minor nonspecific abnormalities unless seizures are present.

Clinical Significance of Minor Electroencephalogram Abnormalities

The gross EEG abnormalities discussed above are by themselves clearly abnormal, and any formulation of the patient's clinical state should attempt to account for them. Lesser degrees of abnormality form a continuum between

the undoubtedly abnormal and the completely normal and are of correspondingly less significance. Findings such as 14- and 6-per-second positive spikes or small sharp waves during sleep, scattered 5- or 6-per-second slowing, minor voltage asymmetries, and persistence of “breakdown” for a few minutes after hyperventilation are interpreted as normal variants or borderline abnormalities. Whereas borderline deviations in an otherwise entirely normal person have no clinical significance, the same minimal EEG findings associated with particular clinical signs and symptoms become important. The significance of a normal or “negative” EEG in certain patients suspected of having a cerebral lesion was discussed above.

As a general clinical principle, the results of the EEG, like those of the EMG and electrocardiogram, are meaningful only in relation to the illnesses under consideration and the clinical state of the patient at the time the recordings were made.

EVOKED POTENTIALS

The stimulation of sense organs or peripheral nerves evokes an electrical response in the corresponding cortical receptive areas and in a number of subcortical relay stations. However, one cannot place a recording electrode near the nuclear relay stations, nor can one detect tiny potentials of only a few microvolts among the much larger background activity in the EEG. The use of computerized averaging methods, introduced by Dawson in 1954, has provided a means of overcoming these problems. Initially, emphasis was on the study of late waves (over 75 ms after the stimulus) because they are of high amplitude and easy to record. However, there is more clinical utility in recording the much smaller, short-latency waveforms, which are received at each nuclear relay within the main sensory systems. These waveforms are maximized by the computer to a point where their latency and voltage can easily be measured. One of the most remarkable properties of evoked potentials is their resistance to anesthesia, sedative drugs, and—in comparison with EEG activity—even damage of the cerebral hemispheres. This permits their use for monitoring the integrity of cerebral pathways in situations that render the EEG useless.

The interpretation of evoked potentials (visual, auditory, and somatosensory) is based on the prolongation of the latencies of the waveforms after the stimulus, the interwave latencies, and asymmetries in timing. Norms for latencies have been established, but it is advisable to confirm these in each laboratory. Typically 2.5 or 3 standard deviations above the mean latency for any measurement is taken as the definition of abnormality (Table 2-4). The amplitudes of the waves are less informative for clinical work.

Visual Evoked Potentials (VER, VEP)

For many years it had been known that a light stimulus flashing on the retina evokes a discernible waveform over

Table 2-4

MAIN SENSORY EVOKED POTENTIAL LATENCIES FROM STIMULUS, MILLISECONDS^a

TYPE OF EVOKED POTENTIAL	MEAN	UPPER LIMIT (MEAN + 3 SD)
PSVER (70-min check size)		
P100 absolute latency	104	118
Intereye difference	2	8
BAER (60 dBSL, 10/s monaural stimuli)		
Interwave latency		
I–III	2.1	2.6
III–V	1.9	2.4
I–V	4.0	4.7
Interside difference for most latencies	0.1	0.4
SEP—median nerve (wrist stimulation)		
Absolute latency		
Erb's point	9.7	12.0
P/N 13 (cervicomedullary)	13.5	16.3
N 19/P 21 (cortical)	19.0	22.1
Interwave latency		
Erb's-P/N 13	3.8	5.2
P/N 13–N 19	5.5	6.8
Interside difference		
P/N 13–N 19	0.3	1.1
SEP—tibial nerve (ankle stimulation; Fz-Cz recording; 165-cm height; absolute latencies are shorter for stimulation at the knee)		
Absolute latency		
Lumbar point (cauda equina)	20	25
N/P 37 (cortex)	36	42.5
Interwave latency		
Lumbar–N/P 37	16.4	21.6
Interside difference		
Lumbar–N/P 37	0.7	1.9

^aNorms must be verified in each laboratory; in most instances they are sensitive to the technique and stimulus used and height of the patient in the cases of limb stimulation.

BAER, brainstem auditory evoked response; PSVER, pattern shift visual evoked response; SSEP, somatosensory evoked response.

the occipital lobes. In the EEG, such responses to fast rates of stimulation are referred to as the occipital driving response (Fig. 2-5 B and C). It also was appreciated decades ago that a visual evoked response is produced by the sudden change of a viewed checkerboard pattern. These responses, produced by rapidly reversing the pattern of black and white squares, are easier to detect and to measure than are flash responses and are more consistent in waveform from one individual to another. The pattern shift stimulus applied first to one eye and then to the other, can demonstrate conduction delays in the visual pathways of patients who have had disease of the optic nerve—even when there are no residual signs of reduced visual acuity, visual field abnormalities, alterations of the optic nerve head, or changes in pupillary reflexes. Furthermore, the presence of a normal visual evoked response belies blindness from a lesion in the anterior visual pathways and their projections to the occipital cortex. Figure 2-6 illustrates the normal pattern shift visual evoked response (PSVER) and two types of delayed

Figure 2-6. Pattern-shift visual evoked responses (PSVERs). Latency measured to first major positive peak (termed P100 because of its latency from the stimulus of approximate 100 msec) and marked by “o.” Upper two tracings: These, from the right and left eyes, are normal. Middle tracings: PSVER from the right eye is normal but the latency of the response from the left eye is prolonged and its duration is increased. Lower tracings: PSVER from both eyes show abnormally prolonged latencies, somewhat greater on the left than on the right. Calibration: 50 ms, 2.5 mV.

responses. Reductions in the amplitude and duration of PSVER usually accompany prolonged latencies but are difficult to quantify.

The expected latency for the positive polarity, by convention a downward deflection, PSVER is near 100 ms (thus the term P100 has also been used to designate the waveform); an absolute latency from the stimulus longer than 118 ms or a difference in latencies of greater than 9 ms between the two eyes signifies involvement of one optic nerve (Table 2-4). Bilateral prolongation of latencies, demonstrated by separate stimulation of each eye, can be caused by lesions in both optic nerves, the optic chiasm, or the visual pathways posterior to the chiasm.

As indicated above, PSVER is especially valuable in proving the existence of active or residual disease of an optic nerve. Patients with previous optic neuritis will have abnormal latencies. Furthermore, similar prolongations of PSVER are found in about one-third of multiple sclerosis patients who have had no history or clinical evidence of optic nerve involvement. This acquires significance in that the finding of abnormal PSVER in a patient with a clinically apparent demyelinating lesion elsewhere in the CNS may usually be taken as evidence of multiple sclerosis, as discussed in Chap. 36.

A compressive lesion of an optic nerve will have the same effect as a primarily demyelinating one. Many

other diseases of the optic nerves—including toxic and nutritional amblyopias, ischemic optic neuropathy, and the Leber type of hereditary optic neuropathy—show abnormalities of the PSVER. Glaucoma and other diseases involving structures anterior to the retinal ganglion cells, if severe enough to affect the optic nerve, may also produce increased latencies. Impaired visual acuity has little effect on the latency but does correlate well with the amplitude of the PSVER (a property that is exploited in some computerized testing for visual acuity). The use of these tests in detecting psychogenic blindness has already been mentioned. By presenting the pattern-shift stimulus to one hemifield, it is possible to isolate a lesion to an optic tract or radiation, or one occipital lobe, but with much less precision than that provided by the usual monocular testing.

Brainstem Auditory Evoked Potentials

The effects of auditory stimuli can be studied in the same way as visual ones by a procedure called brainstem auditory evoked responses, or potentials (BAERs, or BAEPs). Between 1,000 and 2,000 clicks, delivered first to one ear and then to the other, are recorded through scalp electrodes and superimposed on each other by computer and thereby maximized. A series of seven waves appears at the scalp within 10 ms after each stimulus. On the basis of depth recordings and the study of lesions produced in cats as well as pathologic studies of the brainstem in disease, it has been suggested that each of the first five waves is generated by a specific brainstem structure, as indicated in Fig. 2-7, but this has not been established with precision in humans. The generators of waves VI and VII in particular are uncertain. The presence of wave I and its absolute latency test the integrity of the auditory nerve.

Clinical interpretations of BAERs are based mainly on latency measurements from the stimulus and interwave latencies. The most important are the interwave latencies between I and III, and III and V (see Table 2-4). A lesion that affects one of the auditory nuclear relay stations or its immediate connections manifests itself by a delay in the appearance or an absence of all subsequent waves; in other words, the nuclei behave as if they are connected in series. These effects are more pronounced on the side of the stimulated ear than contralaterally. This is difficult to understand, as a majority of the cochlear-superior olivary-lateral lemniscal-medial geniculate fibers cross to the opposite side. It is also surprising that a lesion of one relay station would allow impulses, even though delayed, to continue their ascent and be recordable in the cerebral cortex.

BAEPs are a particularly sensitive means of detecting lesions of the eighth cranial nerve (vestibular schwannoma and other tumors of the cerebellopontine angle) and of the auditory pathways of the brainstem. Almost one-half of patients with definite multiple sclerosis and a lesser number with a possible or probable diagnosis of this disease will show abnormalities of the BAEPs, (usually a prolongation of interwave latencies I to III or III to V), even in the absence of clinical symptoms

Figure 2-7. Short-latency brainstem auditory evoked responses (BAERs). Diagram of the proposed electrophysiologic–anatomic correlations in human subjects. Waves I through V are the ones measured in clinical practice.

and signs of brainstem disease. The BAEPs are also useful in assessing hearing in infants who have been exposed to ototoxic drugs, in young children who cannot cooperate with audiometry, and in those with psychogenic or feigned deafness.

Somatosensory Evoked Potentials (SSEP)

The technique consists of applying 5-per-second painless transcutaneous electrical stimuli to the median, peroneal, or tibial nerves and recording the evoked potentials (for the upper limb) sequentially as they pass the brachial plexus over the Erb point above the clavicle, over the C2 vertebra, and over the opposite parietal cortex, and (for the lower limb) over the lumbar roots of the cauda equina, the nuclei over the cervical spine, and the opposite parietal cortex. The impulses generated in large touch fibers by 500 or more stimuli and averaged by computer can be traced through the corresponding peripheral

nerves, spinal roots, and posterior columns to the cuneate and gracile nuclei in the lower medulla, through the medial lemniscus to the contralateral thalamus, and thence to the sensory cortex of the parietal lobe. Delay between the stimulus site and the Erb point or the lumbar spine indicates peripheral nerve disease; delay from the Erb point (or lumbar spine) to C2 implies an abnormality in the appropriate nerve roots or, more frequently, in the posterior columns; the presence of lesions in the medial lemniscus and thalamoparietal pathway can be inferred from delays of subsequent waves recorded from the parietal cortex (Fig. 2-8). The normal waveforms are designated by the symbols P (positive) and N (negative), with a number indicating the interval of time in milliseconds from stimulus to recording (e.g., N11, N13, P13, P22, etc.). As shorthand for the polarity and approximate latency, the summated wave that is recorded at the cervicomedullary junction is termed N/P13, and the cortical potential from median nerve stimulation seen in two contiguous waves of opposite polarity is called N19–P22.

Figure 2-8. Short-latency SEPs produced by stimulation of the median nerve at the wrist. The set of responses shown at left is from a normal subject; the set at right is from a patient with multiple sclerosis who had no sensory symptoms or signs. In the patient, note the preservation of the brachial-plexus component (EP), the absence of the cervical cord (N11) and lower-medullary components (N/P13), and the latency of the thalamocortical components (N19 and P22), prolonged above the normal mean $+3$ SD for the interval from the brachial plexus potential. Unilateral stimulation occurred at a frequency of 5 per second. Each trace is the averaged response to 1,024 stimuli; the superimposed trace represents a repetition to demonstrate waveform consistency. Recording electrode locations are as follows: FZ, midfrontal; EP, the Erb point (the shoulder); C2, the middle back of the neck over the C2 cervical vertebra; and Cc, the scalp overlying the sensoriparietal cortex contralateral to the stimulated limb. Relative negativity at the second electrode caused an upward trace deflection. Amplitude calibration marks denote 2 mV. (Reproduced by permission from Chiappa and Ropper.)

The corresponding cortical wave after tibial or peroneal nerve stimulation is called N/P37.

For purposes of clinical interpretation, the generators of the SEP waves are assumed to be linked in series, so that an interwave prolongation in latency indicates a conduction defect between the generators of the two peaks involved (Chiappa and Ropper). Normal values are shown in Table 2-4. Recordings with pathologically verified lesions at these levels are to be found in the monograph by Chiappa. This test has been most helpful in establishing the existence of lesions in spinal roots, posterior columns, and brainstem in disorders such as the ruptured lumbar and cervical discs, multiple sclerosis, and lumbar and cervical spondylosis when the clinical data are uncertain. The cerebral counterpart also pertains—namely, that obliteration of the cortical waves (assuming that all preceding waves are unaltered) reflects profound damage to the somatosensory pathways in the hemisphere or to the cortex itself. For example, the bilateral absence of cortical somatosensory waves after cardiac arrest is a powerful predictor of a poor clinical outcome; the persistent absence of a cortical potential on one side after stroke usually indicates such profound damage that only a limited clinical recovery is to be expected.

Evoked potential techniques have also been used in the experimental study of olfactory and trigeminal sensation (see Chap. 12).

Magnetic Stimulation of the Motor System

It is possible, by using single-pulse high-amplitude magnetic stimulation, to directly activate the motor cortex (transcranial magnetic stimulation) and cervical spine segments, and to detect delays or lack of conduction in descending motor pathways. This technique, introduced by Marsden and associates, painlessly stimulates only the largest motor neurons (presumably Betz cells) and the fastest-conducting axons. Cervical magnetic stimulation is believed to activate the anterior roots. The difference in time between the motor cortical and cervical activation of hand or forearm muscles reflects the conduction velocity of the cortical-cervical cord motor neurons. The technique has been used to understand the organization, function, and recovery of the motor cortex and the pathophysiology of stroke, multiple sclerosis, and amyotrophic lateral sclerosis. Although the degree of functional deficit does not precisely correlate with the degree of electrophysiologic change, one expects that refinements of this

technique may be useful in evaluating the status of the corticospinal motor system as well as other cortically based functions.

Endogenous Event-Related Evoked Potentials

Among the very late brain electrical potentials (>100-ms latency) that can be extracted from background activity by computer methods, are a group that cannot be classified as sensory or motor but rather as psychophysical responses to environmental stimuli. These responses are of very low voltage, often fleeting and inconsistent, and of unknown anatomic origin. The most studied types occur approximately 300 ms (P300) after an attentive subject identifies an unexpected or novel stimulus that has been inserted into a regular train of stimuli. Almost any stimulus modality can be used and the potential occurs even when a stimulus has been omitted from a regular pattern. The amplitude of the response depends on the difficulty of the task and has an inverse relationship to the frequency of the unexpected or “odd” event; the latency depends on the task difficulty and other features of testing. There is therefore no single P300; instead, there are numerous types, depending on the experimental paradigm. Prolongation of the latency is found with aging and in dementia as well as with degenerative diseases such as Parkinson disease, progressive supranuclear palsy, and Huntington chorea. The amplitude is reduced in schizophrenia and depression. The potential has been interpreted by some as a reflection of the subject’s orienting behavior or attention and by others, including Donchin, who discovered the phenomenon, as related to an updating of the brain’s representation of the environment. The P300 remains a curiosity for the clinical neurologist because abnormalities are detected only when large groups are compared to normal individuals, and the technique is not as standardized as the conventional evoked potentials. A review of the subject can be found in sections by Altenmüller and Gerloff and by Polich in the Niedermeyer and Lopes DaSilva text on electroencephalography.

ELECTROMYOGRAPHY AND NERVE CONDUCTION STUDIES

These are discussed in Chap. 45.

PSYCHOMETRY, PERIMETRY, AUDIOMETRY, AND TESTS OF LABYRINTHINE FUNCTION

These methods are used in defining and quantitating the nature of the psychologic or sensory deficits produced by disease of the nervous system. They are performed most often to obtain confirmation of a disorder of function in

particular parts of the nervous system or to quantitate, by subsequent examinations, the progression of the underlying illness such as a dementia. A description of these methods and their clinical uses is found in the chapters dealing with cerebral function (Chap. 22), developmental disorders of the cerebrum (Chap. 28), dementia (Chap. 21), and disorders of vision (Chap. 13) and of hearing and equilibrium (Chap. 15).

GENETIC TESTING

Numerous genetic markers of hereditary disease have become available to the clinician and have greatly advanced both diagnosis and categorization of neurologic disease. The main examples are analyses of DNA extracted from blood or other cells for the identification of mutations (e.g., muscular dystrophy, spinocerebellar atrophies, and genetically determined polyneuropathies, and the quantification of abnormally long repetitions of certain trinucleotide sequences, most often used for the diagnosis of Huntington chorea). The use of these tests is elaborated in Chap. 39. The study of mitochondrial genetics has allowed the detection of an entire category of diseases that affect this subcellular structure, as detailed in Chap. 37.

BIOPSY OF MUSCLE, NERVE, SKIN, TEMPORAL ARTERY, BRAIN, AND OTHER TISSUE

The application of light, phase, and electron microscopy to the study of these tissues may be highly informative. The findings are discussed in Chaps. 37 (skin and conjunctivum in the diagnosis of metabolic storage diseases), 45 (muscle), and 46 (nerve). Temporal artery biopsy is indicated when giant cell arteritis is suspected (Chap. 34). Brain biopsy, aside from its main use in the direct sampling of a suspected neoplasm, may be diagnostic in cases of granulomatous angiitis, some forms of encephalitis, infectious abscesses. Biopsy of the pachymeninges or leptomeninges may disclose vasculitis, sarcoidosis, other granulomatous infiltrations, or an obscure infection, but its sensitivity is low. This is usually performed in concert with a biopsy of the underlying brain. Biopsy is now generally avoided in cases of suspected prion disease because of the risk of transmitting the causative agent. Abdominal fat pad biopsy is used in the diagnosis of amyloidosis.

In choosing to perform a biopsy in any of these clinical situations, the paramount issue is the likelihood of establishing a definitive diagnosis—one that would permit successful treatment or otherwise enhance the management of the disease.

- CHAPTER 6 **Tremor, Myoclonus, Focal Dystonias, and Tics**
- CHAPTER 7 **Disorders of Stance and Gait**

The control of motor function, to which much of the human nervous system is committed, is accomplished through the integrated action of a vast array of segmental and suprasegmental motor neurons. As originally conceived by Hughlings Jackson in 1858, purely on the basis of clinical observations, the motor system is organized hierarchically in three levels, each higher level controlling the one below. It was Jackson's concept that the spinal and brainstem neurons represent the lowest, simplest, and most highly organized motor centers; that the motor neurons of the posterior frontal region represent a more complex and less closely organized second motor center; and that the prefrontal parts of the cerebrum are the third and highest motor center. This scheme is still regarded as being essentially correct, although Jackson failed to recognize the importance of the parietal lobe and basal ganglia in motor control.

Since Jackson's time, physiologists, and more recently, experts in functional imaging, have repeatedly analyzed these three levels of motor organization and found them to be valid but to have remarkably complex relationships. Motor and sensory systems, although separated for practical clinical purposes, are not independent entities but are closely integrated. Without sensory feedback, motor control is ineffective. And at the higher cortical levels of motor control, motivation, planning, and other frontal lobe activities that subserve volitional movement are preceded and modulated by activity in the parietal sensory cortex.

Motor activities include not only those that alter the position of a limb or other part of the body (isotonic contraction) but also those that stabilize posture (isometric contraction). Movements that are performed slowly are called *ramp movements*. Very rapid movements, which are too fast for sensory control, are called *ballistic*. Physiologic studies, cast in their simplest terms, indicate that the following parts of the nervous system are engaged primarily in the control of movement and, in the course of disease, yield a number of characteristic derangements.

1. *The large motor neurons in the anterior horns of the spinal cord and the motor nuclei of the brainstem.* The axons of these nerve cells comprise the anterior spinal roots, the spinal nerves, and the cranial nerves, and they innervate the skeletal muscles. These nerve cells and their axons constitute the *lower motor neurons*, complete lesions of which result in a loss of all movement—voluntary, automatic, postural, and reflex. The lower motor neurons are the *final common pathway* by which all neural impulses are transmitted to muscle.
2. *The motor neurons in the frontal cortex adjacent to the rolandic fissure (motor strip)* connect with the spinal motor neurons by a system of fibers known, because of the shape of its fasciculus in the medulla, as the *pyramidal tract*. Because the motor fibers that extend from the cerebral cortex to the spinal cord are not confined to the pyramidal

tract, they are more accurately designated as *the corticospinal tract*, or, alternatively, as *the upper motor neurons*, to distinguish them from the lower motor neurons.

3. *Several brainstem nuclei that project to the spinal cord, notably the pontine and medullary reticular nuclei, vestibular nuclei, and red nuclei.* These nuclei and their descending fibers subserve the neural mechanisms of posture and movement, particularly when movement is highly automatic and repetitive. Certain of these brainstem nuclei are influenced by the motor or premotor regions of the cortex, e.g., via corticoreticulospinal relays.
4. *Two subcortical systems, the basal ganglia (striatum, pallidum, and related structures, including the substantia nigra and subthalamic nucleus) and the cerebellum.* Each of these systems plays an important role in the control of muscle tone, posture, and coordination.

These are the subjects of the following chapters.

Motor Paralysis

Definitions

Paralysis means loss of voluntary movement as a result of interruption of one of the motor pathways at any point from the cerebrum to the muscle fiber. A lesser degree of paralysis is spoken of as paresis. The word plegia comes from a Greek word meaning “to strike,” and the word palsy is from an old French word that has the same meaning as paralysis. One generally uses paralysis or plegia for severe or complete loss of motor function and paresis for partial loss.

THE LOWER MOTOR NEURON

Anatomic and Physiologic Considerations

Each spinal and cranial motor nerve cell, through the extensive arborization of the terminal part of its efferent fiber, comes into contact with only a few or up to 1,000 or more muscle fibers; together, the nerve cell, its axons, and the muscle fibers they subserve constitute the *motor unit*. All variations in the force, range, rate, and type of movement are determined by the number and size of motor units called into action and the frequency and sequence of firing of each motor unit. Weak movements involve relatively few small motor units; powerful movements recruit many more units that accumulate to an increasing size.

Within a few days after interruption of a motor nerve, the individual denervated muscle fibers begin to contract spontaneously. This isolated activity of individual muscle fibers is called *fibrillation*. Inability of the isolated fiber to maintain a stable membrane potential is the likely explanation. Fibrillation is so fine that it cannot be seen through the intact skin, but it can be recorded as a small, repetitive, short-duration potential in the electromyogram (EMG) (Chap. 45). When a motor neuron becomes diseased, it may manifest increased irritability, i.e., the axon is unstable and capable of spontaneous impulse generation, and all the muscle fibers that it controls may discharge sporadically, in isolation from other units. The result of contraction of one or several such motor units is a visible twitch of a muscle fascicle, or *fasciculation*, which appears in the EMG as a large spontaneous muscle action potential. Simultaneous or sequential

spontaneous contractions of multiple motor units cause a rippling of muscle, a condition known as *myokymia*. If the motor neuron is destroyed, all the muscle fibers that it innervates undergo profound atrophy—termed denervation atrophy.

The motor nerve fibers of each ventral root intermingle with those of neighboring roots to form plexuses, and then the named peripheral nerves. Although the muscles are innervated roughly according to segments of the spinal cord, each large muscle is supplied by two or more roots. In contrast, a single peripheral nerve usually provides the complete motor innervation of a muscle or group of muscles. For this reason, paralysis caused by disease of the anterior horn cells or anterior roots has a different topographic pattern than paralysis following interruption of a peripheral nerve. These patterns follow the distribution shown in Table 46-1. For example, section of the L5 motor root causes paralysis of the extensors of the foot with a foot drop and weakness of inversion of the foot, whereas a lesion of the peroneal nerve also causes foot drop but does not affect the invertors of the foot that are also supplied by L5 but via the tibial nerve.

All motor activity, even the most elementary reflex type, requires the synchronous activity of many muscles. Analysis of a relatively simple movement, such as clenching the fist, conveys some idea of the complexity of the underlying neuromuscular arrangements. In this act the primary movement is a contraction of the flexor muscles of the fingers, the flexor digitorum sublimis and profundus, the flexor pollicis longus and brevis, and the abductor pollicis brevis. In the terminology of Beevor, these muscles act as agonists, or prime movers. For flexion to be smooth and forceful, the extensor muscles (antagonists) must relax at the same rate as the flexors contract (reciprocal innervation, or Sherrington law). The muscles that flex the fingers also flex the wrist. If it is desired that only the fingers flex, the extensors of the wrist must be brought into play to prevent its flexion; they are synergists. During this action of the hand, appropriate flexor and extensor muscles stabilize the wrist, elbow, and shoulder; muscles that accomplish this serve as fixators. The coordination of agonists, antagonists, synergists, and fixators is effected mainly by segmental spinal reflexes under the guidance of proprioceptive sensory stimuli. In general, the more delicate the movement, the

more precise must be the coordination between agonist and antagonist muscles.

All voluntary ballistic (phasic) movements towards a target are accomplished by the activation of ensembles of motor neurons, large ones supplying large motor units and small ones, small motor units. The smaller ones are more efficiently activated by sensory afferents from muscle spindles, more tonically active, and more readily recruited in reflex activities, postural maintenance, walking, and running. The large motor units participate mainly in phasic movements, which are characterized by an initial burst of activity in the agonist muscles, then a burst in the antagonists, followed by a third smaller burst in the agonists. The strength of the initial agonist burst determines the speed and distance of the movement, but there is always the same triphasic pattern of agonist, antagonist, and agonist activity (Hallett et al). The basal ganglia and cerebellum set the pattern and timing of the muscle action in any projected motor performance. These points are discussed further in Chaps. 4 and 5.

Unlike the phasic movements just described, certain basic motor activities do not involve reciprocal innervation. In support of the body in an upright posture, when the legs must act as rigid pillars, and in shivering, agonists and antagonists contract simultaneously. Locomotion requires that the extensor pattern of reflex standing be inhibited and that the coordinated pattern of alternating stepping movements be substituted; the latter is accomplished by multisegmental spinal and brainstem reflexes, the so-called locomotor centers. Suprasegmental control of the axial and proximal limb musculature (antigravity postural mechanisms) is mediated primarily by the reticulospinal and vestibulospinal tracts and manipulatory movements of the distal extremity muscles, by the rubrospinal and corticospinal tracts. These aspects of motor function are elaborated further on.

Muscle stretch (tendon) reflex activity and muscle tone depend on the status of the large motor neurons of the anterior horn (the alpha motor neurons), the muscle spindles and their afferent fibers, and the small anterior horn cells (gamma neurons), whose axons terminate on the small intrafusal muscle fibers within the spindles. Each anterior horn cell has on its surface membrane approximately 10,000 receptive synaptic terminals. Some of these terminals are excitatory, others inhibitory; in combination, they determine the activity of the neuron. Beta motor neurons effect cocontraction of both spindle and nonspindle fibers, but the physiologic significance of this innervation is not fully understood. Some of the gamma motor neurons are tonically active at rest, keeping the intrafusal (nuclear chain) muscle fibers taut and sensitive to active and passive changes in muscle length.

A tap on a tendon stretches or perhaps causes vibration of the spindle and activates its nuclear bag fibers. Afferent projections from these fibers synapse directly with alpha motor neurons in the same and adjacent spinal segments; these neurons, in turn, send impulses to the skeletal muscle fibers, resulting in the familiar monosynaptic muscle contraction or monophasic (myotatic) stretch reflex, commonly referred to as the

tendon reflex or "tendon jerk" (Fig. 3-1), more correctly called the muscle stretch or proprioceptive reflex. All this occurs within 25 ms of sudden stretch. The alpha neurons of antagonist muscles are simultaneously inhibited but through disynaptic rather than monosynaptic connections. This is accomplished in part by inhibitory interneurons (*reciprocal inhibition*), which also receive input from descending pathways. Renshaw cells also participate by providing negative feedback through inhibitory synapses of alpha motor neurons (*recurrent inhibition*).

Thus the setting of the spindle fibers and the state of excitability of the alpha and gamma neurons (influenced greatly by descending fiber systems) determine the level of activity of the tendon reflexes and muscle tone (the responsiveness of muscle to stretch). Other mechanisms, of an inhibitory nature, involve the Golgi tendon organs, for which the stimulus is tension produced by active contraction of muscle. These encapsulated receptors, which lie in the tendinous and aponeurotic insertions of muscle, activate afferent fibers that end on internuncial cells, which, in turn, project to alpha motor neurons, thus forming a disynaptic reflex arc. Golgi tendon receptors are silent in relaxed muscle and during passive stretch; they serve, together with muscle spindles, to monitor or calibrate the length and force of muscle contraction under different conditions. They also play a role in naturally occurring limb movements, particularly in locomotion.

The alpha motor neurons of the medial parts of the anterior horn supply trunk or axial muscles, and neurons of the lateral parts supply the appendicular muscles. The largest neurons, in Rexed layer IX (see Fig. 8-1B), innervate large muscles with large motor units. Smaller anterior horn cells innervate small muscles and control more delicate movements, particularly those in the fingers and hand. Both groups of alpha neurons receive projections from neurons in the intermediate Rexed layers (V to VIII) and from propriospinal neurons in the fasciculi proprii of adjacent spinal segments (see Fig. 8-1B). All the facilitatory and inhibitory influences supplied by cutaneous and proprioceptive afferent and descending suprasegmental neurons are coordinated at segmental levels. For further details the reader may consult Burke and Lance and also Davidoff (1992).

There is considerable information concerning the pharmacology of motor neurons. The large neurons of the anterior horns of the spinal cord contain high concentrations of choline acetyltransferase and use acetylcholine as their transmitter at the neuromuscular junction. The main neurotransmitters of the descending corticospinal tract, in so far as can be determined in humans, are aspartate and glutamate. Glycine is the neurotransmitter released by Renshaw cells, which are responsible for recurrent inhibition, and by interneurons that mediate reciprocal inhibition during reflex action. Gamma-aminobutyric acid (GABA) serves as the inhibitory neurotransmitter of interneurons in the posterior horn. L-glutamate and L-aspartate are released by primary afferent terminals and interneurons and act specifically on excitatory amino acid receptors. There are also descending cholinergic,

Figure 3-1. A. Patellar tendon reflex. Sensory fibers of the femoral nerve (spinal segments L2 and L3) mediate this myotatic reflex. The principal receptors are the muscle spindles, which respond to brisk stretching of the muscle effected by tapping the patellar tendon. Afferent fibers from muscle spindles are shown entering only the L3 spinal segment, while afferent fibers from the Golgi tendon organ are shown entering only the L2 spinal segment. In this monosynaptic reflex, afferent fibers entering spinal segments L2 and L3 and efferent fibers issuing from the anterior horn cells of these and lower levels complete the reflex arc. Motor fibers shown leaving the S2 spinal segment and passing to the hamstring muscles demonstrate the disynaptic pathway by which inhibitory influences are exerted upon an antagonistic muscle group during the reflex. B. The gamma loop is illustrated. Gamma efferent fibers (γ) pass to the polar portions of the muscle spindle. Contractions of the intrafusal fibers in the polar parts of the spindle stretch the nuclear bag region and thus cause an afferent impulse to be conducted centrally. The afferent fibers from the spindle synapse with many alpha motor neurons. Because the alpha motor neurons innervate extrafusal muscle fibers, excitation of the alpha motor neurons by spindle afferents causes a cocontraction of the muscle. In this way, both gamma and alpha fibers can simultaneously activate muscle contraction. Both alpha and gamma motor neurons are influenced by descending fiber systems from supraspinal levels. (Adapted by permission from Carpenter MB, Sutin J: *Human Neuroanatomy*, 8th ed. Baltimore, Williams & Wilkins, 1983.)

adrenergic, and dopaminergic axons, which play a less-well-defined role in reflex functions.

Paralysis Due to Lesions of the Lower Motor Neurons

If all, or practically all, peripheral motor fibers supplying a muscle are interrupted, the voluntary, postural, and reflex movements of that muscle are abolished. The muscle becomes lax and soft and does not resist passive stretching, a condition known as flaccidity. Muscle tone—the slight resistance that normal relaxed muscle offers to passive movement—is reduced (hypotonia or atonia). The denervated muscle undergoes extreme atrophy, being reduced to 20 or 30 percent of its original bulk within 3 to 4 months. The reaction of the muscle to sudden stretch, as by tapping its tendon, is lost (areflexia). Damage restricted to only a portion of the motor fibers supplying the muscle results in partial paralysis, or paresis, and a proportionate diminution in the force and speed of contraction. The atrophy will be less and the tendon reflex reduced instead of lost. The electrodiagnosis of denervation depends upon finding fibrillations,

fasciculations, and other abnormalities on needle electrode examination. However, some of these abnormalities do not appear until several days or a week or two after nerve injury (see Chap. 45).

Lower motor neuron (infranuclear) paralysis is the direct result of loss of function or destruction of anterior horn cells or their axons in anterior roots and nerves. The signs and symptoms vary according to the location of the lesion. In any individual case, the most important clinical question is whether sensory changes coexist. The combination of a flaccid, areflexic paralysis and sensory changes usually indicates involvement of mixed motor and sensory nerves or of both anterior and posterior roots. If sensory changes are absent, the lesion must be situated in the anterior gray matter of the spinal cord, in the anterior roots, in a purely motor branch of a peripheral nerve, or in motor axons alone (or in the muscle itself). At times it may be impossible to distinguish between nuclear (spinal) and anterior root (radicular) lesions.

Preserved and often heightened tendon reflexes and spasticity in muscles weakened by lesions of the corticospinal systems attest to the integrity of the spinal segments below the level of the lesion. However, acute

and profound spinal cord lesions and, to a lesser extent, corticospinal lesions in the brainstem and cerebrum, may temporarily abolish spinal myotatic reflexes (“spinal shock”); see Chap. 44). This is caused by the interruption of descending tonic excitatory impulses, which normally maintain a sufficient level of excitation in spinal motor neurons to permit the peripheral activation of segmental reflexes. The attenuation of spinal shock by opiate antagonists, such as naloxone, suggests that the phenomenon is at least in part mediated by the release of previously stored endogenous opiates from the distal terminals of neurons in the periaqueductal gray matter. Once the stored opiates are depleted, the presynaptic inhibition of motor neurons ceases, heralding the end of spinal shock and the beginning of the period of spasticity.

THE UPPER MOTOR NEURON

Anatomic and Physiologic Considerations

The terms pyramidal, corticospinal, and upper motor neuron are often used interchangeably, although they are not altogether synonymous. The pyramidal tract, strictly speaking, designates only those fibers that course longitudinally in the pyramid of the medulla oblongata. Of all the fiber bundles in the brain, the pyramidal tract has been known for the longest time, the first accurate description having been given by Türck in 1851. It descends from the cerebral cortex; traverses the subcortical white matter (corona radiata), internal capsule, cerebral peduncle, basis pontis (ventral pons), and pyramid of the upper medulla; decussates in the lower medulla; and continues its caudal course in the lateral funiculus (column) of the spinal cord—hence the alternative name *corticospinal tract*. This is the only *direct* long-fiber connection between the cerebral cortex and the spinal cord (Fig. 3-2). The *indirect* pathways through which the cortex influences spinal motor neurons are the rubrospinal, reticulospinal, vestibulospinal, and tectospinal; these tracts do not run in the pyramid. All of these pathways, direct and indirect, are embraced by the term *upper motor neuron* or supranuclear, meaning above the anterior horn cells.

A major source of confusion about the pyramidal tract stems from the traditional view, formulated at the turn of the 20th century, that it originates entirely from the large motor cells of Betz in the fifth layer of the precentral convolution (the primary motor cortex, or area 4 of Brodmann¹) (Figs. 3-3 and 22-1). However, there are only some 25,000 to 35,000 Betz cells, whereas the medullary pyramid contains about 1 million axons (Lassek). Thus the pyramidal tract contains many fibers that arise from cortical neurons other than Betz cells, particularly in Brodmann areas 4 and 6 (the frontal cortex immediately rostral to area 4, including the medial portion of the

superior frontal gyrus, i.e., the supplementary motor area); in the primary somatosensory cortex (Brodmann areas 3, 1, and 2); and in the superior parietal lobule (areas 5 and 7). Data concerning the origin of the pyramidal tract in humans are scanty, but in the monkey, by counting the pyramidal axons that remained after cortical excisions and long survival periods, Russell and DeMyer found that 40 percent of the descending axons arose in the parietal lobe, 31 percent in motor area 4, and the remaining 29 percent in premotor area 6. Studies of retrograde transport of tracer substance in the monkey have confirmed these findings.

Fibers from the motor and premotor cortices (Brodmann areas 4 and 6, Fig. 22-1), supplementary motor cortex, and portions of parietal cortex (areas 1, 3, 5, and 7) converge in the corona radiata and descend through the posterior limb of the internal capsule, basis pedunculi, basis pontis, and medulla. As the corticospinal tracts descend in the cerebrum and brainstem, they send collaterals to the striatum, thalamus, red nucleus, cerebellum, and reticular formations. Accompanying the corticospinal tracts in the brainstem are the corticobulbar tracts, which are distributed to motor nuclei of the cranial nerves ipsilaterally and contralaterally (Fig. 3-2). It has been possible to trace the direct projection of axons of cortical neurons to the trigeminal, facial, ambiguus, and hypoglossal nuclei (Iwatsubo et al). No axons were seen to terminate directly in the oculomotor, trochlear, abducens, or vagal nuclei. Insofar as the corticobulbar and corticospinal fibers have a similar origin and the motor nuclei of the brainstem are the homologues of the motor neurons of the spinal cord, the term *upper motor neurons* may suitably be applied to both these systems of fibers.

The corticospinal tracts decussate at the lower end of the medulla, although some of their fibers may cross above this level. The fibers destined for the upper limb neurons cross first (more rostrally). The proportion of crossed and uncrossed fibers varies to some extent from one person to another. About 75 to 80 percent of the fibers cross and the remaining fibers descend ipsilaterally, mostly in the uncrossed ventral corticospinal tract. In exceptional cases, these tracts cross completely; equally rarely, they remain uncrossed. These variations are probably of functional significance in determining the amount of neurologic deficit that results from a unilateral lesion such as capsular infarction. A few well-studied cases are found, such as the one described by Terakawa and colleagues, of acute stroke of the cerebral hemisphere causing hemiplegia on the same side. Also, Yakovlev found 3 instances of completely uncrossed pyramids among 130 autopsies of mentally retarded neonates but considering the maldevelopment of these brains, the finding may not be surprising.

The corticospinal tract is phylogenetically relatively new, being found only in mammals, which probably accounts for its variability between individuals as compared to the older vestibulospinal, rubrospinal and reticulospinalparapyramidal systems, which are invariant among persons. Uncrossed fibers in the corticospinal tract account for mirror movements that are seen during efforts at fine motor tasks, particularly in children, and

¹Numbered areas in this and subsequent chapters refer to Brodmann areas of the cerebral cortex that are discussed in Chap. 23. “Layers” refer to the six neuronal layers of the cerebral cortex, also shown in detail in Chap. 23, on Cerebral Localization.

Figure 3-2. Corticospinal and corticobulbar tracts. The various lines indicate the trajectories of these pathways, from their origin in particular parts of the cerebral cortex to their nuclei of termination.

Figure 3-3. Lateral (A) and medial (B) surfaces of the human cerebral hemispheres, showing the areas of excitable cortex, i.e., areas, numbered according to the scheme of Brodmann. (Reprinted with permission from House EL, Pansky B: *A Functional Approach to Neuroanatomy*, 2nd ed. New York, McGraw-Hill, 1967.) See also Fig. 22-1.

also in some disorders of the nervous system such as the Klippel-Feil syndrome and the Kallmann syndrome. For a more complete discussion of the crossing of the various tracts of the nervous system, the reader is referred to the review by Vulliemoz, Raineteau, and Jabaudon.

Beyond their decussation, the corticospinal pathways descend as well-defined bundles in the anterior and posterolateral columns of white matter (funiculi) of the spinal cord (Fig. 3-2). The course of the noncorticospinal motor pathways (vestibulospinal, reticulospinal, and descending propriospinal) have been traced in humans by Nathan and his colleagues. The lateral vestibulospinal tract lies at the periphery of the cord, where it occupies the most anterolateral portion of the anterior funiculus. The medial vestibulospinal fibers mingle with those of the medial longitudinal fasciculus. Reticulospinal fibers are less compact; they descend bilaterally, and most of them come to lie just anterior to the lateral corticospinal tract. The descending propriospinal pathway consists of a series of short fibers (one or two segments long) lying next to the gray matter.

The *somatotopic organization* of the corticospinal system is of importance in clinical work, especially in relation to certain stroke syndromes. As the descending axons subserving limb and facial movements emerge from the cortical motor strip, they maintain the anatomic organization of the overlying cortex; therefore a discrete cortical-subcortical lesion will result in a restricted weakness of the hand and arm or the foot and leg. More caudally, the descending motor fibers converge and are collected in the posterior limb of the internal capsule, so that even a small lesion there will cause a “pure motor hemiplegia,” in which the face, arm, hand, leg, and foot are affected to more or less the same degree (see Lacunar syndromes in Chap. 34). The axons subserving facial movement are situated rostrally in the posterior limb of the capsule, those for hand and arm in the central portion and those for the foot and leg, caudally (as detailed by Brodal).

This topographic distribution is maintained in the cerebral peduncle, where the corticospinal fibers occupy approximately the middle of the peduncle, the fibers destined to innervate the facial nuclei lying most medially. More caudally, in the basis pontis (base, or ventral part of the pons), the descending motor tracts separate into bundles that are interspersed with masses of pontocerebellar neurons and their cerebellipetal fibers. A degree of somatotopic organization can be recognized here as well, exemplified by selective weakness of the face and hand with dysarthria, or of the leg, which may occur with pontine lacunar infarctions. Anatomic studies in nonhuman primates indicate that arm–leg distribution of fibers in the rostral pons is much the same as in the cerebral peduncle; in the caudal pons, this distinction is less well defined. In humans, a lack of systematic anatomic study leaves the precise somatotopic organization of corticospinal fibers in the pons less certain. Restricted pontine lesions may cause a pure motor hemiplegia that is indistinguishable from the syndrome of the internal capsule. However, a study conducted by Marx and colleagues using sophisticated MRI mapping techniques of patients with hemiplegia from brainstem lesions suggests that the usual somatotopic organization breaks down in the base of the pons, and there is a concentration of fibers innervating proximal muscles lying more dorsally and those exciting distal parts of the limbs, more ventrally.

Another point of uncertainty has been the existence and course of fibers that descend through the lower pons and upper medulla and then ascend again to innervate the facial motor nucleus on the opposite side. Such a connection must exist to explain occasional instances of facial palsy from brainstem lesions caudal to the mid-pons. A discussion of the various hypothesized sites of this pathway, including a recurrent tract (Pick bundle), can be found in the report by Terao and colleagues. They conclude from imaging studies that corticobulbar fibers destined for the facial nucleus descend in the ventromedial pons to the level of the upper medulla, where they decussate and then ascend again; but there is considerable variation between individuals in this configuration.

The descending pontine bundles, now devoid of their corticopontine fibers, reunite to form the medullary pyramid. The brachial–crural pattern may persist in

the pyramids and is certainly reconstituted in the lateral columns of the spinal cord (Fig. 8-3), but it should be emphasized that the topographic separation of motor fibers at cervical, thoracic, lumbar, and sacral levels is not as discrete as usually shown in schematic diagrams of the spinal cord.

The corticospinal tracts and other upper motor neurons terminate mainly in relation to nerve cells in the intermediate zone of spinal gray matter (internuncial neurons), from which motor impulses are then transmitted to the anterior horn cells. Only 10 to 20 percent of corticospinal fibers (presumably the thick, rapidly conducting axons derived from Betz cells) establish direct synaptic connections with the large motor neurons of the anterior horns.

Motor, Premotor, and Supplementary Motor Cortices and Cerebral Control of Movement

The *motor area of the cerebral cortex* is defined physiologically as the region of electrically excitable cortex from which isolated movements can be evoked by stimuli of minimal intensity. The muscle groups of the contralateral face, arm, trunk, and leg are represented in the primary motor cortex (area 4 in Fig. 3-3), those of the face being in the most inferior part of the precentral gyrus on the lateral surface of the cerebral hemisphere and those of the leg in the paracentral lobule on the medial surface of the cerebral hemisphere. The parts of the body capable of the most delicate movements have, in general, the largest cortical representation, as displayed in the motor homunculus ("little man," a term first suggested by Wilder Penfield) shown in Fig. 3-4.

Area 6, the *premotor area*, is also electrically excitable but requires more intense stimuli than area 4 to evoke movements. Stimulation of its caudal aspect (area 6a)

produces responses that are similar to those elicited from area 4. These responses are probably produced by transmission of impulses from all of area 6a to area 4 (as they cannot be obtained after ablation of area 4). Stimulation of the rostral premotor area (area 6a) elicits more general movement patterns, predominantly of proximal limb musculature. The latter movements are effected via pathways other than those derived from area 4 (hence, "parapyramidal"). Very strong stimuli elicit movements from a wide area of premotor frontal and parietal cortex, and the same movements may be obtained from several widely separated points. From this it may be assumed, as Ash and Georgopoulos point out, that the premotor cortex includes several anatomically distinct subregions with different afferent and efferent connections. In general, it may be said that the motor-premotor cortex is capable of synthesizing agonist actions into an almost infinite variety of finely graded, highly differentiated patterns. These are directed by visual (area 7) and tactile (area 5) sensory information and supported by appropriate postural mechanisms.

The *supplementary motor area* is the most anterior portion of area 6 on the medial surface of the cerebral hemisphere (area 6a in Fig. 3-3B). Stimulation of this area may induce relatively gross ipsilateral or contralateral movements, bilateral tonic contractions of the limbs, contraversive movements of the head and eyes with tonic contraction of the contralateral arm, and sometimes inhibition of voluntary motor activity and vocal arrest.

Precisely how the motor cortex controls movements is still a controversial matter. The traditional view, based on the interpretations of Hughlings Jackson and of Sherrington, has been that the motor cortex is organized not in terms of individual muscles but of movements, i.e., the coordinated contraction of groups of muscles. Jackson visualized a widely overlapping representation of muscle

Figure 3-4. The representation of body parts in the motor cortex, commonly called the motor homunculus. The large area of cortex devoted to motor control of the hand, lips, and face is evident. B in the smaller diagram represents the motor cortex; A is the sensory cortex.

groups in the cerebral cortex on the basis of his observation that a patient could recover the use of a limb following destruction of the limb area as defined by cortical stimulation. This view was supported by Sherrington's observations that stimulation of the cortical surface activated not solitary muscles but a combination of muscles, and always in a reciprocal fashion—i.e., in a manner that maintained the expected relationship between agonists and antagonists. He also noted the inconstancy of stimulatory effects; the stimulation of a given cortical point that initiated flexion of a part on one occasion might initiate extension on another.

These interpretations must be viewed with circumspection, as must all observations based on the electrical stimulation of the surface of the cortex. It has been shown that to stimulate motor cells from the surface, the electric current has to penetrate the cortex to layer V, where these neurons are located, inevitably activating a large number of other cortical neurons. The elegant experiments of Asanuma and of Evarts and his colleagues, who stimulated the depths of the cortex with microelectrodes, demonstrated the existence of discrete zones of efferent neurons that control the contraction of individual muscles; moreover, the continued stimulation of a given efferent zone often facilitated rather than inhibited the contraction of the antagonists. These investigators have also shown that cells in the efferent zone receive afferent impulses from the particular muscle to which the efferent neurons project. When the effects of many stimulations at various depths were correlated with the exact sites of each penetration, cells that projected to a particular pool of spinal motor neurons were found to be arranged in radially aligned columns approximately 1 mm in diameter.

The columnar arrangement of cells in the sensorimotor cortex had been appreciated for many years; the wealth of radial interconnections between the cells in these columns led Lorente de Nó to suggest that these “vertical chains” of cells were the elementary functional units of the cortex. This notion received strong support from Mountcastle's observations that all the neurons in a column receive impulses of the same sensory modality, from the same part of the body. It is still not entirely clear whether the columns contribute to a movement as units or whether individual cells within many columns are selectively activated. Both Henneman and Asanuma summarized the evidence for these disparate views.

Evarts and his colleagues also elucidated the role of cortical motor neurons in sensory evoked or planned movement. Using single-cell recording techniques, they showed that pyramidal cells fire about 60 ms prior to the onset of a movement, in a sequence determined by the required pattern and force of the movement. But other, more complex properties of the pyramidal cells were also noted. Some of them received a somatosensory input transcortically from the parietal lobe (areas 3, 1, and 2), which could be turned on or off or gated according to whether the movement was to be controlled, i.e., guided, by sensory input. Many neurons of the supplementary and premotor cortices were activated before a planned movement. Thus pyramidal (area 4) motor neurons were prepared for the oncoming activation by impulses from

the parietal, prefrontal, premotor, and auditory and visual areas of the cortex. This preparatory “set signal” could occur in the absence of any activity in the spinal cord and muscles. The source of the activation signal was found to be mainly in the supplementary motor cortex, which appears to be under the direct influence of the “readiness stimuli” (*Bereitschaft* potential) reaching it from the prefrontal areas for planned movements and from the posterior parietal cortex for motor activities initiated by sensory perceptions. There are also fibers that reach the motor area from the limbic system, presumably subserving motivation and attention. Roland has used functional cerebral blood flow measurements to follow these neural events.

Thus the prefrontal cortex, supplementary motor cortex, premotor cortex, and motor cortex are all responsive to afferent stimuli and are involved prior to, and in coordinated fashion with, a complex movement. As remarked later on, the striatopallidum and cerebellum, which project to these cortical areas, are also activated prior to or concurrently with the discharge of corticospinal neurons (see Thach and Montgomery for a critical review of the physiologic data).

Termination of the Corticospinal and Other Descending Motor Tracts

This has been studied in the monkey by interrupting the descending motor pathways in the medulla and more rostral parts of the brainstem and tracing the distribution of the degenerating elements in the spinal gray matter. On the basis of such experiments and other physiologic data, Lawrence and Kuypers proposed that the functional organization of the descending cortical and subcortical pathways is determined more by their patterns of termination and the motor capacities of the internuncial neurons upon which they terminate than by the location of their cells of origin. Three groups of motor fibers were distinguished according to their differential terminal distribution: (1) The corticospinal and corticobulbar tracts, which project to all levels of the spinal cord and brainstem, terminating diffusely throughout the nucleus proprius of the dorsal horn and the intermediate zone. A portion of these connect directly with the large motor neurons that innervate the muscles of the fingers, face, and tongue; this system provides the capacity for a high degree of fractionation of movements, as exemplified by independent finger movements.

As alluded to above, a large fraction of the fibers in the corticospinal originate from the sensory cortex and appear to function in the modulation of movement by afferent neurons. (2) A *ventromedial pathway*, which arises in the tectum (*tectospinal tract*), vestibular nuclei (*vestibulospinal tract*), and pontine and medullary reticular cells (*reticulospinal tract*) and terminates principally on the internuncial cells of the ventromedial part of the spinal gray matter. This system is mainly concerned with axial movements—the maintenance of posture, integrated movements of body and limbs, and total limb movements. (3) A *lateral pathway*, which is derived mainly from the magnocellular part of the red nucleus and terminates

in the dorsal and lateral parts of the internuncial zone. This pathway adds to the capacity for independent use of the extremities, especially of the hands.

Reference has already been made to the corticomesencephalic, corticopontine, and corticomodullary fiber systems that project onto the reticulospinal, vestibulospinal, rubrospinal, and tectospinal nuclei. These control stability of the head (via labyrinthine reflexes) and of the neck and body in relation to the head (tonic neck reflexes) as well as postures of the body in relation to limb movements. Lesions in these systems are less well understood than those of the corticospinal system. They cause no paralysis of muscles but result in the liberation of unusual postures (e.g., hemiplegic dystonia), heightened tonic neck and labyrinthine reflexes, and decerebrate rigidity. In a strict sense these are all “extrapyramidal,” as discussed in the next two chapters.

Paralysis Caused by Lesions of the Upper Motor Neurons

The corticospinal pathway may be interrupted by a lesion at any point along its course—at the level of the cerebral cortex, subcortical white matter, internal capsule, brainstem, or spinal cord. Usually, when hemiplegia is severe and permanent as a consequence of disease, much more than the long, direct corticospinal pathway is involved. In the cerebral white matter (corona radiata) and internal capsule, the corticospinal fibers are intermingled with corticostriate, corticothalamic, corticorubral, corticopontine, cortico-olivary, and corticoreticular fibers. It is noteworthy that thalamocortical fibers, which are a vital link in an ascending fiber system from the basal ganglia and cerebellum, also pass through the internal capsule and cerebral white matter. Thus lesions in these parts can simultaneously affect both corticospinal and extrapyramidal systems. Attribution of a capsular hemiplegia solely to a lesion of the corticospinal or pyramidal pathway is therefore not entirely correct. The term *upper motor neuron (supranuclear) paralysis*, which recognizes the involvement of several descending fiber systems that influence and modify the lower motor neuron, is more appropriate.

In primates, lesions limited to area 4 of Brodmann, the motor cortex, cause mainly hypotonia and weakness of the distal limb muscles. Lesions of the premotor cortex (area 6) result in weakness, spasticity, and increased stretch reflexes (Fulton). Lesions of the supplementary motor cortex lead to involuntary grasping. Resection of cortical areas 4 and 6 and subcortical white matter in monkeys causes complete and permanent paralysis and spasticity (Laplane et al). These clinical effects have not been as clearly defined in humans.

The one place where corticospinal fibers are entirely isolated is the pyramidal tract in the medulla. In humans, there are a few documented cases of a lesion more or less confined to this location. The result of such lesions has been an initial flaccid hemiplegia (with sparing of the face), from which there is considerable recovery. Similarly in monkeys—as was shown by Tower in 1940 and subsequently by Lawrence and Kuyper and by Gilman and

Marco—interruption of both pyramidal tracts results in a hypotonic paralysis; ultimately, these animals regain a wide range of movements, although slowness of all movements and loss of individual finger movements remain as permanent deficits. Also, the cerebral peduncle had in the past been sectioned in patients in an effort to abolish involuntary movements (Bucy et al). In some of these patients, a slight degree of weakness or only a Babinski sign was produced but no spasticity developed. These observations indicate that a pure pyramidal tract lesion does not result in spasticity. Furthermore, to reiterate a previous comment, control over a wide range of voluntary movements depends at least in part on nonpyramidal motor pathways. Animal experiments suggest that the corticoreticulospinal pathways are particularly important in this respect, because their fibers are arranged somatotopically and influence stretch reflexes. Further studies of human disease, possibly using diffusion tensor imaging techniques, are necessary to settle problems related to volitional movement and spasticity.

The distribution of the paralysis caused by upper motor neuron (supranuclear) lesions varies with the locale of the lesion, but certain features are characteristic of all of them. A group of muscles is always involved, never individual muscles, and if any movement is possible, the proper relationships between agonists, antagonists, synergists, and fixators are preserved. On careful inspection, the paralysis never involves all the muscles on one side of the body, even in the severest forms of hemiplegia. Movements that are invariably bilateral—such as those of the eyes, jaw, pharynx, upper face, larynx, neck, thorax, diaphragm, and abdomen—are affected little or not at all. This occurs because these muscles are bilaterally innervated; i.e., stimulation of either the right or left motor cortex results in contraction of these muscles on both sides of the body. Upper motor neuron paralysis is rarely complete for any long period of time; in this respect it differs from the absolute paralysis that results from destruction of anterior horn cells or interruption of their axons.

Upper motor neuron lesions are characterized further by certain peculiarities of retained movement. There is decreased voluntary drive on spinal motor neurons (fewer motor units are recruitable and their firing rates are slower), resulting in a slowness of movement. There is also an increased degree of co-contraction of antagonistic muscles, reflected in a decreased rate of rapid alternating movements. These abnormalities probably account for the greater sense of effort and the manifest fatigability in effecting voluntary movement of the weakened muscles. Another phenomenon is the activation of paralyzed muscles as parts of certain automatisms (synkinesias). For example, the paralyzed arm may move suddenly during yawning and stretching. Attempts by the patient to move the hemiplegic limbs may also result in a variety of associated movements. Thus, flexion of the arm may result in involuntary pronation and flexion of the leg or in dorsiflexion and eversion of the foot. Also, volitional movements of the paretic limb often evoke imitative (mirror) movements in the normal one or vice versa. Mirror movements are also a feature of Parkinson disease

and of lesions in the upper cervical spinal cord. In some patients, as they recover from hemiplegia, a variety of movement abnormalities emerge, such as tremor, athetosis, and chorea on the affected side. These are expressions of damage to basal ganglionic and thalamic structures and are discussed in Chap. 4.

If the upper motor neurons are interrupted above the level of the facial nucleus in the pons, hand and arm muscles are affected most severely and the leg muscles to a lesser extent; of the cranial musculature, only muscles of the tongue and lower part of the face are involved to any significant degree. Because Broadbent was the first to call attention to this distribution of facial paralysis that relatively spares the forehead muscles, it is referred to as "Broadbent's law." The precise course taken by fibers that innervate the facial nucleus is still somewhat uncertain; however, the majority crosses in the mid-pons to innervate the contralateral facial nerve nucleus. Some fibers may descend to the upper medulla and then ascend recurrently to the pons, (Pick's bundle accounting for the mild facial weakness that is seen with lesions of the lower pons and upper medulla.

At lower levels, such as the cervical cord, complete, acute, and bilateral lesions of the upper motor neurons not only cause a paralysis of voluntary movement but also temporarily abolish the spinal reflexes of segments below the lesion. This is the condition referred to earlier as *spinal shock*, a state of acute flaccid paralysis that is replaced later by *spasticity*. A comparable state of areflexia and hypotonia may occur with acute cerebral lesions but is less sharply defined than is the spinal state. With some acute cerebral lesions, spasticity and paralysis develop together; in others, especially with parietal lesions, the limbs remain flaccid but reflexes are retained.

Spasticity, Hyperreflexia, and the Babinski Sign

The identifying characteristics of paralysis from an upper motor neuron lesion are a predilection for involvement of certain muscle groups, a specific pattern of response of muscles to passive stretch (where resistance increases linearly in relation to velocity of stretch, and a manifest exaggeration of tendon reflexes. The antigravity muscles—the flexors of the arms and the extensors of the legs—are predominantly affected. The arm tends to assume a flexed and pronated position and the leg an extended and adducted one, indicating that certain spinal neurons are reflexly more active than others. At rest, with the muscles shortened to midposition, they are flaccid to palpation and electromyographically silent. If the arm is extended or the leg flexed very slowly, there may be little or no change in muscle tone. By contrast, if the muscles are briskly stretched, the limb moves freely for a very short distance (free interval), beyond which there is an abrupt catch and then a rapidly increasing muscular resistance up to a point; then, as passive extension of the arm or flexion of the leg continues, the resistance melts away. This velocity dependent tone constitutes the "clasp-knife" phenomenon of spasticity. With the limb in the extended or flexed position, a new passive movement may not encounter the same sequence; this entire pattern of response constitutes the lengthening and shortening

reaction. Thus, the essential feature of spasticity is a velocity-dependent increase in the resistance of muscles to a passive stretch stimulus.

Although a clasp-knife relaxation following peak resistance is highly characteristic of cerebral hemiplegia, it is by no means found consistently. At times, a form of velocity-independent hypertonia is found that is termed rigidity and is more characteristic of basal ganglia lesions as discussed in Chap. 4.

Clinicians have known for some time that there is not a constant relationship between spasticity and weakness. Severe weakness may be associated with only the mildest signs of spasticity; in contrast, the most extreme degrees of spasticity, observed in certain patients with cervical spinal cord disease, may seem disproportionate to the extent of weakness, signifying that these two states depend on separate mechanisms. Indeed, the selective blocking of small gamma neurons abolishes spasticity as well as hyperactive segmental tendon reflexes but to leave power unchanged.

The heightened stretch reflexes (tendon jerks) of the spastic state may be a "release" phenomenon—the result of interruption of descending inhibitory pathways, but this appears to be only a partial explanation. Animal experiments have demonstrated that this aspect of the spastic state is also mediated through spindle efferents (increased tonic activity of gamma motor neurons) and, centrally, through reticulospinal and vestibulospinal pathways that act on alpha motor neurons. The clasp-knife phenomenon appears to derive at least partly from a lesion (or presumably a change in central control) of a specific portion of the reticulospinal system.

P. Brown, in a discussion of the pathophysiology of spasticity, emphasized the importance of two systems of fibers: (1) the dorsal reticulospinal tract, which has inhibitory effects on stretch reflexes; and (2) the medial reticulospinal and vestibulospinal tracts, which together facilitate extensor tone. He postulated that in cerebral and capsular lesions, cortical inhibition is reduced, resulting in spastic hemiplegia. In spinal cord lesions that involve the corticospinal tract, the dorsal reticulospinal tract is usually involved as well. If the latter tract is spared, only paresis, loss of support reflexes, and possibly release of flexor reflexes (Babinski phenomenon) occur. Pantano and colleagues suggested that primary involvement of the lenticular nucleus of the basal ganglia and thalamus is the feature that determines the persistence of flaccidity after stroke, but the anatomic and physiologic evidence for this view is insecure.

The most sensitive indications of an upper motor neuron lesion are the signs described by Babinski in 1896 (the great toe sign) and 1903 (the toe abduction, or fan sign). In modern parlance, the toe and fan signs have generally been conflated and termed the Babinski sign. Numerous monographs and articles have been written about the sign: a quite comprehensive one, by van Gijn, and an elegant but more arcane one by Fulton and Keller.

As Babinski himself indicated, a movement resembling the Babinski sign is present in normal infants (see Phillipon and Poirer), but it disappears and its persistence or emergence in late infancy and childhood or

later in life is an invariable indicator of a lesion at some level of the corticospinal tract. In its essential form, the sign consists of extension of the large toe and extension and fanning of the other toes during and immediately after stroking the lateral plantar surface of the foot. The stimulus is applied along the dorsum of the foot from the lateral heel and sweeping upward and across the ball of the foot. The stimulus must be firm but not necessarily painful. Several dozen surrogate responses (with numerous eponyms) have been described over the years, most utilizing alternative sites and types of stimulation, but all have the same significance as the Babinski response.

Clinical and electrophysiologic observations indicate that the extension movement of the toe is a component of a larger synergistic flexion or shortening reflex of the leg—i.e., toe extension when viewed from a physiologic perspective is a flexor protective (nocifensive, or defensive) response. The most characteristic of these is the “triple flexion response”, in which the hip, thigh and ankle flex (dorsiflex) slowly, following an appropriate stimulus. These *spinal flexion reflexes*, of which the Babinski sign is the most characteristic, are common accompaniments to—but not essential components of—spasticity. They are present because of disinhibition or release of motor programs of spinal origin. Important characteristics of these responses are their capacity to be induced by weak superficial stimuli (such as a series of pinpricks) and their tendency to persist for a few moments after the stimulation ceases. With incomplete suprasegmental lesions, the response may be fractionated; for example, the hip and knee may flex but the foot may not dorsiflex, or vice versa.

The hyperreflexic state that characterizes spasticity may take the form of *clonus*, a series of rhythmic involuntary muscular contractions occurring at a frequency of 5 to 7 Hz in response to an abruptly applied and sustained stretch stimulus. It is usually designated in terms of the part of the limb to which the stimulus is applied (e.g., patella, ankle). The frequency is constant within 1 Hz and is not appreciably modified by altering peripheral or central nervous system activities. Clonus requires an appropriate degree of muscle relaxation, integrity of the spinal stretch reflex mechanisms, sustained hyperexcitability of alpha and gamma motor neurons (suprasegmental effects), and synchronization of the contraction-relaxation cycle of muscle spindles.

The cutaneomuscular abdominal and cremasteric reflexes (“cutaneous, or superficial reflexes”) are elicited by rapid, gentle stroking of the skin overlying these muscles, and are usually abolished when the upper motor neuron is damaged. These were referred to as reflexes before the end of the nineteenth century, which leads to some confusion in interpreting the older clinical literature.

Spread, or radiation of reflexes, is regularly associated with spasticity, although the latter phenomenon may be observed to a slight degree in normal persons with brisk tendon reflexes. Tapping of the radial periosteum, for example, may elicit a reflex contraction not only of the brachioradialis but also of the biceps, triceps, or finger flexors. This spread of reflex activity is probably not the

result of radiation of impulses in the spinal cord, but a result of the propagation of a vibration wave from bone to muscle, stimulating the excitable muscle spindles in its path (Lance). Other manifestations of the hyperreflexic state, are the Hoffmann sign and the crossed adductor reflex of the thigh muscles. Also, reflexes may be “inverted,” as in the case of a lesion of the fifth or sixth cervical segment; here the biceps and brachioradialis reflexes are abolished and only the triceps and finger flexors, whose reflex arcs are intact, respond to a tap over the distal radius.

With bilateral cerebral lesions, exaggerated stretch reflexes may be elicited in cranial as well as limb and trunk muscles because of interruption of the corticobulbar pathways. These are seen as easily triggered masseter contractions in response to a brisk downward tap on the chin (“jaw jerk”) and brisk contractions of the orbicularis oris muscles in response to tapping the philtrum or corners of the mouth. In advanced cases, weakness or paralysis or slowness of voluntary movements of the face, tongue, larynx, and pharynx are added (bulbar spasticity or “pseudobulbar” palsy; see also Chap. 25).

The many investigations of the biochemical changes that underlie spasticity and the mechanisms of action of antispasticity drugs have been reviewed by Davidoff. Because glutamic acid is the neurotransmitter of the corticospinal tracts, one would expect its action on inhibitory interneurons to be lost. As mentioned earlier, GABA and glycine are the major inhibitory transmitters in the spinal cord; GABA functions as a presynaptic inhibitor, suppressing sensory signals from muscle and cutaneous receptors. Baclofen, a derivative of GABA, as well as diazepam and progabide, are thought to act by reducing the release of excitatory transmitters from the presynaptic terminals of primary afferent terminals. Actually, none of these agents is entirely satisfactory in the treatment of spasticity when administered orally; the administration of baclofen intrathecally at times has a more beneficial effect. Glycine is the transmitter released by inhibitory interneurons and is measurably reduced in quantity, uptake, and turnover in the spastic animal. There is some evidence that the oral administration of glycine reduces experimentally induced spasticity, but its value in patients is uncertain. Interruption of descending noradrenergic, dopaminergic, and serotonergic fibers is undoubtedly involved in the genesis of spasticity, although the exact mode of action of these neurotransmitters on the various components of spinal reflex arcs remains to be defined.

Table 3-1 summarizes the main attributes of upper motor neuron lesions and contrasts them with those of the lower motor neuron discussed above.

Motor Disturbances Caused by Lesions of the Parietal Lobe

As indicated earlier in this section, a significant portion of the pyramidal tract originates in neurons of the parietal cortex. Also, the parietal lobes are important sources of visual and tactile information necessary for the control of movement. Pause and colleagues have described the motor disturbances caused by lesions of the parietal

Table 3-1

DIFFERENCES BETWEEN UPPER AND LOWER MOTOR NEURON PARALYSIS

UPPER MOTOR NEURON OR SUPRANUCLEAR PARALYSIS	LOWER MOTOR NEURON OR NUCLEAR-INFRA-NUCLEAR PARALYSIS
Muscles affected in groups; never individual muscles	Individual muscles may be affected
Atrophy slight and the result of disuse	Atrophy pronounced; up to 70% of total bulk
Spasticity with hyperactivity of the tendon reflexes and extensor plantar reflex (Babinski sign)	Flaccidity and hypotonia of affected muscles with loss of tendon reflexes
Fasciculations absent	Plantar reflex, if present, is of normal flexor type
Normal nerve conduction studies; no denervation potentials in EMG	Fasciculations may be present
	Abnormal nerve conduction studies; denervation potentials (fibrillations, fasciculations, positive sharp waves) in EMG

cortex. The patient is unable to maintain stable postures of the outstretched hand when his eyes are closed and cannot exert a steady contraction. Exploratory movements and manipulation of small objects are impaired, and the speed of tapping is diminished. Posterior parietal lesions (involving areas 5 and 7 in Fig. 3-3) are more detrimental in this respect than anterior ones (areas 1, 3, and 5), but both regions are affected in patients with the most severe deficits.

APRAXIA AND OTHER NONPARALYTIC DISORDERS OF MOTOR FUNCTION

All that has been said about the cortical and spinal control of the motor system gives one only a limited idea of human motility. Viewed objectively, the conscious and sentient human organism is continuously active—fidgeting, adjusting posture and position, sitting, standing, walking, running, speaking, manipulating tools, or performing the intricate sequences of movements involved in athletic or musical skills. Some of these activities are relatively simple, automatic, and stereotyped. Others have been learned and mastered through intense conscious effort and with long practice have become habitual—i.e., reduced to an automatic level—a process not at all understood physiologically. Still others are complex and voluntary, parts of a carefully formulated plan, and demand continuous attention and thought. What is more remarkable, one can be occupied in several of these variably conscious and habitual activities simultaneously, such as driving through heavy traffic while dialing a cellular phone (not endorsed) and engaging in animated conversation. Moreover, when an obstacle prevents a particular sequence of movements from accomplishing its goal, a new sequence can be undertaken automatically for the same purpose.

The term *apraxia* denotes a disorder in which an attentive patient loses the ability to execute previously learned activities in the absence of weakness, ataxia, sensory loss, or extrapyramidal derangement that would be adequate to explain the deficit. All of the elements of the activity may be demonstrated in circumstances other than in response to the command to execute the activity or gesture. This was the meaning given to apraxia by Liepmann, who introduced the term in 1900.

Apraxia has been divided into three types: ideational, ideomotor, and limb-kinetic. They are described in greater detail in Chap. 23 but a brief account is provided here because of their intimate involvement with motor activity. Any explanation of apraxia requires an appreciation of the interplay between cortical areas that create highly complex motor behaviors.

On the basis of studies of large numbers of patients with lesions of different parts of the brain, it appears that the initiating and planning of complex activities, conceptualizing their purpose, and continuously modifying the components of a motor sequence are directed by the frontal lobes. Lesions of the frontal lobes have the effect of reducing the impulse to think, speak, and act (i.e., abulia, or reduced “cortical tone,” to use Luria’s expression), and a complex activity will not be initiated or sustained long enough to permit its completion. However, clinical and functional imaging data indicate that planned or commanded action is normally first conceptualized not in the frontal lobe, where the impulse to action arises, but in the parietal lobe of the language-dominant hemisphere, where visual, auditory, and somesthetic information is integrated. The formation of ensembles of skilled movements, which Liepmann called a “space-time plan,” depends on the integrity of the dominant parietal lobe; if this part of the brain is damaged, complex patterns of movement cannot be activated at all or the movements are awkward and inappropriate.

The failure to conceive or formulate an action to command, was referred to by Liepmann as *ideational apraxia*. Sensory areas 5 and 7 in the dominant parietal lobe, the supplementary and premotor cortices of both cerebral hemispheres and their integral connections are involved collectively to accomplish these actions. In *ideomotor apraxia*, the patient may know and remember the planned action, but because these areas or their connections are interrupted, he cannot actually execute it with either hand. Certain tasks are said to differentiate ideomotor from ideational apraxia, as discussed further on, but the distinction may be quite subtle. Nonetheless, ideational apraxia has been said to be characterized by difficulty in “what to do,” whereas ideomotor apraxia is a block in “how to do” as a result of an inability to transmit the gesture to executive motor centers.

A third disorder, opaque to many neurologists, is *limb-kinetic apraxia* (or *kinetic-limb apraxia*). It is an ill-defined clumsiness and maladroitness that is the result of an inability to fluidly connect or to isolate individual movements of the hand and arm as described by Kleist. In the originally conceived form, a hand displays awkwardness that is disproportionate to weakness or sensory loss, yet gestures and complex movements can be

accomplished, unlike the case in ideomotor apraxia. Central to the disorder is a breakdown of fine fractionated finger movements for which reason the nature of limb kinetic apraxia and its differentiation from a mild corticospinal disorder has been elusive enough that many neurologists do not view it as a true apraxia.

The term limb-kinetic apraxia has also been applied to cases of paralysis that obscures the apraxia on one side but causes a breakdown of fine finger movements on the opposite side. This is more properly termed "*sympathetic apraxia*". In particular, in a right-handed person, a lesion in the left frontal lobe that includes Broca's area, the left motor cortex, and the deep underlying white matter may cause left-limb apraxia. Clinically, there is a nonfluent aphasia, a right hemiparesis, and clumsiness of the non-paralyzed left hand.

These high-order abnormalities of learned movement patterns have several unique features. Seldom are they evident to the patient himself and therefore they are not sources of complaint, even if they disrupt daily activities such as dressing. Or, if the patient appreciates them, he has difficulty describing the problem except in narrow terms of the activity that is impaired, such as using a phone or dressing. For this reason they are also often overlooked by the examining physician. Obviously, if the patient is confused or aphasic, spoken or written requests to perform an act will not be understood and one must find ways of persuading him to imitate the movements of the examiner. Moreover, the patient must be able to recognize and name the articles that he attempts to manipulate.

In practical terms, the lesion responsible for ideomotor apraxia, which affects both hands, usually resides in the left parietal region. Kertesz and colleagues provided evidence that the lesions responsible for aphasia and apraxia are different, although the two conditions are frequently associated because of their origin in the left hemisphere. The exact location of the parietal lesion, whether in the supramarginal gyrus or in the superior parietal lobe (areas 5 and 7) and whether subcortical or cortical, has been variable. Although the majority of ideational and ideomotor apraxias occur with lesions in the left cerebral hemisphere, the right hemisphere retains some of these capacities. A small number of apraxic patients have right hemisphere damage. This also explains the preservation of most praxis skills in the left hand following callosal lesions. Geschwind accepted Liepmann's proposition that a lesion of a subcortical tract (presumably the arcuate fasciculus) can disconnect the parietal from the left frontal cortex, accounting for the ideomotor apraxia of the right limbs. The apraxia in the left limb is the consequence of a functional disconnection of the left and right premotor association cortices. These conceptualizations, while possibly valid, are of more theoretic than practical significance and depend heavily on the disconnection model discussed in Chap. 23. An alternative view is that there is not an actual disconnection of the two frontal lobes as much as there is a failure of the left to activate the right frontal lobe because the right does not receive instructions from the damaged left parietal lobe. It is the dominant parietal lobe that still embodies the property of praxis.

Of a somewhat different nature is an oral-buccal-lingual apraxia, which is probably the most commonly observed of all apraxias in practice. It may occur with lesions that undercut the left supramarginal gyrus or the left motor association cortex and may or may not be associated with the apraxia of the limbs described above. Such patients are unable to carry out facial movements on command (lick the lips, blow out a match, etc.) although they may do better when asked to imitate the examiner or when confronted with a lighted match. With lesions that are restricted to the facial area of the left motor cortex, the apraxia will be limited to the facial musculature bilaterally and may be associated with a verbal apraxia or cortical dysarthria (namely, Broca's aphasia, see Chap. 22).

So-called apraxia of gait is considered in Chap. 7, but strictly speaking, this not an apraxia as walking is not a learned act. The terms dressing apraxia and constructional apraxia are used to describe special manifestations of nondominant parietal lobe disease, in contrast to the above-described forms of apraxia that result from lesions on the dominant side. Although dressing apraxia in many ways resembles an ideomotor apraxia, it probably has a basis in a form of sensory extinction and a loss of appreciation of extrapersonal space. These issues are discussed further in Chap. 23.

Testing for apraxia is carried out in several ways. First, one observes the actions of the patient as he engages in simulated tasks as dressing, washing, shaving, and using eating utensils. Second, the patient is asked to carry out familiar symbolic acts—wave goodbye, salute the flag, shake a fist as though angry, or blow a kiss. If he fails, he is asked to imitate such acts made by the examiner. Finally, he is asked to show how he would hammer a nail, brush his teeth, take a comb out of his pocket and comb his hair, or to execute a more complex act, such as lighting and smoking a cigarette or opening a bottle of soda, pouring some into a glass, and drinking it. These actions, involving more complex sequences, are said to be tests of ideational apraxia; the simpler and familiar acts are considered tests of ideomotor apraxia. To perform these tasks in the absence of the tool or utensil is always more demanding because the patient must mentally formulate a plan of action rather than engage in a habitual motor sequence. The patient may fail to carry out a commanded or suggested activity (e.g., to take a pen out of his pocket), yet a few minutes later he may perform the same motor sequence automatically.

Children with cerebral diseases that retard mental development are often unable to learn the sequences of movement required in hopping, jumping over a barrier, hitting or kicking a ball, or dancing. They suffer a *developmental motor apraxia*. Certain tests quantitate failure in these age-linked motor skills (see Chap. 28).

In the authors' opinion, the time-honored division of apraxia into ideational, ideomotor, and kinetic types is not entirely satisfactory because of the difficulty separating them in practice. We have sometimes been unable to confidently separate ideomotor from ideational apraxia. The patient with a severe ideomotor apraxia nearly always has difficulty at the ideational level and, in any case, similarly situated left parietal lesions give rise to

both types. Furthermore, in view of the complexity of the motor system, we have frequently been uncertain whether the clumsiness or ineptitude of a hand in performing a motor skill represents a kinetic apraxia or some other subtle fault in hand control by the corticospinal or one of the other parallel motor systems.

A related but poorly understood disorder of movement has been termed the *alien hand*. In the absence of volition, the hand and arm undertake complex and seemingly purposeful movements such as reaching into a pocket or handbag, placing the hand behind the head, tugging on the opposite hand or other body part, and rebuttoning the shirt immediately after it has been unbuttoned by the other hand. These activities may occur even during sleep. The patient is aware of the movements but has the sense that the actions are beyond his control and there is often an impression that the hand is estranged, as if commanded by an external agent (although the limb is recognized as one's own—there is no anosognosia); a grasp reflex and a tendency to grope are usually present. Most instances arise as a result of infarction in the territory of the opposite anterior cerebral artery, including the corpus callosum. When the callosum is involved, Feinberg and colleagues find that there frequently appears to be a conflict between the actions of the hands, the normal one sometimes even restraining the alien one. Damage in the left supplementary motor area from any cause, as well as from the degenerative disease called corticobasal ganglionic degeneration (corticobasal ganglionic syndromes), are associated with a similar alien hand syndrome. A third form that results from a stroke in the posterior cerebral artery territory with associated sensory loss has also been observed by Ay and colleagues.

A possibly related phenomenon has been described by Lhermitte as “utilization behavior,” in which the patient obligatorily seizes and uses objects in the surrounding environment. It is associated with extensive bilateral frontal lobe damage and has been likened, unsatisfactorily in our view, to a bilateral alien hand phenomenon.

Finally, it should be remarked again that the complexity of motor activity is almost beyond imagination. Reference was made earlier to the reciprocal innervation involved in an act as simple as making a fist. Scratching one's shoulder has been estimated to recruit about 75 muscles. But what must be involved in playing a piano concerto? Over a century ago Hughlings Jackson commented that “There are, we shall say, over thirty muscles in the hand; these are represented in the nervous centers in thousands of different combinations, that is, as very many movements; it is just as many chords, musical expressions, and tunes can be made out of a few notes.” The execution of these complex movements, many of them learned and habitual, is made possible by the cooperative activities of not just the motor and sensory cortices but integrally of the basal ganglia, cerebellum, and reticular formation of the brainstem. All are continuously integrated and controlled by feedback mechanisms from the sensory and spinal motor neurons. These points, already touched upon in this chapter, are elaborated in the following three chapters.

A historical perspective that outlines the development of these concepts is given by Faglioni and Basso and an authoritative review of the subject of apraxia can be found in the chapter by Heilman and Gonzalez-Rothi.

PATTERNS OF PARALYSIS AND THEIR DIAGNOSIS

The diagnostic considerations in cases of paralysis can be simplified by using the following subdivision, based on the location and distribution of the muscle weakness:

1. *Monoplegia* refers to weakness or paralysis of all the muscles of one leg or arm. This term is not applied to paralysis of isolated muscles or groups of muscles supplied by a single nerve or motor root.
2. *Hemiplegia*, the commonest form of paralysis, involves the arm, the leg, and sometimes the face on one side of the body. With rare exceptions, mentioned further on, hemiplegia is attributable to a lesion of the corticospinal system on the side opposite to the paralysis.
3. *Paraplegia* indicates weakness or paralysis of both legs. It is most often the result of diseases of the thoracic spinal cord, cauda equina, or peripheral nerves, and rarely, both medial frontal cortices.
4. *Quadriplegia* (tetraplegia) denotes weakness or paralysis of all four extremities. It may result from disease of the peripheral nerves, muscles, or myoneural junctions; gray matter of the spinal cord; or the upper motor neurons bilaterally in the cervical cord, brainstem, or cerebrum. Diplegia is a special form of quadriplegia in which the legs are affected more than the arms. Triplegia occurs most often as a transitional condition in the development of, or partial recovery from, tetraplegia.
5. Isolated paralysis of one or more muscle groups due to disease of muscle, anterior horn cells, or nerve roots.
6. Nonparalytic disorders of movement (e.g., apraxia, ataxia).
7. Hysterical paralysis.

Monoplegia

The examination of patients who complain of weakness of one limb often discloses an asymptomatic weakness of another, and the condition is actually a hemiparesis or paraparesis. Or, instead of weakness of all the muscles in a limb, only isolated groups are found to be affected. Ataxia, sensory disturbances, or reluctance to move the limb because of pain should not be misinterpreted as weakness. Parkinsonism may give rise to the same error, as can rigidity or bradykinesia of other causation or a mechanical limitation because of arthritis and bursitis. The presence or absence of atrophy of muscles in a monoplegic limb is of particular diagnostic help, as indicated below.

Monoplegia without Muscular Atrophy

This is most often caused by a lesion of the cerebral cortex or the spinal cord (where it causes a monoplegia of the leg). Infrequently it results from a restricted subcortical lesion

that selectively interrupts the motor pathways to one limb. A cerebral vascular lesion is the most common cause; a circumscribed tumor or abscess may have the same effect. A small cortical lesion may exceptionally paralyze half the hand or even just the thumb. Multiple sclerosis and spinal cord tumor, early in their course, may cause weakness of one limb, usually the leg. Monoplegia caused by a lesion of the upper motor neuron is usually accompanied by spasticity, increased reflexes, and an extensor plantar reflex (Babinski sign). In acute diseases of the lower motor neurons, the tendon reflexes are reduced or abolished, but atrophy may not appear for several weeks. Hence, before reaching an anatomic diagnosis, one must take into account the mode of onset and duration of the disease.

Monoplegia with Muscular Atrophy

This is more frequent than monoplegia without muscular atrophy. Long-continued disuse of one limb may lead to atrophy, but it is usually of lesser degree than atrophy caused by lower motor neuron disease (denervation atrophy). In disuse atrophy, the tendon reflexes are retained and nerve conduction studies are normal. With denervation of muscles, there may be visible fasciculations and reduced or abolished tendon reflexes in addition to paralysis. If the limb is partially denervated, the EMG shows reduced numbers of motor unit potentials (often of large size) as well as fasciculations and fibrillations. The location of the lesion (in nerves, spinal roots, or spinal cord) can usually be determined by the pattern of weakness, by the associated neurologic symptoms and signs, and by special tests—MRI of the spine, examination of the cerebrospinal fluid (CSF), and electrical studies of nerve and muscle.

A complete atrophic brachial monoplegia is uncommon; more often, only parts of a limb are affected. When present in an infant, it suggests brachial plexus trauma from birth; in a child, poliomyelitis or other viral infection of the spinal cord; and in an adult, syringomyelia, amyotrophic lateral sclerosis, or a brachial plexus lesion. Atrophic crural (leg) monoplegia is more frequent than atrophic brachial monoplegia and may be caused by any lesion of the thoracic cord—i.e., trauma, tumor, myelitis, multiple sclerosis, late radiation effect, etc. These disorders rarely cause severe atrophy. A prolapsed intervertebral disc and several varieties of mononeuropathy almost never paralyze all or most of the muscles of a limb. The effects of a centrally prolapsed disc or other compressive lesion of the cauda equina are rarely confined to one leg. However, a unilateral retroperitoneal tumor or hematoma may paralyze one leg by compressing the lumbosacral plexus. The mode of onset and temporal course differentiate these diseases.

Hemiplegia

This is the most frequent form of paralysis. With rare exceptions (a few unusual cases of poliomyelitis or motor neuron disease), this pattern of paralysis is a result of involvement of the corticospinal pathways.

The site or level of the lesion—i.e., cerebral cortex, corona radiata, capsule, brainstem, or spinal cord—can

usually be deduced from the associated neurologic findings. Diseases localized to the cerebral cortex, cerebral white matter (corona radiata), and internal capsule usually manifest themselves by weakness or paralysis of the leg, arm, and lower face on the opposite side. The occurrence of seizures or the presence of a language disorder (aphasia), a loss of discriminative sensation (e.g., astereognosis, impairment of tactile localization), anosognosia, or a homonymous visual field defect suggests a contralateral cortical or subcortical location.

Damage to the corticospinal and corticobulbar tracts in the upper portion of the brainstem also causes paralysis of the face, arm, and leg of the opposite side (see Fig. 3-2). The lesion in the brainstem may be localized by the presence of a cranial nerve palsy or other segmental abnormality on the same side as the lesion (opposite the hemiplegia). With midbrain lesions there is a third nerve palsy (Weber syndrome), in low pontine lesions, an ipsilateral abducens or facial palsy is combined with a contralateral weakness or paralysis of the arm and leg (Millard-Gubler syndrome). Lesions in the medulla affect the tongue and sometimes the pharynx and larynx on one side and the arm and leg on the other. These “crossed paralyses,” characteristic of brainstem lesions, are described further in Chap. 34.

Even lower in the medulla, a unilateral infarct in the pyramid causes a flaccid paralysis of the contralateral arm and leg, with sparing of the face and tongue. Some motor function may be retained, as in the case described by Ropper and colleagues; interestingly, in this case and in others previously reported, there was considerable recovery of voluntary power even though the pyramid was almost completely destroyed.

Rarely, an ipsilateral hemiplegia may be caused by a lesion in the lateral column of the cervical spinal cord. In the spinal cord, however, the pathologic process is more often larger and induces bilateral signs. A homolateral paralysis that spares the face, if combined with a loss of vibratory and position sense on the same side and a contralateral loss of pain and temperature, signifies disease of one side of the spinal cord (Brown-Séquard syndrome, as discussed in Chap. 44).

As indicated above, muscle atrophy that follows upper motor neuron lesions never reaches the proportions seen in diseases of the lower motor neuron. The atrophy in the former cases is mainly a consequence of disuse.

When the motor cortex and adjacent parts of the parietal lobe are damaged in infancy or childhood, normal development of the muscles, as well as the skeletal system in the affected limbs, is retarded. The limbs and even the trunk are smaller on one side than on the other. This does not happen if the paralysis occurs after puberty, by which time the greater part of skeletal growth has been attained. In hemiplegia caused by spinal cord lesions, muscles at the level of the lesion may atrophy as a result of damage to anterior horn cells or ventral roots.

In the causation of hemiplegia, ischemic and hemorrhagic vascular diseases of the cerebrum and brainstem exceed all others in frequency. Trauma (brain contusion, epidural and subdural hemorrhage) ranks second. Other important causes, less acute in onset, are, in order of frequency, brain tumor, demyelinating disease, brain abscess,

and the vascular complications of meningitis and encephalitis. Most of these diseases can be recognized by their mode of evolution and characteristic imaging, which are presented in the chapters on specific neurologic diseases. Alternating transitory hemiparesis may be the result of a special type of migraine (see discussion in Chap. 10). From time to time, hysteria is found to be the cause of a hemiplegia, as discussed further on.

Paraplegia

Paralysis of both lower extremities may occur with diseases of the spinal cord, nerve roots, or, less often, the peripheral nerves. If the onset is acute, it may be difficult to distinguish spinal from neuropathic paralysis because of the element of spinal shock, which results in flaccidity and abolition of reflexes. In acute spinal cord diseases with involvement of corticospinal tracts, the paralysis or weakness affects all muscles below a given level; if the white matter is extensively damaged, sensory loss below a circumferential level on the trunk is conjoined (loss of pain and temperature sense because of spinothalamic tract damage, and loss of vibratory and position sense from posterior column involvement). Also in bilateral disease of the spinal cord, the bladder and bowel and their sphincters are usually affected. These abnormalities may be the result of an intrinsic lesion of the cord or an extrinsic mass that narrows the spinal canal and compresses the cord.

In peripheral nerve diseases, motor loss tends to involve the distal muscles of the legs more than the proximal ones (exceptions are certain varieties of the Guillain-Barré syndrome and some types of diabetic neuropathy and porphyria); sphincteric function is usually spared or impaired only transiently. Sensory loss, if present, is also more prominent in the distal segments of the limbs, and the degree of loss is often more for one modality than another.

For clinical purposes, it is helpful to separate the acute paraplegias from the chronic ones and to divide the latter into two groups: those beginning in adult life and those occurring in infancy.

The most common cause of *acute paraplegia* (or *quadriplegia* if the cervical cord is involved) is spinal cord trauma, usually associated with fracture–dislocation of the spine. Less-common causes are hematomyelia because of a vascular malformation, or a malformation that causes ischemia by an obscure mechanism, and infarction of the cord as a result of occlusion of the anterior spinal artery or, more often, to occlusion of segmental branches of the aorta because of dissecting aneurysm or atheroma, vasculitis, or nucleus pulposus embolism. Epidural or subdural hemorrhage from a hemorrhagic diathesis or warfarin therapy cause an acute or subacute paraplegia; in a few instances the bleeding follows a lumbar puncture. A special syndrome occurs in older men where chronic lumbar pain is followed after some months or years by the rapid development of paraplegia. This is caused by an arteriovenous fistula in the overlying dura of the lumbar region. Closure of the vascular shunt may lead to rapid reversal of paraplegia—a treatable form of paraplegia.

Paraplegia or quadriplegia that develops more slowly, subacutely over a period of hours or days is caused by postinfectious myelitis, demyelinating or necrotizing myelopathy, or epidural abscess or tumor with spinal cord compression. Paralytic poliomyelitis and acute Guillain-Barré syndrome—the former a purely motor disorder with mild meningitis, the latter predominantly motor but often with sensory disturbances—must be distinguished from the acute and subacute myelopathies and from each other.

In adult life, multiple sclerosis and tumor account for most cases of *chronic spinal paraplegia*, but a wide variety of extrinsic and intrinsic processes may produce the same effect: protruded cervical disc and cervical spondylosis (often with a congenitally narrow canal), epidural abscess and other infections (tuberculous, fungal, and other granulomatous diseases, HIV and HTLV-1), syphilitic meningomyelitis, motor system disease, subacute combined degeneration (vitamin B12 deficiency and copper deficiency), syringomyelia, epidural lipomatosis, neuro-myelitis optica, and degenerative disease of the lateral and posterior columns. (See Chap. 44 for discussion of these spinal cord diseases.)

In *pediatric practice*, delay in starting to walk and difficulty in walking are common problems. These conditions may indicate a systemic disease (such as rickets), mental retardation, or, more commonly, a muscular or neurologic process. Congenital cerebral disease because of periventricular leukomalacia accounts for a majority of cases of infantile diplegia (weakness predominantly of the legs, with minimal weakness of the arms). Present at birth, it becomes manifest in the first months of life and may appear to progress, but actually the progression is only apparent, being exposed as the motor system develops; later there may seem to be slow improvement as a result of the normal maturation processes of childhood. These disorders fall under the heading of cerebral palsy, as discussed in Chap. 38. Congenital malformation or birth injuries of the spinal cord are other possibilities. Friedreich ataxia and familial paraplegia, muscular dystrophy, tumor, and the chronic varieties of polyneuropathy tend to appear later, during childhood and adolescence, and are slowly progressive causes of leg weakness and walking disorder. Transverse (usually demyelinating) myelitis is another cause of acute paraplegia in childhood.

Quadriplegia (Tetraplegia)

All that has been said about the spinal causes of paraplegia applies to quadriplegia, the lesion being in the cervical rather than the thoracic or lumbar segments of the spinal cord. If the lesion is situated in the low cervical segments and involves the anterior half of the spinal cord, as typified by the syndrome resulting from occlusion of the anterior spinal artery, there is a level on the trunk, below which pinprick and thermal sense is lost but there is retained vibration, deep sensation and joint position sense (anterior spinal artery syndrome). In all these processes, the paralysis of the arms may be flaccid and areflexic in type and that of the legs, spastic. If there is pain, it is usually in the neck and shoulders and there is numbness of the hands; elements of ataxia from

posterior column lesions may accompany the paraparesis. Compression of the C1 and C2 spinal cord segments is caused by dislocation of the odontoid process. Rheumatoid arthritis and Morquio disease are other causes of compression of the upper cervical cord special note; in the latter, there is pronounced dural thickening.

A progressive syndrome of monoparesis, biparesis, usually of the arms, and then tri paresis involving the leg on the side of the last affected arm (“around the clock” pattern) is caused by tumors and a variety of other compressive lesions in the region of the foramen magnum and high cervical cord. This is putatively explained by the pattern of corticospinal fiber decussation at the cervicomedullary junction. Bilateral infarction of the medullary pyramids from occlusion of the vertebral arteries or their anterior spinal branches is a rare cause of quadriplegia. Repeated strokes affecting both hemispheres may lead to bilateral hemiplegia, usually accompanied by pseudobulbar palsy (see Chap. 23 on spastic dysarthria and Chap. 25 on pseudobulbar laughing and crying). In infants and young children, aside from developmental abnormalities and anoxia of birth, certain metabolic cerebral diseases (metachromatic and other forms of leukoencephalopathy, lipid storage disease) may be responsible for a quadriplegia or quadriplegia, but always with psychomotor compromise.

Triplegia

Paralysis that remains confined to three limbs is observed only rarely; more often the fourth limb is weak or hyperreflexic, and the syndrome is really an incomplete tetraplegia. As indicated earlier, this pattern of involvement is important, because it may signify an evolving lesion of the upper cervical cord or cervicomedullary junction. A meningioma of the foramen magnum, for example, may begin with spastic weakness of one limb, followed by sequential involvement of the other limbs in the above noted “around-the-clock” pattern. There are usually bilateral Babinski signs early in the process, but there may be few sensory findings. We have also seen this pattern in patients with multiple sclerosis and other intrinsic inflammatory and neoplastic lesions. These same diseases may produce triplegia (or tri paresis) by a combination of paraplegia from a thoracic spinal cord lesion and a separate unilateral lesion in the cervical cord or higher that results in a hemiparesis.

Paralysis of Isolated Muscle Groups

This pattern usually indicates a lesion of one or more peripheral nerves or of several adjacent spinal roots. The diagnosis of an individual peripheral nerve lesion is made on the basis of weakness or paralysis of a particular muscle or group of muscles and impairment or loss of sensation in the distribution of the nerve. Complete or extensive interruption of a peripheral nerve is followed by atrophy of the muscles it innervates and by loss of tendon reflexes of the involved muscles; abnormalities of vasomotor and sudomotor functions and trophic changes in the skin, nails, and subcutaneous tissue may occur if the condition has been chronic.

Detailed knowledge of the motor and sensory innervation of the peripheral nerve in question is needed for a diagnosis. It is impractical to memorize the precise sensorimotor distribution of each peripheral nerve and special manuals, such as *Aids to the Examination of the Peripheral Nervous System*, should be consulted (see also Table 46-1). Electromyography and nerve conduction studies are of great value for localization and to determine if the axon has been damaged or the process affects mainly myelin.

If there is no evidence of upper or lower motor neuron disease but certain movements are nonetheless imperfectly performed, one should look for a disorder of position sense or cerebellar coordination or for rigidity with abnormalities of posture and movement due to disease of the basal ganglia (Chap. 4). In the absence of these disorders, the possibility of an apraxic disorder should be investigated by the methods outlined earlier.

Psychogenic (Hysterical) Paralysis

Psychogenic paralysis may involve one arm or leg, both legs, or all of one side of the body. Tendon reflexes are of normal amplitude, there is no Babinski sign, and atrophy is lacking, features that distinguish it from chronic lower motor neuron disease. Diagnostic difficulty arises only in certain acute cases of upper motor neuron disease that lack the usual changes in reflexes and muscle tone. Sometimes there is loss of sensation in the paralyzed parts and loss of sight, hearing, and smell on the paralyzed side—a pattern of sensory changes that cannot be explained on the basis of organic disease of the nervous system. When the hysterical patient is asked to move the affected limbs, the movements tend to be slow, hesitant, and jerky, often with contraction of agonist and antagonist muscles simultaneously and intermittently (“give-way” weakness). Lack of effort is usually obvious, despite facial and other expressions to the contrary. Power of contraction improves with encouragement and the weakness is inconsistent; some movements are performed tentatively and moments later another movement involving the same muscles is performed naturally.

The Hoover sign and the trunk–thigh sign of Babinski are helpful in distinguishing hysterical from organic hemiplegia. To elicit the Hoover sign, the examiner places both hands under the heels of the recumbent patient, who is asked to press the heels down forcefully. Downward pressure will be felt from the nonparalyzed leg. The examiner then removes his hand from under the nonparalyzed leg, places it on top of the nonparalyzed one, and asks the patient to raise that leg. The sign is manifest in true hemiplegia, by the absence of downward pressure by the paralyzed leg. In psychogenic weakness, the heel of the supposedly paralyzed leg may press down on the examiner’s hand. Or, more useful in our experience, the normal leg fails to demonstrate downward pressure when the hysteric is asked to elevate the supposedly paralyzed one, thereby indicating a lack of voluntary effort (i.e., normally, the good leg is fixated and pressed downward in order to raise the opposite leg). In a similar

maneuver, the examiner tells the patient that he is testing the normal limb, while asking the patient to try to push the knees together. In hysterical weakness, the apparently paralyzed limb adducts with normal power. One can take advantage of midline motor actions in the upper extremity by asking the patient to push his hands together and telling him that the normal side is being tested. In hysterical weakness, there is adduction movement of the supposedly paralyzed limb.

To carry out the Babinski trunk–thigh test, the examiner asks the recumbent patient to sit up while keeping his arms crossed in front of his chest. In the patient with organic hemiplegia from an upper motor neuron lesion, there is an involuntary flexion of the paretic lower limb; in paraplegia, both limbs are flexed as the trunk is flexed; in hysterical hemiplegia, only the normal leg may be flexed; and in hysterical paraplegia, neither leg is flexed. Patients with apparently paralyzed legs who are seated on a rolling desk chair may propel themselves by pedaling along the floor (a sign attributed to Blocq by Okun and colleagues).

Muscular Paralysis and Spasm Unattended by Visible Changes in Nerve or Muscle

A discussion of motor paralysis would be incomplete without some reference to diseases in which muscle weakness may be profound but there are no overt structural changes in motor nerve cells or nerve fibers. Almost any disease of the neuromuscular junction and many diseases of muscle cause this combination. This group comprises myasthenia gravis, inflammatory myopathies, the muscular dystrophies, and myotonia congenita (Thomsen disease), familial periodic paralysis, disorders of potassium, sodium, calcium, and magnesium metabolism, botulism, black widow spider bite, stiff-man syndrome, and the thyroid and other endocrine myopathies. In these diseases, each with a fairly distinctive clinical picture, the abnormality is essentially physiological, biochemical; their investigation requires EMG, special biochemical and histochemical tests, and electron microscopic study. These subjects are discussed in the sections on muscle disease later in this book.

Abnormalities of Movement and Posture Caused by Disease of the Basal Ganglia

In this chapter, disorders of the automatic, static, postural, and other less-modifiable motor activities of the nervous system are discussed. They are an expression of what has come to be called the extrapyramidal motor system, meaning—according to S.A.K. Wilson, who introduced this term—the motor structures of the basal ganglia and certain related thalamic and brainstem nuclei.

The activities of the basal ganglia and the cerebellum are blended with and modulate the corticospinal system and the postural influence of the extrapyramidal system is indispensable to voluntary corticospinal movements. This close association of the basal ganglia and corticospinal systems becomes evident in the course of many forms of neurologic disease. In many aberrant motor patterns, one sees evidence not only of the activity of the basal ganglia but also of labyrinthine, tonic neck, and other postural reflexes that are mediated through nonpyramidal, bulbospinal and other brainstem motor systems. Observations such as these have blurred the original distinctions between pyramidal and extrapyramidal motor systems. Nevertheless, this division remains a useful concept in clinical work because it compels a distinction among several motor syndromes—one that is characterized by a loss of volitional movement accompanied by spasticity—the corticospinal syndrome; a second by bradykinesia, rigidity, and tremor without loss of voluntary movement—the hypokinetic basal ganglionic syndrome; a third by involuntary movements (choreoathetosis and dystonia)—the hyperkinetic basal ganglionic syndrome; and yet another by incoordination (ataxia)—the cerebellar syndrome. Table 4-1 summarizes the main clinical differences between corticospinal and extrapyramidal syndromes.

THE STRIATOPALLIDONIGRAL SYSTEM (BASAL GANGLIA)

Anatomic Considerations

As an anatomic entity, the basal ganglia have no precise definition. Principally they include the caudate nucleus and the lentiform (lenticular, from its lens-like shape) nucleus with its two subdivisions—the putamen and globus pallidus. Insofar as the caudate nucleus and

putamen are really a continuous structure (separated only incompletely by fibers of the internal capsule) and are cytologically and functionally distinct from the pallidum, it is more meaningful to divide these nuclear masses into the striatum (or neostriatum), comprising the caudate nucleus and putamen, and the paleostriatum or pallidum, which has a medial (internal) and a lateral (external) portion. The putamen and pallidum lie on the lateral aspect of the internal capsule, which separates them from the caudate nucleus, thalamus, subthalamic nucleus, and substantia nigra on its medial side (Figs. 4-1 and 4-2). By virtue of their close connections with the caudate and lenticular nuclei, the subthalamic nucleus (nucleus of Luys) and the substantia nigra are included as parts of the basal ganglia. The claustrum and amygdaloid nuclear complex, because of their largely different connections and functions, are usually excluded.

For reasons indicated further on, some physiologists have expanded the list of basal ganglionic structures to include the red nucleus, the intralaminar thalamic nuclei, and the reticular formations of the upper brainstem. These structures receive direct cortical projections and give rise to rubrospinal and reticulospinal tracts that run parallel to the corticospinal (pyramidal) ones; hence they also were once referred to as extrapyramidal. However, these nonpyramidal linkages are structurally independent of the major extrapyramidal circuits and are better termed parapyramidal systems. As the final links in this circuit—the premotor and supplementary motor cortices—ultimately project onto the motor cortex, they are more aptly referred to as prepyramidal (Thach and Montgomery).

Earlier views of basal ganglionic organization emphasized serial connectivity and the funneling of efferent projections to the ventrolateral thalamus and thence to the motor cortex (Fig. 4-3). This concept was based largely on the experimental work of Whittier and Mettler and of Carpenter, in the late 1940s. These investigators demonstrated, in monkeys, that a characteristic movement disorder, which they termed choreoid dyskinesia, could be brought about in the limbs of one side of the body by a lesion localized to the opposite subthalamic nucleus. They also showed that for such a lesion to provoke dyskinesia, the adjacent pallidum and

Table 4-1

CLINICAL DIFFERENCES BETWEEN CORTICOSPINAL AND EXTRAPYRAMIDAL SYNDROMES

	CORTICOSPINAL	EXTRAPYRAMIDAL
<i>Character of the alteration of muscle tone</i>	Clasp-knife effect (spasticity)	Plastic, equal throughout passive movement (rigidity), or intermittent (cogwheel rigidity)
<i>Distribution of hypertonus</i>	Flexors of arms, extensors of legs	Generalized but predominates in flexors of limbs and of trunk
<i>Involuntary movements</i>	Absent	Presence of tremor, chorea, athetosis, dystonia
<i>Tendon reflexes</i>	Increased	Normal or slightly increased
<i>Babinski sign</i>	Present	Absent
<i>Paralysis of voluntary movement</i>	Present	Absent or slight

pallidofugal fibers had to be preserved; that is, a second lesion—placed in the medial segment of the pallidum, in the fasciculus lenticularis, or in the ventrolateral thalamus—abolished the dyskinesia. This experimental hyperkinesia could also be abolished by interruption of the lateral corticospinal tract but not by sectioning of the other motor or sensory pathways in the spinal cord. These observations were interpreted to mean that the subthalamic nucleus exerts an inhibitory or regulating influence on the globus pallidus and ventral thalamus. Removal of this influence by selective destruction of the subthalamic nucleus is expressed physiologically by an irregular activity that is now identified as chorea, presumably arising from the intact pallidum and conveyed to the ventrolateral thalamic nuclei, thence by thalamocortical fibers to the ipsilateral premotor cortex, and from there, to the motor cortex, all in a serial manner.

New observations have made it apparent that there are instead, a number of parallel circuits as detailed further on. However, a general principle that has withstood the test of time is the central role of the ventrolateral and ventroanterior nuclei of the thalamus. Together, these nuclei form a vital link, not only from the basal ganglia but also from the cerebellum, to the motor and premotor cortex. Thus, both basal ganglionic and cerebellar influences are brought to bear, via thalamocortical fibers, on the corticospinal system and on other descending pathways from the cortex. Direct descending pathways from the basal ganglia to the spinal cord are relatively insignificant.

The foregoing view of basal ganglionic organization has been broadened considerably as a result of newer anatomic, physiologic, and pharmacologic data (see reviews of Gombart and colleagues, of DeLong,

Figure 4-1. Overview of the components of the basal ganglia in coronal view. The main nuclei of the basal ganglia are represented in blue, as labeled on the right.

and of Penney and Young). Whereas earlier concepts emphasized the serial connectivity of the basal ganglionic structures as mentioned earlier, current evidence indicates an organization into several parallel basal ganglionic–cortical circuits. These circuits run parallel to the premotor pathway but remain separate anatomically and physiologically. At least five such anatomic circuits have been described, each projecting to a different portion of the frontal lobe: (1) the prototypical motor circuit, converging on the premotor cortex; (2) the oculomotor circuit, projecting onto the frontal eye fields; two prefrontal circuits: (3) one ending in the dorsolateral prefrontal and (4) the other on the lateral orbitofrontal cortex; and (5) a limbic circuit that projects to the anterior cingulate and medial orbitofrontal cortex.

An additional and essential feature of basal ganglionic structure is the nonequivalence of all parts of the striatum. Particular cell types and zones of cells within this structure appear to mediate different aspects of motor control and to utilize specific neurochemical transmitters, as detailed below under “Pharmacologic Considerations” (see also Albin et al and DeLong). This specialization has taken on further importance with the observation that one or another cell type is destroyed preferentially in degenerative diseases such as Huntington chorea.

The most important basal ganglionic connections and circuitry are indicated in Figs. 4-1, 4-2, and 4-3. The striatum, mainly the putamen, is the receptive part of the basal ganglia, receiving topographically organized fibers from all parts of the cerebral cortex and from the

Figure 4-3. Schematic illustration of major efferent and afferent connections of the basal ganglia. The blue lines indicate neurons with excitatory effects, whereas the black lines indicate inhibitory influences. (See text for details; also Fig. 4-2.) pars compacta (pigmented neurons) of the substantia nigra, and that the output nuclei of the basal ganglia consist of the medial (internal) pallidum and the pars reticulata (nonpigmented portion) of the substantia nigra (Fig. 4-3).

It has been proposed on the basis of physiologic, lesional, and pharmacologic studies, that there are two main efferent projections from the putamen; but these models are still in evolution. Nonetheless, there are reasons to conceptualize 1) a *direct* efferent system from the putamen to the medial (internal) pallidum and then to

the substantia nigra, particularly to the pars reticulata, and 2) an *indirect* system originating in the putamen that traverses the lateral (external) pallidum and continues to the subthalamic nucleus, with which it has strong reciprocal connections.

In most ways, the subthalamic nucleus and lateral pallidum operate as a single functional unit, (at least in terms of the effects of lesions in those locations on parkinsonian symptoms and the neurotransmitters involved. The medial pallidum and reticular part of the substantia nigra can be viewed in a similar unitary way, sharing the same input and output patterns. Within the indirect pathway, an internal loop is created by projections from the subthalamic nucleus to the medial segment of the pallidum and pars reticulata. A second offshoot of the indirect pathway consists of projections from the lateral pallidum to the medial pallidonigral output nuclei. A complete account of this intricate connectivity cannot be given, but the main themes outlined here seem valid.

From the internal pallidum, two bundles of fibers reach the thalamus—the ansa lenticularis and the fasciculus lenticularis. The ansa sweeps around the internal capsule; the fasciculus traverses the internal capsule in a number of small fascicles and then continues medially and caudally to join the ansa in the prerubral field. Both of these fiber bundles join the thalamic fasciculus, which then contains not only the pallidothalamic projections but also mesothalamic, rubrothalamic, and dentatothalamic ones. These projections are directed to separate targets in the ventrolateral nucleus of the thalamus and to a lesser extent in the ventral anterior and intralaminar thalamic nuclei. The centromedian nucleus of the intralaminar group projects back to the putamen and, via the parafascicular nucleus, to the caudate. A major projection from the ventral thalamic nuclei to the ipsilateral premotor cortex completes the large cortical–striatal–pallidal–thalamic–cortical motor loop, with conservation of the somatotopic arrangement of motor fibers, again emphasizing the nexus of motor control at the thalamic nuclei.

Physiologic Considerations

In simplest physiologic terms, Denny-Brown and Yanagisawa, who studied the effects of ablation of individual extrapyramidal structures in monkeys, concluded that the basal ganglia function as a kind of clearinghouse where, during an intended or projected movement, one set of activities is facilitated and all other unnecessary ones are suppressed. They used the analogy of the basal ganglia as a brake or switch, the tonic inhibitory (“brake”) action preventing target structures from generating unwanted motor activity and the “switch” function referring to the capacity of the basal ganglia to select which of many available motor programs will be active at any given time. Still other theoretical constructs focus on the role of the basal ganglia in the initiation, sequencing, and modulation of motor activity (“motor programming”). Also, it appears that the basal ganglia participate in the constant priming of the motor system, enabling the rapid execution of motor acts without premeditation—e.g., hitting a baseball. In most ways, these conceptualizations restate the same notions of

balance and selectivity imparted to all motor actions by the basal ganglia.

Physiologic evidence indicates that a balanced functional architecture, one excitatory and the other inhibitory, is operative within the individual circuits. The *direct* striatomedial pallidonigral pathway is activated by glutaminergic projections from the sensorimotor cortex and by dopaminergic nigral (pars compacta)–striatal projections. Activation of this direct pathway inhibits the medial pallidum, which, in turn, disinhibits the ventrolateral and ventroanterior nuclei of the thalamus. As a consequence, thalamocortical drive is enhanced and cortically initiated movements are facilitated. The *indirect* circuit arises from putaminal neurons that contain gamma-aminobutyric acid (GABA) and smaller amounts of enkephalin. These striatal projections have an inhibitory effect on the lateral pallidum, which, in turn, disinhibits the subthalamic nucleus through GABA release, providing subthalamic drive to the medial pallidum and substantia nigra pars reticulata. The net effect is thalamic inhibition that reduces thalamocortical input to the precentral motor fields and impedes voluntary movement. These complex anatomic and physiologic relationships have been summarized in numerous schematic diagrams similar to Fig. 4-4 and those by Lang and Lozano and by Standaert and Young.

Restated, the current view is that enhanced conduction through the indirect pathway leads to hypokinesia by increasing pallidothalamic inhibition, whereas enhanced conduction through the direct pathway results in hyperkinesia by reducing pallidothalamic inhibition. The direct pathway has been conceived by Marsden and Obeso as facilitating cortically initiated movements and the indirect pathway as suppressing potentially conflicting and unwanted motor patterns. In Parkinson disease, e.g., loss of dopaminergic input from the substantia nigra diminishes activity in the direct pathway and increases activity in the indirect pathway; the net effect is to increase inhibition of the thalamic nuclei and to reduce excitation of the cortical motor system.

Further insight into these systems and into the mechanism of Parkinson disease has come from the discovery that the parkinsonian syndrome is reproduced in humans and primates by the toxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). This toxin was discovered accidentally in drug addicts who self-administered an analogue of meperidine. The toxin binds with high affinity to monoamine oxidase (MAO), an extraneural enzyme that transforms it to pyridinium, a toxic metabolite that is bound by melanin in the dopaminergic nigral neurons in sufficient quantities to destroy the cells, probably by interfering with mitochondrial function. In monkeys made parkinsonian by the administration of MPTP, electrophysiologic studies have shown increased activity in the medial globus pallidus and decreased activity in the lateral globus pallidus, as predicted from the above described models. This comes about because of the differential loss of activity of dopaminergic striatal neurons that project to each of these parts of the pallidum. The end result is increased inhibition of thalamocortical neurons. It is, however, difficult to explain why medial pallidal

Figure 4-4. A. Schematic diagram of the main neurotransmitter pathways and their effects in the cortical–basal ganglia–thalamic circuits. The blue lines indicate neurons with excitatory effects; the black lines indicate inhibitory influences. The internal (medial) segment of the globus pallidus (MGP) and the zona reticulata of the substantia nigra (SNpr) are believed to act as one entity that projects via GABA-containing neurons to the thalamus (ventrolateral and ventroanterior nuclei) and to the pedunculopontine nuclei (not shown). Dopaminergic neurons (DA) arising in the pars compacta of the substantia nigra (SNpc) have an excitatory influence on the direct striatopallidal fibers (via D1 receptors) and an inhibitory effect on the indirect striatopallidal fibers (via D2 receptors) that project to the external (lateral) pallidum (LGP) and subthalamic nucleus (STN). Dotted lines in the subsequent figures denote a reduction in activity of the pathway. (See text.) B. Corresponding physiologic state as conceptualized in Parkinson disease, in which hypokinesia is the main finding as a result of reduced dopamine input from the substantia nigra and pars compacta to the striatum via the direct pathway, which results in withdrawal of inhibitory activity of the globus pallidus and, in turn, increased inhibitory drive on the thalamic nuclei, which reduces input to the cortical motor system. C. Schematic diagram of the theorized mechanism in Huntington disease, a hyperkinetic movement disorder resulting from reduced inhibition by the striatum within the indirect pathway, overdriving of the subthalamic nucleus, and causing excess activity in thalamocortical circuits. (See text.)

lesions do not regularly cause parkinsonism. Perhaps it is because the subtle imbalance between the medial and lateral pallidal circuits that exists in Parkinson disease is not reproduced. This subtlety may also explain why crude lesions, such as infarcts, hemorrhages, and tumors, rarely produce the complete parkinsonian syndrome of tremor, bradykinesia, and rigidity. Indeed, striking improvements in parkinsonian symptoms are obtained, paradoxically, by placing lesions in the medial pallidum (pallidotomy) as discussed in Chap. 39.

It is likely that the static model of inhibitory and excitatory pathways and the parsing of a direct and an indirect pathway, as useful as it is as a mnemonic, does not account well for the dynamic activities of the basal ganglia.

In particular, the electrical activity of the neurons in these systems oscillate and influence the frequency of oscillations in other parts of the system, as well as bringing individual cells closer to firing. Another deficiency of currently conceived models is that they do not account for the tremor of Parkinson disease. To further complicate matters, the various subtypes of dopamine receptors act in both excitatory and inhibitory ways under different circumstances depending on their location as discussed below.

The manner in which excessive or reduced activity of various components of the basal ganglia gives rise to hypokinetic and hyperkinetic movement disorders is discussed further on, under “Symptoms of Basal Ganglia Disease.”

Pharmacologic Considerations

A series of pharmacologic observations have considerably enhanced our understanding of basal ganglionic function and led to a rational treatment of Parkinson disease and other extrapyramidal syndromes. Whereas physiologists had for years failed to discover the functions of the basal ganglia by stimulation and crude ablation experiments, clinicians became aware that certain drugs, such as reserpine and the phenothiazines, could produce extrapyramidal syndromes (e.g., parkinsonism, choreoathetosis, dystonia). These observations stimulated the study of central nervous system (CNS) transmitter substances in general. The current view is that the integrated basal ganglionic control of movement can be best understood by considering, in the context of the anatomy described above, the physiologic effects of neurotransmitters that convey the signals between cortex, striatum, globus pallidus, subthalamic nucleus, substantia nigra, and thalamus.

The most important neurotransmitter substances from the point of view of basal ganglionic function are glutamate, GABA, dopamine, acetylcholine, and serotonin. Figure 4-4 summarizes their roles. A more complete account of this subject may be found in the reviews of Penney and Young, of Alexander and Crutcher, and of Rao.

The following is what is known with a fair degree of certainty. Glutamate is the neurotransmitter of the excitatory projections from the cortex to the striatum and of the excitatory neurons of the subthalamic nucleus. GABA is the inhibitory neurotransmitter of striatal, pallidal, and substantia nigra (pars reticulata) projection neurons.

Acetylcholine (ACh), long established as the neurotransmitter at the neuromuscular junction and the autonomic ganglia, is also physiologically active in the basal ganglia. The highest concentration of ACh, as well as of the enzymes necessary for its synthesis and degradation (choline acetyl transferase and acetylcholinesterase), is in the striatum. Acetylcholine is synthesized and released by the large but sparse (Golgi type 2) nonspiny striatal neurons. It has a mixed but mainly excitatory effect on the more numerous spiny neurons within the putamen that constitute the main origin of the direct and indirect pathways described above. It is likely that the effectiveness of atropinic agents—which have been used empirically for many years in the treatment of Parkinson disease and dystonia—depends on their capacity to antagonize ACh at sites within the basal ganglia and in projections from the pedunculopontine nuclei. Acetylcholine also appears to act on the presynaptic membrane of striatal cells and to influence their release of neurotransmitters, as discussed below. In addition, the basal ganglia contain other biologically active substances—substance P, enkephalin, cholecystokinin, somatostatin, and neuropeptide Y—which enhance or diminish the effects of other neurotransmitters, i.e., they act as neuromodulators.

Of the catecholamines, dopamine has the most pervasive role but its influence can be excitatory or inhibitory depending on the site of action and the subtype of dopamine receptor. Disturbances of dopamine signaling are essential abnormalities of several CNS disorders

including parkinsonism, schizophrenia, attention deficit hyperactivity disorder, and drug abuse. Within the basal ganglia, the areas richest in dopamine are the substantia nigra, where it is synthesized in the nerve cell bodies of the pars compacta, and the termination of these fibers in the striatum. In the most simplified models, stimulation of the dopaminergic neurons of the substantia nigra induces a specific response in the striatum—namely, an inhibitory effect on the already low firing rate of neostriatal neurons. However, the effects of dopamine have proved even more difficult to resolve, in large part because there are now five known types of postsynaptic dopamine receptors (D1 to D5), each with a particular anatomic distribution and pharmacologic action. This heterogeneity is exemplified in the excitatory effect of dopamine on the small spiny neurons of the putamen and an inhibitory effect on others.

The five types of dopamine receptors are found in differing concentration throughout various parts of the brain, each displaying differing affinities for dopamine itself and for various drugs and other agents (Table 4-2; also see Jenner). The D1 and D2 receptors are highly concentrated in the striatum and are the ones most often implicated in diseases of the basal ganglia; D3 in the nucleus accumbens, D4 in the frontal cortex and certain limbic structures, and D5 in the hippocampus. In the striatum, the effects of dopamine act as a class of “D1-like” (D1 and D5 subtypes) and “D2-like” (D2, D3, and D4 subtypes) receptors. Activation of the D1 class stimulates adenylyl cyclase, whereas D2 receptor binding inhibits this enzyme. Whether dopamine functions in an excitatory or inhibitory manner at a particular synapse is determined by the local receptor. As mentioned earlier, excitatory D1 receptors predominate on the small spiny putaminal neurons that are the origin of the direct striatopallidal output pathway, whereas D2 receptors mediate the inhibitory influence of dopamine on the indirect striatopallidal output, as indicated in Fig. 4-4.

Some of the clinical and pharmacologic effects of dopamine are made clear by considering both the anatomic sites of various receptors and their physiologic effects. For example, it appears that drug-induced parkinsonian syndromes and tardive dyskinesias (described further on) are prone to occur when drugs are administered that competitively bind to the D2 receptor, but that the newer antipsychosis drugs, which produce fewer of these effects, have a stronger affinity for the D4 receptor. However, the situation is actually far more complex, in part because of the synergistic activities of D1 and D2 receptors, each potentiating the other at some sites of convergence, and the presence on the presynaptic terminals of nigrostriatal neurons of D2 receptors, which inhibit dopamine synthesis and release.

Even these details do not capture the intricacy of neural transmission in the basal ganglia. In contrast to the almost instantaneous actions of glutamate and its antagonist, GABA, at synapses, the monoamines have more protracted effects, lasting for seconds or as long as several hours. Dopamine and related neurotransmitters have a slower influence through the “second messenger” cyclic adenosine monophosphate (cAMP), which, in

turn, controls the phosphorylation or dephosphorylation of numerous intraneuronal proteins. These intracellular effects have been summarized by Greengard.

The effects of certain drugs, some no longer in use, are also best comprehended by understanding the manner in which they alter neurotransmitter function. Several drugs—namely reserpine, the phenothiazines, and the butyrophenones (notably haloperidol)—induce prominent parkinsonian syndromes in humans. Reserpine, for example, depletes the striatum and other parts of the brain of dopamine; haloperidol and the phenothiazines work by a different mechanism, probably by blocking dopamine receptors within the striatum.

The basic validity of the physiologic-pharmacologic model outlined here is supported by the observation that excess doses of L-dopa or of a direct-acting dopamine receptor agonist lead to excessive motor activity. Furthermore, the therapeutic effects of the main drugs used in the treatment of Parkinson disease are understandable in the context of neurotransmitter function. To correct the basic dopamine deficiency from a loss of nigral cells that underlies Parkinson disease, attempts were at first made to administer dopamine directly. However, dopamine as such cannot cross the blood-brain barrier and therefore has no therapeutic effect. But its immediate precursor, L-dopa, does cross the blood-barrier and is effective in decreasing the symptoms of Parkinson disease as well as of the above-described MPTP-induced parkinsonism. This effect is enhanced by the addition of an inhibitor of dopadecarboxylase, an important

enzyme in the catabolism of dopamine. The addition of an enzyme inhibitor of this type (carbidopa or benserazide) to L-dopa results in an increase of dopamine concentration in the brain, while sparing other organs from exposure to high levels of the drug. Similarly, drugs that inhibit catechol *O*-methyltransferase (COMT), another enzyme that metabolizes dopamine, prolong the effects of administered L-dopa.

Because of the pharmacologic effects of ACh and dopamine, it was originally postulated by Ehringer and Hornykiewicz (the latter originated the idea) that a functional equilibrium exists in the striatum between the excitatory activity of ACh and the inhibitory activity of dopamine. In Parkinson disease, the decreased release of dopamine by the substantia nigra onto the striatum disinhibits neurons that synthesize ACh, resulting in a predominance of cholinergic activity—a notion supported by the observation that parkinsonian symptoms are aggravated by centrally acting cholinergic drugs and improved by anticholinergic drugs. According to this theory, administration of anticholinergic drugs restores the ratio between dopamine and ACh, with the new equilibrium being set at a lower-than-normal level because the striatal levels of dopamine are low to begin with. This view has been validated in clinical practice in that one observes a beneficial effect on parkinsonian symptoms after the administration of anticholinergic agents. The use of drugs that enhance dopamine synthesis or its release, or that directly stimulate dopaminergic receptors in the striatum (e.g., pramipexole), represents

another more direct method of treating Parkinson disease as outlined in Chap. 39.

The Pathology of Basal Ganglionic Disease

The extrapyramidal motor syndrome as we know it today was first delineated on clinical grounds and so named by S.A.K. Wilson in 1912. In the disease that now bears his name and that he called hepatolenticular degeneration, the most striking abnormality was a bilaterally symmetrical degeneration of the putamen, sometimes to the point of cavitation. To these lesions Wilson correctly attributed the characteristic symptoms of rigidity and tremor. Shortly thereafter, van Woerkom described a similar clinical syndrome in a patient with acquired liver disease (Wilson's cases were familial), the most prominent lesions again consisting of foci of neuronal degeneration in the striatum. Clinicopathologic studies of Huntington chorea—beginning with those of Meynert (1871) and followed by those of Jelgersma (1908) and Alzheimer (1911)—related the excessive movements and rigidity characteristic of the disease to a loss of nerve cells in the striatum. In 1920, Oskar and Cecile Vogt gave a detailed account of the neuropathologic changes in several patients who had been afflicted with choreoathetosis since early infancy; the changes, which they described as a “status fibrosus” or “status dysmyelinatus,” were confined to the caudate and lenticular nuclei. Surprisingly, it was not until 1919 that Tretiakoff demonstrated the underlying cell loss of the substantia nigra in cases of what was then called paralysis agitans and is now known as Parkinson disease. Finally, a series of observations, culminating with those of J. Purdon Martin and later of Mitchell and colleagues, related hemiballismus to lesions in the subthalamic nucleus of Luys and its immediate connections. While these observations have been invaluable, it has become apparent from clinical work that none of the relationships between anatomic loci and movement disorders are exclusive and the same movement disorder can result from lesions at one of several sites.

Another broad perspective on the result of focal damage in the basal ganglia was afforded by Bhatia and Marsden, who reviewed some 240 cases in which there were lesions in the caudate, putamen, and globus pallidus associated with movement abnormalities. Dystonia occurred in 36 percent, chorea in 8 percent, parkinsonism in only 6 percent, and dystonia-parkinsonism in 3 percent. Bilateral lesions of the lenticular nuclei resulted in parkinsonism in 19 percent and dystonia-parkinsonism in 6 percent. It is also notable that a common associated behavioral abnormality was abulia (apathy and loss of initiative, spontaneous thought, and emotional responsivity), in those with caudate lesions. The deficiencies of this type of case analysis (i.e., the crudeness of computed tomography studies and obtained without regard to the temporal aspects of the clinical disorder), conceded by the authors, are obvious. We find it surprising that choreoathetosis was not more frequent. Needed are detailed anatomic (postmortem) studies of cases in which the disturbances of function were stable for many months or years. However, restating the comments above, there is no consistent association between any type of movement disorder and a particular location in the basal ganglia.

As a prelude to the next section, Table 4-3 summarizes the clinicopathologic correlations of extrapyramidal movement disorders that are accepted by most neurologists; it must be emphasized, however, that there is still some uncertainty as to the finer details.

SYMPTOMS OF BASAL GANGLIA DISEASE

In broad terms, all motor disorders consist of functional deficits (or negative symptoms) and conversely, excessive motor activity (positive symptoms), the latter being ascribed to the release or disinhibition of the activity of undamaged parts of the motor system. When diseases of the basal ganglia are analyzed along these lines, bradykinesia, hypokinesia, and loss of normal postural reflexes

Table 4-3

CLINICOPATHOLOGIC CORRELATIONS OF EXTRAPYRAMIDAL MOVEMENT DISORDERS

SYMPTOMS	PRINCIPAL LOCATION OF MORBID ANATOMY
Unilateral plastic rigidity with rest tremor (Parkinson disease)	Contralateral substantia nigra plus (?) other mesencephalic structures
Unilateral hemiballismus and hemichorea	Contralateral subthalamic nucleus of Luys or Luysial-pallidal connections
Chronic chorea of Huntington type	Caudate nucleus and putamen
Athetosis and dystonia	Contralateral striatum (pathology of dystonia musculorum deformans unknown)
Cerebellar incoordination, intention tremor, and hypotonia	Ipsilateral cerebellar hemisphere; ipsilateral middle or inferior cerebellar peduncle; brachium conjunctivum (ipsilateral if below decussation, contralateral if above)
Decerebrate rigidity, i.e., extension of arms and legs, opisthotonos	Usually bilateral in tegmentum of upper brainstem at level of red nucleus or between red and vestibular nuclei
Palatal and facial myoclonus (rhythmic)	Ipsilateral central tegmental tract with denervation of inferior olivary nucleus and nucleus ambiguus
Diffuse myoclonus	Neuronal degeneration, usually diffuse or predominating in cerebral or cerebellar cortex and dentate nuclei

stand out as the primary negative symptoms, and tremor, rigidity, and the involuntary dyskinetic movements of chorea, athetosis, ballismus and dystonia, as the positive ones. Disorders of phonation, articulation, and locomotion due to basal ganglia disease are more difficult to classify. In some instances this group of disorders is clearly a consequence of rigidity and postural disorders, whereas in others, where rigidity is slight or negligible, they seem to represent primary deficiencies. Psychological stress and anxiety generally worsen the abnormal movements in extrapyramidal syndromes, just as relaxation improves them.

Hypokinesia and Bradykinesia

The terms hypokinesia and akinesia (the extreme form of hypokinesia) refer to a reduction in the spontaneous movements of an affected part and a failure to engage it freely in the natural actions of the body. In contrast to what occurs in paralysis (the primary symptom of corticospinal tract lesions), strength is not significantly diminished. Also, hypokinesia is unlike apraxia, in which a lesion erases the memory of the pattern of movements necessary for an intended act, leaving other actions intact. Hypokinesia is expressed most clearly in the parkinsonian patient where it takes the form of an extreme underactivity (“poverty”) of movement. The frequent automatic, habitual movements observed in the normal individual—such as putting the hand to the face, folding the arms, or crossing the legs—are absent or greatly reduced. In looking to one side, the eyes move, but not the head. In arising from a chair, there is a failure to make the usual small preliminary adjustments, such as pulling the feet back, putting the hands on the arms of the chair, and so forth. Blinking is infrequent. Saliva is not swallowed as quickly as it is produced, and drooling results. The face lacks expressive mobility (“masked facies,” or hypomimia). Speech is rapid, mumbling (or “cluttered”), and monotonic, and the voice is soft.

Bradykinesia, which connotes slowness rather than lack of movement, is another aspect of the same physiologic difficulty. Not only is the parkinsonian patient slightly “slow off the mark” (displaying a longer-than-normal interval between a command and the first contraction of muscle—i.e., increased reaction time), but the velocity of movement, or the time from onset to completion of movement, is slower than normal. Hallett distinguishes between akinesia and bradykinesia, equating akinesia with a prolonged reaction time and bradykinesia with a prolonged time of execution, but he has noted that if bradykinesia is severe, it results in akinesia. This is apparently not the result of slowness in formulating the plan of movement, which nonetheless seems at times to be another component of the parkinsonian syndromes. For a time, bradykinesia was attributed to the frequently associated rigidity, which could reasonably hamper all movements, but the limitation of this explanation became apparent when it was discovered that an appropriately placed stereotactic lesion in a patient with Parkinson disease may abolish rigidity while leaving the hypokinesia unaltered. Thus it appears that apart from their

contribution to the maintenance of posture, the basal ganglia provide an essential element for the performance of the large variety of voluntary and semiautomatic actions required for the full repertoire of natural human motility.

Hallett and Khoshbin, in an analysis of ballistic (rapid) movements in the parkinsonian patient, found that the normal triphasic sequence of agonist–antagonist–agonist activation, as described in the next chapter, is intact but lacks the amplitude (number of activated motor units) to complete the movement. Several smaller triphasic sequences are then needed, which slow the movement. The patient experiences these phenomena as not only slowness but also a perceived weakness. That cells in the basal ganglia participate in the initiation of movement is also evident from the fact that the firing rates in these neurons increase before movement is detected clinically.

In terms of pathologic anatomy and physiology, bradykinesia may be caused by any process or drug that interrupts some component of the cortico-striato-pallido-thalamic circuit. Clinical examples include reduced dopaminergic input from the substantia nigra to the striatum, as in Parkinson disease; dopamine receptor blockade by neuroleptic drugs; extensive degeneration of striatal neurons, as in striatonigral degeneration and the rigid form of Huntington chorea; and destruction of the medial pallidum, as in Wilson diseases.

As illustrated in Fig. 4-4B, which gives a schematic representation of the hypokinetic state of Parkinson disease, changes in the cortico-striato-pallido-thalamic circuit (in this case mainly the direct striatopallidal pathway) can be interpreted in terms of altered neurochemical and resultant physiologic connectivity within the basal ganglia. The reciprocal situation, enhanced motor activity, is summarized in the analogous diagram for Huntington disease (Fig. 4-4C), in which a reduction in the activity of the indirect striatopallidal pathway leads to enhanced excitatory motor drive in the thalamocortical motor pathway.

A number of other disorders of voluntary movement may also be observed in patients with diseases of the basal ganglia. A persistent voluntary contraction of hand muscles, as in holding a pencil, may fail to be inhibited, so that there is interference with the next willed movement. This has been termed tonic innervation, or blocking, and may be brought out by asking the patient to repetitively open and close a fist or tap a finger. Attempts to perform an alternating sequence of movements may be blocked at one point, or there may be a tendency for the voluntary movement to adopt the frequency of a coexistent tremor (entrainment).

Disorders of Postural Fixation, Equilibrium, and Righting

These deficits are also demonstrated most clearly in the parkinsonian patient. The prevailing posture is one of involuntary flexion of the trunk and limbs and of the neck. Anticipatory and compensatory righting reflexes are also manifestly impaired. This occurs early in the course of progressive supranuclear palsy and later in

Parkinson disease. The inability of the patient to make appropriate postural adjustments to tilting or falling and his inability to move from the reclining to the standing position are closely related phenomena. A gentle push on the patient's sternum or a tug on the shoulders may cause a fall or start a series of small corrective steps that the patient cannot control (festination). These postural abnormalities are not attributable to weakness or to defects in proprioceptive, labyrinthine, or visual function, the principal forces that control the normal posture of the head and trunk.

Rigidity and Alterations in Muscle Tone

In the form of altered muscle tone known as rigidity, the muscles are continuously or intermittently firm and tense. Although brief periods of electromyographic silence can be obtained in selected muscles by persistent attempts to relax the limb, there is obviously a low threshold for involuntary sustained muscle contraction, and this is present during most of the waking state, even when the patient appears quiet and relaxed. In contrast to spasticity, the increased resistance on passive movement that characterizes rigidity is not preceded by an initial "free interval" and has an even or uniform quality throughout the range of movement of the limb, like that experienced in bending a lead pipe or pulling a strand of toffee. The contrasting terms clasp-knife for spasticity and lead-pipe for rigidity have been applied to the examiner's physical perception on attempting to smoothly manipulate the patient's limb through an arc of movement. Moreover, the rigidity of extrapyramidal disorder is not velocity-dependent, as it is in spasticity. The tendon reflexes are not enhanced in the rigid limb as they are in spasticity and, when released, the limb does not resume its original position, as happens in spasticity.

Rigidity usually involves both flexor and extensor muscle groups, but it tends to be more prominent in muscles that maintain a flexed posture, i.e., in the flexor muscles of trunk and limbs. It appears to be somewhat greater in the large muscle groups, but this may be merely a matter of muscle mass. Certainly the small muscles of the face and tongue and even those of the larynx are often affected by rigidity. Concordant with the physical examination, in the electromyographic tracing, motor-unit activity is more continuous in rigidity than in spasticity, persisting even after apparent relaxation.

A special feature that may accompany rigidity, first noted by Negro in 1901, is the cogwheel phenomenon. When the hypertonic muscle is passively stretched, e.g., when the hand is dorsiflexed, one encounters a rhythmically interrupted, ratchet-like resistance. Many believe that this phenomenon represents an underlying tremor that, if not manifestly present, emerges faintly during manipulation. In that case it would not be a fundamental property of rigidity and would be found in many tremulous states. However, numerous instances of severe tremor with minimally perceptible cogwheeling, and the opposite, suggest to us on clinical grounds that the phenomenon may be more complex.

Rigidity is a prominent feature of many basal ganglionic diseases, such as Parkinson disease, Wilson disease, striatonigral degeneration (multiple system atrophy), progressive supranuclear palsy, dystonia musculorum deformans (all discussed in Chap. 39), exposure to neuroleptic drugs, and mineralization of the basal ganglia (Fahr disease). Rigidity is characteristically variable in severity at different times; in some patients with involuntary movements, particularly in those with chorea or dystonia, the limbs may actually be intermittently or persistently hypotonic.

Another distinctive type of variable resistance to passive movement is one in which the patient seems unable to relax a group of muscles on request. When the limb muscles are passively stretched, the patient appears to actively resist the movement (gegenhalten, paratonia, or oppositional resistance). Natural relaxation normally requires concentration on the part of the patient. If there is inattentiveness—as happens with diseases of the frontal lobes, dementia, or other confusional states—this type of oppositional resistance may raise a question of parkinsonian rigidity. This is not a manifestation of basal ganglia disorder per se but may indicate that the connections of the basal ganglia to the frontal lobes are impaired. A similar difficulty in relaxation is observed normally in small children. Also not to be mistaken for rigidity or paratonia is the "waxy flexibility" displayed by the psychotic-catatonic patient when a limb placed in a suspended position is maintained for minutes in the identical posture (*flexibilitas cerea*, see Chap. 53).

Involuntary Movements (Chorea, Athetosis, Ballismus, Dystonia)

In deference to usual practice, these symptoms are described as though each represented a discrete clinical phenomenon, readily distinguishable from the others. In reality, they usually occur together or blend imperceptibly into each other and have many points of clinical similarity. There are reasons to believe that they have a common anatomic and physiologic basis although distinct sites in the brain have been tentatively implicated for each. One must be mindful that chorea, athetosis, and dystonia are symptoms and are not to be equated with disease entities that happen to incorporate one of these terms in their names (e.g., Huntington chorea, dystonia musculorum deformans). Here the discussion is limited to the symptoms. The diseases of which these symptoms are a part are considered mainly in Chap. 39.

Somewhat more ambiguous but in common clinical use is the term dyskinesia. It encompasses all the active movement phenomena that are a consequence of disease of the basal ganglia, usually implying an element of dystonia, but it has also been used to refer more specifically to the undifferentiated excessive movements that are induced in Parkinson patients at the peak of L-dopa effect and to numerous dystonic and athetotic movements that may follow the use of neuroleptic drugs ("tardive dyskinesias") that are discussed in Chaps. 6 and 43.

Chorea

Derived from the Greek word meaning “dance,” chorea refers to involuntary arrhythmic movements of a forcible, rapid, jerky type. These movements may be simple or quite elaborate and of variable distribution. Although the movements are purposeless, the patient may incorporate them into a deliberate act, as if to make them less noticeable. When superimposed on voluntary actions, they may assume an exaggerated and bizarre character. Grimacing and peculiar respiratory sounds may be other expressions of the disorder. Usually the movements are discrete, but if very numerous, they become confluent and then resemble athetosis, as described below. In moments when the involuntary movements are held in abeyance, volitional movements of normal strength are possible; but they also tend to be excessively quick and poorly sustained. The limbs are often slack or hypotonic and because of this, the knee jerks tend to be pendular; in other words, with the patient sitting on the edge of the examining table and the foot free of the floor, the leg swings back and forth several times in response to a tap on the patellar tendon, rather than once or twice, as it does normally. A choreic movement may be superimposed on the reflex movement, checking it in flight, so to speak, and giving rise to the “hung-up” reflex.

The hypotonia in chorea as well as the pendular reflexes may suggest a disturbance of cerebellar function. Lacking, however, are “intention” tremor and true incoordination or ataxia. In some circumstances, it may be necessary to distinguish chorea from myoclonus. Chorea differs from myoclonus mainly with respect to the speed of the movements; the myoclonic jerk is much faster and may involve single muscles or part of a muscle as well as groups of muscles. Failure to appreciate these differences often results in an incorrect diagnosis.

Table 4-4 lists diseases characterized mainly by chorea. It is a major feature of Huntington disease, in which the movements tend more typically to be choreoathetotic. There may be subtle additional ataxia of gait, as noted by Breedveld and colleagues. Not infrequently, chorea has its onset in late life without the other identifying features of Huntington disease. It is then referred to as senile chorea, a term that is hardly helpful in understanding the process. Its relation to Huntington chorea in any individual case is settled by genetic testing. A number of less common degenerative conditions are associated with chorea, among them dentatorubropallidolusian atrophy and a form of chorea associated with acanthocytosis of red blood cells. Also, there is an inherited form of chorea of childhood onset without dementia that has been referred to as benign hereditary chorea. These are discussed in Chap. 39.

Typical choreic movements are the dominant feature of Sydenham chorea and of the variety of that disease associated with pregnancy (chorea gravidarum), disorders that are strongly linked through some immune mechanism to streptococcal infection. Striatal abnormalities, usually transient and rarely persistent, have been demonstrated by MRI; (Emery and Vieco). It is perhaps not surprising that antibodies directed against cells of the basal ganglia

Table 4-4

DISEASES CHARACTERIZED BY CHOREA

Inherited disorders

- Huntington disease
- Benign hereditary chorea
- Neuroacanthocytosis
- Dentatorubropallidolusian atrophy
- Wilson disease

Immune mediated chorea

- Sydenham chorea
- Chorea gravidarum
- Lupus erythematosus
- Antiphospholipid antibodies
- Paraneoplastic, often with other movements

Drug-induced chorea

- Neuroleptics (phenothiazines, haloperidol, metoclopramide, and others)
- Oral contraceptives
- Phenytoin (occasionally other antiepileptic drugs)
- Excess dosages of L-dopa and dopamine agonist medications
- Cocaine

Chorea symptomatic of systemic disease

- Thyrotoxicosis
- Polycythemia vera
- Hyperosmolar, nonketotic hyperglycemia
- Toxoplasmosis in AIDS

Hemichorea

- Stroke
- Tumor
- Vascular malformation

have been detected in both acute and late Sydenham chorea (Church et al). Following from the connection to streptococcal infection and the detection of these antibodies, it has been suggested in recent years that the spectrum of poststreptococcal disorders can be extended to tic and obsessive-compulsive behavior in children. In these cases the neurologic problems are said to arise suddenly, subside, and return with future streptococcal infections, as discussed in Chap. 6. This seems unlikely to explain chorea in adults. There have been instances of paraneoplastic chorea associated in a very few cases with lung cancer and anti-CRMP or anti-Hu antibodies of the type described in Chap. 31, as reported by O'Toole and colleagues.

The chronic administration of phenothiazine drugs or haloperidol (or an idiosyncratic reaction to these drugs) is a common cause of extrapyramidal movement disorders of all types, including chorea; these may become manifest during use of the drug or in a delayed “tardive” fashion, as already mentioned. The newer antipsychosis drugs (the atypical neuroleptics) have been far less frequently associated with the problems. Excess dopamine administration in advanced Parkinson disease is perhaps the most common cause of a choreiform dyskinesia in practice, but the movements tend to be more complex and continuous than those seen in chorea.

The use of oral contraceptives sometimes elicits chorea in an otherwise healthy young woman, but many such patients have underlying systemic lupus erythematosus and antiphospholipid antibodies. Whether the chorea (usually unilateral) is the result of a small infarction

(as suggested by a mild hemiparesis on the affected side) or is an immunologic condition is not settled. The reemergence of chorea in these circumstances as steroids are withdrawn or birth control pills are introduced suggests a more complex process than simply a small, deep infarction—perhaps something akin to Sydenham chorea. Also, only about one-third of cases involve a stroke, and some have demonstrated hypermetabolism of the basal ganglia, as in Sydenham chorea. A connection between hemichorea and the antiphospholipid syndrome alone, without lupus, is more tenuous.

The use of phenytoin or other anticonvulsant drugs may cause chorea in sensitive individuals. A transitory chorea may occur in the course of an acute metabolic derangement, mainly with hyperosmolar hyperglycemia, hypoglycemia, or hyponatremia, and with the inhalation of crack cocaine.

Rarely, chorea complicates hyperthyroidism, polycythemia vera, lupus erythematosus or some forms of cerebral arteritis. AIDS has emerged as a cause of a few cases of subacute progressive movement disorders that are initially asymmetrical. The usual associations in AIDS have been with focal lesions in or near basal ganglionic structures such as toxoplasmosis, progressive multifocal leukoencephalopathy, and lymphoma, but a number of instances of chorea are not explained by any of these focal lesions. A paraneoplastic variety may combine several aspects of chorea with athetosis, ballismus, or dystonia; inflammatory lesions are found in the striatum (Chap. 31).

Chorea may be limited to one side of the body (hemichorea). When the involuntary movements involve proximal limb muscles and are of wide range and flinging in nature, the condition is called hemiballismus (see further on). A cerebral infarction is the usual cause. A number of rare paroxysmal kinesigenic disorders, discussed later in this chapter, may have a choreic component.

The review by Piccolo and colleagues puts the frequency of the various causes of chorea in perspective. Of consecutive neurologic admissions to two general hospitals they identified 23 cases of chorea, of which 5 were drug-induced, 5 were AIDS-related, and 6 were caused by stroke. Sydenham chorea and arteritis were each found in 1 case. In 4 cases no cause could be determined, and 1 case proved to be Huntington disease.

The precise anatomic basis of chorea is often uncertain or at least inconsistent. In Huntington chorea, there are obvious lesions in the caudate nucleus and putamen. Yet one often observes vascular lesions in these parts without chorea. The localization of lesions in Sydenham chorea and other choreic diseases has not been determined beyond a generalized disturbance in the striatum, which is evident on some imaging studies. It is of interest that in instances of chorea related to acute metabolic disturbances, there are sometimes small infarctions in the basal ganglia or metabolic changes in the lenticular nucleus, as shown by imaging studies. One suspects from their close clinical similarity that chorea and hemiballismus relate to disorders of the same system of neurons; however, the subthalamic nucleus, the region typically implicated in ballismus, is affected only slightly in Huntington chorea and, on the other hand, transient chorea or ballismus arises from

infarctions in any part of the striatum on the side opposite to the movement, particularly in the caudate.

Athetosis

This term stems from a Greek word meaning “unfixed” or “changeable.” The condition is characterized by an inability to sustain the fingers and toes, tongue, or any other part of the body in one position. The maintained posture is interrupted by relatively slow, sinuous, purposeless movements that have a tendency to flow into one another. As a rule, the abnormal movements are most pronounced in the digits and hands, face, tongue, and throat, but no group of muscles is spared. One can detect as the basic patterns of movement an alternation between extension–pronation and flexion–supination of the arm and between flexion and extension of the fingers, the flexed and adducted thumb being trapped by the flexed fingers as the hand closes. Other characteristic movements are eversion–inversion of the foot, retraction and pursing of the lips, twisting of the neck and torso, and alternate wrinkling and relaxation of the forehead or forceful opening and closing of the eyelids. The movements appear to be slower than those of chorea, but all gradations between the two are seen; in some cases, it is impossible to distinguish between them, hence the term choreoathetosis. An apt description could be of a moving dystonia (see below). Discrete voluntary movements of the hand are executed more slowly than normal, and attempts to perform them may result in a cocontraction of antagonistic muscles and a spread (overflow) of contraction to muscles not normally required in the movement (intention spasm). The overflow appears related to a failure of the striatum to suppress the activity of unwanted muscle groups. Some forms of athetosis occur only during the performance of projected movement (intention or action athetosis). In other forms, the spasms appear to occur spontaneously, i.e., they are involuntary and, if persistent, give rise to more or less fixed dystonic postures.

Athetosis may affect all four limbs or may be unilateral, especially in children who have suffered a hemiplegia at some previous time (posthemiplegic athetosis). Many athetotic patients exhibit variable degrees of rigidity and motor deficit as a result of associated corticospinal tract disease; these may account for the slower quality of athetosis compared to chorea. In other patients with generalized choreoathetosis, as pointed out above, the limbs may be intermittently hypotonic.

The combination of athetosis and chorea of all four limbs is a cardinal feature of Huntington disease and of a state known as double athetosis, which begins in childhood. Athetosis appearing in the first years of life is usually the result of a congenital or postnatal condition such as hypoxia (cerebral palsy) or, rarely, kernicterus. Postmortem examinations in some of the cases have disclosed a unique pathologic change of probable hypoxic etiology, status marmoratus, in the striatum (Chap. 38). In other cases, of probable kernicteric (hyperbilirubinemic) etiology, there has been a loss of nerve cells and myelinated fibers—a status dysmyelinatus—in the same regions. In adults, athetosis may occur as an episodic or persistent

disorder in hepatic encephalopathy, as a manifestation of chronic intoxication with phenothiazines or haloperidol, and as a feature of certain degenerative diseases, most notably Huntington chorea but also Wilson disease, Leigh disease, and other mitochondrial disease variants; less frequently athetosis may be seen with Niemann-Pick (type C) disease, Kufs disease, neuroanthocytosis, and ataxia telangiectasia. It may also occur as an effect of excessive L-dopa in the treatment of Parkinson disease, in which case it appears to be caused by a decrease in the activity of the subthalamic nucleus and the medial segment of the globus pallidus (Mitchell et al). Athetosis, usually in combination with chorea, may occur rarely in patients with AIDS and in those taking anticonvulsants. Localized forms of athetosis may occasionally follow vascular lesions of the lenticular nucleus or thalamus, as in the cases described by Dooling and Adams.

Ballismus

This term designates an uncontrollable, poorly patterned flinging movement of an entire limb. As remarked earlier, it is closely related to chorea and athetosis, indicated by the frequent coexistence of these movement abnormalities and the tendency for ballismus to blend into a less-obtrusive choreoathetosis of the distal parts of the affected limb. Ballistic movements are usually unilateral (hemiballismus) and the result of an acute lesion of or near the contralateral subthalamic nucleus or immediately surrounding structures (infarction or hemorrhage, rarely a demyelinating or other lesion). Rarely, a transitory form is linked to a subdural hematoma or thalamic or parietal lesion. The flinging movements may be almost continuous or intermittent, occurring several times a minute, and of such dramatic appearance that it is not unusual for them to be regarded as hysterical in nature.

Bilateral ballismus is infrequent and usually asymmetrical; here a metabolic disturbance, particularly nonketotic hyperosmolar coma, is the usual cause. In combination with choreoathetosis, a paraneoplastic process is another rare cause. When ballismus persists for weeks on end, as it often did before effective treatment became available, the continuous forceful movements resulted in exhaustion and even death. In most cases, medication with haloperidol or phenothiazine suppresses the violent movements. In extreme cases, stereotactic lesions or implanted stimulating electrodes placed in the ventrolateral thalamus and zona incerta have proved effective (Krauss and Munding).

Dystonia (See Chap. 6 for a discussion of focal dystonias.)

Dystonia is an unnatural spasmodic movement of posture that puts the limb in a twisted posture. It is often patterned, repetitive or tremulous and can be initiated or worsened by attempted movement. There is unwanted overflow contraction of adjacent muscles and a central feature is involuntary cocontraction of agonist and antagonist muscles.

Dystonia may take the form of an overextension or overflexion of the hand, inversion of the foot, lateral flexion or retroflexion of the head, torsion of the spine with

arching and twisting of the back, forceful closure of the eyes, or a fixed grimace (Fig. 4-5; see also Fig. 6-2).

Dystonia, like athetosis, may vary considerably in severity and may show striking fluctuations in individual patients. In its early stages it may be interpreted as an annoying mannerism or hysteria, and only later, in the face of persisting postural abnormality, lack of the usual psychologic features of hysteria, and the emerging character of the illness, is the correct diagnosis made. Dystonia may be limited to the facial, cervical, or trunk muscles or to those of one limb, and it may cease when the body is in repose and during sleep. Severe instances result in grotesque movements and distorted positions of the body; sometimes the whole musculature seems to be thrown into spasm by an effort to move an arm or to speak.

Causes of Generalized Dystonia Generalized dystonia is seen in its most pronounced form as an uncommon heritable disease, dystonia musculorum deformans, which is associated with a mutation in the DYT gene. It was in relation to this disease that Oppenheim and Vogt in 1911 introduced the term dystonia. Dystonia also occurs as a manifestation of many other diseases, each of which is characteristic of a certain age group. These include "double athetosis" caused by hypoxic damage to the fetal or neonatal brain, kernicterus, pantothenate kinase-associated neurodegeneration (formerly Hallett-vorden-Spatz disease), Huntington disease, Wilson disease, lysosomal storage diseases, striatopallidodentatal calcification (sometimes caused by hypoparathyroidism), thyroid disease, and exposure to neuroleptic drugs, as discussed below.

Widespread torsion spasm (another term for dystonia) may also be a prominent feature of certain rare hereditary degenerative disorders, such as familial striatal necrosis with affection of the optic nerves and other parts of the nervous system (Marsden et al, Novotny et al). A distinct subset of patients with an idiopathic dystonia (described by Nygaard et al and discussed in Chap. 39) responds to extremely small doses of L-dopa. The disease is familial, usually autosomal dominant, and the dystonia-athetosis may be combined with elements of parkinsonism. Marked diurnal fluctuation of symptoms is characteristic with the movement disorder worsening as the day wears on and improving with sleep. This process has a number of names, including L-dopa-responsive dystonia and Segawa disease, for which specific causative mutations have been discovered. Another rare hereditary dystonia that has its onset in adolescence or early adulthood is of interest because of the rapid evolution, at times within an hour but more often over days, of severe dystonic spasms, dysarthria, dysphagia, and postural instability with bradykinesia, which may follow (Dobyns et al). A few cases have followed a febrile episode. The disorder is termed rapid-onset dystonia-parkinsonism. It is our understanding that the features of rapid-onset dystonia-parkinsonism are also mild and not responsive to L-dopa. Chapter 39 discusses these hereditary forms of dystonia.

A frequent cause of acute generalized dystonic reactions, more so in the past, has been from exposure to the

Figure 4-5. A. Characteristic dystonic deformities in a young boy with dystonia musculorum deformans. B. Sporadic instance of severe axial dystonia with onset in adult life. C. Incapacitating postural deformity in a young man with dystonia. (Photos courtesy of Dr. I.S. Cooper and Dr. Joseph M. Waltz.)

class of neuroleptic drugs—phenothiazines, butyrophenones, or metoclopramide—and even with the newer agents such as olanzapine, which has the advantage of producing these side effects less frequently than the others. A characteristic, almost diagnostic, example of the drug-induced dystonias consists of retrocollis (forced extension of the neck), arching of the back, internal rotation of the arms, and extension of the elbows and wrists—together simulating opisthotonos. These reactions respond to some extent to diphenhydramine or benztropine given two or three times over 24 to 48 h. L-Dopa, calcium channel blockers, and a number of anticonvulsants and anxiolytics are among a long list of other medications that may on occasion induce dystonia, the various causes of which are listed in Table 4-5. The acute dystonic drug reactions are idiosyncratic and now, probably as common as the “tardive dyskinesias” that had followed long-standing use or the withdrawal of a medication.

Finally, a peculiar and dramatic spasm of a limb or the entire body may be seen in patients with multiple sclerosis. The movements have aspects of dystonia and may be provoked by hyperventilation but they may not be, strictly

speaking, dystonic. They are most likely to occur in patients with large demyelinating lesions of the cervical spinal cord.

Restricted or fragmentary forms of dystonia are the types most commonly encountered in clinical practice. Characteristically the spasms involve only the orbicularis oculi and face or mandibular muscles (blepharospasm-omandibular dystonia), tongue, cervical muscles (torticollis), hand (writer’s cramp), or foot. There may be an associated tremor, or tremor may be the only manifestation of an early dystonia. These are described in Chaps. 6 and 39.

Hemidystonia represents an unusual form of acquired movement that, in our experience, is rarely pure. In an analysis of 33 of their own cases and 157 previously published ones, Chuang and colleagues found stroke, mainly in the contralateral putamen, to be most often responsible. Traumatic and perinatal damage accounted for several cases and a large proportion had no lesions found by imaging tests. In the former, there was a delay of several years between the injury and the start of the movements; these authors also commented on the resistance of this syndrome to drug treatment.

Table 4-5

DISEASES CHARACTERIZED BY DYSTONIA**Hereditary and degenerative dystonias**

- Huntington chorea
- Dystonia musculorum deformans (recessive and autosomal dominant forms)
- Juvenile dystonia—Parkinson syndrome (L-dopa–responsive)
- Dystonia with other hereditary degenerative disorders (neural deafness, striatal necrosis with optic nerve affection, paraplegic amyotrophy)
- Focal dystonias and occupational spasms (see Chap. 6), some of which are allied with hereditary torsion dystonia
- Parkinson disease (occasional)
- Progressive supranuclear palsy

Drug-induced dystonias

- Acute and chronic phenothiazine, haloperidol, metoclopramide, and other neuroleptic intoxications
- L-Dopa excess in Parkinson disease

Symptomatic (secondary) dystonias

- Wilson disease
- Double athetosis (cerebral palsy) caused by cerebral hypoxia
- Kernicterus
- Acquired hepatocerebral degeneration
- AIDS
- Lysosomal storage diseases
- Multiple sclerosis with cord lesion
- Paraneoplastic striatopallidodentatal calcification (Fahr disease)
- Toxic necrosis of lenticular nuclei (e.g., methanol) can be delayed

Idiopathic focal dystonias

- Spasmodic torticollis
- Blepharospasm
- Hemifacial spasm
- Oromandibular dystonia
- Spasmodic dysphonia
- Writer's cramp and other occupational spasms

Treatment

Numerous drugs have been used to treat idiopathic chronic generalized dystonia, with a notable lack of success. However, Fahn has reported beneficial effects (more so in children than in adults) with the anticholinergic agents, trihexyphenidyl, benzotropine, and ethopropazine given in massive amounts—which are achieved by increasing the dosage very gradually. The drug-induced tardive dyskinesias require specialized treatment, as described in Chaps. 6 and 42. Reinstitution of the offending drug or anticholinergic agents is often tried. Tetrabenazine, a centrally active monoamine-depleting agent, is effective but not readily available. The acute dystonic drug reactions are treated as noted above.

Stereotactic surgery on the pallidum and ventrolateral thalamus, a treatment introduced by Cooper in the middle of the last century, had reported generally positive but unpredictable results. In recent years there has been a renewed interest in a derivative of this form of treatment, deep brain stimulation (see Chap. 39). In a controlled trial, Vidailhet and colleagues demonstrated the effectiveness of this approach by stimulating the posteroventral globus pallidus bilaterally. Their patients had an average improvement of 50 percent on most scores of dystonic

movement over 1 year. Increasingly, this is the method resorted to in cases of severe generalized dystonia.

In the focal dystonias, the most effective treatment has proved to be the periodic injection of botulinum toxin into the affected muscles as discussed in Chap. 6.

Paroxysmal Choreoathetosis and Dystonia

Under the names paroxysmal kinesigenic dyskinesia, familial paroxysmal choreoathetosis, and periodic dystonia, among others, are a number of uncommon sporadic or familial disorders characterized by paroxysmal attacks of choreoathetotic movements or dystonic spasms of the limbs and trunk. Both children and young adults are affected.

There are three main forms of familial paroxysmal choreoathetosis. One, which has an autosomal dominant (less often recessive) pattern of inheritance and a tendency to affect males, begins in adolescence or earlier. It is characterized by numerous brief (several minutes) attacks of choreoathetosis provoked by startle, sudden movement, or hyperventilation—hence the title paroxysmal kinesigenic choreoathetosis. There may be many dozens of attacks per day or occasional ones. This disorder responds well to anticonvulsant medication, particularly to phenytoin and carbamazepine.

In a second type, such as those originally described by Mount and Reback and subsequently by Lance and by Plant et al, the attacks take the form of persistent (5 min to 4 h) dystonic spasms and reportedly have been precipitated by the ingestion of alcohol or coffee or by fatigue but not by movement per se (nonkinesigenic type). The attacks may be predominantly one-sided or bilateral. This form of the disease is inherited as an autosomal dominant trait; a few families have displayed diplopia and spasticity and others have shown a familial tendency to infantile convulsions. Each of these types has a different causative gene. Attacks may occur every several days or be separated by years. A favorable response to benzodiazepines (clonazepam) has been reported, even when the drug is given on alternate days (Kurlan and Shoulson).

A third type, formerly thought to be a variant of the Mount-Reback type mentioned above, is precipitated by prolonged exercise. In addition to a response to benzodiazepines, it has the unique characteristic of improving with acetazolamide.

More common than these familial dyskinesias are sporadic cases and those secondary to focal brain lesions, such as the ones reported by Demirkirian and Jankovic. They classify the acquired paroxysmal dyskinesias according to the duration of each attack and the event or activity that precipitates the abnormal movements (kinesigenic, nonkinesigenic, exertional, or hypnagogic). As with the familial cases, the acquired kinesigenically induced movements often improve with anticonvulsants; others respond better to clonazepam.

Some intermittent dyskinesias are an expression of a neurologic or metabolic disease. They may follow injuries such as stroke, trauma, encephalitis, perinatal anoxia, multiple sclerosis, hypoparathyroidism, or thyrotoxicosis, and particularly, nonketotic hyperosmolarity. The most severe instances in our experience have been

related to multiple sclerosis (tetanoid spasms), and, in the setting of HIV infection, as a result of toxoplasmosis, lymphoma, or presumed encephalitis caused by the retrovirus itself. These patients were relatively unresponsive to medications. Also, it should be recalled that oculogyric crises and other nonepileptic spasms have occurred episodically in patients with postencephalitic parkinsonism; these phenomena are now rarely seen with acute and chronic phenothiazine intoxication and with Niemann-Pick disease (type C).

The Identity of Chorea, Athetosis, and Dystonia

It may be evident from the foregoing descriptions that the distinctions between chorea, athetosis, and dystonia are probably not fundamental. Even their most prominent differences—the discreteness and rapidity of choreic movements and the slowness of athetotic ones—are more apparent than real. As pointed out by S.A. Kinnier Wilson, involuntary movements may follow one another in such rapid succession that they become confluent and therefore appear to be slow. In practice, one finds that the patient with relatively slow movements also shows discrete, rapid ones, and vice versa, and that many patients with chorea and athetosis also exhibit a persistent disorder of movement and posture that is essentially dystonic.

In a similar way, no meaningful distinction except one of degree can be made between chorea, athetosis, and ballismus. Particularly forceful movements of large amplitude (ballismus) are observed in some cases of Sydenham and Huntington chorea which, according to traditional teaching, exemplify pure forms of chorea and athetosis. The close relationship between these involuntary movements is illustrated by the patient with hemiballismus who, upon recovery, shows only choreoathetotic flexion–extension movements.

A role for the basal ganglia in cognitive function and abnormal behavior is hinted at provocatively in Parkinson disease, progressive supranuclear palsy, Tourette syndrome, and other processes, as summarized by Ring and Serra-Mestres. Slowness in thinking (bradyphrenia) in some of these disorders was alluded to earlier, but is inconsistent. Again, it would be an oversimplification to assign primary importance to the presence of depression, dementia, psychosis, and other disturbances in disease of the basal ganglia or to view changes in these structures as proximate causes of obsessive-compulsive and other behavioral disorders, but rather some role as part of a larger circuitry is likely. All that can be stated is that the basal ganglia modulate complex behavior, but the precise nature of their effect is not known at this time.

Ataxia and Disorders of Cerebellar Function

The cerebellum is responsible for the coordination of movements, especially skilled voluntary ones, the control of posture and gait, and the regulation of muscular tone. In addition, the cerebellum may play a role in the modulation of the emotional state and some aspects of cognition. The mechanisms by which these functions are accomplished have been the subject of intense investigation by anatomists and physiologists. Their studies have yielded a mass of data, testimony to the complexity of the organization of the cerebellum and its afferent and efferent connections. A coherent picture of cerebellar function is now emerging, although it is not yet possible, with a few exceptions, to relate each of the symptoms of cerebellar disease to a derangement of a discrete anatomic or functional unit of the cerebellum.

Knowledge of cerebellar function has been derived mainly from the study of natural and experimental ablative lesions and to a lesser extent from stimulation of the cerebellum, which actually produces little in the way of movement or alterations of induced movement. Furthermore, none of the motor activities of the cerebellum reaches conscious kinesthetic perception; its main role, a critical one, is to assist in the modulation of willed movements that are generated in the cerebral hemispheres. The following discussion of cerebellar structure and function has, of necessity, been simplified; a fuller account can be found in the writings of Jansen and Brodal, of Gilman, and of Thach and colleagues.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

Early studies of the comparative anatomy and fiber connections of the cerebellum led to its subdivision into three parts (Fig. 5-1): (1) The flocculonodular lobe, located inferiorly, which is phylogenetically the oldest portion of the cerebellum and is much the same in all animals (hence archicerebellum). It is separated from the main mass of the cerebellum, or corpus cerebelli, by the posterolateral fissure. (2) The anterior lobe, or paleocerebellum, which is the portion rostral to the primary fissure. In lower animals, the anterior lobe constitutes most of the cerebellum,

but in humans it is relatively small, consisting of the anterosuperior vermis and the contiguous paravermian cortex. (3) The posterior lobe, or neocerebellum, consisting of the middle divisions of the vermis and their large lateral extensions. The major portion of the human cerebellar hemispheres falls into this, the largest, subdivision.

This anatomic subdivision corresponds roughly with the distribution of cerebellar function based on the arrangement of its afferent fiber connections. The flocculonodular lobe receives special proprioceptive impulses from the vestibular nuclei and is therefore also referred to as the vestibulocerebellum; it is concerned essentially with equilibrium. The anterior vermis and part of the posterior vermis are referred to as the spinocerebellum, since projections to these parts derive to a large extent from the proprioceptors of muscles and tendons in the limbs and are conveyed to the cerebellum in the dorsal spinocerebellar tract (from the lower limbs) and the ventral spinocerebellar tract (upper limbs). The main influence of the spinocerebellum appears to be on posture and muscle tone. The neocerebellum derives its afferent fibers indirectly from the cerebral cortex via the pontine nuclei and brachium pontis, hence the designation pontocerebellum. This portion of the cerebellum is concerned primarily with the coordination of skilled movements that are initiated at a cerebral cortical level. It is now appreciated that certain portions of the cerebellar hemispheres are also involved to some extent in tactual, visual, auditory, and even visceral functions.

Largely on the basis of ablation experiments in animals, three characteristic physiologic patterns corresponding to these major divisions of the cerebellum have been delineated. These constellations find some similarities in the clinical syndromes that are observed when various parts of the cerebellum are damaged and special terminology is applied to the corresponding clinical findings in patients. Lesions of the nodulus and flocculus have been associated with a disturbance of equilibrium and frequently with nystagmus; individual movements of the limbs are not affected. Anterior lobe ablation in primates results in increased shortening and lengthening reactions, somewhat increased tendon reflexes, and

Figure 5-1. Diagram of the cerebellum, illustrating the major fissures, lobes, and lobules and the major phylogenetic divisions (left labels).

an exaggeration of the postural reflexes, particularly the “positive supporting reflex,” in animals, which consists of extension of the limb in response to light pressure on the foot pad. Ablation of a cerebellar hemisphere in cats and dogs yields inconsistent results, but in monkeys it causes hypotonia and clumsiness of the ipsilateral limbs; if the dentate nucleus is included in the hemispheric ablation, these abnormalities are more enduring and the limbs also show an ataxic, or “intention” tremor.

The studies of Chambers and Sprague and of Jansen and Brodal have demonstrated that in respect to both its afferent and efferent projections, the cerebellum is organized into longitudinal (sagittal) rather than transverse zones. There are three longitudinal zones—the vermian, paravermian or intermediate, and lateral—and there seems to be considerable overlap from one to another. Chambers and Sprague, on the basis of their investigations in cats, concluded that the vermian zone coordinates movements of the eyes and body with respect to gravity and movement of the head in space. The intermediate zone, which receives both peripheral and central projections (from motor cortex), influences postural tone and also individual movements of the ipsilateral limbs. The lateral zone is concerned mainly with coordination of movements of the ipsilateral limbs but is also involved in other functions.

The efferent fibers of the cerebellar cortex, which consist essentially of the axons of Purkinje cells, project onto the deep cerebellar nuclei (see below). The projections from Purkinje cells are inhibitory whereas those from the nuclei are excitatory on other parts of the motor nervous system. According to the scheme of Jansen and Brodal, cells of the vermis project mainly to the fastigial nucleus; those of the intermediate zone, to the globose and emboliform nuclei (that are combined in humans as the interpositus nucleus); and those of the lateral zone, to the dentate nucleus.

The deep cerebellar nuclei, in turn, project to the cerebral cortex and certain brainstem nuclei via two main pathways: fibers from the dentate, emboliform, and globose nuclei form the superior cerebellar peduncle, enter the upper pontine tegmentum as the brachium conjunctivum, decussate at the level of the inferior colliculus, and ascend to the ventrolateral nucleus of the thalamus and, to a lesser extent, to the intralaminar thalamic nuclei (Fig. 5-2). Some of the ascending fibers, soon after their decussation, synapse in the red nucleus, but most of them traverse this nucleus without terminating, and pass on to the thalamus. Ventral thalamic nuclear groups that receive these ascending efferent fibers project to the supplementary motor cortex of that side. Since the pathway from the cerebellar nuclei to the thalamus and then on to the motor cortex is crossed, and the connection from the motor cortex through the corticospinal is again crossed, the effects of a lesion in one cerebellar hemisphere are manifest by signs on the ipsilateral side of the body.

One special pathway forms a loop, called the Guillain-Mollaret triangle that is of clinical interest. A small group of fibers of the superior cerebellar peduncle, following their decussation, descend in the ventromedial tegmentum of the brainstem via the central tegmental fasciculus and terminate in the reticulotegmental and paramedian reticular nuclei of the pons and inferior olivary nuclei of the medulla. These nuclei, in turn, project via the inferior cerebellar peduncle back to the cerebellum, mainly the anterior lobe, thus completing a cerebellar–reticular–cerebellar feedback system (Fig. 5-3). Several clinical syndromes result from lesions in the loop, notably palatal myoclonus, one of the few disorders of involuntary movement that continues during sleep.

The fastigial nucleus sends fibers to the vestibular nuclei of both sides and, to a lesser extent, to other nuclei

Figure 5-2. Cerebellar projections to the red nucleus, thalamus, and cerebral cortex. (Adapted by permission from House EL et al: *A Systematic Approach to Neuroscience*, 3rd ed. New York, McGraw-Hill, 1979.)

of the reticular formation of the pons and medulla. There are also direct fiber connections with the alpha and gamma motor neurons of the spinal cord. The inferior olivary nuclei project via the restiform body (inferior cerebellar peduncle) to the contralateral cerebellar cortex and corresponding parts of the deep cerebellar nuclei. Thus the cerebellum influences motor activity through its connections with the motor cortex and brainstem nuclei and their descending motor pathways. Chapter 4 details the integration of basal

ganglionic influences with those of the cerebellum by their confluence in the anterior thalamic nuclei.

Clinicopathologic observations indicate that the cerebellar cortex, and the anterior lobe in particular, is organized somatotopically. This view has been amply confirmed experimentally by mapping of evoked potentials from the cerebellar cortex elicited by a variety of sensory stimuli, and an analysis of the subtle motor effects produced by stimulation of specific parts of the

Figure 5-3. Dentatothalamic and dentatorubrothalamic projections via the superior cerebellar peduncle. The “feedback” circuit via the reticular nuclei and reticulocerebellar fibers is also shown (Mollaret triangle).

cerebellar cortex. The topographic sensory representation of body parts based on these experimental observations is assumed to be similar to the motor map but the latter is probably not as distinct. The similarity between this scheme and the one derived from the study of human disease becomes apparent when one considers the results of cerebellar lesions discussed further on. Diffuse degenerations of the cerebellum, of course, have widespread effects, including motor, articular, gait and eye movements, and subtle behavioral influences.

Role of the Deep Cerebellar Nuclei

The physiologic studies of Allen and Tsukahara and of Thach and colleagues have greatly increased our knowledge of the role of the deep cerebellar nuclei. These investigators studied the effects of cooling the deep nuclei during a projected movement in the macaque monkey. Their observations, coupled with established anatomic data, permit the following conclusions. The dentate nucleus receives information from the premotor and supplementary motor cortices via the pontocerebellar

system and helps to initiate volitional movements. The latter are accomplished via efferent projections from the dentate nucleus to the ventrolateral thalamus and motor cortex. The dentate neurons were shown to fire just before the onset of volitional movements, and inactivation of the dentate neurons delayed the initiation of such movements. The interpositus nucleus also receives cerebrocortical projections via the pontocerebellar system; in addition, it receives spinocerebellar projections via the intermediate zone of the cerebellar cortex. The latter projections convey information from Golgi tendon organs, muscle spindles, cutaneous afferents, and spinal cord interneurons involved in movement. The interpositus nucleus fires in relation to a movement once it has started. Also, the prepositus nucleus appears to be responsible for making volitional oscillations (alternating movements). Its cells fire in tandem with these actions, and their regularity and amplitude are impaired when these cells are inactivated. In addition, Thach has pointed out that the nucleus interpositus normally damps physiologic tremor; he has suggested that this may play a part in the genesis of so-called intention tremor described

further on. The fastigial nucleus controls antigravity and other muscle synergies in standing and walking; ablation of this nucleus greatly impairs these motor activities.

Neuronal Organization of the Cerebellar Cortex

Coordinated and fluid movements of the limbs and trunk result from a neuronal organization in the cerebellum that permits an ongoing and almost instantaneous comparison between desired and actual movements while the movements are being carried out. An enormous number of neurons are committed to these tasks, as attested by the fact that the cerebellum contributes only 10 percent to the total weight and volume of the brain but contains half of the brain's neurons. Also, it has been estimated that there are 40 times more afferent axons than efferent axons in the various cerebellar pathways—a reflection of the enormous amount of incoming (sensory) information that is required for the control of motor function.

The cerebellar cortex is configured as a stereotyped three-layered structure containing five types of neurons (Fig. 5-4). In its relatively regular geometry, it is similar to the columnar architecture of the cerebral cortex, but it differs in the greater degree of intracortical feedback between neurons and the convergent nature of input fibers. The outermost “molecular” layer of the cerebellum contains two types of inhibitory neurons, the stellate cells and the basket cells. They are interspersed among the dendrites of the Purkinje cells, the cell bodies of which lie in the underlying layer. The Purkinje cell axons constitute the main output of the cerebellum, which is directed at the deep cerebellar and vestibular nuclei described above. Purkinje cells are likewise entirely inhibitory and utilize the neurotransmitter gamma-aminobutyric acid (GABA). The innermost “granular” layer contains an enormous number of densely packed granule cells and a few larger Golgi interneurons. Axons of the granule cells travel long distances as “parallel fibers,” which are oriented along the long axis of the folia and form excitatory synapses with Purkinje cells. Each Purkinje cell is influenced by as many as a million granule cells to produce a single electrical “simple spike.”

The predominant afferent input to the cerebellum is via the mossy fibers, which are the axons of the spinocerebellar tracts and the projections from pontine, vestibular, and reticular nuclei. They enter through all three cerebellar peduncles, mainly the middle (pontine input) and inferior (vestibulocerebellar) ones. Mossy fibers ramify in the granule layer and excite Golgi and granule neurons through special synapses termed cerebellar glomeruli. The other main afferent input is via the climbing fibers, which originate in the inferior olivary nuclei (olives) and communicate somatosensory, visual, and cerebral cortical signals (Figs. 5-4 and 5-5). The climbing fibers, so named because of their vine-like configuration around Purkinje cells and their axons, preserve a topographic arrangement from olivary neuronal groups; a similar topographic arrangement is maintained in the Purkinje cell projections. The climbing fibers have specific excitatory effects on Purkinje cells that result in prolonged “complex

spike” depolarizations. The firing of stellate and basket cells is facilitated by the same parallel fibers that excite Purkinje cells, and these smaller cells, in turn, inhibit the Purkinje cells. These reciprocal relationships form the feedback loops that permit the exquisitely delicate inhibitory smoothing of limb movements that are lost when the organ is damaged.

The uniform cortical structure of the cerebellum can reasonably lead to the conjecture that the organ has similar effects on all parts of the cerebrum to which it has projections (cortex, basal ganglia, thalamus, etc.). It would follow that the activities of these cerebral structures (motor, cognitive, sensory) may be modulated in similar ways by cerebellar activity.

Neurochemical Considerations

A number of biochemical considerations are of interest. Four of the five cell types of the cerebellar cortex (Purkinje, stellate, basket, Golgi) are inhibitory; the granule cells are an exception and are excitatory. Afferent fibers to the cerebellum are of three types, two of which have been mentioned above: (1) Mossy fibers, which are the main afferent input to the cerebellum, utilize aspartate. (2) Climbing fibers, which are the axons of cells in the inferior olivary nucleus and project to the Purkinje cells of the opposite cerebellar hemisphere. The neurotransmitter of the climbing fibers is probably glutamate, which acts on amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. (3) Aminergic fibers, which project through the superior cerebellar peduncle and terminate on the Purkinje and granule cells in all parts of the cerebellar cortex. They are of two types: dopaminergic fibers, which arise in the ventral mesencephalic tegmentum and project to the interpositus and dentate nuclei and to the granule and Purkinje cells throughout the cortex, and serotonergic neurons, which are located in the raphe nuclei of the brainstem and project diffusely to the granule cell and molecular layer. The granule cell axons elaborate the excitatory transmitter glutamate. All the inhibitory cerebellar cortical neurons appear to utilize GABA. The neurotransmitters of the deep nuclei have not been fully elucidated.

CLINICAL FEATURES OF CEREBELLAR DISEASE

Two eminent neurologists, Joseph Babinski and Gordon Holmes, were the first to cogently analyze the disturbances of movement and posture that result from lesions of the human cerebellum. For Babinski, the essential function of the cerebellum was the orchestration of muscle synergies in the performance of voluntary movement. A loss or impairment of this function—i.e., asynergia or dyssynergia—resulted in irregularity or fragmentation of the normal motor sequences involved in any given act. This deficit, most apparent in the execution of rapidly alternating movements, was referred to by Babinski as dys- or adiadochokinesis, as discussed below in the description of ataxia. He also pointed out that this was

Figure 5-4. Anatomic organization of the cerebellar cortex in a longitudinal and transverse section of a folium. Shown are the relationships between (a) climbing fibers and Purkinje cells, (b) mossy fibers and both granule cells and Golgi cells, and (c) the parallel fibers that course longitudinally and connect these three main cell types. (Reproduced with permission from Kandel ER, Schwartz JH, Jessel TM: *Principles of Neural Science*, 5th ed. New York, McGraw-Hill, 2013.)

accompanied by certain maladjustments of stance and by catalepsy (perseveration of a posture), features that have not been as appreciated by modern observers.

Holmes summarized the effects of cerebellar disease as being in the acceleration and deceleration of movement. He characterized the effects in a more fundamental way than had Babinski, describing them as defects in the *rate, range, and force* of movement, resulting in an undershooting or overshooting of the target. He used the term *decomposition* to describe the fragmentation of a smooth movement into a series of irregular, jerky components. In Holmes' view, probably incorrectly, these abnormalities were attributable to an underlying hypotonia. The terminal ("intention")

tremor, and the inability to check the displacement of an outstretched limb, both of which he elegantly described, he attributed to this latter defect (see further on). Gilman and colleagues have provided evidence that more than hypotonia is involved in the tremor of cerebellar incoordination. They found that deafferentation of the forelimb of a monkey resulted in dysmetria and kinetic tremor; subsequent cerebellar ablation significantly increased both the dysmetria and tremor, indicating the presence of a mechanism as yet unidentified in addition to depression of the fusimotor efferent-spindle afferent circuit.

Parts of the hypotheses of both Babinski and Holmes have been sustained by modern physiologic and clinical

Figure 5-5. The physiologic organization of cerebellar circuitry. The main output of the deep cerebellar nuclei is excitatory and is transmitted through mossy and climbing fibers. This “main loop” is modulated by an inhibitory cortical loop, which is effected by Purkinje cell output but indirectly includes the other main cell types through their connections with Purkinje cells. Recurrent pathways between the deep nuclei and cortical cells via mossy and climbing fibers complete the cerebellar servomechanism for motor control. (Adapted, with permission, from Raymond JL, Lisberger SG, Mauk DM: The cerebellum: a neuronal learning machine? *Science* 272:1126-1131.)

studies. In an analysis of rapid (ballistic) movements, Hallett and colleagues have demonstrated that with cerebellar lesions, there is a prolongation of the interval between the commanded act and the onset of movement. More prominently, there is a derangement of the normal ballistic triphasic agonist–antagonist–agonist motor sequence, referred to in Chaps. 3 and 4. The agonist burst may be too long or too short, or it may continue into the antagonist burst, resulting in excessive agonist–antagonist cocontraction at the onset of movement. These findings may explain what was described by Babinski and Holmes as asynergia, decomposition of movement, and certainly explain dysmetria. Diener and Dichgans confirmed these fundamental abnormalities in the timing and amplitude of reciprocal inhibition and of cocontraction of agonist–antagonist muscles and remarked that these were particularly evident in pluriarticular movements.

The symptoms produced in animals by ablation of discrete anatomic or functional zones of the cerebellum bear only an imperfect relationship to the symptoms of

cerebellar disease in humans. This is understandable for several reasons. Most of the lesions that occur in humans do not respect the boundaries established by experimental anatomists. Even with lesions that are more or less confined to discrete functional zones (e.g., flocculonodular lobe, anterior lobe), it is difficult to identify the resultant clinical syndromes with those produced by ablation of analogous zones in cats, dogs, and even monkeys, indicating that the functional organization of these parts varies from species to species.

Clinical observations affirm what was stated above—that lesions of the cerebellum in humans give rise to the following abnormalities: (1) incoordination (ataxia) of volitional movement; (2) a characteristic tremor (“intention”, or ataxic tremor, by which is meant a side-to-side oscillation as movement approaches a target), described in detail in Chap. 6; (3) disorders of equilibrium and gait; and (4) diminished muscle tone, particularly with acute lesions. Dysarthria, a common feature of cerebellar disease, is probably predicated on a similar incoordination of the muscles of articulation. In addition, the stability of conjugate eye movements is affected, giving rise to nystagmus.

Extensive lesions of one cerebellar hemisphere, especially of the anterior lobe, cause mild hypotonia, postural abnormalities, ataxia, and a mild weakness of the ipsilateral arm and leg perceived by the patient. Lesions of the deep nuclei and cerebellar peduncles have the same effects as extensive hemispherical lesions. If the lesion involves a limited portion of the cerebellar cortex and subcortical white matter, there may be surprisingly little disturbance of function, or the abnormality may be greatly attenuated with the passage of time. For example, a congenital developmental defect or an early life sclerotic cortical atrophy of half of the cerebellum may produce no clinical abnormalities. Lesions involving the superior cerebellar peduncle or the dentate nucleus cause the most severe and enduring cerebellar symptoms, which manifest mostly as ataxia in the ipsilateral limbs. Disorders of stance and gait depend more on vermal than on hemispherical or peduncular involvement. Damage in the inferior cerebellum causes vestibulocerebellar symptoms—namely, dizziness, vertigo, vomiting, and nystagmus—in varying proportions. These symptoms often share with disturbances of the vestibular system the feature of worsening with changes in head position.

Ataxic Incoordination

The most prominent manifestations of cerebellar disease, namely, the abnormalities of intended (volitional) movement, are classified under the general heading of cerebellar incoordination or ataxia. Following Babinski, the terms dyssynergia, dysmetria, and dysdiadochokinesis came into common usage to describe cerebellar abnormalities of movement. Holmes’s characterization of abnormalities in the rate, range, and force of movement is less confusing, as becomes apparent from an analysis of even simple movements. These abnormalities are brought out by standard neurologic tests, finger-to-nose

and toe-to-finger movement, running the heel down the opposite shin, or tracing a square in the air with a hand or foot. In performing these tests, the patient should be asked to move the limb to the target accurately and rapidly.

The speed of initiating movement is slowed somewhat in cerebellar disease. In a detailed electrophysiologic analysis of this defect mentioned earlier, Hallett and colleagues noted, in both slow and fast movements, that the initial agonist burst was prolonged and the peak force of the agonist contraction was reduced. Also, there is irregularity and slowing of the movement itself, in both acceleration and deceleration. These abnormalities are particularly prominent as the finger or toe approaches its target. All of the foregoing defects in volitional movement are evident in acts that require alternation or rapid change in direction of movement, such as pronation-supination of the forearm or successive touching of each fingertip to the thumb. The normal rhythm of these movements is interrupted by irregularities of force and speed. Even a simple movement may be fragmented ("decomposition" of movement), each component being effected with greater or lesser force than is required. These movement abnormalities together impart a highly characteristic clumsiness to the cerebellar syndromes, an appearance that is not simulated by the weakness of upper or lower motor neuron disorders or by diseases of the basal ganglia.

Normally, deceleration of movement is smooth and accurate, even if sharp changes in the direction of a limb are demanded, as in following a moving target. With cerebellar disease, the velocity and force of the movement are not checked in the normal manner. The excursion of the limb may be arrested prematurely, and the target is then reached by a series of jerky movements. Or the limb overshoots the mark (hypermetria) because of delayed activation and diminished contraction of antagonist muscles; then the error is corrected by a series of secondary movements in which the finger or toe sways around the target before coming to rest, or moves from side to side a few times on the target itself. This side-to-side movement of the finger as it approaches its mark tends to assume a rhythmic quality; it has traditionally been referred to as intention tremor, or ataxic tremor. The tremor is mainly perpendicular to the trajectory of movement and mostly in the horizontal plane (the reason for the latter is not known). The term "intention" as applied to cerebellar tremor, while embedded in neurologic parlance, does not fully capture the necessity for the limb to be in action rather than for the patient to "intend" a movement for the tremor to be manifest. "Action tremor," however, has been used for an entirely different category of oscillations, as discussed in Chap. 6 so that simply "ataxic tremor" or "goal directed action tremor" may be preferable terms.

In addition to intention tremor, there may be a coarse, irregular, wide-range tremor that may be present in a position of repose and enhanced whenever the patient activates limb muscles, either to sustain a posture or to effect a movement. It is elicited by having the patient hold the arms out to the sides with elbows bent ("wing-beating

tremor"). Holmes called it rubral tremor, and although the red nucleus may be the site of the lesion, the nucleus itself is not necessarily involved in this type of tremor. Instead, it is a result of interruption of the fibers of the superior cerebellar peduncle, which traverse the nucleus, for which reason it may be more properly called "cerebellar outflow tremor." Also, with certain sustained postures (e.g., with arms extended and hands on knees), the patient with cerebellar disease may develop a rhythmic oscillation of the fingers having much the same tempo as a parkinsonian tremor. A rhythmic tremor of the head or upper trunk (3 to 4 per second) called titubation, mainly in the anteroposterior plane, often accompanies midline cerebellar disease, but may also be a manifestation of essential tremor (see further on).

Cerebellar dysarthria Cerebellar lesions commonly give rise to a disorder of speech, which may take one of two forms, either a slow, slurring dysarthria, like that following interruption of the corticobulbar tracts, or a scanning dysarthria with variable intonation, so called because words are broken up into syllables, as when a line of poetry is scanned for meter. The latter disorder is uniquely cerebellar; in addition to its scanning quality, speech is slow, and each syllable, after an involuntary interruption, may be uttered with less force or more force ("explosive speech") than is natural. Urban and associates deduced from cases of cerebellar infarction that the articulatory muscles are controlled from the rostral paravermian area of the anterior lobe, and this area is affected in most cases with dysarthria.

Cerebellar eye movement abnormalities Ocular movement may be altered as a result of cerebellar disease, specifically if vestibular connections are involved. Patients with cerebellar lesions are unable to hold eccentric positions of gaze, resulting in a special type of nystagmus and the need to make rapid repetitive saccades to look eccentrically. Conjugate voluntary gaze can be accomplished only by a series of jerky movements. Smooth pursuit movements are slower than normal and require that the patient make small "catch-up" saccades in an attempt to keep the moving target near the fovea. On attempted refixation to a target, the eyes overshoot the target and then oscillate through several corrective cycles until precise fixation is attained. It will be recognized that these nystagmoid abnormalities, as well as those of speech, resemble the abnormalities of volitional ataxic movements of the limbs. Currently it is considered that nystagmus caused by cerebellar disease depends on lesions of the vestibulocerebellum (Thach and Montgomery). Skew deviation (vertical displacement of one eye), vertical nystagmus, ocular flutter, and ocular myoclonus (opsoclonus) may also be the result of cerebellar disease; these abnormalities and other effects of cerebellar lesions on ocular movement are discussed in Chap. 14.

Disorders of equilibrium and gait

The patient with cerebellar disease has variable degrees of difficulty in standing and walking, as described more fully in Chap. 7. Standing with feet together may be impossible or maintained only briefly before the patient pitches to

one side or backward. Closing the eyes may worsen this difficulty slightly, but the Romberg sign (which signifies impaired proprioceptive input) is absent if the patient is allowed to steady himself before closing his eyes. In walking, the patient's steps are uneven and placement of the foot is misaligned, resulting in unexpected lurching.

Data from patients in whom accurate clinicoanatomic correlations can be made, indicate that the disequilibrium syndrome, with normal movements of the limbs, corresponds more closely with lesions of the anterior vermis than with those of the flocculus and nodulus. This conclusion is based in part on the study of a highly stereotyped form of cerebellar degeneration in alcoholics (Chap. 42). In such patients the cerebellar disturbance is often limited to one of stance and gait, in which case the pathologic changes are restricted to the anterior parts of the superior vermis. In more severely affected patients, in whom there is also incoordination of individual movements of the limbs, the changes are found to extend laterally from the vermis, involving the anterior portions of the anterior lobes (in patients with ataxia of the legs) and the more posterior portions of the anterior lobes (in patients whose arms are affected).

Similar clinicopathologic relationships pertain in patients with familial forms of pure cerebellar cortical degeneration. In both the alcoholic and familial degenerative cases, despite a serious disturbance of stance and gait, the flocculonodular lobe may be spared completely. In other diseases, however, involvement of the posterior vermis and its connections with the pontine and mesencephalic reticular formations has caused abnormalities of ocular movement in addition to a gait disorder (see Chap. 14).

Thus the evidence that flocculonodular lesions in humans cause a disturbance of equilibrium is not conclusive. It rests on the observation that with certain tumors of childhood, namely, medulloblastomas, there may be an unsteadiness of stance and gait but no tremor or incoordination of the limbs. Insofar as these tumors are thought to originate from cell rests in the posterior medullary velum, at the base of the nodulus, it has been inferred that the disturbance of equilibrium results from involvement of this portion of the cerebellum. However, the validity of this deduction remains to be proved. By the time such tumors are imaged or viewed at operation or autopsy, they have spread beyond the confines of the nodulus, and strict clinicopathologic correlations are not possible.

The point to be made is that midline anterior cerebellar lesions may produce solely a disorder of stance and gait, i.e., nystagmus, dysarthria, and limb ataxia are absent, so that the entire problem may be missed if the patient is not observed while standing and walking.

Hypotonia

This refers to a decrease in the normal resistance that is offered by muscles to passive manipulation (e.g., flexion and extension of a limb); it is the least evident of the cerebellar abnormalities but may explain certain clinical features not otherwise derived from the above deficits. It is related to a depression of gamma and alpha motor neuron activity, as discussed in Chap. 3. Experimentally,

in cats and monkeys, acute cerebellar lesions and hypotonia are associated with a depression of fusimotor efferent and spindle afferent activity. With the passage of time, fusimotor activity is restored as hypotonia disappears (Gilman et al). As indicated earlier, Holmes believed that hypotonia was a fundamental defect in cerebellar disease, accounting not only for the defects in postural fixation (see below) but also for certain elements of ataxia and the tremor.

Hypotonia is much more apparent with acute than with chronic lesions and may be demonstrated in a number of ways. A conventional test for hypotonia is to tap the wrists of the outstretched arms, in which case the affected limb (or both limbs in diffuse cerebellar disease) will be displaced through a wider range than normal and may oscillate; this is the result of a failure of the hypotonic muscles to fixate the arm at the shoulder. When an affected limb is shaken, the flapping movements of the hand are of wider excursion than normal. If the patient places his elbows on the table with the arms flexed and the hands are allowed to hang limply, the hand of the hypotonic limb will sag. If the standing patient is rotated briefly to and fro at the shoulders, the hypotonic arm will be seen to continue to swing after the other has come to rest. Babinski also was impressed with gross alterations of posture, apparently related to hypotonia. These take the form of passive extension of the neck and involuntary bending of the knees, which are apparent when the patient is lifted from a bed or chair or upon first standing, or slumping of the shoulder on the affected side.

Failure to check a movement is a closely related phenomenon. Thus, after strongly flexing one arm against a resistance that is suddenly released, the patient may be unable to check the flexion movement, to the point where the arm may strike the face. This is the result of a delay in contraction of the triceps muscle, which ordinarily would arrest overflexion of the arm. This abnormality, incorrectly referred to as Holmes' rebound phenomenon, is more appropriately designated as an impairment of the check reflex. Stewart and Holmes, who first described this test, made the point that when resistance to flexion is suddenly removed, the normal limb moves only a short distance in flexion and then recoils very briefly in the opposite direction; in this sense, rebound of the limb is actually deficient in cerebellar disease.

Patients with these various abnormalities of tone may show little or no impairment of motor power, indicating that the maintenance of posture involves more than the voluntary contraction of muscles. It is noteworthy that the signs of cerebellar dysfunction (dysmetria, clumsiness, tremor) are absent in the hypotonic muscles of peripheral nerve disease—indicating that the cerebellum exerts a unique modulating effect on movement that is not explained by loss of tone.

Other Symptoms of Cerebellar Disease

It has been stated by some authors, not in accord with our experience, that there is a slight loss of muscular power and fatigability of muscle with acute cerebellar lesions. Insofar as these symptoms cannot be explained by other

disturbances of motor function, they may be regarded as primary manifestations of cerebellar disease, but they are never severe or persistent and are of little clinical importance; anything approaching a hemiparesis in distribution or severity is not attributable to cerebellar disease.

Myoclonic movements—i.e., brief (50- to 100-ms), random contractions of muscles or groups of muscles—are, in some disease processes, combined with cerebellar ataxia. When multiple myoclonic jerks mar a volitional movement, they may be mistaken for an ataxic tremor. Action myoclonus may be the principal residual sign of hypoxic encephalopathy, as described in the discussion of postanoxic intention, or action myoclonus, in Chap. 40, and it has been proposed that this condition has a cerebellar origin. Myoclonus is described more fully in Chap. 6, where it is pointed out that it more often has its origin in diseases of the cerebral cortex.

More recently uncovered is the participation of the cerebellum in certain aspects of cognitive function and behavior (see the reviews by Leiner et al and by Schmahmann and Sherman). These authors and others have described a wide range of subtle alterations of memory and cognition, language function, and behavior in patients with disease apparently limited to the cerebellum (as determined by CT and MRI imaging). It is true that cerebellar lesions interfere with the establishment of conditioned reflexes and perhaps some deterioration in certain learning tasks as detected by specialized tests. However, it is not entirely clear if there is a uniform clinical pathologic syndrome in which a distinctive cognitive-behavioral deficit or group of deficits are related

to a cerebellar disease or individual lesions. It seems to the current authors that recent investigations into the cerebral influences of the cerebellum are accurate and novel contributions to neurology, but at the same time, the changes referred to are subtle and often inapparent in the bedside neurologic examination. Rarely, as in a patient under our care, a fairly obvious aphasia from a prior insult to the cerebrum can be unmasked by an acute cerebellar lesion, such as a stroke. Slowly developing cerebellar disorders, such as tumors, do not appear to demonstrate this phenomenon.

Differential Diagnosis of Ataxia

In the diagnosis of disorders characterized by generalized cerebellar ataxia (affecting limbs, gait, and speech), the mode of onset, rate of development, and degree of permanence of the ataxia are of particular importance, as summarized in Table 5-1. Each of the major causes is discussed in an appropriate chapter. In adults, paraneoplastic and demyelinating cases account for the largest proportion of cases of subacute onset, and hereditary forms are the usual cause of very slowly progressive and chronic ones, particularly if gait is predominantly affected. The last category of genetic ataxias constitutes a large and heterogeneous group for which the mutation has been established in many cases; they are described in Chap. 39.

Unilateral ataxia without accompanying signs is most often caused by infarction or tumor in the ipsilateral cerebellar hemisphere or by demyelinating disease affecting cerebellar connections to the brainstem.

Table 5-1

DIAGNOSIS OF CEREBELLAR ATAXIA

MODE OF DEVELOPMENT	CAUSES
Acute-transitory	Intoxication with alcohol, lithium, barbiturate, phenytoin or other antiepileptics (associated with dysarthria, nystagmus; Chaps. 42 and 43) Diamox-responsive episodic ataxia (Chap. 37) Childhood hyperammonemias (Chap. 37)
Acute and usually reversible	Postinfectious, with inflammatory changes in CSF (Chap. 36) Viral cerebellar encephalitis (Chap. 33) Myxedema
Acute-enduring	Extreme hyperthermia with coma at onset (Chap. 17) Intoxication with mercury compounds or toluene (glue sniffing; spray painting; Chap. 43) Postanoxic with intention myoclonus Adulterated heroin ("chasing the dragon")
Subacute (over weeks)	Brain tumors such as medulloblastoma, astrocytoma, hemangioblastoma metastasis (usually with headache and papilledema; Chap. 31) Alcoholic-nutritional (Chaps. 41 and 42) Paraneoplastic cerebellar degeneration (Chap. 31) Creutzfeldt-Jakob (prion) disease (Chap. 33) Cerebellar abscess (Chap. 32) Whipple disease (characteristically with myoclonus and oculomasticatory movements) Sprue (gluten enteropathy) Multiple sclerosis
Chronic (months to years)	Friedreich ataxia and other spinocerebellar degenerations; other hereditary cerebellar degenerations (olivopontocerebellar degenerations; cerebellar cortical degenerations [Chap. 39]) Adult form of fragile X premutation syndrome (Chaps. 38 and 39) Hereditary metabolic diseases, often with myoclonus (Chap. 37) Childhood ataxias, including ataxia telangiectasia, cerebellar agenesis

The ataxia of severe sensory neuropathy and of posterior column or posterior spinal root disease (sensory ataxia) simulates cerebellar ataxia; presumably this is a result of involvement of the large peripheral spinocerebellar afferent fibers. Tabes dorsalis and sensory ganglionopathy are prime examples of this type of disorder. However, there should seldom be difficulty in separating the two if one takes note of the loss of distal joint position sense, absence of associated cerebellar signs such as dysarthria or nystagmus, loss of tendon reflexes, and the corrective effects of vision on sensory ataxia. In peripheral neuropathy and in spinal cord disease with ataxia, the Romberg sign is invariably present, reflecting a parallel dysfunction of large afferent fibers in the posterior columns; this sign is not found in lesions of the cerebellar hemispheres except that the patient may initially sway with eyes open and a bit more with eyes closed. A cerebellar type of tremor reaches an extreme form in the large-fiber polyneuropathy related to antibodies against myelin-associated glycoprotein but the features are closer to an enhanced action tremor, as discussed in the next chapter and in Chap. 46. In the Miller Fisher syndrome, which is considered to be a version of acute Guillain-Barré polyneuropathy, sensation is intact or affected only slightly and the severe ataxia and intention tremor are presumably a result of a highly

selective peripheral disorder of spinocerebellar nerve fibers. Disorders of these same fibers in the spinocerebellar tracts of the cord may produce the same sensory-ataxic effects; subacute compressive lesions such as thoracic meningioma or demyelinating lesions are the usual causes. Again, there is a prominent Romberg sign. Occasionally, a cerebellar-like tremor in one limb results from a lesion in the dorsolateral cord that interrupts afferent fibers, presumably those directed to the spinocerebellar tracts.

Vertiginous ataxia is almost solely an ataxia of gait and is distinguished by the obvious complaint of vertigo and listing to one side, past pointing, and torsional-rotatory nystagmus, as discussed in Chap. 15. The nonvertiginous ataxia of gait caused by vestibular paresis (e.g., streptomycin toxicity) has special qualities, which are described in Chap. 7. Vertigo and cerebellar ataxia may be concurrent, as in some patients with a paraneoplastic disease and in those with infarction of the lateral medulla and inferior cerebellum. An unusual and transient ataxia of the contralateral limbs occurs acutely after infarction or hemorrhage in the anterior thalamus (thalamic ataxia); in addition to characteristic signs of thalamic damage, there may be an accompanying unilateral asterixis. Finally, a lesion of the superior parietal lobule (areas 5 and 7 of Brodmann) rarely results in a similar ataxia of the contralateral limbs.

Tremor, Myoclonus, Focal Dystonias, and Tics

The subject of tremor is considered at this point because of its association with diseases of the basal ganglia and cerebellum. In addition, a group of miscellaneous movement disorders—myoclonus, facial and cervical dyskinesias, focal limb dystonias, and tics—is described in this chapter. These disorders are largely involuntary in nature and can be quite disabling but they have an uncertain pathologic basis, as alluded to in Chap. 4, and an indefinite relationship to the extrapyramidal motor disorders or to other standard categories of neurologic disease. They are brought together here mainly for convenience of exposition.

TREMOR

Tremor may be defined as involuntary rhythmic oscillatory movement produced by alternating or irregularly synchronous contractions of reciprocally innervated muscles. Its rhythmic quality distinguishes tremor from other involuntary movements, and its oscillatory nature distinguishes it from myoclonus and asterixis.

Physiologic Tremor

A normal, or physiologic, tremor is embedded in the motor system. It is present in all contracting muscle groups and persists throughout the waking state and even in certain phases of sleep. The movement is so fine that it can barely be seen by the naked eye, and then only if the fingers are firmly outstretched; in most instances special instruments are required for its detection though asking the patient to aim a laser pointer at a distant target will often expose it. It ranges in frequency between 8 and 13 Hz, the dominant rate being 10 Hz in adulthood and somewhat less in childhood and old age. Several hypotheses have been proposed to explain physiologic tremor, a traditional one being that it reflects the passive vibration of body tissues produced by mechanical activity of cardiac origin, but this cannot be the whole explanation. As Marsden has pointed out, several additional factors—such as spindle input, the unfused grouped firing rates of motor neurons, and the natural resonating frequencies and inertia of the muscles and other structures—are probably of greater importance. Certain abnormal tremors, namely, the metabolic varieties of postural or

action tremor and at least one type of familial tremor, are considered by some to be variants or exaggerations of physiologic tremor—i.e., “enhanced physiologic tremor,” as discussed further on.

The following types of tremors, the clinical features of which are summarized in Fig. 6-1 and Table 6-1, are encountered most frequently in clinical practice. In clinical analysis they are usually distinguishable on the basis of (1) relation to movement and posture, (2) frequency, (3) the pattern of activity of opposing (agonist-antagonist pairs) muscles, i.e., synchronous or alternating, and (4) affected body parts. Such a classification also differentiates tremors from a large array of nontremorous movements, such as fasciculations, sensory ataxia, myoclonus, asterixis, *epilepsia partialis continua*, clonus, and rigor (shivering).

Action Tremors

Action tremors are evident during use of the affected body part, as opposed to tremor that is apparent in a position of rest or repose. Action tremors can be conveniently divided into two categories: goal directed action tremor of the ataxic type related to cerebellar disorders (discussed in Chap. 5) and postural tremors, which are either the enhanced physiologic variety or essential tremor (Fig. 6-1). A postural tremor occurs with the limbs and trunk actively maintained in certain positions (such as holding the arms outstretched) and may persist throughout active movement. More particularly, the tremor is absent when the limbs are relaxed but becomes evident when the muscles are activated. The tremor is accentuated as greater precision of movement is demanded, but it does not approach the degree of augmentation seen with cerebellar intention tremor. Most cases of action tremor are characterized by relatively rhythmic bursts of grouped motor neuron discharges that occur not quite synchronously in opposing muscle groups as shown in Fig. 6-2. Slight inequalities in the strength and timing of contraction of opposing muscle groups account for the tremor. In contrast, rest (parkinsonian) tremor, is characterized by alternating activity in agonist and antagonist muscles.

Enhanced Physiologic Tremor

The type of action tremor that seems merely to be an exaggeration of the above-described physiologic tremor,

Figure 6-1. Tremor branch diagram.

can be brought out in most normal persons. It has the same fast frequency as physiologic tremor (about 10 Hz; Fig. 6-2) but with greater amplitude. Such a tremor, best elicited by holding the arms outstretched with fingers spread apart, is characteristic of intense fright and anxiety (hyperadrenergic states), certain metabolic disturbances (hyperthyroidism, hypercortisolism, hypoglycemia), pheochromocytoma, intense physical exertion, withdrawal from alcohol and other sedative drugs, and the toxic effects of several drugs—lithium, nicotinic acid, xanthines (coffee, tea, aminophylline), cocaine, methylphenidate, other stimulant drugs and corticosteroids. Young and colleagues have determined that the enhancement of physiologic tremor that occurs in metabolic and toxic states is not a function of the central nervous system

but is instead a consequence of stimulation of muscular beta-adrenergic receptors by increased levels of circulating catecholamines.

A special type of postural action tremor, closely related to the enhanced physiologic tremor, occurs as the most prominent feature of the early stages of alcohol withdrawal. Withdrawal of other sedative drugs (benzodiazepines, barbiturates) following a sustained period of use produces much the same effect. LeFebvre-D'Amour and colleagues have described two tremors of slightly different frequency, one of which is indistinguishable from essential tremor (see below). Either of these may occur as the individual emerges from a relatively short period of intoxication ("morning shakes"). A number of alcoholics, on recovery from the withdrawal state, exhibit

Table 6-1

MAIN TYPES OF TREMOR

TYPE OF TREMOR	FREQUENCY, HZ	PREDOMINANT LOCATION	ENHANCING AGENTS	ATTENUATING AGENTS
Physiologic (enhanced)	8–13	Hands	Epinephrine, β -adrenergics	Alcohol, β -adrenergic antagonists
Parkinson (rest)	3–5	Hands and forearms, fingers, feet, lips, tongue	Emotional stress	L-Dopa, anticholinergics
Cerebellar (intention, ataxic, "rubral")	2–4	Limbs, trunk, head	Emotional stress	—
Postural, or action	5–8	Hands	Anxiety, fright, β -adrenergics, alcohol withdrawal, xanthines, lithium, exercise, fatigue	β -Adrenergic antagonists in some cases
Essential (familial, senile)	4–8	Hands, head, vocal cords	Same as above	Alcohol, propranolol, primidone
Alternate beat	3.5–6	Hands, head	Same as above	Clonazepam, alcohol, β -adrenergic antagonists
Orthostatic	4–8, irregular	Legs	Quiet standing	Repose, walking, clonazepam, valproate
Tremor of neuropathy	4–7	Hands	—	—
Palatal tremor	60–100/min	Palate, sometimes facial, pharyngeal, proximal limb muscles	—	Clonazepam, valproate
Dystonic	Irregular	Concordant with focal dystonia	—	Local botulinum toxin, gages

Figure 6-2. Types of tremor. In each, the lowest trace is an accelerometric recording from the outstretched hand; the upper two traces are surface EMG from the wrist extensor (upper) and flexor (middle) muscle groups. *A.* A physiologic tremor; there is no evidence of synchronization of EMG activity. *B.* Essential (familial) tremor; the movements are very regular and EMG bursts occur simultaneously in antagonistic muscle groups. *C.* Neuropathic tremor; movements are irregular and EMG bursts vary in timing between the two groups. *D.* Parkinsonian ("rest") tremor; EMG bursts alternate between antagonistic muscle groups. Calibration is 1 s. (Courtesy of Dr. Robert R. Young.)

a persistent tremor of essential (familial) type, described below. The mechanisms involved in alcohol withdrawal symptoms are discussed further in Chap. 42.

Essential (Familial, Hereditary) Tremor

This, the commonest type of tremor, is of lower frequency (4 to 8 Hz) than physiologic tremor and is unassociated with other neurologic changes; thus it is called "essential." It is usually at the lower end of this frequency range and of variable amplitude. Aside from its rate the identifying feature is its appearance or marked enhancement with attempts to maintain a static limb posture. Like most tremors, essential tremor is worsened by emotion, exercise, and fatigue. One infrequent type of essential tremor is faster than the usual essential tremor and of the same frequency (6 to 8 Hz) as enhanced physiologic tremor. Essential tremor may increase in severity to a point where the patient's handwriting becomes illegible and he cannot bring a spoon or glass to his lips without spilling its contents. Eventually, all tasks that require manual dexterity become difficult or impossible. The pathophysiology of this tremor and its treatment are discussed further on.

Typical essential tremor very often occurs in several members of a family, for which reason it has been called familial or hereditary essential tremor. Inheritance is in an

autosomal dominant pattern with high penetrance. The idiopathic and familial types cannot be distinguished on the basis of their physiologic and pharmacologic properties and probably should not be considered as separate entities. This condition has been referred to as "benign essential tremor," but this is hardly so in many patients in whom it worsens with age and greatly interferes with normal activities.

Essential tremor most often makes its appearance late in the second decade, but it may begin in childhood and then persist. A second peak of increased incidence occurs in adults older than 35 years of age. Both sexes are affected. It is a relatively common disorder, with an estimated prevalence of 415 per 100,000 persons older than the age of 40 years (Haerer et al). As described by Elble, the tremor frequency diminishes slightly with age while its amplitude increases.

The tremor practically always begins in the arms and is usually almost symmetrical; in approximately 15 percent of patients, however, it may appear first in the dominant hand. A severe isolated arm or leg tremor should suggest another disease (Parkinson disease or focal dystonia, as described further on).

The tremor may remain limited to the upper limbs or a side-to-side or nodding movement of the head; tremor

of the chin may be added or may occur independently. In certain cases of essential tremor, there is involvement of the jaw, lips, tongue, and larynx, the latter imparting a severe quaver to the voice (voice tremor). Infrequently, the tremor of the head or voice precedes that of the hands. The head tremor is also postural in nature and disappears when the head is supported. It has also been noted that the limb and head tremors tend to be muted when the patient walks. In some of our patients whose tremor remained isolated to the head for a decade or more, there has been little if any progression to the arms and almost no increase of the amplitude of movement.

The lower limbs are usually spared or only minimally affected. In the large series of familial tremor cases by Bain and colleagues, solitary jaw or head tremor was not found but we have observed isolated head tremor, as noted. Most patients with essential tremor will have identified the amplifying effects of anxiety and the ameliorating effects of alcohol on their tremor. We have also observed the tremor to become greatly exaggerated during emergence from anesthesia in a few patients.

Electromyographic studies reveal that the tremor is generated by more or less rhythmic and almost simultaneous bursts of activity in pairs of agonist and antagonist muscles (Fig. 6-2B). Less often, especially in the tremors at the lower range of frequency, the activity in agonist and antagonist muscles alternates ("alternate beat tremor"), a feature more characteristic of Parkinson disease, which the tremor then superficially resembles (see below). Tremor of either pattern may be disabling, but the less common, slower, alternate-beat tremor tends to be of higher amplitude, is more of a handicap, and is usually more resistant to treatment.

Treatment of Essential Tremor

A curious fact about essential tremor of the typical (non-alternate-beat) type is that it can be suppressed by a small amount of alcohol in more than 75 percent of patients; but once the effects of the alcohol have worn off, the tremor returns and may even worsen for a time. Of more therapeutic interest, essential tremor is inhibited by the beta-adrenergic antagonist propranolol (between 80 and 200 mg per day in divided doses or as a sustained-release preparation) taken orally over a long period of time. Often it takes several days or weeks for the effect to be evident. The benefit is variable and often incomplete; most studies indicate that 50 to 70 percent of patients have some symptomatic relief but may complain of side effects such as fatigue, erectile dysfunction, and bronchospasm.

The mechanism and site of action of beta-blocking agents is not known with certainty. It is blockade of the beta-2 adrenergic receptor that most closely aligned with reduction of the tremor. Several but not all of the other beta-blocking drugs are similarly effective to propranolol; metoprolol and nadolol, which are better tolerated than propranolol, are the ones most extensively studied, but they have yielded less consistent results than propranolol. The relative merits of different drugs in this class are discussed by Louis and by Koller et al (2000). Young and

associates have shown that neither propranolol nor ethanol, when injected intraarterially into a limb, decreases the amplitude of essential tremor. These findings, and the delay in action of medications, suggest that their therapeutic effect is due less to blockade of the peripheral beta-adrenergic receptors than to their action on structures within the central nervous system. This is in contrast to the earlier mentioned muscle receptor-mediated effect of adrenergic compounds in physiologic tremor. It is possible that this ambiguity regarding the action of beta-blocking drugs is the result of their effect on physiological tremor that is superimposed on essential tremor.

The barbiturate drug primidone has also been effective in controlling essential tremor and may be tried in patients who do not respond to or cannot tolerate beta-blocking medications, but many patients cannot tolerate the side effects of drowsiness, nausea, and slight ataxia. Treatment should be initiated at 25 mg per day and increased slowly to 75 mg per day in order to minimize these effects. Gabapentin, topiramate (see Connor), mirtazapine, a variety of benzodiazepines and a large number of other drugs have been used with variable success, but at the moment should probably be considered second-line therapies; these alternatives are discussed by Louis. Amantadine also has a modest effect on tremor and may be used as an adjunct.

The alternate-beat, slow, high-amplitude, kinetic-predominant type of essential tremor is more difficult to suppress but has reportedly responded to clonazepam (Biary and Koller); in our experience, however, this approach has not been as successful. Alcohol and primidone have also had less effect than they do in typical essential tremor. Indeed, the tremor has often been resistant to most attempts at suppression, for which reason surgical approaches are now being used (see further on).

Injections of botulinum toxin into a portion of a limb can reduce the severity of essential tremor locally, but the accompanying weakness of arm and hand muscles often proves unacceptable to the patient. The same medication injected into the vocal cords can suppress severe voice tremor as described in a series of cases by Adler and colleagues as well as by others, but caution must be exercised to avoid paralyzing the cords. Doses as low as 1 U of toxin injected into each cord may be effective, with a latency of several days. The long-term repeated use of this treatment has not been adequately studied for essential-type limb or voice tremor.

In resistant cases of essential tremor of the fast or slow variety, stimulation by electrodes implanted in the ventral medial nucleus thalamus or the internal segment of the globus pallidus (of the same type used to treat Parkinson disease) has produced a durable response over many years; details can be found in the small study reported by Sydow and colleagues.

Tremor of Polyneuropathy

Adams and coworkers described a disabling action tremor in patients with chronic demyelinating and paraproteinemic polyneuropathies. It is a particularly prominent feature of the polyneuropathy caused by immunoglobulin M

(IgM) antibodies to myelin-associated glycoprotein (MAG) as mentioned in the preceding chapter. The movements simulate a coarse essential, or ataxic, tremor and typically worsen if the patient is asked to hold his finger near a target. The EMG pattern is more irregular than that in essential (familial) tremor (Fig. 6-2C). Pedersen and colleagues have found it to vary greatly in amplitude with considerable side-to-side oscillation, which is induced by co-contracting muscle activity; they also found little suppression of the tremor with loading of the limb, unlike most other organic tremors. It is hypothesized that there is a disturbance of muscle spindle afferents.

Some cases of acute or chronic inflammatory neuropathy or ganglionopathy may be marked by a similar and prominent ataxic tremor and a faster action tremor. A special type of Guillain-Barré syndrome (Fisher variant) is characterized by a tremor that is indistinguishable from ataxia. Also, the inherited disease, peroneal muscular atrophy (Charcot-Marie-Tooth disease), may be associated with tremor of the essential type but the two may be coincident rather than directly related; this combination of symptoms was the basis on which Roussy and Levy incorrectly set it apart as a distinct disease. Chapter 46 discusses these polyneuropathies.

True action tremors are seen in a number of other clinical settings. A coarse action tremor, sometimes combined with myoclonus, accompanies various types of meningoencephalitis (e.g., in the past it was quite common with syphilitic general paresis) and certain intoxications (methyl bromide and bismuth).

Parkinsonian (Repose, Rest) Tremor

This is a coarse, rhythmic tremor with a frequency of 3 to 5 Hz. Electromyographically, it is characterized by bursts of activity that alternate between opposing muscle groups. The tremor is most often localized in one or both hands and forearms and less frequently in the feet, jaw, lips, or tongue (Fig. 6-2D). It occurs when the limb is in an attitude of repose and is suppressed or diminished by willed movement, at least momentarily, only to reassert itself once the limb assumes a new position. Even though it is termed a "resting" tremor, maintaining the arm in an attitude of repose requires a certain degree of muscular contraction, albeit slight. If the tremulous hand is completely relaxed, as it is when the arm is fully supported at the wrist and elbow, the tremor usually disappears; however, the patient rarely achieves this state. Usually he maintains a state of slight tonic contraction of the trunk and proximal muscles of the limbs. Under conditions of complete rest, i.e., in all except the lightest phases of sleep, the tremor disappears, as do most abnormal tremors except various forms of myoclonus.

Parkinsonian tremor is "alternating" in the sense that it takes the form of flexion-extension or abduction-adduction of the fingers or the hand; pronation-supination of the hand and forearm is also a common presentation. Flexion-extension of the fingers in combination with adduction-abduction of the thumb yields the characteristic "pill-rolling" tremor of Parkinson disease. It continues and may worsen while the patient walks, unlike essential

tremor; indeed, it may first become apparent to the patient during walking. When the legs are affected, the tremor takes the form of a flexion-extension movement of the foot, sometimes the knee. In the jaw and lips, it is seen as up-and-down and pursing movements, respectively. The eyelids, if they are closed lightly, tend to flutter rhythmically (blepharoclonus), and the tongue, when protruded, may move in and out of the mouth at about the same tempo as the tremor elsewhere.

The cogwheel effect, a ratchet-like interruption perceived by the examiner on passive movement of an extremity (the Negro sign). It is said by many authors to be no more than a palpable tremor superimposed on rigidity and as such, is not specific for Parkinson disease although it is most prominent in that condition. This explanation is called into question by the numerous cases in which Parkinson patients display minimal or no resting tremor but nonetheless have the cogwheel phenomenon as mentioned in Chap. 4. Cogwheeling can be brought out by having the patient engage the opposite limb, such as tracing circles in the air; this Froment sign, was originally described in essential tremor.

The parkinsonian tremor frequency is surprisingly constant over long periods, but the amplitude is variable. Emotional stress augments the amplitude and may add to the effects of an enhanced physiologic or essential tremor. With advance of the disease, increasing rigidity of the limbs obscures or reduces it. It is curious how little the tremor interferes with voluntary movement; for example, it is possible for a tremulous patient to raise a full glass of water to his lips and drain its contents without spilling a drop; this is not always the case with "benign" essential tremor, as already emphasized.

Almost always in Parkinson disease, the tremor is asymmetric and at the outset may be entirely unilateral. The tremor of postencephalitic parkinsonism (which is now virtually extinct) often had greater amplitude and involved proximal muscles. In neither disease is there a close correspondence between the degree of tremor and the degree of rigidity or akinesia. A bilateral parkinsonian type of tremor may also be seen in elderly persons without akinesia, rigidity, or mask-like facies. In some of these patients, the tremor is followed years later by the other manifestations of Parkinson disease, but in others it is not, the tremor remaining unchanged for decades or progressing very slowly, unaffected by anti-Parkinson drugs. This probably equates with the earlier mentioned alternate-beat type of essential tremor. Patients with the familial (wilsonian) or acquired form of hepatocerebral degeneration may also show a tremor of parkinsonian type, usually mixed with ataxic tremor and other extrapyramidal motor abnormalities. An alternating tremor may be seen in toxic-drug induced parkinsonism but it is relatively symmetric and tends not to be a prominent feature.

Parkinsonian tremor is suppressed to some extent by the anticholinergic drugs benztropine, trihexyphenidyl, and other anticholinergic drugs such as ethopropazine, a phenothiazine derivative; it is also suppressed less consistently but sometimes impressively by L-dopa and dopaminergic agonist drugs, which are the mainstays of treatment for Parkinson disease as discussed in Chap. 39.

The situation is made more difficult because a parkinsonian tremor is often associated with an additional tremor of faster frequency; the latter is of essential type and responds better to beta-blocking drugs than to anti-Parkinson medications. Stereotactic lesions or electrical stimulation in the basal ventrolateral nucleus of the thalamus diminishes or abolishes tremor contralaterally; other stimulation sites such as the internal segment of the globus pallidus and the subthalamic nucleus are also effective but possibly to a lesser degree. Chapter 39 discusses treatment of Parkinson disease in greater detail.

Intention (Ataxic, Cerebellar, Goal Directed Action) Tremor

As discussed in Chap. 5, the word intention is ambiguous in this context because the tremor itself is not intentional and occurs not when the patient intends to make a movement but only during the most demanding phases of active performance. In this sense it is a kinetic or action tremor, but the latter term has connotations of the essential tremor to neurologists, as described earlier. The term ataxic is a suitable substitute for intention, because this tremor is always combined with cerebellar ataxia and adds to it, as described in Chap. 5. Its salient feature is that it requires for its full expression the performance of an exacting, precise, projected movement. The tremor is absent when the limbs are inactive and during the first part of a voluntary movement but as the action continues and fine adjustments of the movement are demanded (e.g., in touching the tip of the nose or the examiner's finger), an irregular, more or less rhythmic (2- to 4-Hz) interruption of forward progression with side-to-side oscillation appears and may continue for several beats after the target has been reached. Unlike essential and parkinsonian tremors, the oscillations occur in more than one plane but are mainly horizontal and perpendicular to the trajectory of movement. The tremor and ataxia may seriously interfere with the patient's performance of skilled acts. In some patients there is a rhythmic oscillation of the head on the trunk (titubation), or of the trunk itself, at approximately the same rate. As already indicated, this type of tremor points to disease of the cerebellum or its connections, particularly via the superior cerebellar peduncle, but certain peripheral nerve diseases may occasionally simulate it.

There is another, higher amplitude tremor associated with cerebellar ataxia, in which every movement, even lifting the arm slightly or maintaining a static posture with the arms held out to the side, results in a wide-ranging, rhythmic 2- to 5-Hz "wing-beating" movement, sometimes of sufficient force to throw the patient off balance. In such cases, the lesion is usually in the midbrain, involving the rostral projections of the dentatorubrothalamic fibers and the medial part of the ventral tegmental reticular nucleus. Because of the location of the lesion in the region of the red nucleus, Holmes originally called this a rubral tremor. However, experimental evidence in monkeys indicates that the tremor is produced not by a

lesion of the red nucleus per se but by interruption of dentatothalamic fibers that traverse this nucleus—i.e., the cerebellar efferent fibers that form the superior cerebellar peduncle and brachium conjunctivum (Carpenter). This type of tremor is seen most often in patients with multiple sclerosis and Wilson disease, occasionally with vascular and other lesions of the tegmentum of the midbrain and subthalamus, and rarely as an effect of antipsychosis medications. Beta-adrenergic blocking agents, anticholinergic drugs, and L-dopa have little therapeutic effect. It is abolished by a surgical or ischemic lesion in the opposite ventrolateral nucleus of the thalamus. Thalamic stimulation may be particularly helpful in severe cases that are the result of demyelinating lesions in the cerebellar peduncles.

Chapter 5 and the section further on, "Pathophysiology of Tremor," discuss the mechanisms involved in the production of intention, or ataxic tremor.

Geniospasm

This is a strongly familial episodic tremor disorder of the chin and lower lip that begins in childhood and may worsen with age. Psychic stress and concentration are known to precipitate the movements, which are described by Danek as "trembling." Rare instances involve other facial muscles. The disorder must be distinguished from a similar tremor of the chin that is part of essential tremor, facial myokymia or fasciculations, and palatal tremor. The disorder results from a mutation on chromosome 9.

Primary Orthostatic Tremor (See also Chap. 7)

This is a rare but striking tremor isolated to the legs that is remarkable by its occurrence only during quiet standing and its cessation almost immediately on walking. It is difficult to classify and more relevant to disorders of gait than it is to tremors of other types. The frequency of the tremor has been recorded as approximately 14 to 16 Hz, making it difficult to observe and more easily palpable. Nonetheless, it may produce considerable disability as the patient attempts to stabilize himself in response to the tremulousness. An important accompanying feature is the sensation of severe imbalance, which causes the patient to assume a widened stance while standing; these patients are unable to walk a straight line (tandem gait). We have observed prominent tonic contraction of the legs during standing, seemingly in an attempt to overcome imbalance (see Heilman; and Thompson, Rothwell, Day et al). The arms are affected little or not at all. Often the first step or two when the patient begins to walk are halting, but thereafter, the gait is entirely normal. Because falls are infrequent, the condition is often attributed to hysteria. Tremulousness is not present when the patient is seated or reclining, but in the latter positions it can be evoked by strong contraction of the leg muscles against resistance.

Electromyographic recordings demonstrate rhythmic cocontraction of the gastrocnemius and anterior tibialis muscles. Although some authors, such as Wee and

colleagues, have classified the disorder as a type of essential tremor, most of its characteristics suggest otherwise. Sharott and coworkers consider it an exaggerated physiologic tremor in response to imbalance; others have found an intrinsic rhythm at approximately 16 Hz generated by the damaged spinal cord in patients with myelopathy, suggesting a spinal origin for the tremor.

Some cases have responded to the administration of clonazepam, gabapentin, primidone, or sodium valproate alone or in combination but it often proves difficult to treat. A few intractable cases have been treated with an implanted spinal cord stimulator (Krauss et al, 2005).

Dystonic Tremor

Tremors may be an incipient feature of dystonia. When the underlying dystonic posturing is not overt, the tremor may be ascribed to the essential variety or to hysteria. Dystonic tremor is focal, superimposed, for example on torticollis, or it may be evident in a dystonic hand. The movement is not entirely rhythmic, sometimes jerky, and often intermittent. These cases are discussed further on in the section on focal dystonia. In addition, a fair number of patients with dystonia have an essential tremor.

Psychogenic Tremor

Tremor may be a quite dramatic manifestation of hysteria. It simulates many types of organic tremor, thereby causing difficulty in diagnosis. Psychogenic tremors are usually restricted to a single limb, often in the dominant hand; they are gross in nature, are less regular than the common static or action tremors, and diminish in amplitude or disappear if the patient is distracted as, for example, when asked to make a complex movement with the opposite hand. If the examiner restrains the affected hand and arm, the tremor may move to a more proximal part of the limb or to another part of the body ("chasing the tremor"). Other useful features in identifying hysterical tremor are exaggeration of the tremor by loading the limb—e.g., by having the patient hold a book or other heavy object—which reduces almost all other tremors with exception of those produced by polyneuropathy. Hysterical tremor persists in repose and during movement and is less subject than nonhysterical tremors to the modifying influences of posture and willed movement. Tremors of this type often acquire the frequency of a willed movement in a different limb. This can be brought out by asking the patient to rhythmically tap with the unaffected limb.

Tremors of Complex Type

Not all tremors correspond exactly with those described above and several of them may coexist. There is frequently a variation in one or more of the particulars from the typical pattern, or one type of tremor may show a feature ordinarily considered characteristic of another. In some parkinsonian patients, for example, the tremor is accentuated rather than dampened by active movement; in others, the tremor may be very mild or absent in repose

and become obvious only with movement of the limbs. As mentioned above, a patient with a typical parkinsonian tremor may, in addition, show a fine essential tremor of the outstretched hands and occasionally even an element of ataxic tremor as well. In a similar way, essential or familial tremor may, in its advanced stages, assume the aspects of a cerebellar tremor. Further examples include patients with essential or familial tremor or with cerebellar degeneration who display a rhythmic parkinsonian tremor in relation to sustained postures.

Pathophysiology of Tremor

In patients with tremor of either the parkinsonian, postural, or intention type, Narabayashi has recorded rhythmic burst discharges of unitary cellular activity in the nucleus intermedius ventralis of the thalamus (as well as in the medial pallidum and subthalamic nucleus) synchronous with the beat of the tremor. Neurons that exhibit the synchronous bursts are arranged somatotopically and respond to kinesthetic impulses from the muscles and joints involved in the tremor. A stereotaxic lesion in this region of the thalamus abolishes the tremor. The effectiveness of a thalamic lesion may be a result of interruption of pallidothalamic and dentatothalamic projections or, more likely, of projections from the ventrolateral thalamus to the premotor cortex, as the impulses responsible for tremor are ultimately transmitted by the lateral corticospinal tract. Some of what is known about the physiology of specific tremors is noted in the following paragraphs.

Essential Tremor

To date, only a few cases of essential tremor have been examined postmortem, and these have disclosed no consistent lesion to which the tremor could indisputably be attributed (Herskovits and Blackwood; Cerosimo and Koller). A singular case of a 90-year-old woman studied by Louis and colleagues, demonstrated more extensive cerebellar cortical and dentate nucleus cell loss and reactive changes than had been previously recognized.

The question of the existence and locus of a generator for essential tremor as opposed to the unbalancing of a feedback loop system is unresolved. As indicated by McAuley, various studies that demonstrate rhythmic activity in the cortex corresponding to the tremor activity are more suggestive of a common source elsewhere than of a primary generator in the cortex. Based on electrophysiologic recordings in patients, two likely origins of oscillatory activity are the olivocerebellar circuits and the thalamus. Whether a particular structure possesses an intrinsic rhythmicity or, as currently favored, the tremor is an expression of reciprocal oscillations in circuits of the dentato-brainstem-cerebellar or thalamic-tegmental systems is not at all clear. Studies of blood flow in patients with essential tremor by Colebatch and coworkers affirm that the cerebellum is rhythmically activated; on this basis they argue that there is a release of an oscillatory mechanism in the olivocerebellar pathway. Dubinsky and Hallett demonstrated that the inferior olives also become hypermetabolic when essential tremor is activated, but

this has been questioned by Wills and colleagues who recorded increased blood flow in the cerebellum and red nuclei, but not in the olive. These proposed mechanisms are reviewed by Elble and serve to emphasize the points made here.

Although this disorder is familial, a single genetic site has not yet been established; several candidate polymorphisms are promising.

Parkinsonian Tremor

The anatomic basis of parkinsonian tremor is not known. In Parkinson disease, the visible lesions predominate in the substantia nigra, and this was true also of the post-encephalitic form of the disease. In animals, however, experimental lesions confined to the substantia nigra do not result in tremor; neither do lesions in the striatopallidum. Moreover, not all patients with lesions of the substantia nigra have tremor; in some there is only bradykinesia and rigidity. In a group of patients poisoned with the toxin MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), a meperidine analogue that destroys the neurons of the substantia nigra pars compacta (see Chaps. 4 and 39), only half developed a tremor, which had more of the characteristics of a proximal action or postural tremor than of a rest tremor as discussed by Burns and colleagues. In all likelihood, these inconsistencies reflect the complex influence of dopamine on a number of basal ganglionic structures outlined in Chap. 4.

Ward and others have produced a Parkinson-like tremor in monkeys by placing a lesion in the ventromedial tegmentum of the midbrain, just caudal to the red nucleus and dorsal to the substantia nigra. He postulated that interruption of the descending fibers at this site liberates an oscillating mechanism in the lower brainstem; this presumably involves limb innervation via the reticulospinal pathway. Alternative possibilities are that the lesion in the ventromedial tegmentum interrupts the brachium conjunctivum, or a tegmental-thalamic projection, or the descending limb of the superior cerebellar peduncle, which functions as a link in a dentatoreticular-cerebellar feedback mechanism, a hypothesis similar to the one proposed for essential tremor (see Fig. 5-3). The differential effect of drugs on tremor and bradykinesia suggest that they must have separate mechanisms.

Ataxic Tremor (See also Chap. 5)

This has been produced in monkeys by inactivating the deep cerebellar nuclei or by sectioning the superior cerebellar peduncle or the brachium conjunctivum below its decussation. A lesion of the nucleus interpositus or dentate nucleus causes an ipsilateral tremor of ataxic type, as one might expect, associated with other manifestations of cerebellar ataxia. In addition, such a lesion gives rise to a "simple tremor," which is the term that Carpenter applied to a "resting" or parkinsonian tremor. He found that the latter was most prominent during the early postoperative period and was less enduring than ataxic tremor. Nevertheless, the concurrence of the two types of tremor and the fact that both can be abolished by ablation of the contralateral ventrolateral thalamic nucleus

suggest that they have related neural mechanisms, at least in monkeys.

Palatal Tremor ("Palatal Myoclonus")

This is a rare disorder consisting of rapid, rhythmic, involuntary movements of the soft palate. For many years it was considered to be a form of uniphasic myoclonus (hence the terms palatal myoclonus and palatal nystagmus). Because of the persistent rhythmicity, it is now classified as a tremor. There are two forms of this movement, according to Deuschl and colleagues. One is essential palatal tremor that reflects the rhythmic activation of the tensor veli palatini muscles; it has no known pathologic basis. The palatal movement may impart a repetitive audible click, which ceases during sleep. The second, more common form is a symptomatic palatal tremor caused by a diverse group of brainstem lesions that interrupt the central tegmental tract(s); these columns contain descending fibers from midbrain nuclei to the inferior olivary complex (a component of the Guillain-Mollaret triangle described below and in Chap. 5 and Fig. 5-3). The frequency of the tremor varies greatly and is 26 to 420 cycles per minute in the essential form and 107 to 164 cycles per minute in the symptomatic form.

Symptomatic palatal tremor, in contrast to the essential type and all other tremors, persists during sleep and is sometimes associated with ocular myoclonus that is synchronized with the palatal movements. In some cases, the pharynx as well as the facial and extraocular muscles (pendular or convergence nystagmus), diaphragm, vocal cords, and even the muscles of the neck and shoulders partake of the persistent rhythmic movements. A similar phenomenon, in which contraction of the masseters occurs concurrently with pendular ocular convergence, has been observed in Whipple disease (oculomasticatory myorhythmia).

Magnetic resonance imaging (MRI) reveals no lesions to account for essential palatal tremor; in the symptomatic form, however, there are tegmental brainstem lesions and conspicuous enlargement of the inferior olivary nucleus unilaterally or bilaterally. With unilateral palatal tremor, it is the contralateral olive that becomes enlarged. It has been proposed that the lesions in the symptomatic form interrupt the circuit (dentate nucleus-brachium conjunctivum-red nucleus-central tegmental tract-olivary nucleus-dentate nucleus) that Lapresle and Ben Hamida called the triangle of Guillain-Mollaret (Fig. 5-3). The lesions have been vascular, neoplastic, especially demyelinating, or traumatic, and have been found mainly in midbrain or pontine portions of the central tegmental fasciculus.

The physiologic basis of palatal tremor remains conjectural. Matsuo and Ajax postulated a denervation hypersensitivity of the inferior olivary nucleus and its dentate connections, but others have suggested that the critical event is denervation not of the olive but of the nucleus ambiguus and the dorsolateral reticular formation adjacent to it. Dubinsky and colleagues have suggested that palatal tremor may be based on the same mechanism as postural tremor—i.e., presumably

Figure 6-3. Dystonic movement disorders. *A.* Young man with severe spasmodic retrocollis. Note hypertrophy of sternocleidomastoid muscles. *B.* Meige syndrome of severe blepharospasm and facial-cervical dystonia. *C.* Characteristic athetoid-dystonic deformities of the hand in a patient with tardive dyskinesia. (Photographs courtesy of Dr. Joseph M. Waltz.)

a disinhibition of the olive and a rhythmic coupling of neurons in the olive induced by a lesion of the dentato-olivary pathway.

The use of drugs in treating this movement disorder has met with variable success. Clonazepam (0.25 to 0.5 mg/d, increasing gradually to 3.0 to 6.0 mg/d), sodium valproate (250 mg/d, increasing to 1,000 mg/d), and gabapentin (up to 2,100 mg) have suppressed the movement in some cases, particularly the last of these drugs, which reportedly has had a dramatic effect in some patients. Also, tetrabenazine and haloperidol have been helpful on occasion. Selective injection of the palatal muscles with botulinum toxin, while technically demanding, affords modest relief; it is particularly helpful in eliminating the annoying ear clicking.

ASTERIXIS

The movement disorder known as asterixis was described by Adams and Foley in patients with hepatic encephalopathy but it occurs with a variety of systemic metabolic disorders. It consists of arrhythmic lapses of sustained posture that allow gravity or the inherent elasticity of muscles to produce a movement, which the patient then corrects, sometimes with overshoot. Later, Leavitt and Tyler and then Young and Shahani demonstrated that the initial interruption or lapse in posture is associated with EMG silence for a period of 35 to 200 ms. By interlocking EMG and electroencephalogram (EEG) recordings, Ugawa et al found that a sharp wave, probably generated in the motor cortex, immediately precedes the period of EMG silence. This confirmed that asterixis differs physiologically from both tremor and myoclonus, with which it was formerly confused; it has incorrectly been referred to as a “negative tremor.”

Asterixis is most readily evoked by asking the patient to hold his arms outstretched with hands dorsiflexed or to dorsiflex the hands and extend the fingers while resting the forearms on the bed or the arms of a chair. Flexion movements of the hands may then occur arrhythmically once or several times a minute. The same lapses in sustained muscle contraction can be provoked in any muscle group—including, for example, the protruded tongue, the closed eyelids, or the flexed trunk muscles. Sometimes, asterixis can be elicited best by asking the patient to place his hand flat on a table and raise the index finger.

This sign was first observed in patients with hepatic encephalopathy but was later noted with hypercapnia, uremia, and other metabolic and toxic encephalopathies. Asterixis may also be evoked by phenytoin and other anticonvulsants, usually indicating that these drugs are present in excessive concentrations. Similar rapid lapsing movements of the head or arms sometimes appear during drowsiness in normal persons (“nodding off”).

Unilateral asterixis occurs in an arm and leg on the side opposite an anterior thalamic infarction or small hemorrhage, after stereotaxic thalamotomy, and with an upper midbrain lesion, usually as a transient phenomenon after stroke. In two series, Kim and coworkers and

Montalban and colleagues, came to a similar conclusion, namely that unilateral asterixis is usually attributable to an acute thalamic stroke on the contralateral side, but there was an interesting variety of other localizations including the frontal lobe (anterior cerebral artery infarction), midbrain, and cerebellum in a few cases each. Our experience is limited to those arising from thalamic and overlying parietal lesions. Many drugs may unmask unilateral asterixis that has its basis in an underlying lesion of the anterior thalamus.

CLONUS, MYOCLONUS, AND POLYMYOCLONUS

The terms clonus (or clonic), myoclonus (or myoclonic), and polymyoclonus have been used, perhaps indiscriminately, to designate rhythmic or arrhythmic series of brief, shock-like muscular contractions associated with disease of the central nervous system. Clonus refers to a series of rhythmic, monophasic (i.e., unidirectional) contractions and relaxations of a group of muscles, differing in this way from tremors, which are always diphasic or bidirectional. Myoclonus specifies the very rapid, shock-like contractions of a group of muscles, irregular in rhythm and amplitude, and, with few exceptions, asynchronous and asymmetrical in distribution. If such contractions occur singly or are repeated in a restricted group of muscles, such as those of an arm or leg, the phenomenon is termed segmental myoclonus, whereas widespread, lightning-like, arrhythmic repeated contractions are referred to as polymyoclonus. The discussion that follows makes evident that each of the three phenomena has a distinctive pathophysiology and clinical implications.

Reference has already been made in Chap. 3 to the clonus that appears in relation to spasticity and heightened tendon reflexes in diseases affecting the corticospinal tract. It is most easily elicited by forcefully dorsiflexing the ankle; a series of rhythmic jerks of small to moderate amplitude result.

A common and benign example of myoclonus, familiar to many persons, is the “sleep-start” that consists of a jerking of the body, particularly the torso, while falling asleep or occasionally, just prior to waking (see Chap. 18). This movement will be vigorous enough to cause tongue biting and be mistaken for a convulsion.

Epilepsia partialis continua is a special type of rhythmic epileptic activity in which one group of muscles—usually of the face, arm, or leg—is continuously (day and night) involved in a series of rhythmic monophasic contractions. These may continue for weeks, months, or years. In most cases there is a corresponding EEG abnormality. The disorder appears to be cerebral in origin, but in most cases its precise anatomic and physiologic basis cannot be determined (see Chap. 16 for further discussion).

Focal and Regional Myoclonus

Patients with idiopathic epilepsy may complain of a localized myoclonic jerk or a short burst of myoclonic jerks,

occurring particularly on awakening and on the day or two preceding a major generalized seizure, after which these movements cease. One-sided or focal myoclonic jerks are the dominant feature of a particular form of childhood epilepsy—so-called benign epilepsy with rolandic spikes (Chap. 16). Diffuse myoclonic jerks are the main—or sometimes only—manifestation of a fairly common seizure disorder with distinctive EEG features called juvenile myoclonic epilepsy; this diagnosis is suggested by an onset of myoclonus or single seizures during adolescence and myoclonus or lapses in upright posture, usually occurring in the morning, that become prominent with sleep deprivation and several hours after alcohol consumption. Myoclonus may be associated with atypical petit mal and akinetic seizures in the Lennox-Gastaut syndrome (absence or petit mal variants); the patient often falls during the brief lapse of postural mechanisms that follows a single myoclonic contraction. Similarly, in the West syndrome of infantile spasms, the arms and trunk are suddenly flexed or extended in a single massive myoclonic jerk (“jackknife” or “salaam” seizures); mental regression occurs in 80 to 90 percent of these cases, even when the seizures are successfully treated with adrenocorticotrophic hormone (ACTH). These types of special “myoclonic epilepsies” are discussed further below and in Chap. 16 in relation to epilepsy.

Focal simple myoclonus is also one of the notable features of degenerative neurologic conditions, particularly corticobasal ganglionic degeneration; it is generally seen in a limb that is made rigid by this process.

Diffuse Myoclonus (Polymyoclonus)

Under the title paramyoclonus multiplex, Friedreich, in 1881, described a sporadic instance of widespread muscle jerking in an adult. It was probably in the course of this description that the term myoclonus was used for the first time. Muscles were involved diffusely, particularly those of the lower face and proximal segments of the limbs, and the myoclonus persisted for many years, being absent only during sleep. No other neurologic abnormalities accompanied the movement abnormality. The nature and pathologic basis of this disorder were never determined.

Over the years, the term paramyoclonus multiplex, or polymyoclonus has been applied to all varieties of myoclonic disorder (and other motor phenomena as well), to the point where it has nearly lost its specific connotation. Polymyoclonus may occur in pure or “essential” form as a benign, often familial, nonprogressive disease or as part of a more complex progressive syndrome that may prove disabling and fatal. More importantly, there are several acquired forms that are associated with various neurologic diseases as discussed below.

Essential (Familial; hereditary; genetic) Myoclonus

Symptoms may begin at any period of life but usually appear first in childhood and are of unknown etiology. An autosomal dominant mode of inheritance is evident in some families. The myoclonus takes the form of irregular twitches of one or another part of the body, involving groups of muscles, single muscles, or even a

portion of a muscle. As a result, an arm may suddenly flex, the head may jerk backward or forward, or the trunk may curve or straighten. The face, neck, jaw, tongue, ocular muscles, and diaphragm may twitch. According to Wilson, even fascicles of the platysma may twitch. Some muscle contractions cause no visible displacement of a limb. In this and other forms of myoclonus, the muscle contraction is brief (20 to 50 ms)—i.e., faster than that of chorea, with which it may be confused. The speed of the myoclonic contraction is the same whether it involves a part of a muscle, a whole muscle, or a group of muscles. Some of the patients register little complaint, accepting the constant intrusions of motor activity with stoicism; they generally lead relatively normal, active lives. Seizures, dementia, and other neurologic deficits are notably absent. Occasionally there is hint of a mild cerebellar ataxia and, in one family studied by R.D. Adams, essential tremor was present as well, both in family members with polymyoclonus and in those without. Both the tremor and myoclonus were dramatically suppressed by the ingestion of alcohol. Similar families have been observed by Marsden and colleagues. In a Mayo Clinic series reported by Aigner and Mulder, 19 of 94 cases of polymyoclonus were of this “essential” type.

Several of the sleep-related syndromes that involve repetitive leg movements include an element of myoclonus. In a few patients, mainly older ones with severe “restless legs syndrome,” the myoclonus and dyskinesias may become troublesome in the daytime as well. These patients march in place and rock their bodies during sleep (Walters et al). These disorders are discussed in Chap. 19.

Myoclonic Epilepsy (See also Myoclonic Seizures in Chap. 16)

Myoclonic epilepsy constitutes an important syndrome of multiple etiologies. A relatively benign idiopathic form, juvenile myoclonic epilepsy, has been mentioned and is discussed extensively in Chap. 16. A more serious type of myoclonic epilepsy, which in the beginning may be marked by polymyoclonus as an isolated phenomenon, is eventually associated with dementia and other signs of progressive neurologic disease (familial variety of Unverricht and Lundborg). An outstanding feature of the latter is a remarkable sensitivity of the myoclonus to stimuli of all sorts. If a limb is passively or actively displaced, the resulting myoclonic jerk may lead, through a series of progressively larger and more or less synchronous jerks, to a generalized convulsive seizure. In late childhood this type of stimulus-sensitive myoclonus is usually a manifestation of the juvenile form of lipid storage disease, which, in addition to myoclonus, is characterized by seizures, retinal degeneration, dementia, rigidity, pseudobulbar paralysis, and, in the late stages, by quadriplegia in flexion.

Another form of stimulus-sensitive (reflex) myoclonus, inherited as an autosomal recessive trait, begins in late childhood or adolescence and is associated with neuronal inclusions (Lafora bodies thus Lafora-body disease) in the cerebral and cerebellar cortex and in brainstem nuclei. In yet another familial type (described under the

title of Baltic myoclonus by Eldridge and associates), autopsy has disclosed a loss of Purkinje cells but no inclusion bodies. Unlike Lafora-body disease, the Baltic variety of myoclonic epilepsy has a favorable prognosis, particularly if the seizures are treated with valproic acid.

Under the title of cherry-red-spot myoclonus syndrome, Rapin and associates have drawn attention to a familial (autosomal recessive) form of diffuse, incapacitating intention myoclonus associated with visual loss and ataxia. This disorder develops insidiously in adolescence. The earliest sign is a cherry-red spot in the macula that may fade in the chronic stages of the illness. The intellect is relatively unimpaired. The specific enzyme defect appears to be a deficiency of lysosomal alpha-neuroaminidase (sialidase), resulting in the excretion of large amounts of sialylated oligosaccharides in the urine. This has been referred to as type 1 sialidosis to distinguish it from a second type, in which patients are of short stature (as a result of chondrodystrophy) and often have a deficiency of beta-galactosidase in tissues and body fluids. In patients with sialidosis, a mucopolysaccharide-like material is stored in liver cells, but neurons show only a nonspecific accumulation of lipofuscin. A similar clinical syndrome of myoclonic epilepsy is seen in a variant form of neuroaxonal dystrophy and in the late childhood-early adult neuronopathic form of Gaucher disease, in which it is associated with supranuclear gaze palsies and cerebellar ataxia (Chap. 37).

Diffuse Myoclonus with Acquired Neurologic Disease

The clinical settings in which one observes widespread random myoclonic jerks as a transient or persistent phenomenon in adults include structural diseases such as viral encephalitis, Creutzfeldt-Jakob disease, general paresis, advanced Alzheimer and Lewy-body disease, and corticobasal ganglionic degeneration (the degenerative types are discussed in Chap. 39), occasionally in Wilson disease, and more often with acquired metabolic disorders (prototypically uremic and anoxic encephalopathy) and certain drug intoxications, notably with haloperidol, lithium, and amphetamines; Table 6-2 lists these and others. A subacute encephalopathy with diffuse myoclonus may occur in association with the autoantibodies that are characteristically a component of Hashimoto thyroiditis and also in Whipple disease (both are discussed in Chap. 40). An acute onset of polymyoclonus with confusion occurs with lithium intoxication; once ingestion is discontinued, there is improvement (slowly over days to weeks) and the myoclonus is replaced by diffuse action tremors, which later subside. Diffuse, severe myoclonus may be a prominent feature of early tetanus and strychnine poisoning.

Polymyoclonus that occurs in the acute stages of anoxic encephalopathy should be distinguished from postanoxic action or intention myoclonus that emerges with recovery from cardiac arrest or asphyxiation (it is discussed below and in Chap. 40). The factor common to all these disorders is the presence of diffuse neuronal disease.

Table 6-2

CAUSES OF GENERALIZED AND REGIONAL MYOCLONUS

Epileptic forms (myoclonic epilepsies)

- Unverricht-Lundborg disease
- Lafora-body disease
- Baltic myoclonus
- Benign epilepsy with rolandic spikes
- Juvenile myoclonic epilepsy
- Infantile spasms (West syndrome)
- Cherry-red-spot myoclonus (sialidase deficiency)
- Myoclonus epilepsy with ragged red fibers (MERRF)
- Ceroid lipofuscinosis (Kufs disease)
- Tay-Sachs disease
- Epilepsia partialis continua

Essential and hereditary forms

Myoclonic dementias

- Creutzfeldt-Jakob disease
- Subacute sclerosing panencephalitis
- Familial progressive poliodystrophy
- Alzheimer, Lewy-body, and Wilson diseases (occasional in late stages)
- Whipple disease of the central nervous system
- Corticobasal ganglionic degeneration
- Dentatorubropallidolysian atrophy
- AIDS dementia

Myoclonus with cerebellar disease (myoclonic ataxia)

- Opsoclonus-myoclonus syndrome (paraneoplastic [anti-Ri], neuroblastoma, post- and parainfectious)
- Postanoxic myoclonus (Lance Adams type)
- Ramsay-Hunt dyssynergia cerebellaris myoclonica

Metabolic, immune, and toxic disorders

- Cerebral hypoxia (acute and severe)
- Uremia
- Hashimoto thyroiditis
- Lithium intoxication
- Haloperidol and sometimes phenothiazine intoxication
- Hepatic encephalopathy (rare)
- Cyclosporine toxicity
- Nicotinic acid deficiency encephalopathy
- Tetanus
- Other drug toxicities

Focal and spinal forms of myoclonus

- Herpes zoster myelitis
- Other unspecified viral myelitis
- Multiple sclerosis
- Traumatic spinal cord injury
- Arteriovenous malformation of spinal cord
- Subacute myoclonic spinal neuronitis
- Paraneoplastic spinal myoclonus

Myoclonus in association with signs of cerebellar incoordination, including opsoclonus (rapid, irregular, but predominantly conjugate movements of the eyes in all planes as described in Chap. 14) is another syndrome of both children and adults. Most cases run a chronic course, waxing and waning in severity. Many of the childhood cases are associated with occult neuroblastoma, and some have responded to the administration of corticosteroids. In adults, a similar syndrome has been described as a remote effect of carcinoma (mainly of lung, breast, and ovary as discussed at length in Chap. 31), but it also occurs at all ages as a self-limited manifestation of a

benign postinfectious (possibly viral) illness as described by Baringer and colleagues.

As mentioned above, diffuse myoclonus is a prominent and often early feature of the prion transmissible illness Creutzfeldt-Jakob disease, characterized by rapidly progressive dementia, disturbances of gait and coordination, and all manner of mental and visual aberrations (see Chap. 33). Initially the jerks are random but late in the disease they may attain an almost rhythmic and symmetric character. In addition there is an exaggerated startle response, and violent myoclonus may be elicited by tactile, auditory, or visual stimuli in advanced stages of the disease. In this condition too, there is a progressive destruction of neurons, mainly but not exclusively in the cerebral and cerebellar cortices, and a striking degree of gliosis. In addition to parenchymal destruction, the cortical tissue shows a fine-meshed vacuolation, hence the designation subacute spongiform encephalopathy.

In yet another group of myoclonic dementias, the most prominent associated abnormality is a progressive deterioration of intellect. Like the myoclonic epilepsies, the myoclonic dementias may be sporadic or familial and may affect both children and adults. A rare childhood type is subacute sclerosing panencephalitis (SSPE), which is an acquired subacute or chronic (occasionally remitting) disease related to a latent infection with the measles virus (Chap. 33).

Intention or Action (Postanoxic) Myoclonus

This type of myoclonus was described by Lance and Adams in a group of patients who were recovering from hypoxic encephalopathy. When the patient is relaxed, the limb and other skeletal muscles are quiet (except in the most severe cases); only seldom does the myoclonus appear during slow, smooth (ramp) movements. Fast (ballistic) movements, however, especially when directed to a target, as in touching the examiner's finger, elicit a series of irregular myoclonic jerks that differ in speed and rhythmicity from intention tremor. For this reason it was called intention or action myoclonus. Only the limb that is moving is involved; hence it is a localized, stimulus-evoked myoclonus. Speech may be fragmented by the myoclonic jerks, and a syllable or word may be almost compulsively repeated, as in palilalia.

Action myoclonus is almost always associated with cerebellar ataxia. The pathologic anatomy has not been entirely ascertained. Lance and Adams found the irregular discharges to be transmitted via the corticospinal tracts, preceded in some cases by a discharge from the motor cortex. Chadwick and coworkers postulated a reticular loop reflex mechanism, while Hallett and colleagues (1977) found that a cortical reflex mechanism was operative in some cases and a reticular reflex mechanism in others. Whether these are two aspects of one mechanism could not be decided.

Barbiturates and valproic acid have been helpful in some cases. Several clinical trials and case reports have suggested that the antiepileptic levetiracetam may be useful (Krauss et al, 2001). The use of 5-hydroxytryptophan alone

or in combination with tryptophan or other drugs had been recommended in the past (van Woert et al). A combination of several of these medications is usually required to make the patient functional.

Spinal or Segmental Myoclonus (See also Subacute Spinal Neuronitis in Chap. 44)

The notion that monophasic-restricted myoclonus always emanates from the cerebral cortex, cerebellum, or brainstem cannot be sustained, as there are forms that are traceable to a purely spinal cause. The problem takes the form of an almost continuous arrhythmic jerking of a restricted group of muscles, often on one side of the body. Such a subacute spinal myoclonus of obscure origin was described many years ago by Campbell and Garland, and similar cases continue to be cited in the literature. We have seen several in which myoclonus was isolated to the musculature of the abdominal or thoracic wall on one side or to the legs; only rarely were we able to establish a cause, and the spinal fluid has been normal. This form has been referred to as "proprio-spinal" when it involves repetitive flexion or extension myoclonus of the torso that is aggravated by stretching or action.

Examples of myelitis with irregular and strictly segmental myoclonic jerks (either rhythmic or arrhythmic) have been reported in humans and have been induced in animals by the Newcastle virus. Many such myelitic cases involve the legs or a few muscles of one leg. In our experience, this type of myoclonus has occurred following zoster myelitis, postinfectious transverse myelitis, and rarely with multiple sclerosis, epidural cord compression, or after traumatic spinal injury. A paraneoplastic form has also been described, usually associated with breast cancer (Chap. 31). When highly ionic contrast media was in the past used for myelography, painful spasms and myoclonus sometimes occurred in segments where the dye was concentrated by a block to the flow of spinal fluid.

Treatment is difficult and one resorts to a combination of antiepileptic drugs and benzodiazepines, just as in cerebral myoclonus. The glycine inhibitor levetiracetam reportedly has been successful when other drugs have failed (Keswani et al).

Pathophysiology of Polymyoclonus

It seems logical to assume that myoclonus is caused by abnormal discharges of aggregates of motor neurons or interneurons because of the directly enhanced excitability of these cells or the removal of some inhibitory mechanism. Sensory relationships are a prominent feature of polymyoclonus, particularly those related to metabolic disorders, and will eventually shed some light on the mechanism. Flickering light, a loud sound, or an unexpected tactile stimulus to some part of the body initiates a jerk so quickly and consistently that it must utilize a direct sensorimotor pathway or the mechanism involved in the startle reaction. Repeated stimuli may recruit a series of incremental myoclonic jerks that culminate in a generalized convulsion, as often happens in the familial myoclonic syndrome of Unverricht-Lundborg. However, evidence implicating cortical hyperexcitability

in myoclonus is only indirect, being based mainly on the finding that the cortical components of the somatosensory evoked potential are exceedingly large and that in some instances, the myoclonic jerks have a strict time relationship (“time-locked”) to preceding spikes in the contralateral rolandic area (Marsden et al; Brown et al). Conversely, it is just as likely that these potentials originate from subcortical structures that project both to the descending motor pathways and upward to the cortex. In humans, the indication is that postanoxic action myoclonus has its basis in reflex hyperactivity of the reticular formation and that the only consistent damage is in the cerebellum rather than in the cerebral cortex (see above, under “Intention or Action Myoclonus”). As already noted, several types of myoclonus are closely coupled with cerebellar cortical degenerations.

Pathologic examinations have been of little help in determining the essential sites of this unstable neuronal discharge because in most cases, the neuronal disease is so diffuse. Nonetheless, the most restricted lesions associated with myoclonus are located in the cerebellar cortex, dentate nuclei, and pretectal region. A removal of the modulating influence of the cerebellum on the thalamocortical system of neurons has been postulated as a mechanism, but it is uncertain whether the disinhibited motor activity is then expressed through corticospinal or reticulospinal pathways. For example, pentylentetrazol (Metrazol) injections evoke myoclonus in the limbs of animals, and the myoclonus persists after transection of corticospinal and other descending tracts until the lower brainstem (medullary reticular) structures are destroyed.

PATHOLOGIC STARTLE SYNDROMES

To some degree, everyone startles or jumps in reaction to a totally unanticipated, potentially threatening stimulus. This normal startle reflex is probably a protective reaction, being seen also in animals, and its purpose seemingly is to prepare the organism for escape. By pathologic startle we refer to a greatly exaggerated startle reflex and to a group of other stimulus-induced disorders of which startle is a predominant part. In most ways, startle cannot be separated from myoclonus (simplex) except for its generalized nature and a striking evocation by various stimuli. Any stimulus—most often an auditory one but also a flash of light, a tap on the neck, back, or nose, or even the presence of someone behind the patient—can normally evince a sudden contraction of the orbicularis, neck, and spinal musculature and even the legs. However, in the abnormal startle response that occurs in the diseases discussed below, the contraction is of greater amplitude and is more widespread, with less tendency to habituate. There may be a jump and occasionally an involuntary shout and fall to the ground.

Aside from exaggerated forms of the normal startle reflex, the commonest isolated syndrome is so-called startle disease, also referred to as hyperreflexia or hyperreflexia (see Gastaut and Villeneuve). This is a familial disease (e.g., the “jumping Frenchmen of Maine,” and others,

as described further on). The subject has been reviewed by Wilkins and colleagues and by Ryan and associates. The most common mutation is in the 1-subunit of the inhibitory glycine receptor GLRA1 (Shiang et al) but other glycine receptor related genes have been implicated in other cases.

As pointed out by Suhren and associates and by Kurczynski, the condition is transmitted in some families as an autosomal dominant trait. In the proband described by Kurczynski, affected infants were persistently hyper-tonic and hyperreflexic (up to 2 to 4 years of age) and had nocturnal and sometimes diurnal generalized myoclonic jerks, all of which subsided with maturation.

Later in life, excessive startle must be distinguished from epileptic seizures, which may begin with a startle or massive myoclonic jerk (startle epilepsy) and from the multiple tic disorder, Gilles de la Tourette syndrome, of which startle may be a prominent manifestation (Chap. 4). With idiopathic startle disease, even with a fall, there is no loss of consciousness, and the manifestations of tic and other neurologic abnormalities are absent.

An auditory startle response may be a manifestation of other neurologic diseases. It is a prominent feature of Tay-Sachs disease, SSPE, and of some cases of the “stiff-man syndrome.” Auditory, visual, and somatic startle reactions are also conspicuous in some of the lipid storage diseases and, as mentioned, in Creutzfeldt-Jakob disease.

The mechanism of the startle response has been a matter of speculation. In animals, the origin of the phenomenon has been localized in the pontine reticular nuclei, with transmission to the lower brainstem and spinal motor neurons via the reticulospinal tracts. During the startle, the EEG may show a vertex or frontal spike–slow-wave complex, followed by a general desynchronization of the cortical rhythms; between startles the EEG is normal. Some authors have postulated a disinhibition of certain brainstem centers. Others, on the basis of testing by somatosensory evoked potentials, have suggested that hyperactive long-loop reflexes constitute the physiologic basis of startle disease (Markand et al). Wilkins and coworkers consider hyperreflexia to be an independent phenomenon (different from the normal startle reflex) and to fall within the spectrum of stimulus-sensitive myoclonic disorders. Presumably, the altered glycine receptor in startle disease is the source of some form of hyperexcitability in one or another of the motor or reticular alerting systems.

The nature of the phenomenon displayed by the “jumping Frenchmen of Maine” has been disputed. The syndrome was described originally by James Beard, in 1868 among small pockets of French-speaking lumberjacks in northern Maine. The subjects displayed a greatly exaggerated response to minimal stimuli, to which there was no adaptation. The reaction consisted of jumping, raising the arms, screaming, and flailing of limbs, sometimes with echolalia, echopraxia, and a forced obedience to commands, even if this entailed a risk of serious injury. A similar syndrome in Malaysia and Indonesia is known as *latah* and in Siberia as *myriachit*. This syndrome has been framed in psychologic terms as conditioned responses (Saint-Hilaire et al) or as culturally determined behavior (Simons). Possibly some of the complex

secondary phenomena can be explained in this way, but the stereotyped onset with an uncontrollable startle and the familial occurrence in our view attest to a clear biologic basis for all these syndromes.

Treatment

Clonazepam controls the startle disorders to varying degrees. Levetiracetam has reportedly been helpful in some patients. Also, the act of flexing the neck and bringing the arms close to the torso may reduce the intensity of an attack (Vigevano maneuver).

SPASMODIC TORTICOLLIS AND OTHER FOCAL DYSTONIAS

The focal or segmental dystonias, in contrast to the generalized dystonic disorders described in Chap. 4, are intermittent, brief or prolonged spasms or contractions of a group of adjacent muscles that places the body part in a forced and unnatural position. When limited to the neck muscles, the most common type of focal dystonia, the spasms may be more pronounced on one side, with rotation and partial extension of the head (idiopathic cervical dystonia, or torticollis), or the posterior or anterior neck muscles may be involved predominantly and the head becomes hyperextended (retrocollic spasm, or retrocollis) or inclined forward (procollic spasm, or anterocollis). Other dystonias restricted to craniocervical muscle groups are spasms of the orbicularis oculi, causing forced closure of the eyelids (blepharospasm) and contraction of the muscles of the mouth and jaw, which may cause forceful opening or closure of the jaw and retraction or pursing of the lips (oromandibular dystonia). With the latter condition, the tongue may undergo forceful involuntary protrusion; the throat and neck muscles may be thrown into violent spasm when the patient attempts to speak or the facial muscles may contract in a grimace; the laryngeal muscles may be involved, imparting a high-pitched, strained quality to the voice (spasmodic dysphonia). More often, spasmodic dysphonia (sometimes incorrectly termed “spastic” dysphonia) occurs as an isolated phenomenon (Chap. 23).

Of the large number of focal dystonias seen in the movement disorder clinic of Columbia Presbyterian Hospital, 44 percent were classified as torticollis, 26 percent as spasmodic dysphonia, 14 percent as blepharospasm, 10 percent as focal dystonia of the right hand and arm (writer’s cramp), and 3 percent as oromandibular dystonia.

These movement disorders are involuntary and cannot be inhibited, thereby differing from habit spasms or tics. At one time, torticollis was thought to be a type of psychological disorder but all now agree that it is a localized form of dystonia. As discussed in Chap. 4, it is characteristic of these spasms and of similar focal dystonias that occur in the hands or feet to display a simultaneous activation of agonist and antagonist muscles (co-contraction), to have a tendency for the spasm to spread to adjacent muscle groups that are not normally activated in the movement (overflow), and to include an

arrhythmic intermixed tremor; but these features tend not to be as prominent in most focal dystonias as in the generalized varieties (described in Chap. 4). The tremor in particular may cause difficulty in diagnosis if the slight degree of underlying dystonia is not appreciated by careful observation and by palpation of the involved muscles.

Any of the typical forms of restricted dystonia may represent a tardive dyskinesia; i.e., they complicate treatment with neuroleptic drugs (see further on in “Drug-Induced Tardive Dyskinesias” and “Treatment”). Also, restricted dystonias of the hand or foot often emerge as components of a number of degenerative diseases—Parkinson disease, corticobasal ganglionic degeneration, and progressive supranuclear palsy (all described in Chap. 39). These dystonias may also occur in metabolic diseases such as Wilson disease and nonwilsonian hepatolenticular degeneration. Rarely, a focal dystonia emerges transiently after a stroke that involves the striatopallidal system, mainly the internal segment of the pallidum or the thalamus, but the varied locations of these infarctions makes it difficult to draw conclusions about the mechanism of dystonia. Several such cases that fall into the category of symptomatic or secondary dystonias are described by Krystkowiak and colleagues and by Munchau and colleagues. Janavs and Aminoff have summarized several types that are caused by acquired systemic disorders, including hypoxia, infections such as AIDS, drugs, and autoantibodies, including from systemic lupus erythematosus.

The pathogenesis of the idiopathic focal dystonias is uncertain, although there is evidence that some of them, like the generalized dystonias, are genetically determined. Authoritative commentators, including Marsden, classed the apparently idiopathic adult-onset focal dystonias with the category of genetically determined generalized torsion dystonia. This view is based on several lines of evidence: the recognition that each of the focal dystonias may appear as an early component of generalized syndrome in children, the occurrence of focal and segmental dystonias in family members of these children, as well as a tendency of the dystonia in some adult patients to spread to other body parts. Perhaps the most compelling observation in this regard has been the finding that there are families in which the only manifestation of the DYT1 mutation (the gene associated with generalized torsion dystonia) is a late-onset writer’s cramp or other focal dystonia. Whether this explains most or even many of the cases of adult onset focal dystonia is unclear but it does emphasize the phenotypic variability associated with the DYT1 mutation. The genetics of primary torsion dystonia is more complex than portrayed here, and is reviewed in Chap. 39.

It is noteworthy that no consistent pathologic changes have been demonstrated in any of the idiopathic or genetically determined dystonias. Most physiologists cast the disorder in terms of reduced cortical inhibition of unwanted muscle contractions, as summarized by Berardelli and colleagues. Specific physiologic changes in the cortical areas that are pertinent to the dystonias associated with overuse of certain body parts (occupational dystonias) are described below.

Spasmodic Torticollis (Idiopathic Cervical Dystonia)

This, the most frequent form of restricted dystonia, is localized to the neck muscles. It usually begins in early to middle adult life (peak incidence in the fifth decade), is somewhat more common in women, as a subtle tilting or turning of the head and tends to worsen slowly (Fig. 6-3A). With the exception of the finding of DYT1 gene abnormality in a few patients, it is idiopathic. The quality of the neck and head movements varies; they may be deliberate and smooth or jerky but most often cause a persistent deviation of the head to one side. Sometimes brief bursts of myoclonic twitching or a slightly irregular, high-frequency tremor accompanies deviation of the head, possibly representing an effort to overcome the contraction of the neck muscles; however, the tremor tends to beat in the direction of the dystonic movement. At times the tremor is far more dominant than is the dystonia, causing difficulty in diagnosis. The spasms are often worse when the patient stands or walks and are characteristically reduced or abolished by a contactual stimulus, such as placing a hand on the chin or neck or exerting mild but steady counterpressure on the side of the deviation or sometimes on the opposite side, or bringing the occiput in contact with the back of a high chair. These maneuvers, termed *gestes*, become less effective as the disease progresses. In many cases, the spasms are reduced when the patient lies down. In chronic cases, as the dystonic position typically becomes increasingly fixed in position, the affected muscles undergo hypertrophy. Pain in the contracting muscles is a common complaint, especially if there is associated cervical arthropathy.

The most prominently affected muscles are the sternocleidomastoid, levator scapulae, and trapezius. EMG studies also show sustained or intermittent activity in the posterior cervical muscles on both sides of the neck. The levator spasm lifts the affected shoulder slightly, and tautness in this muscle is sometimes the earliest feature. As a general observation, we have been impressed with information gained from palpating the muscles of the neck and shoulder in order to establish which muscles are the predominant causes of the spasm and to direct treatment to them as noted further on. In most patients the spasms remain confined to the neck muscles and persist in unmodified form, but in some the spasms spread, involving muscles of the shoulder girdle and back or the face and limbs. The distinction between these patterns is not fundamental. About 15 percent of patients with torticollis also have oral, mandibular, or hand dystonia, 10 percent have blepharospasm, and a similarly small number have a family history of dystonia or tremor (Chan et al). As already noted, no neuropathologic changes have been found in the single case studies reported by Tarlov and by Zweig and colleagues.

Spasmodic torticollis is resistant to treatment with L-dopa and other antiparkinsonian agents, although occasionally they give slight relief. They are, however, effective in those few instances in which dystonia is a prelude to Parkinson disease. In a few of our patients

(four or five of several dozens), the condition disappeared without therapy, an occurrence observed in 10 to 20 percent in the series of Dauer et al. In their experience, remissions usually occurred during the first few years after onset in patients whose disease began relatively early in life; however, nearly all these patients relapsed within 5 years.

Treatment

The periodic (every 3 to 6 months) injection of small amounts of botulinum toxin directly into several sites in the affected muscles is by far the most effective form of treatment. The injections are best guided by palpation of muscles in spasm and by EMG analysis to determine which of the tonically contracted muscles are most responsible for the aberrant postures. All but 10 percent of patients with torticollis have had some degree of relief from symptoms with this treatment. Adverse effects (excessive weakness of injected muscles, local pain, and dysphagia—the latter from a systemic effect of the toxin) are usually mild and transitory. Five to 10 percent of patients eventually become resistant to repeated injections because of the development of neutralizing antibodies to the toxin (Dauer et al). Trihexyphenidyl or benzotropine, in high doses, may allow some amelioration but they are difficult to tolerate.

In the past decade, the use of deep brain stimulation has found some success in the treatment of idiopathic cervical dystonia. The internal segments of the globus pallidus and the subthalamic nuclei have been used as targets. This approach is certainly preferable to the former use of ablative lesions in these areas and in the thalamus. In the most severe cases and those refractory to treatment with botulinum toxin, a combined sectioning of the spinal accessory nerve and of the first three cervical motor roots bilaterally has been successful in reducing spasm of the muscles without totally paralyzing them. Considerable relief has been achieved for as long as 6 years in one-third to one-half of cases treated in this way (Krauss et al; Ford et al).

Blepharospasm

Patients in mid and late adult life, predominantly women, may present with the complaint of inability to keep their eyes open that is a manifestation of involuntary closure of the eyelids. Any attempt to look at a person or object is associated with a persistent tonic, symmetric spasm of the eyelids (see Fig. 6-3B). During conversation, the patient struggles to overcome the spasms and is distracted by them. All customary activities are hampered to a varying extent. Reading and watching television are impossible at some times but surprisingly easy at others. Jankovic and Orman in a survey of 250 such patients found that 75 percent progressed in severity over the years to the point, in about 15 percent of cases, of making the patients functionally blind. Some instances of blepharospasm are a component of the Meige syndrome that includes jaw spasms (see next section). Blepharospasm may also be a result of drug induced tardive dyskinesia.

One's first inclination is to think of this disorder as photophobia or a response to an ocular irritation, and, indeed, the patient may state that bright light is annoying (ocular inflammation, especially of the iris, may produce severe reflex blepharospasm). However, the spasms persist in dim light and even after anesthesia of the corneas. Extraocular movements are normal. Blepharospasm may occur as an isolated phenomenon, but just as often it is combined with oromandibular spasms and sometimes with spasmodic dysphonia, torticollis, and other dystonic fragments. With the exception of a depressive reaction in some patients, psychiatric symptoms are lacking, and the use of psychotherapy, biofeedback, acupuncture, behavior modification therapy, and hypnosis has generally failed to cure the spasms. No neuropathologic lesion or neurochemical profile has been established in any of these disorders (Marsden et al; see also Hallett). A genetic basis is possible although few cases seem to be inherited.

Treatment

The most effective treatment consists of the injection of botulinum toxin into several sites in the orbicularis oculi and adjacent facial muscles. The benefit lasts for 3 to 6 months and repeated cycles of treatment are usually required. There appear to be few adverse systemic effects because of the low doses used. In the treatment of blepharospasm, a variety of antiparkinsonian, anticholinergic, and tranquilizing medications may be tried, but one should not be optimistic about the chances of success. A few of our patients have had temporary and partial relief from L-dopa and we have found it useful to conduct a brief trial in most patients. Sometimes the blepharospasm disappears spontaneously (in 13 percent of the cases in the series of Jankovic and Orman). Thermolytic destruction of part of the fibers in the branches of the facial nerves that innervate the orbicularis oculi muscles is reserved for the most resistant and disabling cases.

Other Causes of Blepharospasm

There are several clinical settings other than the one described above in which blepharospasm or a condition that simulates it, may be observed. In the days following cerebral infarction or hemorrhage, the stimulus of lifting the patient's eyelids may lead to strong involuntary closure of the lids. Reflex blepharospasm, as Fisher has called this phenomenon, takes liberty with the term as it more in the character of an apraxia of opening of the lids. It is more commonly associated with a left than a right hemiplegia. A homolateral blepharospasm has also been observed with a small thalamomesencephalic infarct. In patients with Parkinson disease, progressive supranuclear palsy, or Wilson disease and with other lesions in the rostral brainstem, light closure of the eyelids may induce blepharospasm and an inability to open the eyelids voluntarily.

We have seen an instance of blepharospasm as part of paraneoplastic midbrain encephalitis, and there have been several reports of it with autoimmune disease such as systemic lupus but the mechanism in these cases is as obscure as for the idiopathic variety. Also among our patients have been two with myasthenia gravis and

blepharospasm of the type described by Roberts and colleagues, but we have been unable to ascertain if this represented a second disturbance or simply an exaggerated response to keeping the lids open. Finally, eye closure with fluttering of the lids in patients with a high degree of suggestibility is usually indicative of a psychological disorder. Blepharospasm induced by pain from ocular conditions such as iritis and rosacea of the eyelids has already been mentioned.

Lingual, Facial, and Oromandibular Spasms

These special varieties of involuntary movements also appear in later adult life, with a peak age of onset in the sixth decade. Women are affected more frequently than men. The most common type is characterized by forceful opening of the jaw, retraction of the lips, spasm of the platysma, and protrusion of the tongue; or the jaw may be clamped shut and the lips may purse (Fig. 6-3B). Other patterns include lateral jaw deviation and bruxism. Common terms for this condition are Meige syndrome, after the French neurologist who gave an early description of it, and Brueghel syndrome, because of the similarity of the grotesque grimace to that of a subject in a Brueghel painting called *De Gaper*. Difficulty in speaking and swallowing (spastic or spasmodic dysphonia) and blepharospasm are also frequently conjoined, and occasionally patients with these disorders develop torticollis or dystonia of the trunk and limbs. A number have tremor of affected muscles or of the hands as well. All these prolonged, forceful spasms of facial, tongue, and neck muscles have followed the administration of phenothiazine and butyrophenone drugs. More often, however, the dyskinetic disorder induced by neuroleptics is somewhat different, consisting of choreoathetotic chewing, lip smacking, and licking movements (tardive orofacial dyskinesia, rabbit-mouth syndrome; see later).

Very few cases of the Meige syndrome have been studied neuropathologically. In most of them no lesions were found. In one patient there were foci of neuronal loss in the striatum (Altrocchi and Forno); another patient showed a loss of nerve cells and the presence of Lewy bodies in the substantia nigra and related nuclei (Kulisevsky et al); both are of uncertain significance.

A form of focal dystonia that affects only the jaw muscles has been described (masticatory spasm of Romberg); a similar dystonia may be a component of orofacial and generalized dystonias. In the cases described by Thompson and colleagues, the problem began with brief periods of spasm of the pterygoid or masseter muscle on one side. Early on, the differential diagnosis includes bruxism, hemifacial spasm, the odd rhythmic jaw movements associated with Whipple disease, and tetanus. As the illness progresses, forced opening of the mouth and lateral deviation of the jaw may last for days and adventitious lingual movements may be added. A form that occurs with hemifacial atrophy has been described by Kaufman. An intermittent spasm that is confined to one side of the face (hemifacial spasm) is not, strictly speaking, a dystonia and is considered with disorders of the facial nerve in Chap. 47.

Treatment

As with the other focal and regional dystonias, much greater success has been obtained with injections of botulinum toxin into the masseter, temporal, and medial pterygoid muscles. High doses of benzotropine and related anticholinergic drugs may be helpful, but are not as good as botulinum toxin treatment. Many other drugs have been used in the treatment of these craniocervical spasms, but none has effected a cure.

Writer's Cramp, Musician's Spasm, and Other Task-Specific Dystonias

Occupational cramps or spasms are included here because the prevailing opinion is that they are an acquired form of restricted or focal "task-specific" dystonias. Men and women are equally affected, most often between the ages of 20 and 50 years. In the most common form, writer's cramp, the patient observes, upon attempting to write, that all the muscles of the thumb and fingers either go into spasm or are inhibited by a feeling of stiffness and pain or hampered in some other inexplicable way. The spasm may be painful and can spread into the forearm or even the upper arm and shoulder. Sometimes the spasm fragments into a tremor that interferes with the execution of fluid, curvilinear movements. Immediately upon cessation of writing, the spasm disappears. At all other times and in the execution of grosser movements, the hand is normal, and there are no other neurologic abnormalities. Many patients learn to write in new ways or to use the other hand, though that, too, may become involved. A few of our younger patients have developed spasmodic torticollis at a later date.

The performance of other highly skilled motor acts, such as playing the piano or fingering the violin, may acquire a similar highly task-dependent spasm ("musician's cramp", now commonly called "musician's dystonia") or in the past, telegrapher's palsy. The "loss of lip" in trombonists and other instrumentalists represents an analogous phenomenon, seen only in experienced musicians. In each case a delicate motor skill, perfected by years of practice and performed almost automatically, suddenly comes to require a conscious and labored effort for its execution. Discrete movements are impaired by a spreading recruitment of unneeded muscles (intention spasm). Once developed, the disability persists in varying degrees of severity, even after long periods of inactivity of the affected part.

In monkeys, Byl and colleagues found that sustained, rapid, and repetitive highly stereotypical movements greatly expand the area of cortical representation of sensory information from the hand. These authors hypothesized that degradation of sensory feedback to the motor cortex was responsible for excessive and persistent motor activity, including dystonia. A similar enlargement of the area of cortical response to magnetic stimulation has also been found by a number of investigators in patients with writer's cramp and the volume of gray matter was decreased in the sensorimotor

cortex, thalamus, and cerebellum corresponding to the affected hand in the report by Delmaire and coworkers. Berardelli et al have reviewed other theories pertaining to the physiology of the focal dystonias.

Treatment

A high degree of success has been obtained by injections of botulinum toxin into specifically involved muscles, such as those of the hand and forearm in cases of writer's cramp (Cohen et al; Rivest et al), and this is now the most widely used form of therapy. The best results are obtained by guiding the injection from both palpation and EMG detection of the specific muscles that are active in the dystonic posture.

Transcutaneous electrical stimulation (TENS) of the forearm in 20-minute sessions has a modest effect according to a study by Tinazzi and colleagues. It had been claimed that the patient can be helped by a deconditioning procedure that delivers an electric shock whenever the spasm occurs or by biofeedback, but these forms of treatment have not been rigorously tested and have been largely abandoned in favor of botulinum treatments.

Drug-Induced Tardive (Delayed) Dyskinesias (See also Chap. 43)

Dyskinesia is a broadly encompassing term that is applied to many hyperkinetic involuntary movements including those taking the conventional forms of dystonia, chorea, athetosis, and tremor and the less well-defined ones that are produced by L-dopa therapy in Parkinson disease. When modified by the adjective tardive, it refers specifically to movements induced by the use of neuroleptic drugs, often, but not always phenothiazines, which are delayed in onset from the initiation of drug therapy and persist after the drugs are withdrawn. These movements are distinguished from acute dystonic reactions that occur in the first few days of exposure to medications, are aborted by anticholinergic drugs, and do not persist (see Chap. 53).

Tardive dyskinesias are intermittent or persistent and not subject to the will of the patient. The facial, lingual, eyelid, and bulbar muscles are most often involved but neck, shoulder, and spine muscles with arching of the back may be implicated in individual cases as noted below. There may be added blepharospasm and truncal, hand, or neck movements and akathisia of the legs, but these are not nearly so prominent as the orofacial and lingual dyskinesias.

Longer exposure is more likely to cause the movements. If the drug is discontinued immediately after the movements appear, the problem may not persist. The problem is easily recognized and familiar to all physicians who treat psychiatric patients. Oromandibular spasm and blepharospasm (Meige syndrome) and Huntington disease may cause difficulty in diagnosis.

In addition to the typical neuroleptic drugs, less familiar ones such as metoclopramide, pimozide, amoxapine, and clebopride, some of which are used for disorders other than psychosis, and newer agents such

as risperidone may also be causative. Less often, the movements arise soon after cessation of one of these same drugs.

There are a number of other drug-induced tardive movement syndromes, mainly varieties of dystonias, some of which have been mentioned earlier, and akathisia (see further on). Often they begin focally in the neck and spread over time to the limbs. One highly characteristic pattern combines retrocollis, backwards arching of the trunk, internal rotation of the arms, extension of the elbows, and flexion of the wrists simulating an opisthotonic posture. Other patients may have both orofacial and cervical dyskinesias. Many patients report that the dystonia abates during walking and other activities, quite unlike idiopathic torsion dystonia. These drug-induced dyskinesias are viewed as the result of changes in the concentration of dopamine receptors, five of which are currently known, as discussed in Chap. 4. Blockade and subsequent unmasking of the D2 receptor have been specifically linked to the development of the tardive syndromes.

Treatment

Little has been found to be consistently effective. If the movements follow withdrawal of one of the offending drugs, reinstatement of the medication in small doses often reduces the dyskinesias but may have the undesired side effects of causing parkinsonism and drowsiness. For this reason most clinicians who are experienced in this field avoid using the offending drugs if possible and choose to use the newer atypical neuroleptic drugs for the treatment of the underlying psychiatric condition. The newer "atypical" neuroleptic drugs have less of a propensity to cause tardive dyskinesia. The movements tend to lessen over a period of months or years and mild cases abate on their own or leave little residual effect; rarely have the symptoms worsened.

Dopamine and noradrenergic-depleting drugs such as reserpine and tetrabenazine have also been successful if used carefully but the more effective of the two, tetrabenazine, is difficult to obtain in the U.S. The dystonias also respond to anticholinergic drugs (trihexyphenidyl 2.5 mg once or twice daily, increased by small increments weekly up to 12.5 mg) if high enough doses can be tolerated.

Further discussion of the side effects of the antipsychosis drugs is found in Chaps. 43 and 53.

TICS AND HABIT SPASMS

When idle, adults often display a wide variety of fidgeting types of small amplitude movement, gestures, and mannerisms. They are slower and more complex than tics and spasms. Others, throughout their lives are given to odder and more intrusive but benign habitual movements. These range from simple, highly idiosyncratic mannerisms (e.g., of the lips and tongue) to repetitive actions such as sniffing, clearing the throat, protruding the chin, or blinking whenever these individuals become tense. Stereotypy and irresistibility are the main identifying features of these phenomena. The patient admits

to making the movements and feels compelled to do so in order to relieve perceived tension. Such movements can be suppressed for a short time by an effort of will, but they reappear as soon as the subject's attention is diverted. In certain cases the tics become so ingrained that the person is unaware of them and seems unable to control them. An interesting feature of many tics is that they correspond to coordinated acts that normally serve some purpose to the organism. It is only their incessant repetition when uncalled for that marks them as habit spasms or tics. The condition varies widely in its expression from a single isolated movement (e.g., blinking, sniffing, throat clearing, tongue clicking, or stretching the neck) to a complex of movements.

Children between 5 and 10 years of age are especially likely to develop these habit spasms. These consist of blinking, hitching up one shoulder, sniffing, throat clearing, jerking the head or eyes to one side, grimacing, etc. If ignored, such spasms seldom persist for longer than a few weeks or months and tend to diminish on their own. In adults, relief of nervous tension by sedative or tranquilizing drugs may be helpful, but the disposition to tics persists. A putative relationship to streptococcal infection is discussed below.

Special types of rocking, head bobbing, hand waving (in autism) or hand wringing (typical of Rett syndrome), and other movements, particularly self-stimulating movements, are disorders of motility unique to the developmentally delayed child or adult. These "rhythmic" have no known pathologic anatomy in the basal ganglia or elsewhere in the brain. Apparently they represent a persistence of some of the rhythmic, repetitive movements of normal infants. In some cases of impaired vision and photic epilepsy, eye rubbing or moving the fingers rhythmically across the field of vision is observed, especially again in developmentally delayed children.

Gilles de la Tourette Syndrome

Multiple tics—sniffing, snorting, involuntary vocalization, and troublesome compulsive and aggressive impulses—constitute the rarest and most severe tic syndrome—Gilles de la Tourette syndrome (his complete surname). The problem begins in childhood, in boys three times more often than in girls, usually as a simple tic. As the condition progresses, new tics are added to the repertoire. It is the multiplicity of tics and the combination of motor and vocal tics that distinguish the disorder from the more benign, restricted tic disorders.

Vocal tics, usually loud and irritating in pitch, are characteristic. Some patients display repetitive and annoying motor behavior, such as jumping, squatting, or turning in a circle. Other common types of repetitive behavior include the touching of other persons and repeating one's own words (palilalia) and the words or movements of others. Explosive and involuntary cursing and the compulsive utterance of obscenities (coprolalia) are the most dramatic manifestations. Interestingly, the latter phenomena are uncommon in Japanese patients, whose decorous culture and language contain few obscenities. The full repertoire of tics and compulsions comprised

by Gilles de la Tourette syndrome has been described by Tolosa and Bayes and in the reviews by Jankovic and by Leckman, which are recommended.

Stone and Jankovic have noted the occurrence of persistent blepharospasm, torticollis, and other dystonic fragments in a small number of patients. Isometric contractions of isolated muscle groups (tonic tics) may also occur. As in other tic disorders, there is a premonitory sensation of tightness, discomfort or paresthesia, or a psychic sensation or urge that is relieved by the movement. A fair proportion stutter or display a mild dysfluency of speech. So-called soft neurologic signs are noted in half of the patients. Feinberg and associates have described four patients with arrhythmic myoclonus and vocalization, but it is not clear whether these symptoms represent an unusual variant of the disease or a new syndrome. A degree of cyclicity of symptoms has been noted by several authors; tics tend to happen in groups over minutes or hours and they are clustered over weeks and months. This gives the appearance of a waxing and waning process.

The course of the illness is unpredictable. In half of adolescents the tics subside spontaneously by early adulthood and those that persist become milder with time. Others undergo long remissions only to have tics recur, but in other patients the motor disorder persists throughout life. This variability emphasizes the difficulty in separating transient habit spasms from the Gilles de la Tourette chronic multiple tic syndrome. Isolated and mild but lifelong motor tics probably represent a variant of Tourette syndrome insofar as they display the same predominantly male heredofamilial pattern and similar responses to medication.

An attention-deficit hyperactivity disorder (see Chap. 28), obsessive-compulsive traits, or both are said to be evident at some time in the course of the illness, and these interfere to a greater degree than do the tics with progress in school. Poor control of temper, impulsiveness, self-injurious behavior, and certain sociopathic traits are seen in a few but by no means all affected children. Evidence of "organic" impairment by psychologic tests was found in 40 to 60 percent of patients in the series reported by Shapiro and colleagues, but intelligence did not deteriorate. Nonspecific abnormalities of the EEG have occurred in more than half of the patients but are not consistent enough to be considered a feature of the disease.

In one-third of the cases reported by Shapiro and colleagues, isolated tics were observed in other members of the family. Several other studies have reported a familial clustering of cases in which the pattern of transmission appears to be autosomal dominant with incomplete penetrance (Pauls and Leckman) but this has been disputed and several predisposing genes have been found by linkage analysis. In any biologic explanation, the marked predominance of males must be accounted for. At the moment, Tourette syndrome cannot be attributed to a single genetic locus. Nonetheless, support for a primary genetic nature of Tourette syndrome derives from twin studies, which have revealed higher concordance rates in monozygotic twin pairs than in dizygotic pairs. An ethnic bias (Ashkenazi Jews) has been reported, ranging from 19 to 62 percent in several series, but this has not been borne

out in equally large series in areas that do not have a high proportion of this ethnic population (Lees et al).

As to causation, little is known. There is no consistent association with infection, trauma, or other disease except the putative connection to streptococcal infections discussed further on. Hyperactive children who have been treated with stimulants appear to be at increased risk of developing or exacerbating tics (Price et al) but a causal relationship has not been established beyond doubt (see comments regarding treatment below). MRI has shown no uniform abnormalities; functional imaging has demonstrated numerous but inconsistent abnormalities. Histopathologic changes have not been discerned in the few brains examined by the usual methods. However, Singer and coworkers (1991), who analyzed pre- and postsynaptic dopamine markers in postmortem striatal tissue, found a significant alteration of dopamine uptake mechanisms; more recently, Wolf and colleagues have found that differences in D2 dopamine receptor binding in the head of the caudate nucleus reflected differences in the phenotypic severity of Gilles de la Tourette syndrome. These observations, coupled with the facts that L-dopa exacerbates the symptoms of the syndrome and that haloperidol, which blocks dopamine (particularly D2) receptors, is an effective treatment, support a dopaminergic abnormality in the basal ganglia, more specifically in the caudate. In this respect, instances of compulsive behavior in relation to lesions in the head of the caudate nucleus and its projections from orbitofrontal and cingulate cortices may be pertinent.

PANDAS syndrome

Using the model of Sydenham chorea, a recent line of investigation has implicated streptococcal infection in the genesis of abruptly appearing Tourette syndrome and of less-generalized tics in children. This association has been extended by some authors to explain obsessive-compulsive behavior of sudden and unexplained onset. These putative poststreptococcal disorders were summarized by Swedo and colleagues under the acronym PANDAS (pediatric autoimmune neuropsychiatric disorders with streptococcal infection). In a few cases there has been a relapsing course that is similar to that seen in Sydenham chorea. Two health database studies have suggested a modest association between tic disorder, obsessive-compulsive disorder and streptococcal infection. These observations taken together are intriguing but not confirmed and several groups have been unable to differentiate patients with PANDAS and Gilles de la Tourette syndrome from controls on the basis of epidemiologic factors or serum autoantibodies to streptococcus (Singer et al, 2005 and Schrag and coworkers).

Treatment

Two classes of drugs are used in treatment. The alpha2-adrenergic agonists clonidine and guanfacine have been useful in several studies, but not in others. These are not as potent as treatment with neuroleptic drugs, but their side effects are far less severe and they are recommended as the first treatment. The newer drug, guanfacine has the advantage over clonidine of daily dosing and less sedating effect.

The initial dose is 0.5 to 1 mg given at bedtime and gradually increased as needed to a total dose of 4 mg. Clonidine is started as a bedtime dose of 0.05 mg and increased every several days by 0.05 mg until a total dose of about 0.1 mg three times daily; guanfacine is given as 1 mg at bedtime and increased by 1 mg monthly, up to 3 mg if needed. The neuroleptics haloperidol, pimozide, sulpiride, and tiapride have proved to be effective therapeutic agents but should be used only in severely affected patients and usually after the adrenergic agents have been tried. Haloperidol is instituted in small doses (0.25 mg initially, increasing the dosage gradually to 2 to 10 mg daily). The addition of bupropion mesylate (0.5 mg daily) at the outset of treatment may help to prevent the adverse motor effects of haloperidol. Pimozide, which has a more specific antidopaminergic action than haloperidol, may be more effective than haloperidol; it should be given in small amounts (0.5 mg daily) to begin with and increased gradually to 8 to 9 mg daily. The atypical neuroleptics, such as risperidone, have also been used with some success. The potent agent tetrabenazine, a drug that depletes monoamines and blocks dopamine receptors, may be useful if high doses can be tolerated. Further details of the use of these drugs can be found in the review by Leckman.

Another interesting approach has been to inject botulinum toxin in muscles affected by prominent focal tics, including the vocal ones as described by Scott and colleagues; curiously, this treatment is said to relieve the premonitory sensory urge. Kurlan and associates noted a lessening of tics after treatment with naltrexone, 50 mg daily. According to a trial conducted by the Tourette's Syndrome Study Group, the hyperactivity component of the Tourette syndrome can be treated safely with methylphenidate or clonidine without fear of worsening the tics. Deep brain stimulation shows promise in the treatment of drug resistant cases.

Isolated or limited motor tics in males, generally an inherited trait, is often greatly aided by clonazepam.

Akathisia

This term was coined by Haskovec in 1904 to describe an inner feeling of restlessness, an inability to sit still, and a compulsion to move about. When sitting, the patient constantly shifts his body and legs, crosses and uncrosses his legs, and swings the free leg. Running in place and persistent pacing are also characteristic. This abnormality of movement is most prominent in the lower extremities and may not be accompanied, at least in mild forms of akathisia, by perceptible rigidity or other neurologic abnormalities. In its advanced form, patients complain of difficulty in concentration, distracted, no doubt, by the constant urge to move.

First noted in patients with Parkinson disease and what is now known to be Alzheimer disease, akathisia is now observed most often in patients receiving neuroleptic drugs (Chap. 43). However, this disorder may be observed in psychiatric patients who are receiving no medication and in some unmedicated patients with Parkinson disease; it can also be induced in normal individuals by the administration of neuroleptic drugs or L-dopa.

The main diagnostic considerations are an agitated depression, particularly in patients already on neuroleptic medications, and the "restless legs" syndrome—a sleep disorder that may be evident during wakefulness in severe cases (Chap. 19). Patients with the restless leg syndrome describe a crawling or drawing sensation in the legs rather than an inner restlessness, although both disorders create an irresistible desire for movement. At times these distinctions are blurred. Many of the medications used for the restless legs syndrome, such as clonazepam, may be tried, or treatment can be directed to the akathisia by selecting a less potent neuroleptic (if it is the suspected cause) or by using an anticholinergic medication, amantadine, or—perhaps the more effective and best tolerated—beta-adrenergic-blocking drugs.

Disorders of Stance and Gait

Certain disorders of motor and sensory function manifest themselves most clearly as impairments of upright stance and locomotion; their evaluation depends on knowledge of the neural mechanisms underlying the peculiarly human function of standing and bipedal walking. The analysis of stance, carriage, and gait is a rewarding exercise; with some experience, the examiner can sometimes reach a neurologic diagnosis merely by noting the manner in which the patient enters the office. Considering the frequency of falls that result from gait disorders and their consequences, such as hip fracture, and the resultant need for hospital and nursing home care, this is an important subject for all physicians. The substantial dimensions of the social and economic problem of falls and the elderly have been described by Tinetti and Williams.

NORMAL GAIT

Obviously, gait varies considerably from one person to another and it is a commonplace observation that a person may be identified by the sound of his footsteps, notably the pace and the lightness or heaviness of tread. The manner of walking and the carriage of the body may even provide clues to an individual's personality and occupation. Sherlock Holmes expressed pride in his talent for reading such clues. It is said that Charcot could often make the correct diagnosis, even before seeing the patient, based on the sound of patient walking down the hallway on the way to the examining room. Furthermore, the gaits of men and women differ, a woman's steps being quicker and shorter. The changes in stance and gait that accompany aging—the slightly stooped posture and slow, stiff tread as described in Chap. 29, on aging—are so familiar that they are not perceived as abnormalities.

The normal gait seldom attracts attention but it should be observed with care if slight deviations from normal are to be appreciated. The body is erect, the head is straight, and the arms hang loosely and gracefully at the sides, each moving rhythmically forward with the opposite leg. The feet are slightly externally rotated, the steps are approximately equal, and the medial malleoli almost touch as each foot passes the other. The medial edges of the heels, as they strike the ground with each step, lie almost along a straight line. As each leg moves

forward, there is coordinated flexion of the hip and knee, dorsiflexion of the foot, and a barely perceptible elevation of the hip, so that the foot clears the ground. Also, with each step, the thorax advances slightly on the side opposite the swinging lower limb. The heel strikes the ground first, and inspection of the shoes will show that this part is most subject to wear.

The normal gait cycle, defined as the period between successive points at which the heel of the same foot strikes the ground, is illustrated in Fig. 7-1, based on the studies of Murray and coworkers, and of Olsson. In this figure, the cycle is initiated by the heel strike of the right foot. The stance phase, during which the foot is in contact with the ground, occupies 60 to 65 percent of the cycle. The swing phase begins when the right toes leave the ground. For 20 to 25 percent of the walking cycle, both feet are in contact with the ground (double-limb support). In later life, when the steps shorten and the cadence (the rhythm and number of steps per minute) decreases, the proportion of double-limb support increases (see further on). Surface electromyograms show an alternating pattern of activity in the legs, predominating in the flexors during the swing phase and in the extensors during the stance phase.

When analyzed in greater detail, the requirements for locomotion in an upright, bipedal position may be reduced to the following elements: (1) antigravity support of the body, (2) stepping, (3) the maintenance of equilibrium, and (4) a means of propulsion. Locomotion is impaired in the course of neurologic disease when one or more of these mechanical principles are prevented from operating normally.

The muscles of greatest importance in maintaining the erect posture are the erector spinae and the extensors of the hips and knees. The upright support of the body is provided by righting and antigravity reflexes, which allow a person to arise from a lying or sitting position to an upright bipedal stance and to maintain firm extension of the knees, hips, and back, modifiable by the position of the head and neck. These postural reflexes depend on the afferent vestibular, somatosensory (proprioceptive and tactile), and visual impulses, which are integrated in the spinal cord, brainstem, and basal ganglia. Transection of the neuraxis between the red and vestibular nuclei leads to exaggeration of these antigravity reflexes—decerebrate rigidity.

Figure 7-1. The normal gait cycle, based on the studies of Olsson and of Murray et al. See text for details.

Stepping, the second element, is a basic movement pattern present at birth and integrated at the spinal mid-brain and diencephalic levels. It is elicited by contact of the sole with a flat surface and a shifting of the center of gravity—first laterally onto one foot, allowing the other to be raised, and then forward, allowing the body to move onto the advancing foot. Rhythmic stepping movements can be initiated and sustained in decerebrate or “spinal” cats and dogs. This is accomplished through the activity of interneurons that are organized as rhythmic “locomotor generators,” akin to the pattern generators that permit the rhythmic movement of wings or fins. There is no clear evidence for a similar system of locomotor control in monkeys or humans, in whom the spinal mechanisms for walking cannot function independently of vaguely organized higher command centers. The latter are located in the posterior subthalamic region, caudal midbrain tegmentum, and pontine reticular formation; they control the spinal gait mechanisms through the reticulospinal, vestibulospinal, and tectospinal pathways in the ventral cord (see Eidelberg and colleagues and Lawrence and Kuypers). In the human, the brainstem locomotor regions are also activated by frontal cortical areas.

The frontal lobe is absolutely integral to initiating and engaging the gait cycle. The presence of a true “gait center” in the cerebrum is uncertain, although frontal lesions can devastate gait as discussed further on. Most often, it has been the supplementary motor areas relating to the legs (superior frontal gyri on both sides) that are implicated as pointed out by Della Sala and colleagues but Benson and coworkers have emphasized that the frontal periventricular areas are disproportionately involved when subcortical vascular disease compromises walking. The gait disorder of frontal lobe disease has a number of special characteristics including difficulty

with starting to walk, short steps, widened base, difficulty lifting the feet off the floor (the magnetic gait) and a tendency to fall backwards (retropulsion). In all likelihood, the medial frontal lobes embody automatic programs for walking that are intimately tied to adjacent networks in the striatum.

Equilibrium involves the maintenance of balance in relation to gravity and to the direction of movement in order to retain a vertical posture. The center of gravity during the continuously unstable equilibrium that prevails in walking must shift within narrow limits from side to side and forward as the weight is borne first on one foot, then on the other. This is accomplished through the activity of highly sensitive postural and righting reflexes that have both peripheral (stretch reflexes) and central (vestibulocerebellar reflexes) components. These reflexes are activated within 100 ms of each shift in the support surface and require reliable afferent information from the visual, vestibular, and proprioceptive systems.

Propulsion is provided by leaning forward and slightly to one side and permitting the body to fall a certain distance before being checked by the support of the leg. Here, both forward and alternating lateral movements must occur. But in running, where at one moment both feet are off the ground, a forward drive or thrust by the trailing leg is also required.

ABNORMAL GAITS

General Comments

Because normal body posture and locomotion require intact vestibular function, proprioception, and vision (we see where we are going and adjust our steps), the

effects of deficits in these senses are worth noting. A blind person—or a normal one who is blindfolded or walks in the dark—moves cautiously, with arms slightly forward to avoid collisions, and shortens his step slightly on a smooth surface; with shortening of the step, there is less rocking of the body and the gait is unnaturally stiff and cautious.

Patients with a chronic vestibulopathy show unsteadiness in standing and walking, often without widening their base, and an inability to descend stairs without holding onto the banister. They complain of a particular type of imbalance, usually with movement but at times when standing still—a sensation that may be likened to being on the deck of a rolling ship. Running and turning quickly are even more impaired, with lurching in all directions. The patient has great difficulty in focusing his vision on a fixed target when he is moving or on a moving target when he is either stationary or moving. When the body is in motion or the head is moved suddenly, objects in the environment may appear momentarily blurred or actually jiggle up and down or from side to side (oscillopsia). Driving a car or reading on a train is difficult or impossible; even when walking, the patient may need to stop in order to read a sign. These abnormalities indicate a loss of stabilization of ocular fixation by the vestibular system during body movements (the vestibular-ocular reflex, or VOR). An elderly person has difficulty compensating for these abnormalities. Proof that the gait of such persons with vestibulopathy is dependent on visual clues comes from their performance blindfolded or in the dark, when their unsteadiness and staggering increase to the point of falling. When standing with eyes closed, they sway more than normal but generally do not fall over (i.e., they do not have a Romberg sign, as described below). The diagnosis is confirmed by testing labyrinthine function (caloric and rotational testing, electronystagmography, and posture platform testing).

Chronic disorders of vestibular function in relation to gait disorders are most often the result of prolonged administration of aminoglycoside antibiotics or other toxic medications, which destroy the hair cells of the vestibular labyrinth. Vestibular suppressants, such as meclizine and similar medications, mostly anticholinergic and antihistaminic that are available over the counter, can lead to decreased function of the vestibular system, with a persistent gait disorder, if used for more than a few weeks. This also occurs in some patients in the late stages of Ménière disease and, infrequently, for no definable reason. The literature is replete with references to a “multimodal” gait disorder in the elderly that is the result of an ostensible aging of the vestibular organ, together with impaired proprioceptive function caused by distal neuropathy in the elderly, and impaired vision.

A loss of proprioception—as occurs in patients with severe large-fiber polyneuropathy, posterior nerve root lesions (e.g., tabes dorsalis, lumbosacral compression), or interruption of the posterior columns in the spinal cord (multiple sclerosis, vitamin B12 deficiency, spondylotic or tumor compression)—abolishes or seriously impairs the capacity for independent locomotion.

After years of training, such patients still have difficulty in initiating gait and in forward propulsion. As J. Purdon Martin illustrated, they hold their hands slightly in front of the body, bend the body and head forward, walk with a wide base and irregular, uneven steps, but still rock the body. If they are tilted to one side, they fail to compensate for their abnormal posture. If they fall, they cannot rise without help; they are sometimes unable to crawl or to get into an “all fours” posture. They have difficulty in getting up from a chair. When standing, if instructed to close their eyes, they sway markedly and fall (Romberg sign); this sign is the clearest indication that the origin of the problem is a loss of proprioceptive sensibility.

With lesions of the basal ganglia, both in monkeys and in humans, the posture of the body and the postural responses to perturbations in equilibrium are faulty. There is difficulty in taking the first step; once it is taken, and in extreme cases, the body pitches forward and a fall can be prevented only by catch-up stepping (propulsive festination). Similarly, a step backward may induce a series of quickening steps in that direction (retropulsive festination). Corrective righting reflexes are clearly faulty when the patient is pushed off balance (Denny-Brown). These abnormalities are elaborated further on, under “Parkinsonian and Festinating Gait.”

Pain in the hips or knees can lead to a disorder (antalgic gait) that can be challenging to distinguish from neurological causes of gait problems. Slowness of the swing phase and reduction in the amount of time spent with the painful limb in contact with the ground may be clues to recognizing rheumatological and orthopedic causes of a gait disorder.

Examination of the Patient with Abnormal Gait

When confronted with a disorder of gait, the examiner must observe the patient’s stance and the dominant positions of the legs, trunk, and arms, and their inter-relationship. It is good practice to watch patients as they walk into the examining room, when they are apt to walk more naturally than during the performance of commanded tasks. They should be asked to stand with feet together and head erect, with eyes open and then closed. A normal person can stand with feet together and eyes closed while moving the head from side to side, a test that blocks both visual and vestibular cues and induces certain compensatory trunk and leg movements that depend solely on proprioceptive afferent mechanisms (Ropper). As already mentioned, the Romberg sign—marked swaying or falling with the eyes closed but not with the eyes open—usually indicates a loss of postural sense, not of cerebellar function, although with vestibular or cerebellar disease there may be an exaggeration of swaying. Swaying due to nervousness may be overcome by asking the patient to touch the tip of his nose alternately with the forefinger of one hand and then the other.

Next, the patient should be asked to walk, noting in particular any hesitation in starting and negotiating

Table 7-1

FEATURES OF GAIT ABNORMALITIES

	CADENCE	STEP LENGTH	BASE	OTHER ASSOCIATED SIGNS
Cerebellar	Irregular	Slightly short	Wide	Erratic shifting of weight and step
Sensory ataxic (tabetic)	Normal	Short	Slightly wide	Excessive force in step resulting in stamping of feet; Romberg sign
Steppage	Normal	Normal	Normal	Overlifting and slapping of feet
Plegic	Slow	Short	Narrow	Circumduction and scraping of affected leg(s)
Dystonic	Slow	Normal	Erratic	Twisting athetoid movements interrupt walking
Parkinsonian-festinating	Slow until festination	Short	Normal	Quickening step, forward leaning, shuffling, may have trouble with gait initiation
Waddling-myopathic	Normal	Normal	Slightly wide	Overlifting of hip(s)
Toppling	Slow until fall	Short	Widened (protective)	Sudden loss of balance
Normal pressure hydrocephalus	Slow	Short	Slightly wide	Numerous problems with axial body movement
Frontal lobe	Slow	Greatly shortened	Slightly wide (protective)	Difficulty starting and stopping; tendency for feet to "stick" to floor
Aging and marche à petit pas	Slow	Slightly shortened	Slightly widened	Cautious, slight forward lean

turns, width of base, length of stride, foot clearance, arm swing, and cadence. A tendency to veer to one side, as occurs with unilateral cerebellar or vestibular disease, can be brought out by having the patient walk around a chair. When the affected side is toward the chair, the patient tends to walk into it; when it is away from the chair, there is a veering outward in ever-widening circles. More delicate tests of gait are walking a straight line heel to toe ("tandem walking test"), walking backward, and having the patient arise quickly from a chair, walk briskly, stop and turn suddenly, walk back, and sit down again. Turning the patient three full revolutions with eyes open, first right and then left, each time followed by asking the patient to walk naturally, allows the examiner to stress the vestibular apparatus and to compare the two sides. The patient affected by a vestibular or cerebellar process will veer to the side of a lesion. Marching in place with eyes closed (Unterberger, or Fukada stepping tests) also reveals a rotation in the yaw plane (rotation around the vertical axis), indicating an asymmetrical disorder in the plane of the horizontal semicircular ducts or their connections.

It is instructive to observe the patient's postural reaction to a sudden push or tug backward at the shoulders and forward or to the side. With postural instability of any type there is a delay or inadequacy of corrective actions. Finally, the patient may be asked to hop on one leg and to jog. If all these tests can be successfully executed, it may be assumed that any difficulty in locomotion is not because of impairment of a proprioceptive, labyrinthine-vestibular, basal ganglionic, or cerebellar mechanism. Detailed musculoskeletal and neurologic examination is then necessary to determine which of several other disturbances of function is responsible for the patient's disorder of gait.

The following types of abnormal gait (Table 7-1) are so distinctive that, with practice, they can be recognized at a glance and interpreted correctly.

Cerebellar Gait

The main features are a wide base (separation of legs), unsteadiness, irregularity of steps, and lateral veering. Steps are uncertain, some are shorter and others longer than intended, and the patient may compensate for these abnormalities by shortening his steps or even keeping both feet on the ground simultaneously, which creates the appearance of shuffling. Cerebellar gait is often referred to as "reeling" or "drunken," but these terms are not correct and are characteristic instead of intoxication and of certain types of labyrinthine disease, as explained further on.

With cerebellar ataxia, the unsteadiness and irregular swaying of the trunk are prominent when the patient arises from a chair or turns suddenly while walking and may be most evident when he has to stop walking abruptly and sit down; it may be necessary to grasp the chair for support. Cerebellar ataxia may be so severe that the patient cannot sit without swaying or assistance. If it is less severe, standing with feet together and head erect is difficult. In its mildest form, the ataxia is best demonstrated only by having the patient walk a line heel to toe; after a step or two, he loses his balance and finds it necessary to place one foot to the side to avoid falling.

As already emphasized, the patient with cerebellar ataxia who sways perceptibly when standing with feet together and eyes open will sway somewhat more with eyes closed. This slight increase in swaying may lead misattribution to a cerebellar sign of what is simply loss of proprioceptive input to the cerebellum. By contrast, removal of visual clues from a patient with proprioceptive loss causes

a marked increase in swaying or falling (the Romberg sign). Thus, the defect in cerebellar disease is primarily in the coordination of the sensory input from proprioceptive, labyrinthine, and visual information with reflex movements, particularly those that are required to make rapid adjustments to changes in posture and position. This integrative deficiency is also reflected in the stepping test, in which the patient is asked to march on the spot with eyes closed as already mentioned. Those with vestibular and sometimes unilateral cerebellar disease have difficulty remaining stable and have a tendency to turn to the left or right or to move forward (occasionally backward) after 5 or 10 steps.

Cerebellar abnormalities of stance and gait are usually accompanied by signs of cerebellar incoordination of the legs, but they need not be. The presence of the latter signs depends on involvement of the cerebellar hemispheres as distinct from the anterosuperior (vermian) midline structures that dominate in the control of gait as described in Chap. 5. If the cerebellar lesions are bilateral, there is often titubation (tremor) of the head and trunk.

Cerebellar gait is seen most commonly in patients with multiple sclerosis, cerebellar tumors (particularly those affecting the vermis—e.g., medulloblastoma), stroke (ischemic and hemorrhage) paraneoplastic cerebellar syndrome, and prominently, in the cerebellar degenerations. Walking without the support of a cane or the arm of a companion brings out a certain stiffness of the legs and firmness of the muscles. The latter abnormality may be analogous to positive supporting reactions observed in cats and dogs following ablation of the anterior vermis; such animals react to pressure on the foot pad with an extensor thrust of the leg.

Reeling Gait of Intoxication

This is characteristic of inebriation with alcohol, sedative drugs, and antiepileptic drugs. The drunken patient totters, reels, tips forward and then backward, appearing each moment to be on the verge of losing his balance and falling. Control over the trunk and legs are greatly impaired. The steps are irregular and uncertain. Such patients appear indifferent to the quality of their performance, but under certain circumstances they can momentarily correct the defect. As indicated above, the adjectives drunken and reeling are used frequently to describe the gait of cerebellar disease, but the similarities between them are only superficial. The severely intoxicated patient reels or sways in many different directions and seemingly makes little or no effort to correct the staggering by watching his legs or the ground, as occurs in cerebellar or sensory ataxia. Also, the variability of the drunken gait is noteworthy. Despite wide excursions of the body and deviation from the line of march, the drunken patient may, for short distances, be able to walk on a narrow base and maintain his balance. In contrast, the patient with cerebellar gait has great difficulty in correcting his balance if he sways or lurches too far to one side. Milder degrees of the drunken gait more closely resemble the gait disorder that follows loss of labyrinthine function (see earlier discussion).

Gait of Sensory Ataxia

This disorder is caused by an impairment of joint position or muscular kinesthetic sense resulting from interruption of afferent nerve fibers in the peripheral nerves, posterior roots, sensory ganglia, posterior columns of the spinal cords, or medial lemnisci, and occasionally from a lesion of both parietal lobes. Whatever the location of the lesion, its effect is to deprive the patient of knowledge of the position of his limbs and, more relevant to gait, to interfere with a large amount of afferent proprioceptive and related information that does not attain conscious perception. A sense of imbalance is usually present but these patients do not describe dizziness. They are aware that the trouble is in the legs and not in the head, that foot placement is awkward, and that the ability to recover quickly from a misstep is impaired. The resulting disorder is characterized by varying degrees of difficulty in standing and walking; in advanced cases, there is a complete failure of locomotion, although muscular power is retained.

The principal features of sensory-ataxic gait are the brusqueness of movement of the legs and stamping of the feet as the foot is forcibly brought down onto the floor (apparently to detect the location of the foot as a substitute for proprioception). The feet are placed far apart to correct the instability, and patients carefully watch both the ground and their legs. As they step out, their legs are flung abruptly forward and outward, in irregular steps of variable length and height. The body is held in a slightly flexed position, and some of the weight is supported on the cane that the severely ataxic patient usually carries. To use Ramsay Hunt's characterization, the patient with this gait disorder is recognized by his "stamp and stick." The most specific feature is that the ataxia is markedly exaggerated when the patient is deprived of visual cues, as in walking in the dark. Such patients, when asked to stand with feet together and eyes closed, show greatly increased swaying and usually, the fully expressed Romberg sign with falling off to one side. It is said that in cases of sensory ataxia, the shoes do not show wear in any one place because the entire sole strikes the ground at once. Examination usually discloses a loss of position sense in the feet and legs and usually of vibratory sense as well. The peripheral or central location of the sensory lesions can be further determined by the state of the tendon reflexes.

Formerly, a disordered gait of this type was observed most frequently with tabes dorsalis, hence the term tabetic gait; but it is also seen in Friedreich ataxia and related forms of spinocerebellar degeneration, subacute combined degeneration of the spinal cord (vitamin B12 deficiency), a large number of sensory polyneuropathies, and those cases of multiple sclerosis or compression of the spinal cord (spondylosis and meningioma are the common causes) in which the posterior columns are involved.

Steppage or Equine Gait (Foot-Drop Gait)

This gait pattern is caused by paralysis of the pretibial and peroneal muscles, with resultant inability to dorsiflex the foot (foot drop). The steps are regular and even, but

the advancing foot hangs with the toes pointing toward the ground. In its purest form it is the result of peroneal nerve or fifth lumbar root damage. Walking is accomplished by excessive flexion at the hip, the leg being lifted abnormally high in order for the foot to clear the ground. There is a slapping noise as the foot strikes the floor. Thus there is a superficial similarity to the tabetic gait, especially in cases of severe polyneuropathy, where the features of steppage and sensory ataxia may be combined. However, patients with steppage gait alone are not troubled by a perception of imbalance; they fall from tripping on carpet edges and curbstones.

Foot drop may be unilateral or bilateral and occurs in diseases that affect the peripheral nerves of the legs or motor neurons in the spinal cord, such as chronic acquired neuropathies (diabetic, inflammatory, toxic, and nutritional), Charcot-Marie-Tooth disease (peroneal muscular atrophy), progressive spinal muscular atrophy, and poliomyelitis. It may also be observed in certain types of muscular dystrophy in which the distal musculature of the limbs is involved.

A particular disorder of gait, also of peripheral origin and resembling steppage gait, may be observed in patients with painful dysesthesias of the soles of the feet. Because of the exquisite pain evoked by tactile stimulation of the feet, the patient treads gingerly, as though walking barefoot on hot sand or pavement, with the feet rotated in such a way as to limit contact with their most painful portions. The usual cause is one of the painful peripheral neuropathies (most often alcoholic-nutritional but also toxic and amyloid types), causalgia, or erythromelalgia.

Hemiplegic and Paraplegic (Spastic) Gaits

The patient with hemiplegia or hemiparesis holds the affected leg stiffly and does not flex it freely at the hip, knee, and ankle. The leg tends to rotate outward to describe a semicircle, first away from and then toward the trunk (circumduction). The foot scrapes the floor, contact being made by the toe and outer sole of the foot. One can recognize a spastic gait by the sound of slow, rhythmic scuffing of the foot and wearing of the medial toe of the shoe. The arm on the affected side is weak and stiff to a variable degree; it is carried in a flexed position and does not swing naturally. In the hemiparetic child, the arm tends to abduct as he steps forward. This type of gait disorder is most often a sequela of stroke or trauma but may result from any condition that damages the corticospinal pathway on one side.

The spastic paraplegic or paraparetic gait is, in effect, a bilateral hemiplegic gait. Each leg is advanced slowly and stiffly, with restricted motion at the hips and knees. The legs are extended or slightly bent at the knees and the thighs may be strongly adducted, causing the legs almost to cross as the patient walks (scissor-like gait). The steps are regular and short and the patient advances only with great effort as though wading waist-deep in water. The defect is in stiffness of the stepping mechanism and in propulsion, not in support or equilibrium.

A spastic paraparetic gait is the major manifestation of cerebral diplegia (Little disease, a type of cerebral

palsy), the result of anoxic or other damage to the brain in the perinatal period. This disorder of gait is also seen in a variety of chronic spinal cord diseases involving the dorsolateral and ventral tracts, most often multiple sclerosis, but also including syringomyelia, any type of chronic meningomyelitis, subacute combined system disease of both the pernicious anemia and nonpernicious anemia types, spinal cord compression or traumatic injury, adrenomyeloneuropathy, and familial forms of spastic paraplegia. Frequently in these diseases, the effects of posterior column disease are added, giving rise to a mixed gait disturbance—a spinal spastic ataxia, characteristic of multiple sclerosis and certain spinal cord degenerations such as Friedreich ataxia.

Parkinsonian and Festinating Gait

Diminished or absent arm swing, forward bent torso, short or shuffling steps, turning en bloc, hesitation in starting to walk, shuffling, or “freezing” when encountering doorways or other obstacles are the features of the parkinsonian gait. When they are joined to the typical tremor, unblinking and mask-like facial expression, general attitude of flexion, and poverty of movement, there can be little doubt as to the diagnosis. The arms are carried slightly flexed and ahead of the body and do not swing. The legs are stiff and bent at the knees and hips. The steps are short, and the feet barely clear the ground as the patient shuffles along.

Once walking has started, the upper part of the body advances ahead of the lower part, and the patient is impelled to take increasingly short and rapid steps as though trying to catch up to his center of gravity. The steps become more and more rapid, and the patient could easily break into a trot and collide with an obstacle or fall if not assisted. The term *festination* derives from the Latin *festinare*, “to hasten,” and appropriately describes the involuntary acceleration or hastening that characterizes the gait of patients with Parkinson disease. Festination may be apparent when the patient is walking forward or backward. The defects are in rocking the body from side to side, so that the feet can clear the floor, and in moving the legs quickly enough to overtake the center of gravity. The problem is compounded by the inadequacy of postural support reflexes, demonstrable in the standing patient by falling in response to a push against the sternum or a tug backward on the shoulder. A normal person readily retains his stability or adjusts to modest displacement of the trunk with a single step, but the parkinsonian patient may lean backward with the upper torso and then stagger or fall unless someone stands by to prevent it.

Quite often, one encounters an elderly patient with only the instability and freezing components of the parkinsonian gait disorder, so-called *lower-half parkinsonism*. Usually, this is not a manifestation of idiopathic Parkinson disease although a few patients are responsive to L-dopa for a brief period. It may be an early manifestation of progressive supranuclear palsy, a basal ganglionic degeneration, normal pressure hydrocephalus, or widespread subcortical vascular damage as discussed further on in this chapter, but it also occurs as a virtually isolated

phenomenon that progresses independently of other movement disorders or of dementia. The basis is then probably a particular isolated frontal lobe degeneration (see further on). Within a few years, as pointed out by Factor and colleagues in their two papers, the patient is usually reduced to a chair-bound state.

Other very unusual gaits are sometimes observed in Parkinson disease and were particularly prominent in the postencephalitic form, which is now practically extinct. For example, such a patient may be unable to take a step forward or does so only after he takes a few hops or one or two steps backward (aptly mimicked by the Monty Python troupe in their skit, "Ministry of Silly Walks"). Or walking may be initiated by a series of short steps or a series of steps of increasing size. Occasionally such a patient may run better than he walks or walk backward better than forward. Often, walking so preoccupies the patient that talking simultaneously is impossible for him and he must stop to answer a question.

Choreoathetotic and Dystonic Gaits

Diseases characterized by involuntary movements and dystonic postures seriously affect gait. In fact, a disturbance of gait may be the initial and dominant manifestation of such diseases, and the testing of gait often brings out abnormalities of movement of the limbs and posture that are otherwise not conspicuous.

As the patient with congenital athetosis or Huntington chorea stands or walks, there is a continuous play of irregular movements affecting the face, neck, hands, and, in the advanced stages, the large proximal joints and trunk. The position of the arms and upper parts of the body varies with each step, at times giving the impression of a puppet. There are jerks of the head, grimacing, squirming and twisting movements of the trunk and limbs, and peculiar respiratory noises. One arm may be thrust aloft and the other held behind the body, with wrist and fingers undergoing alternate non-rhythmic flexion and extension, supination and pronation. The head may incline in one direction or the other, the lips alternately retract and purse, and the tongue intermittently protrudes from the mouth. The legs advance slowly and awkwardly, the result of superimposed involuntary movements and postures. Sometimes the foot is plantarflexed at the ankle and the weight is carried on the toes; or the foot may be dorsiflexed or inverted. An involuntary movement may cause the leg to be suspended in the air momentarily, imparting a lilt or waltzing character to the gait, or it may twist the trunk so violently that the patient may fall.

In dystonia musculorum deformans and focal dystonias, the first symptom may be a limp caused by inversion or plantarflexion of the foot or a distortion of the pelvis as discussed in Chap. 4. One leg may be rigidly extended or one shoulder elevated, and the trunk may assume a position of exaggerated flexion, lordosis, or scoliosis. Because of the muscle spasms that deform the body in this manner, the patient may have to walk with knees flexed. The gait may seem normal as the first steps are taken, the abnormal postures asserting themselves

as the patient continues to walk. Prominence of the buttocks owing to a lumbar lordosis, combined with flexion of one or both legs at the hip, gives rise to the so-called dromedary gait of Oppenheim. In the more advanced stages, walking becomes impossible owing to torsion of the trunk or the continuous flexion of the legs.

Stiff-person syndrome, an unusual nondystonic disorder causing severe axial muscle spasm, imparts a characteristic appearance of stiffness of the legs and buttock muscles, slow propulsion, and lumbar lordosis; there is sometimes a mild superimposed ataxic disturbance of gait (see Chap. 55). Another unusual disorder affecting the body position during walking is camptocormia, a severe forward bending of the trunk at the waist that is symptomatic of either a dystonia, Parkinson disease, or one of several muscle diseases that focally weaken the extensors of the spine. Kyphosis because of spinal deformities does the same and all of these conditions cause the patient to walk while looking at the ground beneath the feet, but they rarely cause falling.

Chapter 4 more fully describes the general features of the gaits of choreoathetosis and dystonia.

Waddling (Gluteal, or Trendelenburg) Gait

This gait is characteristic of the gluteal muscle weakness that is seen in the progressive muscular dystrophies, but it occurs as well in chronic forms of spinal muscular atrophy, in certain inflammatory myopathies, lumbosacral nerve root compression, and with congenital dislocation of the hips.

In normal walking, as weight is placed alternately on each leg, the hip is fixated by the gluteal muscles, particularly the gluteus medius, allowing for a slight rise of the opposite hip and tilt of the trunk to the weight-bearing side. With weakness of the glutei, however, there is a failure to stabilize the weight-bearing hip, causing it to bulge outward and the opposite side of the pelvis to drop, with inclination of the trunk to that side. The alternation in lateral trunk movements results in the roll or waddle. With unilateral gluteal weakness, often the result of damage to the first sacral nerve root, tilting and dropping of the pelvis ("pelvic ptosis") is apparent on only one side as the patient overlifts the leg when walking.

In several of the muscular dystrophies, an accentuation of lumbar lordosis is often seen. Also, childhood cases may be complicated by muscular contractures, leading to an equinovarus position of the foot, so that the waddle is combined with walking on the toes ("toe walking").

Toppling Gait

Toppling, meaning tottering and falling, occurs with brainstem and cerebellar lesions, especially in the older person following a stroke. It is a frequent feature of the lateral medullary syndrome, in which falling occurs to the side of the infarction. In patients with vestibular neuronitis, falling also occurs to the same side as the lesion. With midbrain strokes, the falls tend to be backward. In patients with progressive supranuclear palsy (discussed

in Chap. 39), where dystonia of the neck is combined with paralysis of vertical gaze and pseudobulbar features, unexplained falling is often an early and prominent feature. The falls of progressive supranuclear palsy may derive from such a disorder of the righting mechanism. In the advanced stages of Parkinson disease, falling of a similar type may be a serious problem, but it is more surprising how relatively infrequently it occurs. In addition, the gait is uncertain and hesitant—features that are enhanced, no doubt, by the hazard of falling unpredictably. The cause of the toppling phenomenon is unclear; it does not have its basis in weakness, ataxia, or loss of deep sensation. It appears to be a disorder of balance that is occasioned by precipitant action or the wrong placement of a foot and by a failure of the righting reflexes. Slowness of motor response is another factor.

In a related defect caused by a vestibular disorder, the patient may describe a sense of being pushed (pulsion) rather than of imbalance. It is most fully manifest in the lateral medullary syndrome. In midbrain disease, including progressive supranuclear palsy, a remarkable feature is the lack of appreciation of a sense of imbalance.

Primary Orthostatic Tremor

This unusual fast tremor of the legs may devastate gait. As discussed in Chap. 6, it is present only when the patient stands or exerts force with the legs while seated. The tremor ceases upon walking. In reaction to a perception of severe imbalance, which is characteristic of the disorder, the patient assumes a widened and often stiff-legged stance.

Gait Disorder in Normal-Pressure Hydrocephalus (See also Chap. 30)

Progressive difficulty in walking is typically the initial and most prominent symptom of normal-pressure hydrocephalus (NPH), a disorder of cerebrospinal fluid (CSF) circulation. However, the gait disturbance in NPH has few specific features. Certainly it cannot be categorized as an ataxic or spastic gait or what has been described as an “apraxic” gait; nor does it have more than a superficial resemblance to the parkinsonian gait. Its main features—slowed cadence, widened base and short steps—are the natural compensations observed in patients with all manner of gait disorders. Patients with the gait disorder of NPH may complain of a sense of imbalance or vague dizziness, but most have difficulty in articulating the exact problem. Like most patients with disorders of frontal lobe function, they are better able to carry out the motions of stepping while supine or sitting but have difficulty in taking steps when upright or attempting to walk. If these patients are observed as they get on and off an examining table and in and out of bed, they display poor management of the entire axial musculature, moving their bodies without shifting the center of gravity or adjusting their limbs appropriately. Changes in posture, even rolling over in bed, are made en bloc. The erect posture is assumed in an awkward manner—with hips and knees only slightly flexed and stiff and a delay in swinging the legs over the side of the bed.

Tone in the leg muscles of the NPH patient is often slightly increased, with a tendency to cocontraction of flexor and extensor muscle groups. Walking is perceptibly slower than normal, the body is held stiffly, arm swing is diminished, and there is a tendency to fall backward—features that are reminiscent of Parkinson disease, although the lack of arm swing and the stooped posture are more prominent in Parkinson disease than in NPH and, of course, the other major features of Parkinson disease are lacking. We have been impressed that NPH causes parkinsonian shuffling only when the hydrocephalus is very advanced.

As with the related “frontal gait,” described below, patients with NPH often have difficulty initiating gait and have short steps that are helped by marching to a cadence or in step with the examiner. In patients with untreated NPH, one observes a progressive deterioration of stance and gait—from an inability to walk to an inability to stand, sit, and rise from or turn over in bed. There is no hint of ataxia but a study of the mechanics of the gait in NPH by Stolze and colleagues described a widened base and slight outward rotation of the feet. Also distinguishing the gait of NPH from that of Parkinson disease in their study was a response in the latter to acoustic and visual cues for cadence. Sudarsky and Simon quantified these defects by means of high-speed cameras and computer analysis. They reported a reduction in height of step, an increase in sway, and a decrease in rotation of the pelvis and counter-rotation of the torso.

Frontal Lobe Disorders of Gait

Standing and walking may be severely disturbed by diseases that affect the frontal lobes, particularly their medial parts and their connections with the basal ganglia. This disorder is sometimes spoken of as a frontal lobe as an “apraxia of gait” among numerous other labels, because the difficulty in walking cannot be accounted for by weakness, loss of sensation, cerebellar incoordination, or basal ganglionic abnormality. Whether the gait disorder should be designated as an apraxia, in the sense of the original concept of the loss of ability to perform a learned act, is questionable, as walking is instinctual and not learned. Patients with so-called apraxia of gait do not have apraxia of individual limbs, particularly of the lower limbs; conversely, patients with apraxia of the limbs usually walk normally. More likely, the frontal gait disorder represents a loss of integration, at the cortical and basal ganglionic levels, of the essential elements of stance and locomotion that are acquired in infancy and often lost in old age.

Patients typically assume a posture of slight flexion with the feet placed farther apart than normal. They advance slowly, with small, shuffling, hesitant steps. At times they halt, unable to advance without great effort, although they do much better with a little assistance or with exhortation to walk in step with the examiner or to a marching cadence. Walking and turning are accomplished by a series of tiny, uncertain steps that are made with one foot, the other foot being planted on the floor as a pivot.

“Lower-half” Parkinson has been applied to the pattern as mentioned earlier but the cause is rarely idiopathic Parkinson disease. The term “marche à petit pas” is used when the cause is vascular damage to the frontal white matter. There is a need to seek support from a companion’s arm or nearby furniture. The initiation of walking becomes progressively more difficult; in advanced cases, the patient makes only feeble, abortive stepping movements in place, unable to move his feet and legs forward; eventually, the patient can make no stepping movements whatsoever, as though his feet were glued to the floor. These late phenomena have been referred to as “magnetic feet” and the difficulty initiating gait as “slipping clutch” syndrome (Denny-Brown) or “gait ignition failure” (Atchison et al). In some patients, difficulty in the initiation of gait may be an early and apparently isolated phenomenon but invariably, with the passage of time, the other features of the frontal lobe gait disorder become evident. Finally, as in untreated NPH, these patients become unable to stand or even to sit; without support, they fall helplessly backward or to one side.

Until the late stages of the process, these patients, while seated or supine are able to make complex movements with their legs, such as drawing imaginary figures or pedaling a bicycle and, quite remarkably, to simulate the motions of walking, all at a time when their gait is seriously impaired. Eventually, however, all movements of the legs become slow and awkward, and the limbs, when passively moved, offer variable counterresistance (paratonia or gegenhalten). As with Parkinson disease, difficulty in turning over in bed may eventually become impossible.

These advanced motor disabilities are usually associated with dementia, but the gait and mental disorders need not evolve in parallel. Thus, some patients with Alzheimer disease may show a serious degree of dementia for several years before a gait disorder becomes apparent; in other conditions, such as NPH and Binswanger disease, the opposite pertains. Or both the dementia and gait disorder may progress more or less together. Grasping, groping, hyperactive tendon reflexes and Babinski signs may or may not be present. The end result in some cases is a “cerebral paraplegia in flexion” (Yakovlev’s term), in which the patient lies curled up in bed, immobile and mute, with the limbs fixed by contractures in an attitude of flexion.

On the basis of bilateral but isolated frontal lobe infarction in the territory of the anterior cerebral artery (medial frontal lobes), the existence of a “gait center” has been proposed as mentioned in the introduction (see Della Sala). In the most severe and localized instance of complete gait failure from a frontal lobe stroke we have observed, the lesion was situated in the left pericallosal, medial supplementary motor area. Benson and colleagues have reported in an analysis of MRIs from a selected group of stroke patients, that specific periventricular frontal and occipitoparietal ischemic lesions in the deep white matter are associated with deterioration of gait. Isolated pontine ischemic changes were associated with gait disequilibrium in another study by Kwa and colleagues for the Amsterdam Vascular Medicine Group.

The clinical validity of all of these observations in regard to localization is uncertain but generally converges on the notion that ischemic damage at any of the aforementioned sites in the white matter can alter walking.

In addition to NPH and Alzheimer disease, the causes of the frontal lobe gait disorder include large neoplasms (meningioma, infiltrating glioma—gliomatosis cerebri), subcortical arteriosclerotic encephalopathy (Binswanger disease; see Thompson and Marsden), frontotemporal lobar degeneration (formerly Pick disease), and frontal lobe damage from trauma, stroke, or the residual of a ruptured anterior communicating aneurysm.

Gait of the Aged

An alteration of gait unrelated to overt cerebral disease is an almost universal accompaniment of aging and probably a variant of frontal lobe gait deterioration (Fig. 7-2). Lost with aging are speed, balance, and many of the quick and graceful adaptive movements that characterize the gait of younger individuals. The main objective characteristics are a slightly stooped posture, varying degrees of slowness and stiffness of walking, shortening of the stride, slight widening of the base, and a tendency to turn *en bloc*. The shortening of stride and widening of the base provide the support that enables the elderly individual to more confidently maintain his balance, but they result in a somewhat guarded gait, like that of a person walking on a slippery surface or in the dark.

Also lacking to a varying degree in the elderly is the ability to make the rapid compensatory postural changes (“rescue responses”) that are necessary to cushion or prevent a fall. A slight misstep, a failure to elevate the foot sufficiently, or tipping of the center of gravity to one side often cannot be corrected—features no doubt

Figure 7-2. Diagram illustrating the changes in posture and gait that accompany aging (“senile gait”). With aging (figure on left), there occurs a decrease in the length of stride, excursion of the hip, elevation of the toes of the forward foot and the heel of the rear foot, shoulder flexion on forward arm swing, and elbow extension on backward swing. (Redrawn by permission from Murray et al.)

that account for the frequency of falls and fear of falling among the elderly. Most persons with this type of gait disturbance are aware of impaired balance and their need for caution to avoid falls (the “cautious gait”; see Nutt et al). As such, this gait lacks specificity, being combined with a general adaptive or defensive pattern of walking. Added to this, as long recognized by orthopedic specialists, knee buckling that is attributable to quadriceps weakness from osteoarthritis contributes to the problem, as discussed by Felson and colleagues. Furthermore, osteoarthritis, the almost inevitable accompaniment of aging, contributes to the disruption of gait as a result of pain and a reduced range of motion and is a component of many gait disorders.

The nature of the elderly gait disorder is not fully understood. It may simply represent a mild degree of cerebral neuronal loss, attributable to aging itself, which in a severe (pathologic) form is the frontal lobe disorder of gait discussed above. Inadequate proprioception, slowness in making corrective postural responses, diminished vestibular function, and weakness of pelvic and thigh muscles are probably contributing factors, as are degenerative joint changes of the spine, hips, and knees. However, Baloh and colleagues have found that changes in sensory function do not correlate well with deterioration in gait. Fisher remarked on the similarity of the senile gait to that of NPH and suggested that hydrocephalus underlies the gait disorder of many elderly.

We prefer to emphasize here the common and particularly vexing problem encountered so often in practice of an elderly person with gait disturbance but minimal dementia. Factor and colleagues identify this as a primary freezing gait disorder of many etiologies and it conforms to “lower-half Parkinson” pattern as discussed earlier. Walking deteriorates over a period of months or years in an elderly individual, sometimes while residing in a nursing home, so that the tempo is unclear. The disturbance has most of the features of NPH or of a frontal gait disorder; but frontal atrophy is not marked, the ventricles are not enlarged, there is no response to drainage of CSF, and cervical spondylosis or neuropathy is not found. Sometimes a functional imaging study such as positron emission tomography (PET) shows hypometabolism in the frontal lobes. Presumably this reflects a degenerative process, perhaps of the frontotemporal variety. The changes in gait due to aging are discussed further in Chap. 29, on aging.

Gaits of the Developmentally Delayed

The array of peculiar gait in this group of persons defies easy analysis. An ungainly stance with the head too far forward or the neck extended and arms held in odd positions, a wide-based gait with awkward lurches or feet stomping the floor—each patient with his own ungraceful style—these are but a few of the peculiarities that meet the eye. One tries in vain to relate them to a disorder of proprioception, cerebellar deficit, or pyramidal or extrapyramidal disease.

The only plausible explanation that comes to mind is that these variants of gait are based on a lag in the

natural developmental sequence of the cerebral and spinal mechanisms involved in bipedal locomotion, posture, and righting. The acquisition of the refinements of locomotion—such as running, hopping, jumping, dancing, balancing on one foot, kicking a ball—is age-linked; i.e., each has its average age of acquisition. There are wide individual variations. The rhythmic rocking movements and hand clapping, odd mannerisms, waving of the arms, tremors, and other stereotyped patterns mentioned in Chap. 28, make gait even more maladroit. The Lincoln-Oseretsky scale is an attempt to quantitate these maturational delays in the locomotor sphere (see Chap. 28).

Hysterical Gait (See also Chap. 51)

This may take one of several forms, many well described by Keane. There may be a hysterical monoplegia, hemiplegia, or paraplegia. In walking, the patient may hesitate and advance the leg in a grossly ataxic or tremulous manner. Typically, patients with a hysterical paralysis of the leg do not lift the foot from the floor while walking; instead, they tend to drag the leg as a useless member or push it ahead of them as though it were on a skate. In hysterical hemiparesis, the characteristic circumduction seen in *bona fide* spastic paresis of the leg is absent, as are hemiparetic postures, hyperactive tendon reflexes, and Babinski sign. The hysterical paraplegic cannot very well drag both legs and usually depends on canes or crutches or remains helpless in bed or in a wheelchair; after months or longer of immobilization, the muscles may be flaccid or rigid from shortening, with development of contractures. The hysterical gait may take other dramatic forms. Some patients look as though they are walking on stilts, others assume extreme dystonic postures, and still others lurch wildly in all directions without falling, actually demonstrating by their gyrations a normal ability to make rapid and appropriate postural adjustments. The hysterical gait disorder may be accompanied by similarly exaggerated movements of the arms, as though to impress the observer with the great effort required to walk and maintain balance. Baik and Lang have emphasized the high frequency of coincident psychogenic movement and gait disorders in their speciality clinic. Leg movements in bed may be unimpaired or the patient may display a Hoover sign (described in Chap 3), which belies genuine leg weakness. Some of the patients exhibit additional abnormalities of the voice and visual fields, tremors, and asthenic weakness of muscle contraction.

Astasia-abasia—a term used to describe a psychogenic gait disorder in which patients, although unable to either stand or walk, display more or less normal use of their legs while in bed and have an otherwise normal neurologic examination and body carriage. When such patients are placed on their feet, they may take a few steps and then become unable to advance their legs; they lurch in all directions and crumple to the floor if not assisted.

On the other hand, one should not assume that a patient who manifests a disorder of gait or inability to walk but no other neurologic abnormality is necessarily suffering from hysteria. Lesions that are restricted to the

anterosuperior cerebellar vermis may cause an ataxia or severe instability that becomes manifest only when the patient attempts to stand and walk; this is also true of very advanced NPH, frontal lobe disease, and various intoxications such as with alcohol or antiepileptic medications. Cases of severe peripheral neuropathy, particularly if there is prominent sensory loss, may also greatly impair the ability to stand or walk, and the unusual condition of orthostatic leg tremor (see Chap. 6) that may produce buckling of the legs when the patient stands for some period of time, a situation often mistaken for hysteria.

Rehabilitative Measures

Once the gait abnormality has stabilized, i.e., neither progressive nor regressive, one should explore the possibility of rehabilitation by a combination of medical therapy and other corrective measures. The antispasticity agents baclofen and tizanidine are somewhat helpful when stiffness of the limbs exceeds weakness. They may reduce spasticity of the legs, but sometimes at the expense of exposing, to a greater degree than before, a loss of muscle power—the net effect being to the patient's disadvantage. In extreme cases, a subarachnoid pump infusion of baclofen may be effective for spasticity.

Hypofunction of the labyrinths, as in drug-induced or idiopathic vestibulopathy, has greatly challenged physiatrists. Balance training and the more effective use of postural correction and vision have helped some of these patients to be more steady and better able to function (see Baloh and Honrubia). Vestibular sedatives (e.g. meclizine) should be discontinued. Exercises to strengthen leg muscles can be beneficial in many circumstances, as can weight loss. Likewise, gait ataxia from proprioceptive defects can probably be corrected to some extent by careful attention to visual control and proper placement of the feet. Ventricular shunting in idiopathic hydrocephalus has restored locomotion in patients with this syndrome. Once dementia becomes conjoined with any of the gait disorders that occur in advanced age or with frontal lobe disease, rehabilitation stands less chance of success, since the ability to attend to small changes in terrain and posture is lost. Progression from the use of a cane, to a pronged cane, and finally to a four-posted walker allows patients with all types of gait disorders to maintain some mobility. The optimal use of these orthoses is best directed by experienced physical therapists and physiatrists.

Gait training with encouragement has been a useful maneuver to improve psychogenic gait disorders but some prove resistant.

Pain and Other Disorders of Somatic Sensation, Headache, and Backache

CHAPTER 8 **Pain**

CHAPTER 9 **Other Somatic Sensation**

CHAPTER 10 **Headache and Other Craniofacial Pains**

CHAPTER 11 **Pain in the Back, Neck, and Extremities**

Pain is an important sign of illness, and it stands preeminent among all the sensory experiences by which humans judge the existence of disease within themselves. Indeed, pain is the most common medical symptom. Relatively few diseases do not have a painful phase and in many, pain is a characteristic without which diagnosis must be in doubt.

The painful experiences pose manifold problems in virtually every field of medicine; physicians must therefore be prepared to recognize disease in patients who have felt only the first rumblings of discomfort, before other symptoms and signs have appeared. Even more problematic are patients who seek treatment for pain that appears to have little or no structural basis; further inquiry may disclose that fear of serious disease, worry, or depression has aggravated some relatively minor ache or that the complaint of pain has become the means of seeking attention, drugs or monetary compensation. They must also cope with the “difficult” pain patients in whom no amount of investigation brings to light either medical or psychiatric illness. Finally, the physician must be prepared to manage patients who require relief from intractable pain caused by established and incurable disease. To deal intelligently with pain problems requires familiarity with the anatomy of sensory pathways and the sensory supply of body segments as well as insight into the psychological factors that influence the perception of and reaction to pain.

The ambiguity with which the term pain is used is responsible for some of our difficulty in understanding it. One aspect, the easier to comprehend, is the transmission of impulses along certain pathways in response to potentially tissue-damaging stimuli, i.e., nociception. Far more abstruse is its quality as a mental state intimately linked to emotion, i.e., the quality of anguish or suffering—“a passion of the soul,” in the words of Aristotle—which defies definition and quantification. This duality (nociception and suffering) is of practical importance for certain drugs or surgical procedures, such as cingulotomy, may reduce the patient’s reaction to painful stimuli, leaving awareness of the sensation largely intact. Alternatively, interruption of certain neural pathways may abolish all sensation in an affected part but the symptom of pain may persist (i.e., denervation dysesthesia or anesthesia dolorosa), even in an amputated limb

(“phantom pain”). Finally, unlike most sensory modalities—which are aroused by a specific stimulus such as touch-pressure, heat, or cold—pain can be evoked by any one of these stimuli if it is intense enough.

It is apparent to us that in highly specialized medical centers, and often even in “pain centers,” few physicians are capable of handling difficult and unusual pain problems in any comprehensive way. In fact, it is to the neurologist that other physicians regularly turn for help with these matters. Although much has been learned about the anatomy of pain pathways, their physiologic mechanisms, and which structures to ablate in order to produce analgesia, relatively little is known about which patients should be subjected to these destructive operations or how to manage their pain by medical means. The practice of pain medicine challenges every thoughtful physician, for it demands a high degree of skill in medicine, neurology, and psychiatry.

ANATOMY AND PHYSIOLOGY OF PAIN

Historical Perspective

For more than a century, views on the nature of pain sensation have been dominated by two major theories. One, the *specificity theory*, was from the beginning associated with the name of von Frey. He asserted that the skin consisted of a mosaic of discrete sensory spots and that each spot, when stimulated, gave rise to one sensation—either pain, pressure, warmth, or cold; in his view, each of these sensations had a distinctive end organ in the skin and each stimulus-specific end organ was connected by its own private pathway to the brain. A second theory was that of Goldscheider, who abandoned his own earlier discovery of pain spots to argue that they simply represented pressure spots, a sufficiently intense stimulation of which could produce pain. According to the latter theory, there were no distinctive pain receptors, and the sensation of pain was the result of the summation of impulses excited by pressure or thermal stimuli applied to the skin. Originally called the *intensity theory*, it later became known as the *pattern or summation theory*.

In an effort to conciliate the pattern and specificity theories, Head and colleagues, in 1905, formulated a novel

concept of pain sensation, based on observations that followed his purposeful division of the cutaneous branch of the radial nerve in his own forearm. The zone of impaired sensation contained an innermost area in which superficial sensation was completely abolished. This was surrounded by a narrower ("intermediate") zone, in which pain sensation was preserved but poorly localized; extreme degrees of temperature were recognized in the intermediate zone but perception of touch, lesser differences of temperature, and two-point discrimination were abolished. To explain these findings, Head postulated the existence of two systems of cutaneous receptors and conducting fibers: (1) an ancient *protopathic* system, subserving pain and extreme differences in temperature and yielding ungraded, diffuse impressions of an all-or-none type; and (2) a more recently evolved *epicritic* system, which mediated touch, two-point discrimination, and lesser differences in temperature, as well as localized pain. The pain and hyperesthesia that follow damage to a peripheral nerve were attributed to a loss of inhibition that was normally exerted by the epicritic upon the protopathic system. This theory was used for many years to explain the sensory alterations that occur with both peripheral and central (thalamic) lesions. It lost credibility for several reasons but mainly because Head's original observations and deductions upon which they were based could not be confirmed (see Trotter and Davies; also Walshe). Nevertheless, both fast and slow forms of pain conduction were later corroborated (see below).

A later refinement of the pattern and specificity concepts of pain was made in 1965 when Melzack and Wall articulated their "gate-control" theory. They observed, in decerebrate and spinal cats, that peripheral stimulation of large myelinated fibers produced a negative dorsal root potential and that stimulation of small unmyelinated C (pain) fibers caused a positive dorsal root potential. They postulated that these potentials, which were a reflection of presynaptic inhibition or excitation, modulated the activity of secondary transmitting neurons (T cells) in the dorsal horn and that this modulation was mediated through inhibitory (I) cells. The essence of this theory was that the large-diameter fibers excited the I cells, which, in turn, caused a presynaptic inhibition of the T cells; conversely, the small pain afferents inhibited the I cells, leaving the T cells in an excitatory state. Melzack and Wall emphasized that pain impulses from the dorsal horn must also be under the control of a descending system of fibers from the brainstem, thalamus, and limbic lobes.

At first the gate-control mechanisms seemed to offer an explanation of the pain of ruptured disc and of certain chronic neuropathies (particularly those with large fiber out-fall) and attempts were made to relieve pain by subjecting the peripheral nerves and dorsal columns (presumably their large myelinated fibers) to sustained transcutaneous electrical stimulation. Such selective stimulation would theoretically "close" the gate. In some clinical situations these procedures have indeed given relief from pain, but not necessarily as a result of stimulation of large myelinated fibers alone (see Taub and Campbell). But in a number of other instances relating to pain in large- and small-fiber neuropathies, the clinical

behavior has been quite out of keeping with what one would expect on the basis of the gate-control mechanism. As with preceding theories, flaws have been exposed in the physiologic observations on which the theory is based. These and other aspects of the gate-control theory of pain have been critically reviewed by Nathan.

During the last few decades there has been a significant accrual of information on cutaneous sensibility, demanding modification of earlier anatomic-physiologic and clinical concepts. Interestingly, much of this information is still best described and rationalized in the general framework of the oldest theory, that of specificity, as is evident from the ensuing discussion on pain and that on other forms of cutaneous sensibility in the next chapter.

Pain Receptors and Peripheral Afferent Pathways

In terms of peripheral pain mechanisms, there is indeed a high degree, though not absolute, specificity in the von Frey sense. In keeping with distinctions between nerve types, the sensory (and motor) fibers have been classified according to their size and function (Table 8-1). It is now well established that two types of afferent fibers in the distal axons of primary sensory neurons respond maximally to nociceptive (i.e., potentially tissue-damaging) stimuli. One type is the very fine, unmyelinated, slowly conducting C fiber (0.3 to 1.1 μ in diameter); the other is the thinly myelinated, more rapidly conducting A- δ fiber (2 to 5 μ in diameter). The peripheral terminations of both of these primary pain afferents or receptors are the free, profusely branched nerve endings in the skin and other organs; these are covered by Schwann cells but contain little or no myelin.

There is considerable evidence, based on their response characteristics, that a degree of subspecialization exists within these freely branching, nonencapsulated endings and their small-fiber afferents. Three categories of free endings or receptors are recognized: mechanoreceptors, thermoreceptors, and polymodal nociceptors. Each ending transduces stimulus energy into an action potential in the distal nerve membranes. The first two types of receptors are activated by innocuous mechanical and thermal stimulation, respectively; the mechanoeffects are transmitted by both A- δ and C fibers and the thermal effects mostly by C fibers. The majority of C fibers are polymodal and are most effectively excited by noxious or tissue-damaging stimuli, but they can respond to both mechanical and thermal stimuli and to chemical mediators such as those associated with inflammation. Moreover, certain A- δ fibers respond to light touch, temperature, and pressure as well as to pain stimuli and are capable of discharging in proportion to the intensity of the stimulus. The stimulation of single fibers by intraneural electrodes indicates that they can also convey information concerning the nature and location of the stimulus. These observations on the polymodal functions of A- δ and C fibers would explain the earlier observations of Lele and Weddell that modes of sensation other than pain can be evoked from structures such as the cornea, which is innervated solely by free nerve endings.

Table 8-1

CLASSIFICATION AND FUNCTION OF SENSORY PERIPHERAL NERVE FIBERTYPES AND SYMPTOMS ASSOCIATED WITH INTRINSIC DYSFUNCTION OF EACH TYPE

FIBER TYPE	ALTERNATIVE DESIGNATION	FIBER DIAMETER	CONDUCTION VELOCITY (m/s)	FUNCTION AND SYMPTOMS OF DYSFUNCTION
A- α and - β Large, heavily myelinated	II	5–20	30–70	Touch, pressure
A- γ	Ia	3–6	15–30	Spindle afferents
A- δ Small, thinly myelinated	III	2–5	12–30	Pain and temperature, soma touch (sharp, lancinating, prickly pain)
B	1–3	3–15		
C Small, unmyelinated; polymodal	IV	0.3–1.1	0.5–2	Slow pain and temperature (dull, burning, poorly localized pain)

The manner in which painful stimuli are translated into electrical depolarizations in nerve endings is beginning to be understood. A number of specialized molecules, when activated by noxious stimuli, open cationic channels in membranes of the nerve ending. Opening of these channels, in turn, activates voltage-gated sodium channels and generates an action potential in the sensory axon. Mannion and Woolf have summarized the regulation and activation of these receptor molecules.

The peripheral afferent pain fibers of both A- δ and C types have their cell bodies in the dorsal root ganglia; central extensions of these nerve cells project, via the dorsal root, to the dorsal horn of the spinal cord (or, in the case of cranial pain afferents, to the spinal trigeminal nucleus, the medullary analogue of the dorsal horn). The pain afferents occupy mainly the lateral part of the root entry zone. Within the spinal cord, many of the thinnest fibers (C fibers) form a discrete bundle, the tract of Lissauer (Fig. 8-1A). That the tract of Lissauer is predominantly a pain pathway is shown (in animals) by the ipsilateral segmental analgesia that results from its transection but it contains deep sensory or propriospinal fibers as well. Although it is customary to speak of a lateral and medial division of the posterior root (the former contains small pain fibers and the latter, large myelinated fibers), the separation into discrete functional bundles is not complete, and in humans the two groups of fibers cannot be differentially interrupted by selective rhizotomy.

Dermatome Distribution of Pain Fibers

(See Fig. 9.1) Each sensory unit (the sensory nerve cell in the dorsal root ganglion, its central and peripheral extensions, and cutaneous and visceral endings) has a unique topography that is maintained throughout the sensory system from the periphery to the sensory cortex. The discrete segmental distribution of the sensory units permits the construction of sensory maps, so useful to clinicians (see Fig. 9-1). This aspect of sensory anatomy is elaborated in the next chapter, which includes maps of

the sensory dermatomes and cutaneous nerves. However, as a means of quick orientation to the topography of peripheral pain pathways, it is useful to remember that the facial structures and anterior cranium lie in the fields of the trigeminal nerves; the back of the head, second cervical; the neck, third cervical; the epaulet area, fourth cervical; the deltoid area, fifth cervical; the radial forearm and thumb, sixth cervical; the index and middle fingers, seventh cervical; the little finger and ulnar border of hand and forearm, eighth cervical–first thoracic; the nipple, fifth thoracic; the umbilicus, tenth thoracic; the groin, first lumbar; the medial side of the knee, third lumbar; the great toe, fifth lumbar; the little toe, first sacral; the back of the thigh, second sacral; and the genitoanal zones, third, fourth, and fifth sacral segments. The distribution of pain fibers from deep structures, although not fully corresponding to those from the skin, also follows a segmental pattern. The first to fourth thoracic nerve roots are the important sensory pathways for the heart and lungs; the sixth to eighth thoracic, for the upper abdominal organs; and the lower thoracic and upper lumbar, for the lower abdominal viscera. These areas of projection from visceral structures roughly correspond to the areas of adjacent root innervation, with some exceptions because of routing of sensory nerves to organs that migrate with development.

Neurologically relevant maps of pain projection from the bones, ligaments, and adjacent musculoskeletal structures have been termed *sclerotomes*; they differ slightly in their distribution from the dermatomes. A further discussion of referred pain and a figure comparing sclerotomes and dermatomes is given later in the chapter.

The Dorsal Horn

The afferent pain fibers, after traversing the tract of Lissauer, terminate in the posterior gray matter or dorsal horn, predominantly in the marginal zone. Most of the fibers terminate within the segment of their entry into the cord; some extend ipsilaterally to one or two adjacent rostral and caudal segments; and some project, via the

Figure 8-1. A. Spinal cord in transverse section illustrating the course of the afferent fibers and the major ascending pathways. Fast-conducting pain fibers are not confined to the spinothalamic tract but are scattered diffusely in the anterolateral funiculus (see also Fig. 8-3). (Adapted from Martin JH: *Neuroanatomy: Text and Atlas*. New York, McGraw-Hill, 2003, with permission.) B. Transverse section through a cervical segment of the spinal cord illustrating the subdivision of the gray matter into laminae according to Rexed and the entry and termination of the main sensory fibers. (Adapted from Fields HL: *Pain*. New York, McGraw-Hill, 1987, with permission.)

anterior commissure, to the contralateral dorsal horn. The cytoarchitectonic studies of Rexed in the cat (the same organization pertains in primates and probably in humans) have shown that second-order neurons, the sites of synapse of afferent sensory fibers in the dorsal horn, are arranged in a series of six layers or laminae (Fig. 8-1B). Thinly myelinated (A- δ) fibers terminate principally in lamina I of Rexed (marginal cell layer of Waldeyer) and also in the outermost part of lamina II; some A- δ pain fibers penetrate the dorsal gray matter and terminate in the lateral part of lamina V. Unmyelinated (C) fibers terminate in lamina II (substantia gelatinosa). Yet other cells that respond to painful cutaneous stimulation are located in ventral horn laminae VII and VIII. The latter neurons are responsive to descending impulses from brainstem nuclei as well as segmental sensory impulses. From these cells of termination, second-order axons connect with ventral and lateral horn cells in the same and adjacent spinal segments and subservise both somatic and autonomic reflexes. The main bundle of secondary neurons subserving pain sensation projects contralaterally (and to a lesser extent ipsilaterally) to higher levels; this constitutes the *spinothalamic tract*, discussed below.

A number of important observations have been made concerning the mode of transmission and modulation of pain impulses in the dorsal horn and brainstem. Excitatory amino acids (glutamate, aspartate) and nucleotides such as adenosine triphosphate (ATP) are the putative transmitters at terminals of primary A- δ sensory afferents. Also, A- δ pain afferents, when stimulated, release several neuromodulators that play a role in the transmission of pain sensation. Slower neurotransmission by C neurons involves other substances, of which the most important is the 11-amino-acid peptide known as

substance P ("P" for powder extracted from animal tissue and urine by von Euler in 1931). In animals, substance P excites nociceptive dorsal root ganglion and dorsal horn neurons; furthermore, destruction of substance P fibers produces analgesia. In patients with the rare condition of congenital neuropathy and insensitivity to pain, there is a marked depletion of dorsal horn substance P.

A large body of evidence indicates that opiates are important modulators of pain impulses as they are relayed through the dorsal horn and through nuclei in the medulla and midbrain. Thus, opiates have been noted to decrease substance P; at the same time, flexor spinal reflexes, which are evoked by segmental pain, are reduced. Opiate receptors of three types are found on both presynaptic primary afferent terminals and postsynaptic dendrites of small neurons in lamina II. Moreover, lamina II neurons, when activated, release enkephalins, endorphins, and dynorphins—all of which are endogenous, morphine-like peptides that bind specifically to opiate receptors and inhibit pain transmission at the dorsal horn level. The subject of pain modulation by opiates and endogenous morphine-like substances is elaborated further on.

Spinal Afferent Tracts for Pain

The (Anterolateral, or Lateral) Spinothalamic Tract

As indicated above, axons of secondary neurons that subserve pain sensation originate in laminae I, II, V, VII, and VIII of the spinal gray matter. The principal bundle of these axons decussates in the anterior spinal commissure and ascends in the anterolateral fasciculus of the opposite side of the cord as the *spinothalamic tract* to terminate in brainstem and thalamic structures (Fig. 8-2).

Figure 8-2. The spinothalamic tract (pain, thermal sense) is shown. In the bottom section, the fibers that form the spinothalamic tract cross over two or three segment rostral to their entry into the cord, not at the same level as depicted. Offshoots from the ascending anterolateral fasciculus (spinothalamic tract) to nuclei in the medulla, pons, and mesencephalon and nuclear terminations of the tract are indicated. The cortical representation of sensation is shown grossly; it is shown more explicitly in Fig. 9-5 and discussed in Chap. 9. The lemniscal (posterior column) system is shown in Fig. 9-4.

It is of clinical consequence that the axons carrying pain impulses from each dermatome decussate one to three segments rostral to the level of root entry. For this reason, a discrete lesion of the lateral spinal cord creates a loss of pain and thermal sensation of the *contralateral* trunk, the dermatomal level of which is *two to three segments below that of the spinal cord lesion*. As the ascending fibers cross the cord, they are added to the inner side of the spinothalamic tract (the principal afferent pathway of the anterolateral fasciculus), so that the longest fibers from the sacral segments come to lie most superficially and fibers from successively more rostral levels occupy progressively deeper positions (Fig. 8-3). This somatotopic arrangement is of importance to the neurosurgeon performing an operation for pain relief, insofar as the depth to which the funiculus is cut will govern the level of analgesia that is achieved; for the neurologist, it provides an explanation of the pattern of “sacral sparing” of pain and thermal sensation created by centrally placed lesions of the spinal cord. The termination of this tract, mainly in the thalamus, is described further on.

Other Spinocerebral Afferent Tracts

In addition to the anterolateral spinothalamic tract—a fast-conducting pathway that projects directly to the thalamus—the anterolateral fasciculus of the cord contains several more slowly conducting, medially placed systems of fibers. One such group of fibers projects directly to the reticular core of the medulla and midbrain and then to the medial and intralaminar nuclei of the thalamus; these fibers are referred to as the *spinoreticulothalamic* or *paleospinothalamic* pathway. At the level of

the medulla, these fibers synapse in the nucleus gigantocellularis; more rostrally, they connect with nuclei of the parabrachial region, midbrain reticular formation, periaqueductal gray matter, and hypothalamus. A second, more medially placed pathway in the anterolateral cord ascends to the brainstem reticular core via a series of short interneuronal links. It is not clear whether these spinoreticular fibers are collaterals of the spinothalamic tracts, as Cajal originally stated, or whether they represent an independent system, as more recent data seem to indicate. Probably both statements are correct. There is also a third, direct spinohypothalamic pathway in the anterolateral fasciculus.

The conduction of diffuse, poorly localized pain arising from deep and visceral structures (gut, periosteum, peritoneum) has been ascribed to these slow-conducting, indirect pathways. Melzack and Casey have proposed that this fiber system (which they refer to as *paramedian*), with its diffuse projection via brainstem and thalamus to the limbic and frontal lobes, subserves the affective aspects of pain, i.e., the unpleasant feelings engendered by pain. It is evident that these spinoreticulothalamic pathways continue to evoke the psychic experience of pain even when the direct spinothalamic pathways have been interrupted. However, it is the direct spinothalamic pathway, which projects to the ventroposterolateral (VPL) nucleus of the thalamus and thence to discrete areas of the sensory cortex, that subserves the *sensory-discriminative* aspects of pain, i.e., the processes that underlie the localization, quality, and possibly the intensity of the noxious stimulus. Also, the pathways for *visceral pain* from the esophagus, stomach, small bowel, and

Figure 8-3. Spinal cord showing the segmental and laminated arrangement of nerve fibers within major tracts. On the left side are indicated the “sensory modalities” that appear to be mediated by the two main ascending pathways. C, cervical; L, lumbar; S, sacral; Th, thoracic. (Adapted by permission from Brodal A: *Neurological Anatomy*, 3rd ed. New York, Oxford University Press, 1981.)

proximal colon are carried largely in the vagus nerve and terminate in the nucleus of the solitary tract (nucleus tractus solitarius [NTS]) before projecting to the thalamus, as described below. Other abdominal viscera still activate the NTS when the vagus is severed in animals, probably transmitting impulses through the splanchnic plexus.

It should be emphasized that the foregoing data concerning the cells of termination of cutaneous nociceptive stimuli and the cells of origin of ascending spinal afferent pathways have all been obtained from studies in animals (including monkeys). In humans, the specific cells of origin of the direct spinothalamic tract fibers have not been fully identified. Information about this pathway in humans has been derived from the study of postmortem material and from the examination of patients subjected to anterolateral cordotomy for intractable pain. What can be stated of clinical importance is that unilateral section of the anterolateral funiculus produces a relatively complete loss of pain and thermal sense on the opposite side of the body, extending to a level two or three segments below the lesion as noted earlier. After a variable period of time, pain sensibility usually returns, probably being conducted by pathways that lie outside the anterolateral quadrants of the spinal cord that gradually increase their capacity to conduct pain impulses. One of these is a longitudinal polysynaptic bundle of small myelinated fibers in the center of the dorsal horn (the dorsal intracornual tract); another consists of axons of lamina I cells that travel in the dorsal part of the lateral funiculus.

Thalamic Terminus of Pain Fibers

The direct spinothalamic fibers separate into two bundles as they approach the thalamus. The lateral division terminates in the ventrobasal and posterior groups of nuclei, the most important of which is the VPL nucleus. The medial contingent terminates mainly in the intralaminar complex of nuclei and in the nucleus submedialis. Spinoreticulothalamic (paleospinothalamic) fibers project onto the medial intralaminar (primarily parafascicular and centrolateral) thalamic nuclei; i.e., they overlap with the terminations of the medially projecting direct spinothalamic pathway. Projections from the dorsal column nuclei, which have a modulating influence on pain transmission, are mainly to the ventrobasal and ventroposterior group of nuclei. Each of the four thalamic nuclear groups that receives nociceptive projections from the spinal cord has a distinct cortical projection and each is thought to play a different role in pain sensation (see below).

One practical conclusion to be reached from these anatomic and physiologic studies is that, at thalamic levels, fibers and cell stations transmitting the nociceptive impulses are not organized into discrete loci. In general, neurophysiologic evidence indicates that as one ascends from peripheral nerve to spinal, medullary, mesencephalic, thalamic, and limbic levels, the predictability of neuron responsiveness to noxious stimuli diminishes. Thus it comes as no surprise that neurosurgical lesions that interrupt afferent pathways at progressively higher levels of the brainstem and thalamus become decreasingly successful.

Thalamocortical Projections

The ventrobasal thalamic complex and the ventroposterior group of nuclei project to two main cortical areas: the primary sensory (postcentral) cortex (a small number terminate in the precentral cortex) and the upper bank of the sylvian fissure. These cortical projections are described more fully in Chap. 9 but it can be stated here that they are concerned mainly with the reception of tactile and proprioceptive stimuli and with all discriminative sensory functions, including pain. The extent to which either cortical area is activated by thermal and painful stimuli is uncertain. Certainly, stimulation of these (or any other) cortical areas in a normal, alert human being does not produce pain. The intralaminar nuclei, which also project to the hypothalamus, amygdaloid nuclei, and limbic cortex, probably mediate the arousal and affective aspects of pain and autonomic responses.

The thalamic projection to the primary sensory cortex that is distributed mainly along the postcentral gyrus of the anterior parietal lobe is shown in Fig. 9-5 (the "sensory homunculus"). The cortical representation allows for accurate localization of the site of origin of a painful stimulus but the notion that thalamic projections terminate solely in this region is an oversimplification.

Thalamic and cerebral cortical localization of *visceral sensation* is not well known. However, cerebral evoked potentials and increased cerebral blood flow (by positron emission tomography [PET] studies) have been demonstrated in the thalamus and pre- and postcentral gyri of patients undergoing rectal balloon distention (Silverman et al; Rothstein et al).

Descending Pain-Modulating Systems

The discovery of a system of descending fibers and way stations that modulate activity in nociceptive pathways has proved to be a major addition to our knowledge of pain. The endogenous pain control system that has been studied most extensively emanates from the frontal cortex and hypothalamus and projects to cells in the periaqueductal region of the midbrain and then passes to the ventromedial medulla. From there it descends in the dorsal part of the lateral fasciculus of the spinal cord to the posterior horns (laminae I, II, and V; see further discussion under "Endogenous Pain-Control Mechanisms"). Several other descending pathways, noradrenergic and serotonergic, arise in the locus ceruleus, dorsal raphe nucleus, and nucleus reticularis gigantocellularis and are also important modifiers of the nociceptive response. The clinical significance of these pain-modulating pathways, still under study, is discussed further on.

PHYSIOLOGIC ASPECTS OF PAIN

The stimuli that activate pain receptors vary from one tissue to another. The adequate stimulus for skin is one that has the potential to injure tissue, i.e., pricking, cutting, crushing, burning, and freezing. These stimuli

are ineffective when applied to the stomach and intestine, where pain is produced by an engorged or inflamed mucosa, distention or spasm of smooth muscle, and traction on the mesenteric attachment. In skeletal muscle, pain is caused by ischemia (the basis of intermittent claudication), necrosis, hemorrhage, and injection of irritating solutions as well as by injuries of connective tissue sheaths. Prolonged contraction of skeletal muscle evokes an aching type of pain. Ischemia is also the most important cause of pain in cardiac muscle. Joints are insensitive to pricking, cutting, and cautery, but pain can be produced in the synovial membrane by inflammation and by exposure to hypertonic saline. The stretching and tearing of ligaments around a joint can evoke severe pain. Injuries to the periosteum give rise to pain but probably not to other sensations. Blood vessels are a source of pain when pierced by a needle or involved in an inflammatory process. Distention of arteries or veins, as occurs with thrombotic or embolic occlusion, may be sources of pain; other mechanisms of headache relate to traction on arteries or inflammation of the meningeal structures by which they are supported. (The subject of headache and its origins is taken up in Chap. 10.) Pain from intraneural lesions probably arises from the sheaths of the nerves. Nerve root(s) and sensory ganglia, when compressed (e.g., by a ruptured disc), give rise to pain.

With damage to tissue, there is a release of proteolytic enzymes, which act locally on tissue proteins to liberate substances that excite peripheral nociceptors. These pain-producing substances—which include histamine, prostaglandins, serotonin, and similar polypeptides, as well as potassium ions—elicit pain when they are injected intraarterially or applied to the base of a blister. Other pain-producing substances such as kinins are released from sensory nerve endings or are carried there by the circulation. Local vascular permeability is also increased by these substances.

In addition, direct stimulation of nociceptors releases polypeptide mediators that enhance pain perception. The best studied of these is substance P, which is released from the nerve endings of C fibers in the skin during peripheral nerve stimulation. It causes erythema by dilating cutaneous vessels and edema by releasing histamine from mast cells; it also acts as a chemoattractant for leukocytes. This reaction, called *neurogenic inflammation* by White and Helme, is mediated by antidromic action potentials from the small nerve cells in the spinal ganglia and is the basis of the axon reflex of Lewis; the reflex is abolished in peripheral nerve diseases and can be studied electrophysiologically as an aid to clinical localization.

Perception of Pain

The *threshold for perception of pain*, i.e., the lowest intensity of a stimulus recognized as pain, is approximately the same in all persons. Inflammation lowers the threshold for perception of pain by a process called *sensitization*. This process, termed allodynia, allows ordinarily innocuous stimuli to produce pain in sensitized tissues. The pain threshold is, of course, raised by local anesthetics and by certain lesions of the nervous system as well as

by centrally acting analgesic drugs. Mechanisms other than lowering or raising the pain threshold are important as well. Placebos reduce pain in about one-third of the groups of patients in which such effects have been recorded. Acupuncture at sites anatomically remote from painful operative fields also reduces the pain in some individuals. Distraction and suggestion, by turning attention away from the painful part, reduce the awareness of and response to pain but not the threshold for its perception. Strong emotion (fear or rage) suppresses pain, presumably by activation of the above-described descending noradrenergic system. The experience of pain appears to be lessened in manic states and enhanced in depression. Anxious patients in general have the same pain threshold as normal subjects but their reaction may be excessive or abnormal. The pain thresholds of frontal lobotomized subjects are also unchanged but they react to painful stimuli only briefly or casually if at all.

The conscious awareness or perception of pain occurs only when pain impulses reach the thalamocortical level. The precise roles of the thalamus and cortical sensory areas in this mental process are not fully understood. It was believed that the recognition of a noxious stimulus as such is a function of the thalamus and that the parietal cortex is necessary for appreciation of the intensity, localization, and other discriminatory aspects of sensation. This traditional separation of sensation (in this instance, awareness of pain) and perception (awareness of the nature of the painful stimulus) has evolved to the view that sensation, perception, and the various conscious and unconscious responses to a pain stimulus comprise an indivisible process. That the cerebral cortex governs the patient's reaction to pain cannot be doubted. It is also likely that the cortex can suppress or otherwise modify the perception of pain in the same way that corticofugal projections from the sensory cortex modify the rostral transmission of other sensory impulses from thalamic and dorsal column nuclei. It has been shown that central transmission in the spinothalamic tract can be inhibited by stimulation of the sensorimotor areas of the cerebral cortex, and, as indicated above, a number of descending fiber systems have been traced to the dorsal horn laminae from which this tract originates.

The functional imaging studies by Wager and coworkers has given insights into the ensemble of brain regions that are activated by painful stimuli. In addition to the expected thalamic and parietal sensory regions, the hypothalamus, and both insular and cingulate cortices, are prominently involved, in proportion to the intensity of the stimulus. These investigators have sought to develop an imaging "pain signature" that could, in the future, objectify the pain response. Moreover, physical pain in their experiments could be differentiated from social and emotional pain. Whether this reductionist approach to pain will find clinical use is discussed by Jaillard and Ropper.

Endogenous Pain-Control Mechanisms

An important contribution to our understanding of pain has been the discovery of a neuronal analgesia system

that can be activated by the administration of opiates or by naturally occurring brain substances that share the properties of opiates. This endogenous system was first demonstrated by Reynolds, who found that stimulation of the ventrolateral periaqueductal gray matter in the rat produced a profound analgesia without altering behavior or motor activity. Subsequently, stimulation of other discrete sites in the medial and caudal regions of the diencephalon and rostral bulbar nuclei (notably raphe magnus and paragigantocellularis) was shown to have the same effect. Under the influence of such electrical stimulation, the animal could be operated on without anesthesia and move around in an undisturbed manner despite the administration of noxious stimuli. Investigation disclosed that the effect of stimulation-produced analgesia (SPA) is inhibition of the neurons of laminae I, II, and V of the dorsal horn, i.e., the neurons that are activated by noxious stimuli. In human subjects, stimulation of the midbrain periaqueductal gray matter through stereotactically implanted electrodes has also produced a state of analgesia, though not consistently. Other sites in which electrical stimulation is effective in suppressing nociceptive responses are the rostroventral medulla (nucleus raphe magnus and adjacent reticular formation) and the dorsolateral pontine tegmentum. These effects are relayed to the dorsal horn gray matter via a pathway in the dorsolateral funiculus of the spinal cord. Ascending pathways from the dorsal horn, conveying noxious somatic impulses, are also important in activating the modulatory network.

Opiates also act pre- and postsynaptically on the neurons of laminae I and V of the dorsal horn, suppressing afferent pain impulses from both the A- δ and C fibers. Furthermore, these effects can be reversed by the opioid antagonist naloxone. Interestingly, naloxone can reduce some forms of stimulation-produced analgesia. Levine and colleagues have demonstrated that not only does naloxone enhance clinical pain, but it also interferes with

the pain relief produced by placebos. These observations suggest that the heretofore mysterious beneficial effects of placebos (and perhaps of acupuncture) may be a result of activation of an endogenous system that shuts off pain through the release of pain-relieving endogenous opioids, or *endorphins* (see below). Prolonged pain and fear are the most powerful activators of this endogenous opioid-mediated modulating system. The same system is probably operative under a variety of other stressful conditions; for example, some soldiers, wounded in battle, require little or no analgesic medication ("stress-induced analgesia"). The opiates also act at several loci in the brainstem, at sites corresponding with those producing analgesia when stimulated electrically and generally conforming to areas in which neurons with endorphin receptors are localized.

Soon after the discovery of specific opiate receptors in the central nervous system (CNS), several naturally occurring peptides, which proved to have a potent analgesic effect and to bind specifically to opiate receptors, were identified. These endogenous, morphine-like compounds are generically referred to as *endorphins*, meaning "the morphines within." The most widely studied are β -endorphin, a peptide sequence of the pituitary hormone β -lipotropin, and two other peptides, *enkephalin* and *dynorphin*. They are found in greatest concentration in relation to opiate receptors in the midbrain. At the level of the spinal cord, exclusively enkephalin receptors are found. Figure 8-4 illustrates a theoretical construct of the roles of enkephalin (and substance P) at the point of entry of pain fibers into the spinal cord. A subgroup of dorsal horn interneurons that are in contact with spinothalamic tract neurons also contains enkephalin.

Thus it appears that the central effects of a painful condition are determined by many ascending and descending systems using a variety of transmitters. A deficiency in a particular region would explain persistent or excessive pain. Some aspects of opiate addiction and also the discomfort that follows withdrawal of the drug

Figure 8-4. Mechanism of action of enkephalin (endorphin) and morphine in the transmission of pain impulses from the periphery to the CNS. Spinal interneurons containing enkephalin synapse with the terminals of pain fibers and inhibit the release of the presumptive transmitter, substance P. As a result, the receptor neuron in the dorsal horn receives less excitatory (pain) impulses and transmits fewer pain impulses to the brain. Morphine binds to unoccupied enkephalin receptors, mimicking the pain-suppressing effects of the endogenous opiate enkephalin.

might conceivably be accounted for in this way. Indeed, it is known that some of these peptides not only relieve pain but suppress withdrawal symptoms.

Finally it should be noted that the descending pain-control systems contain noradrenergic and serotonergic, as well as opiate, connections. A descending norepinephrine-containing pathway, as mentioned, has been traced from the locus ceruleus in the dorsolateral pons to the spinal cord, and its activation blocks spinal nociceptive neurons. The rostroventral medulla contains a large number of serotonergic neurons from which descending fibers inhibit dorsal horn cells concerned with pain transmission, perhaps providing a rationale for the use of certain antidepressant medications that are serotonin agonists in patients with chronic pain.

CLINICAL AND PSYCHOLOGIC ASPECTS OF PAIN

Terminology (Table 8-2)

Several terms, related to the experience of altered sensations and pain, are often used interchangeably but each has specific meaning. *Hyperesthesia* is a general term for heightened cutaneous sensitivity. The term *hyperalgesia* refers to an increased sensitivity and a lowered threshold to painful stimuli. Inflammation and burns of the skin are common causes of hyperalgesia. The term *hypalgesia*, or *hypoalgesia*, refers to the opposite state—i.e., a decreased sensitivity and a raised threshold to painful stimuli. A demonstrable reduction in pain perception (i.e., an elevated threshold) associated with an increased reaction to the stimulus once it is perceived, is sometimes referred to as *hyperpathia* (subtly different from hyperalgesia). In this circumstance there is an excessive reaction to all stimuli, even those (such as light touch) that normally do not evoke pain, a symptom termed *allodynia*.

Table 8-2

NOMENCLATURE IN THE DESCRIPTION OF PAIN AND ABNORMAL SENSATION (SEE ALSO TABLE 9-1)

<i>Dysesthesia</i> : Any abnormal sensation described as unpleasant by the patient
<i>Hyperalgesia</i> : Exaggerated pain response from a normally painful stimulus; usually includes aspects of summation with repeated stimulus of constant intensity and aftersensation
<i>Hyperpathia</i> : Abnormally painful and exaggerated reaction to a painful stimulus; related to hyperalgesia
<i>Hyperesthesia (hypesthesia)</i> : Exaggerated perception of touch stimulus
<i>Allodynia</i> : Abnormal perception of pain from a normally nonpainful mechanical or thermal stimulus; usually has elements of delay in perception and of aftersensation
<i>Hypoalgesia (hypalgesia)</i> : Decreased sensitivity and raised threshold to painful stimuli
<i>Anesthesia</i> : Reduced perception of all sensation, mainly touch
<i>Pallanesthesia</i> : Loss of perception of vibration
<i>Analgesia</i> : Loss of perception of pain stimulus
<i>Paresthesia</i> : Spontaneous positive, prickling sensation that is not unpleasant; usually described as “pins and needles”
<i>Causalgia</i> : Burning pain in the distribution of one or more peripheral nerves

The elicited allodynic pain may have unusual features, outlasting the stimulus and being diffuse, modifiable by fatigue and emotion, and often being mixed with other sensations. The mechanism of these abnormalities is not clear but both hyperpathia and allodynia are common features of neuropathic or neurogenic pain, such as the pain generated by peripheral neuropathy. These features are also exemplified by causalgia, a type of burning pain that results from interruption of a peripheral nerve (see “Causalgia and Reflex Sympathetic Dystrophy”).

Skin Pain and Deep Sensibility

As indicated earlier, the nerve endings in each tissue are activated by different mechanisms, and the pain that results is characterized by its quality, locale, and temporal attributes. *Skin pain* is of two types: a pricking pain, evoked immediately on penetration of the skin by a needle point, or a stinging or burning pain that follows in a second or two. Together they constitute the “double response” of Lewis. Both types of dermal pain can be localized with precision. Compression of nerves by the application of a tourniquet to a limb abolishes pricking pain before burning pain because large fibers are more susceptible to pressure. The first (fast) pain is transmitted by the larger (A- δ) fibers and the second (slow) pain, which is somewhat more diffuse and longer lasting, by the thinner, unmyelinated C fibers.

Deep pain from visceral and skeletomuscular structures is usually aching in quality; if intense, it may be sharp and penetrating (knife-like). Occasionally visceral derangements cause a burning type of pain, as in the “heartburn” of esophageal irritation and rarely in angina pectoris. The pain is felt as being deep to the body surface. It is diffuse and poorly localized, and the margins of the painful zone are not well delineated, presumably because of the relative paucity of nerve endings in viscera. Visceral pain produces two additional sensations. First, there is tenderness at remote superficial sites (“referred hyperalgesia”) and, second, an enhanced pain sensitivity in the same and in nearby organs (“visceral hyperalgesia”). This is a restatement of Head’s early observations, discussed above, and the referred “Head zones,” where somatic and visceral sensibility overlap as discussed below. The concept of visceral hyperalgesia has received considerable attention in a number of pain syndromes in reference to the transition from acute to chronic pain, particularly in headache.

Referred Pain

The localization of deep pain of visceral origin raises a number of problems. Deep pain has indefinite boundaries and its location is distant from the visceral structure involved. It tends to be referred not to the skin overlying the viscera of origin but to other areas innervated by the same spinal segment (or segments). This pain, projected to some fixed site at a distance from the source, is called *referred pain*. The ostensible explanation for the site of referral is that small-caliber pain afferents from deep structures project to a wide range of lamina V neurons in the dorsal horn, as do cutaneous afferents. The convergence of deep and cutaneous afferents on the same dorsal horn cells, coupled with the fact that cutaneous afferents

are far more numerous than visceral afferents and have direct connections with the thalamus, is probably responsible for the phenomenon.

Because the nociceptive receptors and nerves of any given visceral or skeletal structure may project upon the dorsal horns of several adjacent spinal or brainstem segments, the pain from these structures may be fairly widely distributed. For example, afferent pain fibers from cardiac structures, distributed through segments T1 to T4, may be projected to the inner side of the arm and the ulnar border of the hand and arm (T1 and T2) as well as the precordium (T3 and T4). Once this pool of sensory neurons in the dorsal horns of the spinal cord is activated, additional noxious stimuli may heighten the activity in the whole sensory field ipsilaterally and, to a lesser extent, contralaterally.

The regions of projection of pain that originate in the bones and adjacent ligamentous structures have been called by Kellgren, "sclerotomes." His maps of pain referral patterns were established from studies of the injection of hypertonic saline into muscle and interspinous ligaments. Although dermatomes and sclerotomes overlap, the patterns are slightly different as shown in Fig. 8-5, which is taken from Inman and Saunders. These sclerotomatous projections are useful to neurologists in analyzing the origins of unusual pains of the cranium, spine, and limbs (see Chaps. 10 and 11).

Another peculiarity of localization is *aberrant reference*, explained by an alteration of the physiologic status of the pools of neurons in adjacent segments of the spinal cord. For example, cervical arthritis or gallbladder disease, causing low-grade discomfort by constantly activating their particular segmental neurons, may induce a shift of cardiac pain cephalad or caudad from its usual locale. Once it becomes chronic, any pain may spread quite widely in a vertical direction on one side of the body. On the other hand, painful stimuli arising from a distant site exert an inhibitory effect on segmental nociceptive flexion reflexes in the leg, as demonstrated by DeBroucker and colleagues. Yet another clinical peculiarity of segmental pain is the reduction in power of muscle contraction that it may cause (reflex paralysis, or algesic weakness).

Chronic Pain

One of the most perplexing issues in the study of pain is the manner in which chronic pain syndromes arise. Several theories have been offered, none of which satisfactorily accounts for all the clinically observed phenomena. One hypothesis proposes that in an injured nerve, the unmyelinated sprouts of A- δ and C fibers become capable of spontaneous ectopic excitation and after-discharge and are susceptible to ephaptic activation. A second proposal derives from the observation that these injured nerves are also sensitive to locally applied or intravenously administered catecholamines because of an overabundance of adrenergic receptors on the regenerating fibers. Either this mechanism or ephapse (nerve-to-nerve cross-activation) is thought to be the basis of causalgia (persistent burning and aching pain in the territory of a partially injured nerve and beyond) and its associated reflex sympathetic dystrophy; either would explain the relief afforded in these conditions by sympathetic block. This subject is discussed in greater detail

in relation to peripheral nerve injuries (see "Peripheral Nerve Pain" and Chap. 46).

Central sensory structures, e.g., sensory neurons in the dorsal horns of the spinal cord or thalamus, if chronically bombarded with pain impulses, may become autonomously overactive (being maintained in this state perhaps by excitatory amino acids) and may remain so even after the peripheral pathways have been interrupted. Peripheral nerve lesions have been shown to induce enduring derangements of central (spinal cord) processing (Fruhstorfer and Lindblom). For example, avulsion of nerves or nerve roots may cause chronic pain even in analgesic zones (anesthesia dolorosa or "deafferentation pain"). In experimentally deafferented animals, neurons of lamina V begin to discharge irregularly in the absence of stimulation. Later the abnormal discharge subsides in the spinal cord but can still be recorded in the thalamus. Consequently, painful states such as causalgia, spinal cord pain, and phantom pain are not abolished simply by cutting spinal nerves or spinal tracts.

Certainly none of these phenomena can adequately explain the entire story of chronic pain. It is likely that structural changes in the spinal cord, of the type alluded to above, are able to produce persistent stimulation of pain pathways. Indo and colleagues review the molecular changes in the spinal cord that may give rise to persistence of pain after the cessation of an injurious episode. It is an open question whether the early treatment of pain may prevent the cascade of biochemical events that allows for both spread and persistence of pain in conditions such as causalgia, but it has been the experience of most clinical pain experts that preemptive treatment of certain painful conditions (e.g., herpes zoster) may reduce the risk of a chronic pain syndrome.

Pain has several other singular attributes. It does not appear to be subject to negative adaptation—i.e., pain may persist as long as the stimulus is operative—whereas other somatic stimuli, if applied continuously, soon cease to be perceived. Furthermore, prolonged stimulation of pain receptors sensitizes them, so that they become responsive to even low grades of stimulation, even to touch (allodynia).

The Emotional Reaction to Pain

Another remarkable characteristic of pain is the strong feeling or affect with which it is endowed, nearly always unpleasant. Since pain embodies this element, psychological conditions assume great importance in all persistent painful states. It is of interest that despite this strong affective aspect of pain, it is difficult to recall precisely, or to reexperience from memory, a previously experienced acute pain. Also, the patient's tolerance of pain and capacity to experience it without verbalization are influenced by culture and personality. Some individuals—by virtue of training, habit, and phlegmatic temperament—remain stoic in the face of pain, and others react in an opposite fashion. In other words, there are inherent variations among individuals that determine the limbic system's response to pain. In this regard, it is important to emphasize that pain may be the presenting or predominant symptom in a depressive illness (Chap. 52). Price reviews this subject of the affective dimension of

Figure 8-5. Sclerotome maps taken from Inman and Saunders with permission. The projections of pain from osteal and periosteal structures such as ligaments were established by the injection of hypertonic saline or formic acid into the upper extremity (A) and lower extremity (B) and can also be found in the articles of Kellgren. They may be compared to the dermatomal maps shown in Figs. 9-1 through 9-3.

pain in detail, but it must be acknowledged that the models offered are largely theoretical. It is noteworthy, however, that on functional imaging studies regions of the cerebrum that are activated by experimentally induced physical pain overlap with those for the experience of emotional pain, as reported by Wager and colleagues.

Finally, a comment should be made about the devastating behavioral effects of chronic pain. To quote from Ambroise Paré, a sixteenth-century French surgeon, "There is nothing that abateth so much the strength as paine." Continuous pain increases irritability and fatigue, disturbs sleep, and impairs appetite. Patients in pain may seem irrational about their illness and make unreasonable demands on family and physician. Characteristic is an unwillingness to engage in or continue any activity that might enhance their pain. They withdraw from the main current of daily affairs as their thoughts and speech come to be dominated by the pain. Once a person is subjected to the tyranny of chronic pain, depressive symptoms are practically always added. A person's entire identity may be dominated by the mixture of pain and depression (*l'homme douloureux*). Determining the cause and effect is usually a futile exercise. Pain is depression and depression is pain.

APPROACH TO THE PATIENT WITH PAIN AS THE PREDOMINANT SYMPTOM

One learns quickly in dealing with patients that not all pain is the consequence of serious disease. Every day, healthy persons of all ages have pains that must be taken as part of normal sensory experience. To mention a few, there are the "growing pains" of presumed bone and joint origin of children; the momentary shock-like pains over an eye or in the temporal or occipital regions ("ice-pick" pain), which strike with such suddenness as to raise the suspicion of a ruptured intracranial aneurysm; inexplicable split-second jabs of pain elsewhere; the more persistent ache in the shoulder, hip, or extremity that subsides spontaneously or in response to a change in position; the fluctuant precordial discomfort of gastrointestinal origin, which conjures up fear of cardiac disease; and the breath-taking "stitch in the side" caused by intercostal or diaphragmatic cramp during exercise. These "normal pains," as they may be called, tend to be brief and to depart as obscurely as they came. Such pains come to notice only when elicited by an inquiring physician or when experienced by a patient given to worry and introspection. They must always be distinguished from the pain of disease.

Whenever pain—by its intensity, duration, and the circumstances of its occurrence—appears to be abnormal or when it constitutes the chief complaint or one of the principal symptoms, the physician must attempt to reach a tentative decision as to its mechanism and cause. This is accomplished by a thorough interrogation of the patient, with the physician carefully seeking out the main characteristics of the pain in terms of the following:

- Location
- Mode and time of onset
- Associated features, e.g., nausea, muscle spasm

- Quality and time-intensity attributes
- Duration
- Severity
- Provoking and relieving factors

Knowledge of these factors in every common disease is the lore of medicine. The severity of pain is often difficult to assess. Extreme degrees of pain are betrayed by the patient's demeanor but lesser degrees can be roughly estimated by the extent to which the pain has interfered with the patient's sleep, work, and other activities, or by the patient's need for bed rest. Some physicians find it helpful, particularly in gauging the effects of analgesic agents, to use a "pain scale," i.e., to have the patient rate the intensity of his pain on a scale of zero (no pain) to 10 (worst pain) or to mark it on a line (the Visual Analog Pain Scale). It has been our experience that this effort to quantify pain is often unhelpful to the neurological analysis as patients rarely rate pain as trivial, when they have already decided to consult a physician about the problem. For most patients, pain that necessitates medical consultation is, by definition, severe. This general approach is put to use every day in the practice of general medicine. Together with the physical examination, including maneuvers designed to reproduce and relieve the pain and ancillary diagnostic procedures, it enables the physician to identify the source of most pains and the diseases of which they are a part. Whether the earlier mentioned functional imaging techniques will offer an additional tool to evaluate pain remains to be determined.

Once the pains caused by the more common and readily recognized diseases of each organ system are eliminated, there remain a significant number of chronic pains that fall into one of four categories: (1) pain from an obscure medical disease, the nature of which has not yet been disclosed by diagnostic procedures; (2) pain associated with disease of the central or peripheral nervous system (i.e., neurogenic, or neuropathic pain); (3) pain associated with psychiatric disease; and (4) pain of unknown cause.

Pain Caused by Undiagnosed Medical Disease

Here the source of the pain is usually in a bodily organ and is caused by a lesion that irritates and destroys nerve endings. Consequently, the term *nociceptive pain* is often used even though it is ambiguous. It usually means an involvement of structures bearing the origin of pain fibers. Cancer is the most frequent example. Osseous metastases, tumors of the kidney, pancreas, or liver, peritoneal tumor implants, invasion of retroperitoneal tissues or the hilum of the lung, and infiltration of nerves of the brachial or lumbosacral plexuses can be extremely painful, and the origin of the pain may remain obscure for a long time. Sometimes it is necessary to repeat all diagnostic procedures after an interval of a few months, even though at first they were negative. From experience one learns to be cautious about reaching a diagnosis from insufficient data. Treatment in the meantime is directed to the relief of pain, at the same time instilling in the patient a need to cooperate with a program of expectant observation.

Neurogenic, or Neuropathic Pain

These terms are generally used interchangeably to designate pain that arises from direct stimulation of nervous tissue itself, central or peripheral, exclusive of pain as a consequence of stimulation of C fibers by lesions of other bodily structures (i.e., the nociceptive pain described above). This category comprises a variety of disorders involving single and multiple nerves, notably trigeminal neuralgia and those caused by herpes zoster, diabetes, and trauma; neuromas and neurofibromas, a number of polyneuropathies of diverse type; root irritation, e.g., from a prolapsed disc; spinal arachnoiditis and spinal cord injuries; the thalamic pain syndrome of Dejerine-Roussy; and, rarely, parietal lobe infarction such as the ones described by Schmahmann and Leifer. As a rule, lesions of the cerebral cortex and white matter are associated not with pain but with hypalgesia. Schott (1995) reviewed the clinical features that characterize central pain. Particular diseases giving rise to neuropathic pain are considered in their appropriate chapters but the following remarks are of a general nature, applicable to all of the painful states that compose this group.

The sensations that characterize neuropathic pain vary and are often multiple—burning, gnawing, aching, and shooting or lancinating qualities are described. There is an almost invariable association with one or more of the symptoms of hyperesthesia, hyperalgesia, allodynia, and hyperpathia (see above). The abnormal sensations coexist in many cases with a sensory deficit and local autonomic dysfunction. Furthermore, the pain generally responds poorly to treatment, including the administration of opioid medications.

Peripheral Nerve Pain

Painful states that fall into this category are in most cases related to disease of the peripheral nerves, and it is to pain from this source that the term *neuropathic* is more strictly applicable. Pain states of peripheral nerve origin far outnumber those caused by spinal cord, brainstem, thalamic, and cerebral disease. Although the pain is localized to a sensory territory supplied by a nerve, plexus or nerve root, it often radiates to adjacent areas. Sometimes the onset of pain is immediate on receipt of injury; more often it appears at some point during the evolution or recession of the disorder. The disease of the nerve may be obvious, expressed by the usual sensory, motor, reflex, and autonomic changes, or these changes may be undetectable by standard tests. In the latter case, the term *neuralgia* is used.

The postulated mechanisms of peripheral nerve pain are diverse and differ from those of central diseases. Some of the major ideas were mentioned in the earlier section on chronic pain. One mechanism is denervation hypersensitivity, first described by Walter Cannon. He noted that when a group of neurons is deprived of its natural innervation, they become hyperactive. Others point to a reduced density of certain types of fibers in nerves supplying a causalgic zone as the basis of the burning pain but the comparison of the density of nerves from painful and nonpainful neuropathies has not proved to be consistently different.

For example, Dyck and colleagues, in a study of painful versus nonpainful axonal neuropathies, concluded that there was no difference between them in terms of the type of fiber degeneration. Also, the occurrence of ectopic impulse generation all along the surface of injured axons and the possibility of ephaptic activation of unsheathed axons seem applicable particularly to some causalgic states. Stimulation of the *nervi nervorum* of larger nerves by an expanding intraneural lesion or a vascular change was postulated by Asbury and Fields as the mechanism of nerve trunk pain. The sprouting of adrenergic sympathetic axons in response to nerve injury has already been mentioned and is an ostensible explanation for the abolition of causalgic pain by sympathetic blockade. This has given rise to the term *sympathetically sustained pain* for some cases of causalgia, as discussed below.

Regenerating axonal sprouts, as in a neuroma, are also hypersensitive to mechanical stimuli. On a molecular level, it has been shown that voltage-gated sodium channels accumulate at the site of a neuroma and all along the axon after nerve injury, and that this gives rise to ectopic and spontaneous activity of the sensory nerve cell and its axon. Such firing has been demonstrated in humans after nerve injury. This mechanism is concordant with the relief of neurogenic pain by sodium channel-blocking anti-epileptic drugs. Spontaneous activity in nociceptive C fibers is thought to give rise to burning pain; firing of large myelinated A fibers is believed to produce dysesthetic pain induced by tactile stimuli. The abnormal response to stimulation is also influenced by sensitization of central pain pathways, probably in the dorsal horns of the spinal cord, as outlined in the review by Woolf and Mannion. Hyperalgesia and allodynia are thought to result from such a spinal cord mechanism. Several observations have been made regarding the neurochemical mechanisms that might underlie these changes but none provides a consistent explanation. Possibly more than one of these mechanisms is operative in a given peripheral nerve disease.

Evidence that the sodium channel can generate neural pain is given by the extraordinary disease “paroxysmal extreme pain disorder” also known as “familial rectal pain syndrome.” Here, a mutation of the sodium channel gene, *SCN9A*, leads to the early onset of paroxysmal autonomic changes and attacks of excruciating deep burning pain in the rectum, eye, or jaw, or diffusely, as described by Fertleman and coworkers. Similar but more diffuse painful states such as erythromelalgia and paroxysmal extreme pain disorder are being uncovered that are predicated on similar voltage-gated sodium channel mutations and more impressively, by the congenital absence of the ability to experience pain due to a loss of function mutation in a sodium channel gene and a mutation in the tyrosine kinase receptor gene. Fischer and Waxman provide a summary of the mutations in the sodium channel gene and their clinical presentations.

Causalgia and Reflex Sympathetic Dystrophy (Complex Regional Pain Syndrome)

Causalgia is the name that Weir Mitchell applied to a rare (except in time of war) type of peripheral neuralgia

consequent upon trauma, with partial interruption of the median or ulnar nerve and, less often, the sciatic or peroneal nerve (see also "Chronic Pain" further on and discussion in Chap. 46). It is characterized by persistent, severe pain in the hand or foot, most pronounced in the digits, palm of the hand, or sole. The pain has a burning quality and frequently radiates beyond the territory of the injured nerve. The painful parts are exquisitely sensitive to contact, so the patient cannot bear the pressure of clothing or drafts of air; even ambient heat, cold, noise, or emotional stimuli intensify the causalgic symptoms. The affected extremity is kept protected and immobile, often wrapped in a cloth moistened with cool water. Sudomotor, vasomotor, and, later, trophic abnormalities are usual accompaniments of the pain. The skin of the affected part is moist and warm or cool and soon becomes shiny and smooth, at times scaly, devoid of hair, and discolored.

A number of theories have been proposed to explain the causalgic syndrome. For many years it was attributed to a short-circuiting of impulses, the result of an artificial connection between efferent sympathetic and somatic afferent pain fibers at the point of the nerve injury. The demonstration that causalgic pain could be abolished by depletion of neurotransmitters at sympathetic adrenergic endings shifted the presumed site of sympathetic-afferent interaction to the nerve terminals and suggested that the abnormal cross-excitation is chemical rather than electrical in nature. Another possible explanation is that an abnormal adrenergic sensitivity develops in injured nociceptors and that circulating or locally secreted sympathetic neurotransmitters trigger the painful afferent activity. Another theory holds that a sustained period of bombardment by sensory pain impulses from one region results in the sensitization of central sensory structures. "True causalgia" of this type can be counted on to respond favorably, if only temporarily, to procaine block of the appropriate sympathetic ganglia and, for a longer time, to regional sympathectomy. Prolonged cooling and the intravenous injection of guanethidine, a sympathetic-blocking drug, into the affected limb (with the venous return blocked for several minutes) may alleviate the pain for days or longer. Epidural infusions, particularly of analgesics or ketamine, intravenous infusion of bisphosphonates, and spinal cord stimulators are other forms of treatment (see Kemler et al). The roles of the central and sympathetic nervous systems in causalgic pain have been critically reviewed by Schott and by Schwartzman and McLellan.

Increasingly, reflex sympathetic dystrophy has been reported after limb and bone injury but in the absence of evident damage to adjacent nerves. Oaklander and Fields have speculated that this is due to an induced small fiber neuropathy; limited confirmation of this notion is given by those authors.

Recent investigations have begun to define the molecular changes that occur in sensory neurons and the spinal cord in cases of chronic pain of this type. Alterations in *N*-methyl-*D*-aspartate (NMDA) receptors, induction of cyclooxygenase and prostaglandin synthesis, and changes in gabaergic inhibition in the dorsal horns are all implicated (Woolf).

The term *causalgia* is, in our view, best reserved for the syndrome described above—i.e., persistent burning pain and local abnormalities of autonomic innervation from trauma to a major nerve in an extremity. Some neurologists use "causalgia" to describe only the burning feature of pain due to partial nerve injury. Others have applied the term to a wide range of conditions that are characterized by persistent burning pain but have only an inconstant association with sudomotor, vasomotor, and trophic changes and an unpredictable response to sympathetic blockade. These latter states, which have been described under a plethora of terms (e.g., complex regional pain syndrome type 2, Sudeck atrophy of bone, minor causalgia, shoulder-hand syndrome, algodystrophy, or algoneurodystrophy), may follow non-traumatic lesions of the peripheral nerves or even lesions of the CNS ("mimocausalgia").

We have no explanation for the so-called causalgia-dystonia syndrome (Bhatia et al) in which a fixed dystonic posture is engrafted on a site of causalgic pain. The clinical features of both the causalgic and dystonic elements of the syndrome have been somewhat unusual in the cases reported. The degree of injury was often trivial or nonexistent and no signs of a neuropathic lesion were evident. Remarkably, both the causalgia and dystonia spread from their initial sites to widely disparate parts of the limbs and body. The syndrome did not respond to any form of treatment, although some patients recovered spontaneously. Another interesting type of causalgia and reflex sympathetic dystrophy follows deep venous thrombosis in a leg and had in the literature been recorded as "algodystrophy." It may be similar to the left shoulder and hand changes that come on months after a myocardial infarction ("shoulder-hand syndrome").

The treatment of reflex sympathetic dystrophy is largely unsatisfactory, although a certain degree of improvement can be expected if treatment is started early and the limb is mobilized. The options for treatment are discussed further on.

Central Neurogenic Pain

There are several configurations of central lesions that damage the sensory system and produce severe pain. Deafferentation of secondary neurons in the posterior horns or of sensory ganglion cells that terminate on them may cause the deafferented cells to become continuously active and, if stimulated by a microelectrode, to reproduce pain. In the patient whose spinal cord has been transected, there may be intolerable pain in regions below the level of the lesion. It may be exacerbated or provoked by movement, fatigue, or emotion and projected to areas disconnected from suprasegmental structures (akin to the phantom pain in the missing part of an amputated limb). Here, and in the rare cases of intractable pain with lateral medullary or pontine lesions, loss of the descending inhibitory systems seems a likely explanation. This may also explain the pain of the Dejerine-Roussy *thalamic syndrome* described in Chap. 9. Altered sensitivity and hyperactivity of central neurons are alternative possibilities.

Further details concerning the subject of neuropathic pain can be found in the older but still informative writings of Scadding and of Woolf and Mannion.

Pain in Association with Psychiatric Diseases

It is not unusual for patients with depression to have pain as a dominant symptom. As emphasized previously, most patients with chronic pain of all types are depressed. Wells and colleagues, in a survey of a large number of depressed and chronic pain patients, have corroborated this clinical impression. Fields has elaborated a theoretical explanation of the overlap of pain and depression. In such cases, one is faced with an extremely difficult clinical problem—that of determining whether a depressive state is primary or secondary. Complaints of weakness and fatigue, depression, anxiety, insomnia, nervousness, irritability, palpitations, etc., are woven into the clinical syndrome, attesting to the prominence of a psychiatric disorder. In some instances the diagnostic criteria for depression cited in Chap. 52 provide some insight, but in others it is impossible to make this determination and may not be necessary as depression and pain are so often coincident. Empiric treatment with antidepressant medication or, failing this, with electroconvulsive therapy is one way out of the dilemma.

Intractable pain may also be the leading symptom of both somatization and conversion reactions. Experienced physicians are familiar with the patient who has undergone multiple surgical procedures to address painful complaints (so-called Briquet disease). The recognition and management of this group of disorders are discussed in Chap. 51.

The desire for compensation (e.g. workman's compensation, disability status) is usually colored by persistent complaints of headaches, neck pain (whiplash injuries), low back pain, and other painful conditions. The question of ruptured disc is often raised, and laminectomy and spinal fusion may be performed (sometimes more than once) on the basis of dubious radiologic findings. Long delay in the settlement of litigation, allegedly to determine the seriousness of the injury, only enhances the symptoms and prolongs the disability. The medical and legal professions have no certain approach to such problems and often work at cross-purposes. We have found that a frank, objective appraisal of the injury, an assessment of any psychiatric problem, and encouragement to settle the legal claims as quickly as possible work in the best interests of all concerned. Although hypersuggestibility and relief of pain by placebos may reinforce the physician's belief that there is a prominent factor of hysteria or malingering (see Chap. 56), such data are difficult to interpret.

The possibility of drug addiction as a motivation for visiting the physician and reporting severe pain should be addressed. It is impossible to assess pain in addicted individuals, for their complaints are woven into their need for medication. Temperament and mood should be evaluated carefully; the physician must remember that the depressed patient often denies feeling dysphoric and may even occasionally smile. The use of alcohol to self-medicate for pain usually indicates a depressive illness

or lifelong alcohol dependence. When no medical, neurologic, or psychiatric disease can be established, one may be resigned to managing the painful state by the use of nonnarcotic medications and periodic clinical reevaluations. Such a course, though not altogether satisfactory, is preferable to prescribing excessive opioids or subjecting the patient to ablative surgery.

Chronic Pain of Indeterminate Cause

Pain in the thorax, abdomen, flank, back, face, head, or other part that cannot be traced to any visceral abnormality can create challenging clinical problems. In most cases, obscure neurologic sources, such as a spinal cord tumor and neuroma, have been excluded by repeated examinations and imaging procedures. A psychiatric disorder to which the patient's symptoms and behavior might be attributed cannot be discerned. Yet the patient complains continuously of pain, is disabled, and spends a great deal of effort and resources seeking medical aid.

In such a circumstance, some physicians and surgeons, rather than concede their helplessness, may resort to extreme measures, such as exploratory thoracotomy, laparotomy, or laminectomy. Or they may injudiciously attempt to alleviate the pain and avoid drug addiction by severing roots and spinal tracts, often with the result that the pain moves to an adjacent segment or to the other side of the body.

This type of patient benefits from being seen more than once by the physician. All the medical facts should be reviewed and the clinical and laboratory examinations repeated if some time has elapsed since they were last done. Tumors in the hilum of the lung or mediastinum; in the retropharyngeal, retroperitoneal, and paravertebral spaces; or in the uterus, testicle, kidney, or prostate pose a special difficulty in diagnosis, often being undetected for many months. More than once, we have seen a patient for months before a kidney or pancreatic tumor became apparent. Neurofibroma causing pain in an unusual site, such as one side of the rectum or vagina, is another type of tumor that may defy diagnosis for a long time. Truly neurogenic pain is almost invariably accompanied by alterations in cutaneous sensation and other neurologic signs, the finding of which facilitates diagnosis; however, the appearance of the neurologic signs may be delayed—for example, in brachial neuritis.

Because of the complexity and difficulty in diagnosis and treatment of chronic pain, most medical centers have found it advisable to establish pain clinics. Here a staff of internists, anesthesiologists, neurologists, neurosurgeons, and psychiatrists can review each patient in terms of drug dependence, neurologic disease, and psychiatric problems. Success is achieved by treating each aspect of chronic pain, and addressing the individual's problem rather than treating it generically with emphasis on increasing the patient's tolerance of pain by means of biofeedback, meditation, and related techniques; by using special analgesic procedures (discussed later in the chapter); by establishing a regimen of pain medication that does not lead to a rebound exaggeration of pain between doses; and by controlling depressive illness.

Rare and Unusual Disturbances of Pain Perception

Lesions of the parietooccipital regions of one cerebral hemisphere sometimes have peculiar effects on the patient's capacity to feel and react to pain. Under the title of *pain hemiagnosia*, Hecaen and Ajuriaguerra described several cases of left-sided paralysis from a right parietal lesion, which, at the same time, rendered the patient hypersensitive to noxious stimuli. When pinched on the affected side, the patient, after a delay, became agitated, moaned, and seemed distressed but made no effort to fend off the painful stimulus with the other hand or to withdraw from it. In contrast, if the good side was pinched, the patient reacted normally and moved the normal hand at once to the site of the stimulus to remove it. The motor responses seemed no longer to be guided by sensory information from one side of the body.

There are also two varieties of rare individuals who from birth are totally indifferent to pain coupled with anhidrosis ("congenital insensitivity to pain") or are incapable of feeling pain ("universal analgesia"). The former have been found by Indo and colleagues to have a mutation in the a neural tyrosine kinase receptor, a nerve growth factor receptor; those in the second group suffer from either a congenital lack of pain neurons in dorsal root ganglia, or to a mutation in the sodium channel discussed earlier. A similar loss of pain sensibility is encountered in the Riley-Day syndrome (congenital dysautonomia, see Chap. 26).

The phenomenon of *asymbolia for pain* is another rare and unusual condition wherein the patient, although capable of distinguishing the different types of pain stimuli from one another and from touch, is said to make none of the usual emotional, motor, or verbal responses to pain. The patient seems totally unaware of the painful or hurtful nature of stimuli delivered to any part of the body, whether on one side or the other. The current interpretation of *asymbolia for pain* is that it represents a particular type of agnosia (analognosia) or apractagnosia (see Chap. 22), in which the person loses his ability to adapt his emotional, motor, and verbal actions to the consciousness of a nociceptive impression. Pre-frontal lobe lesions from stroke, trauma, tumor, or in former times frontal lobotomy, can produce a version of this syndrome.

Treatment of Intractable Pain

Once the nature of the patient's pain and underlying disease has been determined, therapy must include some type of pain control. Initially, of course, attention is directed to the underlying disease with the idea of eliminating the source of the pain by appropriate medical, surgical, or radiotherapeutic measures. When the primary disease is not treatable, the physician should, if time and the circumstances permit, attempt to use the milder measures for pain relief first—for example, non-narcotic analgesics and antidepressants or anti-epileptic drugs before resorting to narcotics, local nerve blocks or contemplating surgical approaches for pain relief. Not all situations allow this graduated approach, and large doses

of narcotics may be required early in the course of illness—for example, to treat the pain of visceral and bone cancer. The same measured strategy is appropriate in the treatment of neuropathic pain and of pain of unclear origin except that one generally stops short of ablative procedures that irrevocably damage nerves or parts of the central nervous system.

The field of pain relief has been changed by the introduction of analgesic procedures that block nerves, alter neural conduction, or administer conventional medications in new ways. These have become the province of pain clinics and hospital pain services usually led by departments of anesthesiology. In addition, a number of special procedures or unique medications are highly effective for pain relief but are unique to specific situations. These include certain forms of headache and limb pain (temporal arteritis and polymyalgia rheumatica treated with corticosteroids, or migraine relief with "triptan" drugs); trigeminal neuralgia, which may be relieved by microvascular decompression of a branch of the basilar artery or by controlled damage of the gasserian ganglion; and painful dystonic disorders that are relieved by the injection of botulinum toxin. Special procedures that have been devised to treat various forms of spinal back pain fall into the same category. The following discussion provides some guidance for the physician who is asked to undertake or participate in the treatment of chronic pain or of neuropathic pain.

Narcotics (Opioids and Opiates)

A useful way in which to undertake the management of chronic pain that affects several parts of the body, as in the patient with metastases, is with codeine or oxycodone taken together with aspirin, acetaminophen, or another nonsteroidal antiinflammatory drug (NSAID), or tramadol. The analgesic effects of these types of drugs are additive, which is not the case when narcotics are combined with diazepam or phenothiazine. Antidepressants and antiepileptic drugs, as discussed further on, may have a beneficial effect on pain even in the absence of overt depression. This is true particularly in cases of neuropathic pain (painful polyneuropathy and some types of radicular pain). Sometimes these non-narcotic agents may, in themselves or in combination with these treatment modalities, be sufficient to control the patient's pain and the use of narcotics can then be kept in reserve.

Should the foregoing measures prove to be ineffective, one must turn to narcotic agents. Methadone and levorphanol are sometimes useful drugs with which to begin, because of their effectiveness by mouth and the relatively slow development of tolerance. Some pain clinics prefer the use of shorter-acting drugs such as oxycodone, given more frequently through the day. The oral route should be used whenever possible, as it is more comfortable for the patient than the parenteral route. Also, the oral route is associated with fewer side effects except for nausea and vomiting, which tend to be worse than with parenteral administration. Should the latter become necessary, one must be aware of the ratios of oral-to-parenteral dosages required to produce

Table 8-3

DRUGS FOR THE MANAGEMENT OF CHRONIC PAIN

GENERIC NAME	ORAL DOSE, mg	INTERVAL	COMMENTS
Nonopioid analgesics			
Aspirin	650	q4h	Enteric-coated preparations available
Acetaminophen	650	q4h	Side effects uncommon
Ibuprofen	400	q4–6h	
Naproxen	250–500	q12h	Delayed effects may be due to long half-life
Ketorolac	10–20	q4–6h	Useful postoperatively and for weaning from narcotics. Can be used intramuscularly
Trisalicylate	1,000–1,500	q12h	Fewer gastrointestinal or platelet effects than aspirin
Indomethacin	25–50	q8h	Gastrointestinal side effects common
Tramadol	50	q6h	Potent nonnarcotic with similar side effects but less respiratory depression
Narcotic analgesics			
Codeine	30–60	q4h	Nausea common
Oxycodone	—	5–10 q4–6h	Usually available combined with acetaminophen or aspirin
Morphine	10 q4h	60 q4h	
Morphine, sustained release	—	90 q12h	Oral slow-release preparation
Hydromorphone	1–2 q4h	2–4 q4h	Shorter acting than morphine sulfate
Levorphanol	2 q6–8h	4 q6–8h	Longer acting than morphine sulfate; absorbed well orally
Methadone	10 q6–8h	20 q6–8h	Delayed sedation because of long half-life
Meperidine	75–100 q3–4h	300 q4h	Poorly absorbed orally; normeperidine is a toxic metabolite
Fentanyl	25 to 100 µg	apply q72h	Parenteral and transcutaneous (“patch”) use
Antiepileptic and related drugs			
Phenytoin	100	q6–8h	Side effects of drowsiness, ataxia, nystagmus
Carbamazepine	200–300	q6h	
Gabapentin	300–2,700	q8h	
Pregabalin	25–100	q8h	
Special Agents			
Mexiletine	150–200	q4–6h	Heart block
Ketamine	—	10–25 µg/kg/h IV	Dysphoria, confusion

equivalent analgesia. The main medications used in the treatment of pain are summarized in Table 8-3.

If oral medication fails to control the pain, the parenteral administration of codeine or more potent opioids becomes necessary. One may begin with methadone, dihydromorphine (Dilaudid), or levorphanol, given at intervals of 4 to 6 h because of their relatively long duration of action (particularly in comparison to meperidine). Alternatively, one may first resort to the use of transdermal patches of drugs such as fentanyl, which provide relief for 24 to 72 h and which we have found particularly useful in the treatment of pain from brachial or lumbosacral plexus invasion by tumor and of painful neuropathies such as those caused by diabetes and systemic amyloidosis. Long-acting morphine preparations are useful alternatives.

Should long-continued injections of opiates become necessary, the optimal dose for the relief of pain should be established and the drug then given at regular intervals around the clock, rather than “as needed.” The administration of morphine (and other narcotics) in this way represents a laudable shift in attitude among physicians. For many years it was widely believed that the drug should be given in the smallest possible doses, spaced as far apart as possible, and repeated only when severe pain reasserted itself. It has become clear that this approach results in unnecessary discomfort and, in the

end, the need to use larger doses. Most physicians now realize that the fear of creating narcotic dependence and the expected phenomenon of increasing tolerance must be balanced against the overriding need to relieve pain. The most pernicious aspect of addiction, that of compulsive drug-seeking behavior with its attendant sociopathic behaviors, occurs only rarely in this setting and usually in patients with a previous history of addiction or alcoholism, with depression as the primary problem, or with certain characterologic disorders that have been loosely referred to as “addiction proneness.” Even in patients with severe acute or postoperative pain, the best results are obtained by allowing the patient to determine the dose and frequency of intravenous medication, a method known as patient-controlled analgesia (PCA). Again, the danger of producing addiction is minimal.

Guidelines for the use of orally and parenterally administered opioids for cancer-related pain are contained in the article of Cherny and Foley and in the publication of the U.S. Department of Health and Human Services, which unfortunately, is no longer easily obtained.

The approach outlined above conforms to our understanding about pain-control mechanisms. Aspirin and other NSAIDs are believed to prevent the activation of nociceptors by inhibiting the synthesis of prostaglandins in skin, joints, viscera, and other structures in the peripheral nervous system. Morphine and meperidine

given orally, parenterally, or intrathecally presumably produce analgesia by acting as “false” neurotransmitters at opiate receptor sites in the posterior horns of the spinal cord—sites that are normally activated by endogenous opioid peptides. The separate sites of action of NSAIDs and opioids provide an explanation for the therapeutic usefulness of combining these drugs. Opioids not only act directly on the central pain-conducting sensory systems but also exert a powerful action on the affective component of pain.

Supplemental Medications for the Treatment of Pain

Tricyclic antidepressants, especially the methylated forms (imipramine, amitriptyline, and doxepin), block serotonin reuptake and thus enhance the action of this neurotransmitter at synapses and putatively facilitate the action of the intrinsic opiate analgesic system. As a general rule, relief is afforded with tricyclic antidepressants in the equivalent dose range of 75 to 125 mg daily of amitriptyline, but little benefit accrues with higher amounts. The specific serotonin reuptake inhibitors (SSRI) antidepressants seem not to be as effective for the treatment of chronic neuropathic pain (see review by McQuay and colleagues) but these agents have not yet been extensively investigated in this clinical condition.

Antiepileptic drugs (AEDs) have a beneficial effect on many central and peripheral neuropathic pain syndromes but are generally less effective for causalgic pain caused by partial injury of a peripheral nerve. The mode of action of phenytoin, carbamazepine, gabapentin, levetiracetam, and other AEDs in suppressing the lancinating pains of tic douloureux and certain polyneuropathies, as well as pain after spinal cord injury and myelitis, is not fully understood, but they are widely used. Their action has been attributed to the blocking of sodium channels on axons, thereby reducing the evoked and spontaneous activity in nerve fibers. The full explanation is certainly more complex and related to separate central and peripheral sites, as summarized by Jensen. Often, large doses must be utilized—for example, more than 2,400 mg per day for gabapentin for full effect—but the soporific and ataxic effects may be poorly tolerated.

Most often a combination of medications is used for the treatment of intractable chronic pain. A common combination is the addition of gabapentin to an opioid such as morphine, and perhaps not surprisingly, this was superior to either drug alone in a crossover trial in patients with postherpetic neuralgia and diabetic neuropathy conducted by Gilron and colleagues but at the expense of side effects and lower tolerated doses of both drugs.

Table 8-3 summarizes the main analgesics (nonnarcotic and narcotic), antiepileptics, and antidepressant drugs in the management of chronic pain.

Treatment of Cancer Pain

If the patient is ridden with neoplastic disease and will not live longer than a few weeks or months and has widespread pain, surgical measures are usually not advisable. Pain from widespread osseous metastases, even in patients with hormone-insensitive tumors, may

be relieved by radiation therapy or by hypophysectomy. If these are not feasible, opioid medications are required and are effective, but they must be prescribed in adequate doses. Many patients prefer transdermal fentanyl to oral or intravenous agents. Usually, nerve section is not a satisfactory way of relieving restricted pain of the trunk and limbs because the overlap of adjacent nerves prevents complete denervation. Other procedures to be considered are the regional delivery of narcotic analogues, such as fentanyl or ketamine by means of an external pump and a catheter that is implanted percutaneously in the epidural space in proximity to the dorsal nerve roots of the affected region; this device can be used safely at home.

Treatment of Neuropathic Pain

The treatment of pain induced by nerve root or intrinsic peripheral nerve disease is a challenge for the neurologist and employs several techniques that are generally administered by an anesthesiologist. One usually resorts first to one of the antiepileptic drugs discussed earlier and listed in Table 8-3. The next simplest treatments are topical; if the pain is regional and has a predominantly burning quality, capsaicin cream can be applied locally, care being taken to avoid contact with the eyes and mouth. The irritative effect of this chemical, which releases substance P, seems in some cases to mute the pain. We have also had success with several concoctions of “eutectic” mixtures of local anesthetic (EMLA) creams or the simpler lidocaine gel with ketorolac, gabapentin, and other medications; these are applied directly to the affected area, usually the feet, in the morning and evening. Concoctions such as topical Ketamine mixed in soy lecithin to produce a gel with drug concentration of 5 mg/ml, have been reportedly useful in treating post herpetic neuralgia according to Quan and associates in a small randomized trial. Aspirin mixed with chloroform in cold cream is said to be very effective in the topical treatment of post herpetic neuralgia, as suggested by King (see Chap. 10). These preparations may provide considerable relief in postherpetic neuralgia and some painful peripheral neuropathies, but they are totally ineffective in others.

Several types of spinal injections, including epidural, root, and facet blocks, have long been used for the treatment of pain. Injections of epidural corticosteroids or mixtures of analgesics and steroids are helpful in selected cases of lumbar or thoracic nerve root pain, and occasionally in painful peripheral neuropathy, but precise criteria for the use of this measure are not well established. Several studies do not support a beneficial effect but there is little doubt, in our view, that quite a few patients are helped, if only for several days or weeks (see Chap. 11). Nerve root blocks with lidocaine or with longer-acting local anesthetics are sometimes helpful in establishing the precise source of radicular pain. Their main therapeutic use in our experience has been for thoracic radiculitis from shingles, chest wall pain after thoracotomy, and diabetic radiculopathy. Similar local injections are used in the treatment of occipital neuralgia. Injection of analgesic compounds into and around facet joints and the extension of this procedure, radiofrequency ablation of

the small nerves that innervate the joint, are as controversial as epidural injections, with most studies failing to find a consistent benefit. Despite these drawbacks, we have found both of these approaches very useful when pain can be traced to a derangement of these joints, as discussed in Chap. 11.

The intravenous infusion of lidocaine has a brief beneficial effect on many types of pain, including neuropathic varieties, localized headaches, trigeminal neuralgia, and other facial pains; it is said to be useful in predicting the response to longer-acting agents such as mexiletine, its oral analogue, although this relationship has been erratic in our experience (see Table 8-3). Mexiletine is given in an initial dose of 150 mg per day and slowly increased to a maximum of 300 mg three times daily; it should be used very cautiously in patients with heart block and has fallen very much out of favor in many centers, partly due to cardiac conduction abnormalities during and after the infusion.

Reducing sympathetic activity within somatic nerves by direct injection of the sympathetic ganglia in affected regions of the body (stellate ganglion for arm pain and lumbar ganglia for leg pain) has met with mixed success in neuropathic pain, including that of causalgia and reflex sympathetic dystrophy. A variant of this technique uses regional intravenous infusion of a sympathetic-blocking drug (bretylum, guanethidine, reserpine) into a limb that is isolated from the systemic circulation by the use of a tourniquet. This is known as a "Bier block," after the developer of regional anesthesia for single-limb surgery. These techniques, as well as the administration of clonidine by several routes and the intravenous infusion of the adrenergic blocker phentolamine, is predicated on the concept of "sympathetically sustained pain," meaning pain that is mediated by the interaction of sympathetic and pain nerve fibers or by the sprouting of adrenergic axons in partially damaged nerves. These forms of treatment have been under study for many decades and have given variable results but the most consistent responses to regional sympathetic blockade are obtained in cases of true causalgia resulting from partial injury of a single nerve.

A number of other treatments have proven successful in some patients with reflex sympathetic dystrophy and other neuropathic pains but the clinician should be cautious about their chances of success over the long run. A novel one of these has been the use of bisphosphonates (pamidronate, alendronate), which have been beneficial in painful disorders of bone, such as Paget disease and metastatic bone lesions. It is theorized that this class of drug reverses the bone loss consequent to reflex sympathetic dystrophy but how this relates to pain control is unclear (Schott, 1997). Electrical stimulation of the posterior columns of the spinal cord by an implanted device, as discussed below, has become popular. Another treatment of last resort is the intravenous or epidural infusion of drugs such as ketamine; sometimes this has a lasting effect on causalgic pain.

The approaches enumerated here are usually undertaken in sequence; a combination of drugs—such as gabapentin, narcotics, and clonidine—in addition to anesthetic techniques—is usually required. The ongoing attention

and support of the neurologist often becomes the patient's mainstay. Further references can be found in the thorough review by Katz.

Ablative Surgery in the Control of Pain

It is our considered opinion that a program of medical therapy should always precede ablative surgical measures. Only when a variety of analgesic medications (including opioids) and only when certain practical measures, such as regional analgesia or anesthesia, have completely failed, should one turn to neurosurgical procedures. Also, one should be very cautious in suggesting a procedure of last resort for pain that has no established cause as, for example, limb pain that has been incorrectly identified as causalgic because of a burning component but where there has been no nerve injury.

The least-destructive procedure consists of surgical exploration for a neuroma if a prior injury or operation may have partially sectioned a peripheral nerve. Magnetic resonance imaging of the region should be performed first and will demonstrate most such lesions, but we are uncertain if all small neuromas are visualized, and it is this ambiguity that justifies exploration. Another nondestructive procedure is implantation of a spinal electrical stimulator, usually adjacent to the posterior columns. This procedure, in which there is now a resurgence of interest, has afforded only incomplete relief in our patients and may be difficult to maintain in place. However Kemler and colleagues found a sustained reduction in pain intensity and an improved quality of life in patients with intractable reflex sympathetic dystrophy, even after 2 years in a randomized trial. It is clear that careful selection of patients is the best assurance of a good outcome. We can add from experience with our patients that a temporary trial of the stimulator is advisable before committing to its permanent use. The ill-advised use of nerve section and dorsal rhizotomy as definitive measures for the relief of regional pain was discussed above under "Treatment of Intractable Pain."

Spinothalamic tractotomy, in which the anterior half of the spinal cord on one side is sectioned at an upper thoracic level, effectively relieves pain in the opposite leg and lower trunk. This may be done as an open operation or as a transcutaneous procedure in which a radiofrequency lesion is produced by an electrode. The analgesia and thermoanesthesia may last a year or longer, after which the level of analgesia tends to descend and the pain tends to return. Bilateral tractotomy is also feasible but with greater risk of loss of sphincteric control and, at higher levels, of respiratory paralysis. Motor power is nearly always spared because of the position of the corticospinal tract in the posterior part of the lateral funiculus.

Pain in the arm, shoulder, and neck is more difficult to relieve surgically. High cervical transcutaneous cordotomy has been used successfully, with achievement of analgesia up to the chin. Commissural myelotomy by longitudinal incision of the anterior or posterior commissure of the spinal cord over many segments has also been performed, with variable success. Dorsal root entry zone (DREZ) lesions may relieve pain in the distribution

of one or two nerve roots. Lateral medullary tractotomy is another possibility but must be carried almost to the mid-line to relieve cervical pain. The risks of this latter procedure and also of lateral mesencephalic tractotomy (which may actually produce pain) are so great that neurosurgeons have abandoned these operations.

Stereotactic surgery on the thalamus for one-sided chronic pain is still used in a few centers and the results have been instructive. Lesions placed in the ventroposterior nucleus are said to diminish pain and thermal sensation over the contralateral side of the body while leaving the patient with all the misery or affective experience of pain; lesions in the intralaminar or parafascicular-centromedian nuclei relieve the painful state without altering sensation (Mark). Because these procedures have not yielded predictable benefits to the patient, they are now seldom used. The same unpredictability pertains to cortical ablations. Patients in whom a severe depression of mood is associated with a chronic pain syndrome have been subjected to bilateral stereotactic cingulotomy or the equivalent—subcaudate tractotomy. A considerable degree of success has been claimed for these operations but the results are difficult to evaluate. Orbito-frontal leukotomy has been discarded because of the personality change that it produces.

Non-Medical Methods for the Treatment of Pain

Included under this heading are certain techniques such as biofeedback, meditation, imagery, acupuncture, spinal manipulation, as well as transcutaneous electrical stimulation. Among the most intriguing treatments has

been mirror therapy in which the patient is instructed to perform movements in the painful arm while watching the same moves in a mirror, made by the unaffected arm. The majority of patients in one blinded trial benefited in terms of pain and mobility, but this study by Cacchio and coworkers included only patients with strokes and paretic limbs, not those with peripheral nerve injury. Each of these may be of value in the context of a comprehensive pain management program, usually conducted in a pain clinic as a means of providing relief from pain and suffering, reducing anxiety, and diverting the patient's attention, even if only temporarily, from the painful body part. Attempts to quantify the benefits of these techniques—judged usually by a reduction of drug dosage—have given mixed or negative results. Nevertheless, it is unwise for physicians to dismiss these methods, as well-motivated and apparently psychologically stable persons have reported subjective improvement with one or another of these methods and in the final analysis, this is what really matters. Conventional psychotherapy in combination with the use of medication and, at times, electroconvulsive therapy can be of benefit in the treatment of associated depressive symptoms, as discussed above (under "Pain in Association with Psychiatric Diseases") but it should not otherwise be expected to change the experience of pain.

Whatever treatment is undertaken, medical, procedural or surgical, the objective should be to allow and encourage increased use and mobilization of the affected limb or part, as success at this is most closely associated with relief of pain and reduced suffering.

Other Somatic Sensation

Sensory and motor functions are interdependent, as was dramatically illustrated by the early animal experiments of Claude Bernard and Charles Sherrington, in which practically all effective movement of a limb was abolished by eliminating only its sensory innervation (sectioning of posterior roots). Interruption of other sensory pathways and destruction of the parietal cortex also has profound effects on motility. To a large extent, human motor activity depends on a constant influx of sensory impulses (most of them not consciously perceived). Sensory motor integration is therefore necessary for normal nervous system function but disease may affect motor or sensory functions independently. There may be loss or impairment of sensory function, and this can represent the principal manifestation of neurologic disease.

This chapter deals with general somatic sensation, i.e., afferent impulses that arise in the skin, muscles, or joints. One form of somatic sensation—pain—was discussed in Chap. 8. Because of its overriding clinical importance, pain has been accorded a chapter of its own, but that chapter and this chapter are of one piece. The special senses—vision, hearing, taste, and smell—are considered in the next section (Chaps. 12 to 15), and visceral sensation, most of which does not reach consciousness, is considered with the disorders of the autonomic nervous system (Chap. 26).

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

An understanding of sensory disorders depends upon knowledge of functional anatomy. It is necessary to be familiar with the sensory receptors in the skin and deeper structures, the distribution of the peripheral nerves and roots, and the pathways by which sensory impulses are conveyed from the periphery and through the spinal cord and brainstem to the thalamus and cerebral cortex. These aspects of sensory anatomy and physiology were touched upon in Chap. 8 in relation to the perception of pain and are elaborated upon here to include all forms of somatic sensation. An appropriate starting point is Fig. 9-1 that shows the cutaneous distribution of the peripheral nerves.

All sensation depends on impulses that are excited by stimulation of receptors and conveyed to the central nervous system by afferent (sensory) fibers. Sensory receptors are of two general types: those in the skin, mediating superficial sensation (*exteroceptors*), and those in the deeper somatic structures (*proprioceptors*). Skin receptors are particularly numerous and transduce four types of sensory experience: warmth, cold, touch, and pain; these are conventionally referred to as *sensations* or *senses*, e.g., tactile sensation or sense of touch. Proprioceptors inform us of the position of our body or parts of our body; of the force, direction, and range of movement of the joints (kinesthetic sense); and a sense of pressure, both painful and painless. Histologically, a wide variety of sensory receptors have been described, varying from simple, free dendrite terminals to highly branched and encapsulated structures, the latter bearing the names of the anatomists who first described them (see below). These are called “dendrites” because the direction of flow of physiologic activity and of sensory information from these structures in the periphery is toward the cell body.

Mechanisms of Cutaneous Sensation

As indicated in the preceding chapter, it had been thought that each of the primary modalities of cutaneous sensation is subserved by a morphologically distinct end organ, each with its separate peripheral nerve fibers. According to this formulation, postulated by von Frey, each type of end organ was thought to respond only to a particular type of stimulus and to subservise a specific modality of sensation: Meissner corpuscles (named after Georg Meissner), touch; Merkel discs (named after Friedrich Sigmund Merkel), pressure; Ruffini plumes (names after Angelo Ruffini), warmth and skin stretch; Krause end bulbs (named after Wilhelm Krause), cold; Pacini (pacinian) corpuscles (named after Filippo Pacini), vibration and tickle; and for pain, nerve endings that not associated with transducer (“free nerve endings”). The last of these are also termed “naked” because they are surrounded by Schwann cells but are not myelinated (Fig. 9-2).

This *specificity theory*, as it came to be called, has held up best in respect to the peripheral mechanisms for pain, insofar as certain primary afferent fibers, namely the

Figure 9-1. The cutaneous fields of peripheral nerves. (Reproduced by permission from Haymaker W, Woodhall B: *Peripheral Nerve Injuries*, 2nd ed. Philadelphia, Saunders, 1953.)

C and A- δ fibers and their free nerve ending receptors, respond maximally to noxious stimuli. Even these freely branching receptor endings and their pain fibers convey considerable non-noxious information; that is, their specificity as pain fibers is not absolute (Chap. 8). Nor has it been possible to ascribe a specific function to each of the many other types of receptors. Thus, Merkel discs and Meissner corpuscles within nerve plexuses around the hair follicles, and free nerve endings can all be activated by moving or stationary tactile stimuli. Conversely, a single type of receptor seems capable of generating more than one sensory modality. Lele and Weddell found that with appropriate stimulation of the cornea, each of the four primary modalities of somatic sensibility (touch, warmth, cold, pain) could be recognized, even though the cornea contains only fine, free nerve endings. In the outer ear, which is also sensitive to these four modalities, only two types of receptors—freely ending and perifollicular—are present. The lack of organized receptors—e.g., the end bulbs of Krause and Ruffini—in the cornea and ear makes it evident that these types of receptors are not

essential for the recognition of cold and warmth as von Frey and other early anatomists had postulated.

Particularly instructive have been the observations of Kibler and Nathan, who studied the responses of warm and cold spots to different stimuli. (Warm and cold spots are those small areas of skin that respond most consistently to thermal stimuli with a sensation of warmth or cold.) They found that a cold stimulus applied to a warm spot gave rise to a sensation of cold and that a noxious stimulus applied to a warm or cold spot gave rise only to a painful sensation; they also noted that mechanical stimulation of these spots gave rise to a sensation of touch or pressure. These observations indicate that cutaneous receptors, some not easily distinguishable from one another on morphologic grounds, are probably endowed with only a relative degree of specificity, in the sense that each responds *preferentially* (i.e., has a lower threshold) to one particular form of stimulation. However, among the freely branching nociceptors there is some degree of specialization, as discussed in Chap. 8. Such end organs can then be classed as mechanoreceptors, thermoreceptors,

Figure 9-2. The location and morphology of mechanoreceptors in hairy and hairless (glabrous) skin of the human hand. Receptors are located in the superficial skin, at the junction of the dermis and epidermis, and more deeply in the dermis and subcutaneous tissue. The receptors of the glabrous skin are Meissner's corpuscles, located in the dermal papillae; Merkel disk receptors, located between the dermal papillae; and bare nerve endings. The receptors of the hairy skin are hair receptors, Merkel's receptors (having a slightly different organization than their counterparts in the glabrous skin), and bare nerve endings. Subcutaneous receptors, beneath both glabrous and hairy skin, include Pacinian corpuscles and Ruffini endings. Nerve fibers that terminate in the superficial layers of the skin are branched at their distal terminals, innervating several nearby receptor organs; nerve fibers in the subcutaneous layer innervate only a single receptor organ. The structure of the receptor organ determines its physiological function. (Reproduced with permission from Kandel ER, Schwartz JH, Jessell TM: *Principles of Neural Science*, 4th ed. New York: McGraw-Hill, 2000.)

or nociceptors, depending on their selective sensitivity to mechanical, thermal, or noxious stimuli respectively (Sinclair; Light and Perl).

Physiologic studies have shown that the *quality* of sensation depends on the type of nerve fiber that is activated. Different diseases therefore evoke a variety of sensory symptoms. Microstimulation of single sensory fibers in a peripheral nerve of an awake human subject arouses different sensations, depending on which fibers are stimulated and not on the frequency of stimulation. On the other hand, the frequency of stimulation governs the *intensity* of sensation, as does the number of sensory units that are stimulated. Stated somewhat differently, afferent impulse frequency (*temporal summation*) is encoded by the brain in terms of magnitude or intensity of sensation. In addition, as the intensity of stimulation increases, more sensory units are activated (*spatial summation*).

Localization of a stimulus was formerly thought to depend on the simultaneous activation of overlapping sensory units. Tower defined a peripheral sensory unit as a dorsal root ganglion cell, its central and distal processes, and all the sensory endings in the territory supplied by those distal processes (the receptive field of the sensory cell). In the very sensitive pulp of the finger, where the error of localization is less than 1 mm, there are 240 overlapping, low-threshold mechanoreceptors per square centimeter. Highly refined physiologic techniques have demonstrated that activation of even a single

sensory unit is sufficient to localize the point stimulated and that the body map in the parietal lobe is capable, by its modular columnar organization, of encoding such refined topographic information. Also, each point in the skin that is stimulated may involve more than one type of receptor. To gain access to its receptor, a stimulus must pass through the skin and possess sufficient energy to transduce, i.e., depolarize, the nerve ending.

Not only does the threshold of stimulation vary but the nerve impulse that is generated is a graded one, not an all-or-none phenomenon like an action potential in nerve. This poorly understood peripheral generator potential determines the frequency of impulses in the nerve and to what degree it is sustained or fades out (i.e., adapts to the stimulus or fatigues). However, the mechanism by which a stimulus is translated into a sensory experience, i.e., is encoded, is now partially understood. Special molecules transduce physical alterations by opening cationic channels. As mentioned in Chap. 8, these changes lead to the opening of voltage-gated sodium channels, which generates an action potential. It is probably fair to say that each type of specialized ending has a membrane structure that facilitates the transduction process for a particular type of stimulus. In general, the encapsulated endings, which are more highly myelinated, are of low-threshold type, variably adaptable to continued stimulation (Meissner and pacinian corpuscles are rapidly adapting; Merkel discs and Ruffini endings are slowly adapting) and are connected

to large sensory fibers (see Lindblom and Ochoa). The pacinian receptors are the most deeply situated (Fig. 9-1).

Sensory Pathways

Sensory Nerves

Fibers that mediate superficial sensation are located in cutaneous sensory or mixed sensorimotor nerves. In cutaneous nerves, unmyelinated pain and autonomic fibers exceed myelinated fibers by a ratio of 3 or 4:1. The myelinated fibers are of two types: small, lightly myelinated, A- δ fibers for pain and cold, as discussed in Chap. 8, and larger, faster-conducting A- α fibers for touch and pressure. Nonmyelinated autonomic fibers are efferent (postganglionic) and innervate piloerector muscles, sweat glands, and blood vessels. The differing conduction velocities of the fibers of these are discussed in Chap. 45.

A single cutaneous (touch, pain, and temperature) type of afferent fiber connects to several receptors, all of one type, which are irregularly distributed in the skin and account for sensory spots. Stimuli from a given spot are therefore conveyed by two or more fibers. The proprioceptive fibers subservise pressure sense and, with endings in articular structures, the sense of position and movement; they enable one to discriminate the form, size, texture, and weight of objects. Sensations of tickle, itch, and wetness are believed to arise from combinations of several types of receptors.

Itch is a distinctive sensation that can be separated on clinical and neurophysiologic grounds from touch and from pain. Two aspects are recognized: a brief primary localized itch at the site of stimulus or injury, and a subsequent more diffuse sensation that is greatly intensified by gentle touch. Itch sensation is transmitted by specific C fibers, not by touch mechanisms, for regions of analgesia no longer can be stimulated to itch but areas anesthesia retain this sensation. There is, however, no specialized peripheral itch receptor, the sensation depending instead on the spinal connections to itch pathways. Several forebrain regions are activated by itch, i.e., there is no central "itch center." From the perspective of neurologic diseases, the main cause of itch is postherpetic neuralgia, but cases of paroxysmal itch of central origin are known to be caused by multiple sclerosis. The pathophysiology of itching has been discussed by Greaves and Wall and is reviewed further by Yosipovitch and colleagues.

Spinal Roots

All the sensory neurons have their cell bodies in the dorsal root ganglia. The peripheral extensions of these cells constitute the sensory nerves; the central projections of these same cells form the posterior (dorsal) roots and enter the spinal cord. Each dorsal root contains all the fibers from skin, muscles, connective tissue, ligaments, tendons, joints, bones, and viscera that lie within the distribution of a single body segment (somite). This segmental innervation has been amply demonstrated in humans and animals by observing the effects of lesions that involve one or two spinal nerves, such as (1) herpes zoster,

which also causes visible vesicles in the corresponding area of skin; (2) the effects of a prolapsed intervertebral disc, which causes hypalgesia in a single root zone; and (3) surgical section of several roots on each side of an intact root (method of remaining sensibility). Maps of the dermatomes derived from these several types of data are shown in Figs. 9-3 and 9-4. It should be noted that there is considerable overlap from one dermatomal segment to the other, more so for touch than for pain. By contrast, there is less overlap between adjacent

Figure 9-3. Distribution of the sensory spinal roots on the surface of the body (dermatomes). (Reproduced by permission from Sinclair.)

Figure 9-4. Dermatomes of the upper and lower extremities, outlined by the pattern of sensory loss following lesions of single nerve roots. (Reproduced by permission from Keegan and Garrett.)

peripheral nerves and almost none between the divisions of the trigeminal nerve. Also, the maps differ somewhat according to the methods used in constructing them. In contrast to most dermatomal charts, those of Keegan and Garrett (based on the injection of local anesthetic into single dorsal root ganglia) show bands of hypalgesia to be continuous longitudinally from the periphery to the spine (Fig. 9-4). The distribution of pain fibers from deep structures, although not exactly corresponding to that of pain fibers from the skin, also follows a segmental pattern. In Chap. 8 it was commented that the areas of projection of referred pain from the visceral organs and musculoskeletal structures roughly correspond to the overlying dermatomes but they have distinctive patterns, termed sclerotomes (Fig. 8-5).

Posterior Root Entry Zone, Dorsal Horns and Posterior Columns

In the dorsal roots, the sensory fibers are first rearranged according to function. Large and heavily myelinated fibers enter the cord just medial to the dorsal horn and divide into ascending and descending branches. The descending fibers and some of the ascending ones enter the gray matter of the dorsal horn within a few segments of their entrance and synapse with nerve cells in the posterior horns as well as with large ventral horn cells that subserve segmental reflexes. Some of the ascending fibers run uninterrupted in the dorsal columns of the *same side of the spinal cord*, terminating in the gracile and cuneate nuclei in the upper cervical spinal cord and medulla (Fig. 9-5). The central axons of the primary sensory neurons are joined in the posterior columns by other secondary neurons whose cell bodies lie in the posterior horns of the spinal cord (see below). The fibers in the posterior columns assume a medial position as new fibers from each successively higher root are added laterally, thereby creating somatotopic laminations (see Fig. 8-3).

Of the long ascending posterior column fibers, which are activated by mechanical stimuli of skin and subcutaneous tissues and by movement of joints, only about 25 percent (from the lumbar region) reach the gracile nuclei at the upper cervical cord. The remaining fibers send collaterals to, or terminate in, the dorsal horns of the spinal cord, at least in the cat (Davidoff). An estimated 20 percent of ascending fibers originate from cells in Rexed layers IV and V of the posterior horns (see Fig. 8-1) and convey impulses from low-threshold mechanoreceptors that are sensitive to hair movement, skin pressure, or noxious stimuli. There are also descending fibers in the posterior columns, including fibers from cells in the dorsal column nuclei.

The posterior columns contain a portion of the fibers for the sense of touch as well as the fibers mediating the senses of touch-pressure, vibration, direction of movement and position of joints, and stereoesthesia—recognition of surface texture, shape, numbers, and figures written on the skin and two-point discrimination—all of which depend on patterns of touch-pressure (see Fig. 8-2). The nerve cells of the nuclei gracilis and cuneatus and accessory cuneate nuclei give rise to a secondary afferent path, which crosses the midline in the medulla and ascends as the medial lemniscus to the posterior thalamus. However, the fiber pathways in the posterior columns are not the sole mediators of proprioception in the spinal cord (see “Posterior [Dorsal] Column Syndrome” further on).

In addition to the well-defined posterior column pathways, there are cells in the more loosely structured “reticular” part of the dorsal column that receive secondary ascending fibers from the dorsal horns of the spinal cord and from ascending fibers in the posterolateral columns. These dorsal column fibers project to brainstem nuclei, cerebellum, and thalamic nuclei. Many other cells of the dorsal horn nuclei are interneurons, with both excitatory and inhibitory effects on local reflexes or on the primary ascending neurons. They are also under the influence of the sensorimotor cortex. Some act on descending corticospinal motor neurons. The functions

Figure 9-5. The main somatosensory pathways emphasizing the posterior column–lemniscal system (*thicker tract lines*). See Fig. 8-2 for comparison with the spinothalamic system.

of many of the extrathalamic projections of dorsal column cells are unknown (Davidoff).

Thinly myelinated or unmyelinated fibers, subserving mainly pain sensibility, but some sensitive to touch and pressure, enter the cord on the lateral aspect of the dorsal horn and synapse with dorsal horn cells, mainly within a segment or two of their point of entry into the cord. The dorsal horn cells, in turn, give rise to secondary sensory fibers, some of which may ascend ipsilaterally but most of which decussate and ascend in the spinothalamic tracts, as described in Chap. 8 (see Figs. 8-1

and 8-2). Observations based on surgical interruption of the anterolateral funiculus indicate that fibers mediating touch and deep pressure occupy the ventromedial part (anterior spinothalamic tract). Also as remarked in Chap. 8, an ascending tract of secondary sensory axons lies in or medial to the descending corticospinal system.

After the posterior columns terminate in the gracile and cuneate nuclei of the rostral cervical cord and medulla, synapses are made with fibers that cross the midline and ascend to form the medial lemniscal tracts in the brainstem. The lemniscal system is situated in a

paramedian position, changing orientation slightly at different levels of the brainstem, and joining the spinothalamic system in the rostral midbrain to terminate in the posterior thalamic nuclei (see below and also Fig. 8-2).

Trigeminal Connections

The pathways mediating cutaneous sensation from the face and head—especially touch, pain, and temperature—are conveyed to the brainstem by the trigeminal nerve. After entering the pons, the pain and temperature fibers turn caudally and run through the ipsilateral medulla as the descending spinal trigeminal tract, terminating in the long, vertically oriented nucleus caudalis, or spinal trigeminal nucleus, that lies beside it and extends to the second or third cervical segment of the cord, where it becomes continuous with the posterior horn of the spinal gray matter. Axons from the neurons of this nucleus cross the midline and ascend as the trigeminal quintothalamic tract (also termed, somewhat imprecisely, trigeminal lemniscus) along the medial side of the spinothalamic tract (see Fig. 8-2), of which it is the equivalent.

Thalamocortical Connections

The ventral posterior thalamic nucleus receives fibers from the medial lemniscal, spinothalamic, and trigeminal (fibers from the principal sensory and spinal trigeminal nuclei) tracts, and projects mainly to two somatosensory cortical areas. The first area (S1) corresponds to the postcentral cortex or Brodmann areas 3, 1, and 2. S1 afferents are derived primarily from the ventral posterolateral nucleus (VPL, the terminus of medial lemniscal and spinothalamic fibers) and the ventral posteromedial nucleus (VPM, the terminus of trigeminal fibers) and are distributed somatotopically, with the leg represented uppermost and the face lowermost (face and hand are juxtaposed). Electrical stimulation of this area yields sensations of tingling, numbness, and warmth in specific regions on the *opposite* side of the body. The information transmitted to S1 is tactile and proprioceptive, derived mainly from the dorsal column–medial lemniscus system and concerned mainly with sensory discrimination. The second somatosensory area (S2) lies on the upper bank of the sylvian fissure, adjacent to the insula. Localization of function is less discrete in S2 than in S1, but S2 is also organized somatotopically, with the face rostrally and the leg caudally. The sensations evoked by electrical stimulation of S2 are much the same as those of S1 but, in distinction to the latter, may be felt bilaterally. Of note is the failure of cortical stimulation to evoke pain sensation.

Undoubtedly, the perception of sensory stimuli involves more of the cerebral cortex than the two discrete areas described above. Some sensory fibers probably project to the precentral gyrus and others to the superior parietal lobule. Moreover, S1 and S2 are not purely sensory in function; motor effects can be obtained by stimulating them electrically. It has been shown that sensory neurons in VPL, cuneate and gracile nuclei, and sensory neurons in the dorsal horns of the spinal cord all receive descending as well as ascending cortical projections. This reciprocal arrangement probably influences movement and the transmission and interpretation of pain, as discussed in Chap. 8.

Sensory homunculus

Figure 9-6. The “sensory homunculus,” or cortical representation of sensation in the postcentral gyrus; compare this to the distribution of body areas in the motor cortex as shown in Fig. 3-4. (Reproduced with permission from Kandel ER, Schwartz JH, Jessell TM: *Principle of Neural Science*, 4th ed. New York, McGraw-Hill, 2000.)

Provided that the subcortical structures, especially the thalamus, are intact, certain sensations such as pain, touch, pressure, and extremes of temperature can reach consciousness. Their accurate localization, however, as well as the patient’s ability to make other fine sensory discriminations, depends to a large extent on the integrity of the sensory cortex. This clinical distinction is elaborated in the discussion of the sensory syndromes further on.

Figure 9-6 (“sensory homunculus”) shows the cortical representation of sensory information in the postcentral gyrus. As in the case of the motor representation (see Fig. 3-4), a disproportionate area is devoted to localization in the fingers, lips, and face.

From this brief account of the various channels of sensory information, one must conclude that at every level there is the possibility of feedback control from higher levels. Most external and some internal stimuli are highly complex and induce activity in more than one sensory system. In every system there is sufficient redundancy to allow lesser-used systems to compensate partially for the deficits incurred by disease.

EXAMINATION OF SENSATION

Most neurologists would agree that sensory testing is the most difficult part of the neurologic examination. For

one thing, test procedures are relatively crude and are unlike those natural modes of stimulation with which the patient is familiar. It is also fair to say that few diagnoses are made solely on the basis of the sensory examination; more often the exercise serves to complement the motor examination. Quite often, no objective sensory loss can be demonstrated despite symptoms that suggest the presence of such an abnormality. Only rarely does the opposite pertain, i.e., one discovers a sensory deficit when there has been no complaint of sensory symptoms. Sensory symptoms in the nature of paresthesia or dysesthesia may be generated along axons of nerves not sufficiently diseased to impair or reduce sensory function; in the latter instance, loss of function may have been so mild and gradual as to pass unnoticed. Always there is some difficulty in evaluating the response to sensory stimuli, as it depends on the patient's interpretation of sensory experiences. This, in turn, will depend on the patient's general awareness and responsiveness and ability to cooperate, as well as degree of suggestibility. Children, by virtue of their simple and direct responses, are often better witnesses than more sophisticated individuals who are likely to analyze their feelings minutely and report small and insignificant differences in stimulus intensity.

General Considerations

Before proceeding to sensory testing, the physician should question patients about their symptoms; this, too, poses particular problems. Patients may be confronted with derangements of sensation that are unlike anything they have previously experienced, and they have limited terms to describe what they feel. They may say that a limb feels "numb" and "dead" when in fact they mean that it is weak. Occasionally a loss of sensation is discovered almost accidentally, e.g., by a lack of pain on touching an object hot enough to blister the skin or unawareness of articles of clothing and other objects in contact with the skin. More often, disease induces new and unnatural sensory experiences such as a band of tightness, a feeling of the feet being encased in cement, lancinating pains, an unnatural feeling when stroking the skin, a sensation as if walking on pebbles, and so on.

If nerves, sensory roots, or spinal tracts are damaged or partially interrupted, the patient may complain of tingling or prickling feelings ("like Novocain" or like the feelings in a limb that has "fallen asleep," the common colloquialism for nerve compression), cramp-like sensations, or burning or cutting pain occurring either spontaneously or in response to stimulation.

Experimental data support the view that partially damaged touch, pressure, thermal, and pain fibers become hyperexcitable and generate ectopic impulses along their course, either spontaneously or in response to a natural volley of stimulus-evoked impulses (Ochoa and Torebjork). These abnormal sensations are experienced as *paresthesias*, or *dysesthesias* if they are severe and distressing, as noted in Table 8-2. Another positive sensory symptom is *allodynia*, referring to a phenomenon in which one type of stimulus evokes another type of sensation—e.g., touch may induce pain.

Table 9-1

ORIGIN OF ABERRANT SENSATIONS

SYMPTOMS	STRUCTURES AFFECTED
Paresthesia, tingling, buzzing	Large fibers (in nerve or posterior columns)
Burning, heat, cold	Small fibers
Prickling pain	Combined small- and large-fiber
Pseudocramp	A type of paresthesia, probably related to large-fiber dysfunction
Band tightness	Lemniscal system of cord
Lancinating pain	Small-fiber neuropathy and radiculopathy
Hyperalgesia	Partial peripheral nerve damage

The clinical description of a sensation may divulge the particular sensory fibers involved (Table 9-1). It is known that stimulation of touch fibers gives rise to a sensation of tingling and buzzing; of muscle proprioceptors, to pseudocramp (the sensation of cramping without actual muscle contraction); of thermal fibers, to heat (including burning) and coldness; and of A- δ fibers, to prickling and pain. Paresthesia arising from ectopic discharges in large sensory fibers can be induced by nerve compression, hypocalcemia, hypomagnesemia, certain medications (niacin foremost among them), and diverse diseases of nerves. Band-like sensations on a limb or the trunk are the result of dysfunction in large sensory fibers, either in the periphery or their continuation in the posterior columns. Certain sensory symptoms suggest an anatomic location of nerve disease; for example, lancinating pains that radiate to the back or neck implicate root or, less often, sensory ganglion disease.

The presence of persistent paresthesiae incriminates a lesion involving sensory pathways in nerves, spinal cord, or higher structures. Most often, the large fibers in the peripheral nerves or posterior columns are involved. Evanescent paresthesia, of course, is usually of no significance. Every person has had the experience of resting a limb on the ulnar, sciatic, or peroneal nerve and having the extremity "fall asleep." This is because of compressive interruption of axonal transport and not of ischemia of the nerves or other components of the limb as is commonly assumed. The hyperventilation of anxiety may cause paresthesia of the lips and hands (sometimes unilateral) from diminution of CO₂ and thereby of ionized calcium; tetany may also occur, with carpopedal spasms. However, these sensory experiences are transient and should not be confused with the persistent, albeit frequently fluctuating, paresthesia of structural disease of the nervous system. Severe acral and peripheral paresthesias with perversion of hot and cold sensations are characteristic of certain neurotoxic shellfish poisonings (*ciguatera*) and some toxins, such as mercury.

Also worth comment are vibratory paresthesias, which we have encountered in only a handful of patients. One articulate physician described the sensation as a high-amplitude, low-frequency "buzz" that was distinctly different from the more common prickling paresthesia, burning, numbness, etc. We have the impression that these sensations are almost always a manifestation

of central sensory disease, in one case probably attributable to the posterior columns and in another to cerebral disease. Beyond this, little is known about this symptom.

Effect of Age on Sensory Function

A matter of importance in the testing of sensation is the progressive impairment of sensory perception that occurs with advancing age. This requires that sensory thresholds, particularly in the feet and legs, be assessed in relation to age standards. The effect of aging is most evident in relation to vibratory sense, but proprioception, the perception of touch, and fast pain are also diminished with age. Sweating and vasomotor reflexes are reduced as well. These changes, which are discussed further in Chap. 29, are probably caused by neuronal loss in dorsal root ganglia and are reflected in a progressive depletion of fibers in the posterior columns. Receptors in the skin and special sense organs (taste, smell) also wither with age.

Terminology of Sensory Signs and Symptoms (See also Table 8-2)

A few additional terms require definition, as they are encountered in discussions of sensation. Some of these, relating to pain sensation, were mentioned in Chap. 8. *Anesthesia* refers to a complete loss and *hypesthesia* to a partial loss of all forms of sensation. Loss or impairment of specific cutaneous sensations may be indicated by an appropriate prefix or suffix, e.g., *thermoanesthesia* or *thermohypesthesia* (loss and reduction in temperature sense), *analgesia* (loss of pain sense), *hypalgesia* (reduction in pain sensibility), *tactile anesthesia*, and *pallanesthesia*, or *apallescetia* (loss of vibratory sense). The term *hyperesthesia*, as explained in Chap. 8, refers to an increased sensitivity to various stimuli and is usually used with respect to cutaneous sensation. It implies a heightened activity of the sensory apparatus. Under certain conditions (e.g., sunburn), there does appear to be an enhanced sensitivity of cutaneous receptors, but usually the presence of hyperesthesia betrays an underlying sensory defect. Careful testing will demonstrate an elevated threshold to tactile, painful, or thermal stimuli; but once the stimulus is perceived, it may have a severely painful or unpleasant quality (*hyperpathia*). Some clinicians use this last term to denote an exaggerated response to a painful stimulus (*hyperalgesia* which is subtly different from hyperpathia, denotes an abnormally painful reaction to a painful stimulus; Table 8-2). In *alloesthesia*, or *allesthesia*, a tactile or painful stimulus delivered on the side of hemisensory loss is experienced in a corresponding area of the opposite side or at a distant site on the same side. This phenomenon is observed most frequently with right-sided putaminal lesions (usually hemorrhage) and with anterolateral lesions of the cervical spinal cord; it presumably depends on the existence of an uncrossed ipsilateral spinothalamic pathway (see the original studies of Ray and Wolff).

Testing of Sensory Function

The detail with which sensation is tested is determined by the clinical situation. If the patient has no sensory

complaints, it is sufficient to test vibration and position sense in the fingers and toes and the perception of pinprick over the extremities, and to determine whether the findings are the same in symmetrical parts of the body. A rough survey of this sort occasionally detects sensory defects of which the patient was unaware. More thorough testing is in order if the patient has complaints referable to the sensory system or if one finds localized atrophy or weakness, ataxia, trophic changes of joints, or painless ulcers.

A few other general rules are useful. It is easier for a patient to perceive the boundary of an abnormal area of sensation if the examiner proceeds from an area of reduced sensation toward the normal area. One should not press the sensory examination in the presence of fatigue, for an inattentive patient is a poor witness. Also, the examiner must avoid suggesting symptoms to the patient. After explaining in the simplest terms what is required, the examiner interposes as few questions and remarks as possible. Patients should generally not be asked, "Do you feel that?" each time they are touched; they are simply told to say "yes" or "sharp" every time they are touched or feel pain. Repetitive pinpricks within a small area of skin should be avoided, as this will make inapparent a subtle hypalgesia, because of the phenomenon of temporal summation as discussed earlier. In patients who may be overinterpreting slight changes in pinprick, differentiating between warm and cold is often more informative than differentiating between "sharp" and "dull." The patient should not directly observe the part under examination. A cooperative patient may, if asked to use a pin or his fingertips, outline an analgesic or anesthetic area or determine whether there is a graduated loss of sensation in the distal parts of a leg or arm. Finally, the findings of the sensory examination should be accurately recorded in narrative or on a chart by shading affected regions on a preprinted figure of the body or a sketch of a hand, foot, face, or limb.

Described below are the usual bedside methods of testing sensory function. These tests are sufficient for most clinical purposes. For clinical investigation and research into the physiology of pain, which require the detection of threshold values and quantification of sensory impairment, a wide range of instruments are available. Their use has been described by Dyck and colleagues (see also Lindblom and Ochoa and Bertelsmann et al).

Testing of Tactile Sensation

This is usually done with a wisp of cotton or light touch of a finger. The patient is first acquainted with the stimulus by applying it to a normal part of the body. Then, with eyes closed, he is asked to indicate if the sensation feels "natural" or to say "yes" each time various other parts are touched. A patient who is simulating sensory loss may say no in response to a tactile stimulus. Cornified areas of skin, such as the soles and palms, will require a heavier stimulus than other areas and the hair-clad parts a lighter one because of the numerous nerve endings around the follicles. Patients will be more sensitive to a moving stimulus of any kind than to a stationary one. The deft application of the examiner's or the patient's

roving fingertips is a useful refinement and aids in demarcating an area of tactile loss, as Trotter and Davies originally showed.

More precise testing is possible by using a von Frey hair. By this method, a stimulus of constant strength can be applied and the threshold for tactile sensation determined by measuring the force required to bend a hair of known length. Spurious areas of hypesthesia may arise when a series of contactual stimuli lead to a decrement of sensation, either through adaptation of the end organ or because the initial sensation outlasts the stimulus and seems to spread.

Testing of Pain Perception

This is most efficiently assessed by pinprick, although it may be evoked by a variety of noxious stimuli. Patients must understand that they are to report the feeling of sharpness, not simply the feeling of contact or pressure of the pinpoint. If pinpricks are applied rapidly in one area, their effect may be summated and a heightened perception of pain may result; therefore they should be delivered about one per second and not over the same spot. Small differences in intensity can be discounted. An effective approach is to ask the patient to compare the pin sensation in two areas on a scale of 1 to 10; a report of "8 or 9" as compared to "10" is usually insignificant.

It is almost impossible, using an ordinary pin, to apply each stimulus with equal intensity. A pinwheel (Wartenberg wheel) is sometimes more effective because it allows the application of a more constant pressure, but risk of transmission of blood-borne infection from patient to patient has made this method outdated. This difficulty can be overcome to some extent by the use of an algometer, which delivers stimuli of constant intensity. Quantification of small-fiber sensation can be better assessed in the clinical laboratory by the use of thermal stimuli delivered by a computerized device as described below.

If an area of diminished or absent touch or pain sensation is encountered, its boundaries should be demarcated to determine whether it has a segmental or peripheral nerve distribution or is lost below a certain level on the trunk. As mentioned, such areas are best delineated by proceeding from the region of impaired sensation toward the normal. The changes may be confirmed by dragging a pin lightly over the parts in question. Areas of reduced pinprick sensation can be profitably corroborated by the thermal sense examination.

Testing of Deep-Pressure Pain

One can estimate the perception of this modality simply by lightly pinching or pressing deeply on the tendons, muscles, or bony prominences. Pain can often be elicited by heavy pressure even when superficial sensation is diminished; conversely, in some diseases, such as tabetic neurosyphilis, loss of deep-pressure pain may be more striking than loss of superficial pain. This uncomfortable examination can be omitted in routine neurological cases.

Testing of Thermal Sense

A quick but rough way to assess thermal loss (or to corroborate a previously found zone of hypalgesia) is to warm one side of a tuning fork by rubbing it briskly against the palm and apply its alternate sides to the patient's skin and asking the patient which side is colder (or warmer). This suffices for most bedside examinations.

If more careful examination is required, the skin should first be exposed to room air for a brief time before the examination. The test objects should be large, ideally two stoppered test tubes containing hot (45°C/113°F) and cold (20°C/68°F) tap water with thermometers that extend into the water through the flask stoppers. Extreme degrees of heat and cold may be employed first to delineate roughly an area of thermal sensory impairment. The side of each tube is applied successively to the skin for a few seconds and the patient is asked to report whether the flask feels "less hot" or "less cold" in comparison to a normal part. The qualitative change can then be quantitated as far as possible by recording the differences in temperature that the patient is able to recognize as the difference in temperature between the two tubes is gradually reduced. A normal person can detect a difference of 1°C (1.8°F) or even less in the range of 28°C (82.4°F) to 32°C (89.6°F); in the warm range, differences between 35°C (95°F) and 40°C (104°F) can be recognized, and in the cold range, between 10°C (50°F) and 20°C (68°F). If the temperature of the test object is below 10°C (50°F) or above 50°C (122°F), sensations of cold or heat become confused with pain. This technique has been largely supplanted by commercially manufactured electronic devices that can present a series of slightly differing thermal stimuli in sequence to a probe placed on the finger or toe. Special algorithms are used for the order and magnitude of temperature change and to determine whether the patient's reports are consistent and valid. The results are reported in the form of a "just noticeable difference" (JND) between temperatures or intensities of pain.

Testing of Proprioceptive Sense

Awareness of the position and movements of our limbs, fingers, and toes is derived from receptors in the muscles, tendons (Golgi tendon organs, according to Roland and Ladegaard-Pederson) and joints and is probably facilitated by the activation of skin receptors (Moberg). The two modalities comprising proprioception, i.e., sense of movement and of position, are usually both impaired, although clinical situations do arise in which perception of the position of a limb or digits is lost while that of passive and active movement (kinesthesia) of these parts is retained. The opposite occurs but is infrequent.

Abnormalities of position sense may be disclosed in several ways. When the patient has his arms outstretched and eyes closed, the affected arm will wander from its original position; if the patient's fingers are spread apart, they may undergo a series of changing postures ("piano-playing" movements, or pseudoathetosis); in attempting to touch the tip of his nose with his index finger, the patient may miss the target repeatedly, but the performance is corrected when the eyes are open.

Perception of passive movement is first tested in the fingers and toes as the defect, when present, is reflected maximally in these parts. It is important to grasp the digit at the sides, perpendicular to the plane of movement; otherwise the pressure applied by the examiner may allow the patient to identify the direction of movement. This applies as well to testing of the more proximal segments of the limb. The patient should be instructed to report each movement as being “up” or “down” from the previous position (directional kinesthesia). It is useful to demonstrate the test with a large and easily identified movement, but once the idea is clear to the patient, the smallest detectable changes should be determined. The part being tested should be moved rapidly. Normally, a very slight degree of movement is appreciated in the digits (as little as 1 degree of an arc). The test should be repeated enough times to eliminate chance (50 percent of responses). Defective perception of passive movement is judged by comparison with a normal limb or, if perception is bilaterally defective, on the basis of what the examiner has learned through experience to be normal. Slight impairment may be disclosed by a slowness of response or, if the digit is displaced very slowly, by an unawareness or uncertainty that movement has occurred; or, after the digit has been displaced in the same direction several times, the patient may misjudge the first movement in the opposite direction; or, after the examiner has moved the toe, the patient may make a number of small voluntary movements of the toe in an apparent attempt to determine its position or the direction of the movement. Inattentiveness will also cause some of these errors.

The lack of position sense in the legs can also be demonstrated by displacing the limb from its original position and having the patient, with eyes closed, place the other leg in the same position or point to the great toe. If proprioception is abnormal in axial structures, the patient will be unable to maintain his balance with feet together and eyes closed (*Romberg sign*). This test is often interpreted imprecisely. In the Romberg position, even a normal person whose eyes are closed will sway slightly, and the patient who lacks balance because of cerebellar ataxia or some other motor disorder will sway considerably more if his visual cues are removed. Only a marked discrepancy in balance with eyes open and with eyes closed qualifies as a Romberg sign. The most certain indication of abnormality is the need to step to the side or backward to avoid falling. Mild degrees of unsteadiness in an anxious or suggestible patient may be overcome by diverting his attention, e.g., by having him touch the index finger of each hand alternately to his nose while standing with eyes closed or by following the examiner's finger with his eyes. Patients with authentic proprioceptive problems will sway when their gaze is diverted from the ground and then become more unsteady when the eyes are closed. Patient with factitious unsteadiness, usually will remain stable when they look at the ceiling or a distant object and then become very unsteady when the eyes are closed. It is important to remember that any defect in proprioception (e.g. peripheral neuropathy, myelopathy or vestibulopathy) will lead to a Romberg sign even though the sign, described

by Moritz Romberg, was meant to diagnose tabes dorsalis.

Testing of Vibratory Sense

This is a composite sensation comprising touch and rapid alterations of deep-pressure sense. The only cutaneous structure capable of registering such stimuli of this frequency is the rapidly adapting pacinian corpuscle. The conduction of vibratory sense depends on both cutaneous and deep afferent fibers that are carried in the muscle spindle afferent fibers and ascend mainly in the dorsal columns of the cord. Consequently, it is rarely affected by lesions of single nerves but will be disturbed in patients with disease of multiple peripheral nerves, dorsal columns, medial lemniscus, and thalamus. Vibration and position sense are usually impaired in similar conditions, although one of them (most often vibration sense) may be affected disproportionately. With advancing age, vibration is the sensation most commonly diminished, especially at the toes and ankles (see further on).

Vibration sense is tested by placing a tuning fork with a low rate and long duration of vibration (generally 128 Hz) over the bony prominences, making sure that the patient responds to the vibration, not simply to the pressure of the fork, and that he is not trying to listen to it. As with thermal and pain testing, there are mechanical devices that quantitate vibration sense. Quantitative tuning forks with a 0-8 scale are available but it is sufficient for most clinical purposes to compare the point tested with a normal part of the patient or the examiner. The examiner may detect the vibration after it ceases for the patient by holding a finger under the distal interphalangeal joint, the handle of the tuning fork being placed on the dorsal aspect of the joint. Or the vibrating fork is allowed to run down until the moment that vibration is no longer perceived, at which point the fork is transferred quickly to the corresponding part of the examiner and the time to extinction is noted. There is a small degree of accommodation to the vibration stimulus, so that slight asymmetries detected by rapid shifting from a body part on one side to the other should be interpreted accordingly. The perception of vibration at the patella after it has disappeared at the ankle or at the anterior iliac spine after it has disappeared at the knee is indicative of a length-dependent peripheral neuropathy. The approximate level of pinprick loss from a spinal cord lesion can be corroborated by testing vibratory sensation over the iliac crests and successive dorsal vertebral spines.

Testing of Discriminative (Parietal Lobe Cortical) Sensation

Damage to the parietal lobe sensory cortex or to the thalamocortical projections results in a particular type of disturbance—namely, an inability to make sensory discriminations and to integrate spatial and temporal sensory information (see further under “Sensory Loss Caused by Lesions of the Parietal Lobe” and Chap. 22). Lesions in these structures usually disturb complex sensory perception but leave the primary modalities (touch, pain, temperature, and vibration sense) relatively little affected. The integrity of discriminative sensory functions can be assessed only if

it is first established that the primary sensory modalities on which they depend (mainly touch) are largely normal. If a cerebral lesion is suspected, discriminative function should be tested further in the following ways.

Two-Point Discrimination

The ability to distinguish two points from one is tested by using a compass, the points of which should be blunt and applied simultaneously and painlessly. The distance at which such stimuli can be recognized as a distinct pair varies but is roughly 1 mm at the tip of the tongue, 2 to 3 mm on the lips, 3 to 5 mm at the fingertips, 8 to 15 mm on the palm, 20 to 30 mm on the dorsal hands and feet, and 4 to 7 cm on the trunk. It is characteristic of the patient with a lesion of the sensory cortex to mistake two points for one, although occasionally the opposite occurs.

Cutaneous Localization and Figure Writing (Graphesthesia)

Localization of cutaneous tactile or painful stimuli is tested by touching various points on the body and asking the patient to place the tip of his index finger on the point stimulated or on the corresponding point of the examiner's limb. Recognition of numbers or letters traced on the skin (these should be larger than 4 cm on the palm) with a pencil or similar object or the direction of a line drawn across the skin also depends on localization of tactile stimuli. Normally, traced numbers as small as 1 cm can be detected on the pulp of the finger if drawn with a pencil. According to Wall and Noordenbos, these are also the most useful and simple tests of posterior column function.

Appreciation of Texture, Size, and Shape

Appreciation of texture depends mainly on cutaneous impressions, but recognition of the shapes and sizes of objects is based on sensory experience from deeper receptors as well. Inability to recognize shape and form is frequently a manifestation of cortical disease, but a similar clinical defect will occur if tracts that transmit proprioceptive and tactile sensation are interrupted by lesions of the spinal cord and brainstem (and, of course, of the peripheral nerves). This type of sensory defect is called *stereoanesthesia* (see further on, under "Posterior [Dorsal] Column Syndrome") and is distinguished from *astereognosis*, which connotes an inability to identify an object by palpation, even though the primary sense data (touch, pain, temperature, and vibration) are intact. In practice, pure astereognosis is rarely encountered, and the term is employed when the impairment of superficial and vibratory sensation in the hands seems to be of insufficient severity to account for the defect in tactile object identification. Defined in this way, astereognosis is either right- or left-sided and, with the qualifications mentioned below, is the product of a lesion in the opposite hemisphere, involving the sensory cortex, particularly S2 or the thalamoparietal projections.

The traditional doctrine that somatic sensation is represented only in the contralateral parietal lobe is not absolute. Beginning with the report by Oppenheim in 1906, there have been sporadic patients who showed bilateral

astereognosis or loss of tactile sensation as a result of an apparently unilateral cerebral lesion. The correctness of these observations was corroborated by Semmes and colleagues, who tested a large series of patients with traumatic lesions involving either the right or left cerebral hemisphere. They found that the impairment of sensation (particularly discriminative sensation) following right- and left-sided lesions was not strictly comparable; the left hand as well as the right tended to be impaired by injury to the left sensorimotor region, whereas only the left hand tended to be affected by injury to the right sensorimotor region. These observations, with minor qualifications, were also confirmed by Carmon and by Corkin and associates, who investigated the sensory effects of cortical excisions in patients with focal epilepsy. Thus it appears that certain somatosensory functions in some patients are mediated not only by the contralateral hemisphere but also by the ipsilateral one, although the contribution of the former is undoubtedly the more significant.

The traditional concept of left hemispheric dominance in respect to tactile perception has been questioned by Carmon and Benton, who found that the right hemisphere is particularly important in perceiving the direction of tactile stimuli. Also, Corkin and associates observed that patients with lesions of the right hemisphere show a consistently greater failure of tactile-maze learning than those with left-sided lesions, pointing to a relative dominance of the right hemisphere in the mediation of tactile performance involving a spatial component. Certainly the phenomenon of sensory inattention or extinction is more prominent with lesions of the right as opposed to the left parietal lobe and is most informative if the primary and secondary sensory cortical areas are spared. These matters are considered further on in this chapter and in Chap. 22.

Finally, there is a distinction between astereognosis and tactile agnosia. Some authors (e.g., Caselli) have defined tactile agnosia as a strictly unilateral disorder, right or left, in which the impairment of tactile object recognition is unencumbered by a disturbance of the primary sensory modalities. Such a disorder would be designated by others as a pure form of astereognosis (see above). In our view, *tactile agnosia* is a disturbance in which a one-sided lesion lying posterior to the postcentral gyrus of the *dominant* parietal lobe results in an inability to recognize an object by touch in *both* hands. According to this view, tactile agnosia is a disorder of apperception of stimuli and of translating them into symbols, akin to the defect in naming parts of the body, visualizing a plan or a route, or understanding the meaning of the printed or spoken word (visual or auditory verbal agnosia). These and other agnosias are discussed in Chap. 22.

SENSORY SYNDROMES

Sensory Changes Caused by Interruption of a Single Peripheral Nerve

In these cases, the distribution of sensory loss will vary, depending on whether the nerve involved is predominantly muscular, cutaneous, or mixed. Following division of a *cutaneous nerve*, the area of sensory loss is always

less than its anatomic distribution because of overlap from adjacent nerves. That the area of tactile loss is greater than that for pain relates both to a lack of collateralization (regeneration) from adjacent tactile fibers (in contrast to rapid collateral regeneration of pain fibers) and to a greater overlap of pain sensory units. If a large area of skin is involved, the sensory defect characteristically consists of a central portion in which all forms of cutaneous sensation are lost, surrounded by a zone of partial loss, which becomes less marked as one proceeds from the center to the periphery. Perceptions of deep pressure and passive movement are intact because these modalities are mediated by nerve fibers from subcutaneous structures and joints. Along the margin of the hypesthetic zone, the skin becomes excessively sensitive (hyperesthetic); light contact may be felt as smarting and mildly painful, more so as one proceeds from the periphery of the area to its center. According to Weddell, the dysesthesias are attributable to the greater sensitivity of collateral regenerating fibers that have made their way from surrounding healthy pain fibers into the denervated region.

Particular types of lesions have differing effects on sensory nerve fibers, as discussed earlier, but they are nearly always to some extent multimodal. *Compression* of a nerve ablates mainly the function of large touch and pressure fibers and leaves the function of small pain, thermal, and autonomic fibers intact; procaine and ischemia have the opposite effect. The tourniquet test is instructive in this respect. A sphygmomanometer cuff is applied above the elbow, inflated to a point well above the systolic pressure, and maintained there for as long as 30 min. (This is not particularly painful if the patient does not contract the forearm and hand muscles.) Paresthesiae appears within a few minutes, followed by sensory loss—first of touch and vibration, then of cold, fast pain, heat, and slow pain, in that order and spreading centripetally. Physiologic studies have confirmed the theory of Lewis and colleagues that compression blocks the function of nerve fibers in order of their size. Release of the cuff results in postcompression paresthesia, which has been shown to arise from spontaneous activity that is generated along the myelinated nerve fibers from ectopic sites at a distance from the compression. Within seconds of releasing the cuff, other changes appear—the cold, blanched hand becomes red and hot and there is an array of tingling, stinging, cramp-like sensations that reach maximum intensity in 90 to 120 s and slowly fade (Lewis et al). Sensory function is recovered in an order inverse to that in which it was lost. Similar spontaneous and ectopic discharges probably explain the paresthetic symptoms early in the acute demyelinating neuropathies, even before the appearance of sensory loss or numbness. It is worth emphasizing that these features of compression are not because of nerve ischemia, as commonly stated; instead, they result from reversible physiologic changes in the myelin and underlying axon.

Certain maneuvers for the provocation of positive sensory phenomena—for example, the *Tinel sign* of tingling upon percussion of a regenerating peripheral nerve and the *Phalen sign* of paresthesia in the territory of the median nerve on wrist flexion—typify the susceptibility of a damaged nerve to pressure. In the case of a severed nerve,

regeneration from the proximal end begins within days. The thin, regenerating sprouts are unusually sensitive to mechanical stimulation, which produces tingling, or the Tinel sign.

Sensory Changes Caused by Involvement of Multiple Nerves (Polyneuropathy) (Table 9-2)

In most instances of polyneuropathy, the sensory changes are accompanied by varying degrees of motor and reflex loss. Usually the sensory impairment is bilaterally symmetrical. Because in most types of polyneuropathy the longest and largest fibers are the most affected, sensory loss is most severe over the feet and legs and, if the upper limbs are affected, over the hands. The term *glove-and-stocking*, employed to describe the distribution of sensory loss of polyneuropathy, draws attention to the predominantly distal pattern of involvement but fails to indicate that the change from normal to impaired sensation is characteristically gradual. (In psychogenic sensory loss, by contrast, the border between normal and absent sensation is usually sharply defined.) The abdomen, thorax, and face are spared except in the most severe cases, in which sensory changes may be found over the anterior thoracoabdominal escutcheon and around the mouth.

Table 9-2

EXAMINATION FEATURES OF THE PERIPHERAL AND SPINAL CORD SENSORY SYNDROMES

Polyneuropathy

- Symmetrical distal sensory loss
- Sensory loss may affect one modality preferentially
- Areflexia or hyporeflexia
- Weakness, if present, symmetrical

Polyradiculopathy

- Asymmetrical sensory and motor loss
- Proximal and distal parts of limb differentially affected
- Reflex loss limited to region of affected root(s)

Ganglionopathy

- Implicates all sensory modalities
- Proximal body parts affected
- Ataxia

Tabetic syndrome

- Prominent loss of vibratory and position sense in feet
- Romberg sign
- Secondary (Charcot) joint deformities
- Areflexia

Myelopathy

- Complete transverse lesion: loss of all sensory modalities below level of lesion
- Syringomyelia: loss of pain and thermal sense with preservation of touch and joint position/vibration over restricted region of neck, cape, arms, hands
- Anterior spinal artery syndrome: loss of pain sense with preservation of vibration and joint position below level of lesion
- Posterior column: same as tabetic but reflexes preserved
- Hemicord (Brown-Séquard): loss of pain sense opposite to the lesion and beginning several levels below it; loss of vibration and joint position sense on the side of the lesion and below it

(See Fig. 9-7 and also Chap. 46.)

When the neuropathy is primarily demyelinating rather than axonal, paresthesia is an early feature. It is reported in the distal territories of nerves; when short nerves (e.g., the trigeminal) are involved, the paresthesia appears in proximal body parts, such as the perioral region.

The sensory loss of polyneuropathy usually involves all modalities of sensation, and—although it is difficult to equate the degrees of impairment of pain, touch, temperature, vibration, and position senses—one modality may be impaired disproportionately to the others. This clinical feature is explained by the fact that particular diseases of the peripheral nerves selectively damage sensory fibers of different size. For example, degeneration or demyelination of the large fibers that subservise kinesthetic sense causes a loss of vibratory and position sense and relative sparing of pain, temperature, and, to some degree, tactile perception. When extreme, such a polyneuropathy results in pseudoathetoid movements of the outstretched fingers or toes; it may also result in a sensory ataxia because of affection of the large-diameter nerves destined for the spinocerebellar tracts.

By contrast, involvement of the small-caliber myelinated and unmyelinated axons affects pain, temperature, and autonomic sensation, with preservation of proprioceptive, vibration, and tactile sense—producing a syndrome called “pseudosyringomyelia,” because it simulates the dissociated pain from tactile sensory loss that is seen in this disease of the spinal cord (see further on, under “Sensory Spinal Cord Syndromes”). Prolonged analgesia may lead to trophic ulcers and Charcot joints. These patterns of sensory loss, as well as those produced by the plexopathies and mononeuritis multiplex, are discussed further in Chap. 46.

Sensory Changes from Involvement of Nerve Roots (Radiculopathy) (Figs. 9-1, 9-2, and 9-3 and Table 9-2)

The surface innervation of the sensory nerve roots serves as one of the most useful and dependable guides to localization in neurology and the main dermatomes are known to all physicians. Because of considerable overlap from adjacent roots, division of a single sensory root does not produce complete loss of sensation in any area of skin. However, compression of a single sensory cervical or lumbar root (e.g., by a herniated intervertebral disc) can cause a segmental impairment of cutaneous sensation. When two or more contiguous roots have been completely divided, a zone of sensory loss can be demonstrated; this is surrounded by a narrow zone of partial loss in which a raised threshold accompanied by excessive sensitivity may or may not be evident. For reasons not altogether clear, partial sensory loss from root lesions is easier to demonstrate by the use of a painful stimulus than by a tactile or pressure stimulus.

Disease of the nerve roots frequently gives rise to “shooting” (lancinating) pains and burning sensations that project down the course of their sensory nerves. The common examples are sciatica, from lower lumbar or upper sacral root compression, and sharp pain radiating

from the shoulder and down the upper arm, from cervical disc protrusion.

When multiple roots are affected (*polyradiculopathy*) by an infiltrative, inflammatory, or compressive process, the syndrome is more complex and must be differentiated from polyneuropathy. The distinguishing features of a polyradiculopathy, aside from pain, are asymmetrical muscle weakness that involves both proximal and distal parts differentially in each limb and a pattern of sensory loss that is consistent with affection of several roots, not necessarily contiguous ones. Details are found in Chap. 46.

Sensory Changes from Involvement of Sensory Ganglia (Sensory Neuronopathy, Ganglionopathy) (Table 9-2)

Widespread disease of the dorsal root ganglia produces many of the same sensory defects as disease of the posterior nerve roots, but it is unique in that proximal areas of the body also show pronounced sensory loss; the face, oral mucosa, scalp, trunk, and genitalia may be sites of hypesthesia and hypalgesia. Proprioception is diminished or lost in distal and, to some extent, proximal body parts, giving rise also to ataxic movements, often quite severe, and to pseudoathetosis. Tendon reflexes are lost. Sometimes there are additional features of dysautonomia, but strength is entirely spared. Recognition of this unusual pattern of pansensory loss is of considerable diagnostic importance, because it raises for consideration a number of underlying diseases that might otherwise be overlooked; these diseases are discussed in Chap. 46. The main causes of this syndrome are paraneoplastic, connective tissue disease, particularly Sjögren syndrome, toxic exposure, and idiopathic inflammation.

Tabetic Syndrome

The tabetic syndrome may be considered a type of polyradiculopathy or ganglionopathy, but it is often considered with diseases of the spinal cord because it produces Wallerian degeneration of posterior columns. It results from damage to the large proprioceptive and other fibers of the posterior lumbosacral (and sometimes cervical) roots. It was in the past typically caused by neurosyphilis but also by diabetes mellitus, and other diseases that involve the posterior roots or dorsal root ganglia. Numbness or paresthesia and “lightning” or lancinating pains are frequent complaints; areflexia, abnormalities of gait (gait of sensory ataxia), and hypotonia without significant muscle weakness are found on examination. The sensory loss may involve only vibration and position senses in the lower extremities, but loss or impairment of superficial or deep pain sense or of touch may appear in severe cases. In this case, loss of deep tendon reflexes distinguishes the sensory root syndrome from a lesion in the posterior columns. The feet and legs are most affected in tabes, much less often the arms and trunk. The Romberg sign is prominent. Frequently, atonicity of the bladder with retention of urine and trophic joint changes (Charcot joints) and crises of abdominal (“gastric”) pains are associated.

Cases of congenital absence of all cutaneous sensation resulting from the lack of development of small

sensory ganglion cells may produce the tabetic syndrome; this is discussed in Chap. 8. A similar but partial defect may be found in the Riley-Day syndrome (Chap. 26). There are also forms of hereditary polyneuropathy that cause universal insensitivity.

Sensory Spinal Cord Syndromes (Fig. 9-7)

See also Chap. 44.

Complete Spinal Sensory Syndrome

With a complete transverse disruption of the spinal cord, the most striking loss is of power; most characteristic, however, is a loss of all forms of sensation below a level that corresponds to the lesion. There may be a narrow zone of hyperesthesia at the upper margin of the anesthetic zone. Loss of pain, temperature, and touch sensation begins one or two segments below the level of the lesion; vibratory and position senses have less-discrete levels but they can be detected by careful examination. The sensory (and motor) loss in spinal cord lesions that involve both gray and white matter is expressed in patterns corresponding to bodily segments or dermatomes. These are shown in Figs. 9-3 and 9-4 and are most obvious on the trunk, where each intercostal nerve has a transverse distribution.

Also, it is important to remember that during the subacute evolution of a transverse spinal cord lesion, there may be a discrepancy between the level of the lesion and that of the sensory loss, the latter ascending as the lesion progresses. This can be understood if one conceives of a lesion as evolving from the periphery to the center of the cord, affecting first the outermost fibers carrying pain and temperature sensation from the legs. Conversely, a lesion advancing from the center of the cord will affect these modalities in the reverse order, in a pattern of *sacral sparing*, meaning that sensation is preserved over the buttocks and anal region but is absent over the trunk and legs.

Hemisection of the Spinal Cord (Brown-Séquard Syndrome)

Disease may be confined to or predominate on one side of the spinal cord; pain and thermal sensation are affected on the opposite side of the body, and proprioceptive sensation is affected on the same side as the lesion. Although rarely present in its entirety, a partial Brown-Séquard syndrome is common in practice. The loss of pain and temperature sensation begins one or two segments below the lesion. An associated spastic motor paralysis on the side of the lesion completes the syndrome (Fig. 9-7). Tactile sensation is not greatly affected, as the fibers from one side of the body are distributed in tracts (posterior columns, anterior and lateral spinothalamic) on both sides of the cord.

Syringomyelic Syndrome (Lesion of the Central Gray Matter)

Because fibers conducting pain and temperature sensation cross the cord in the anterior commissure, a lesion of considerable vertical extent in this location characteristically abolishes these modalities on one or both sides over several segments (dermatomes) but spares tactile sensation (Fig. 9-7). This type of *dissociated sensory loss* usually occurs in a segmental distribution, and because the lesion frequently involves other parts of the gray matter, varying degrees of segmental amyotrophy and reflex loss are usually present as well. If the lesion has spread to the white matter, corticospinal, spinothalamic, and posterior column signs will be conjoined. The most common cause of such a lesion in the cervical region is the centrally situated developmental syringomyelia; less-common causes are intramedullary tumor, trauma, and hemorrhage. A *pseudosyringomyelic* syndrome was mentioned earlier in relation to small-fiber neuropathies that simulate syringomyelia.

Figure 9-7. Sites of lesions of the characteristic spinal cord sensory syndromes (shaded areas indicate regions of damage). Lower right figure shows variable extent of damage to mid-axial cord but always sparing the posterior columns.

Posterior (Dorsal) Column Syndrome

Paresthesias in the form of tingling and pins-and-needles sensations or girdle- and band-like sensations are common complaints with posterior column disease. In some cases there may be the additional feature of a diffuse, burning, unpleasant sensation in response to pinprick. Loss of vibratory and position sense occurs below the level of the lesion, but the perception of pain and temperature is affected relatively little or not at all. Because posterior column lesions are caused by the interruption of central projections of the dorsal root ganglia cells, they may be difficult to distinguish from a process that affects large fibers in sensory roots (tabetic syndrome); however, the tendon reflexes are spared in the former and eliminated in tabes. In some diseases that involve the dorsal columns, vibratory sensation may be involved predominantly, whereas in others position sense is more affected.

With complete posterior column lesions, only a few of which have been verified by postmortem examinations, not only is the patient deprived of knowledge of movement and position of parts of the body below the lesion but all types of sensory discrimination are impaired (see Nathan et al for a review of the subject). If the lesion is in the high cervical region, there is clumsiness in the palpation of objects and an inability to recognize the qualities of objects by touch, even though touch-pressure sensation is relatively intact. Stereoaesthesia is also expressed by impaired graphesthesia and tactile localization. There may be unusual disturbances of touch and pressure, manifesting as lability of threshold, persistence of sensation after removal of the stimulus, and sometimes tactile and postural hallucinations. Nathan and colleagues confirmed this counterintuitive observation that lesions of the posterior columns cause only slight defects in touch and pressure sensation and that lesions of the anterolateral spinothalamic tracts also cause minimal or no defects in these modalities. This is not easily reconciled with clinical observations of patients with lesions in the posterior columns. However, a combined lesion in both pathways causes a total loss of tactile and pressure sensibility below the lesion.

The loss of sensory functions that follows a posterior column lesion—such as impaired two-point discrimination; figure writing; detection of size, shape, weight, and texture of objects; and ability to detect the direction and speed of a moving stimulus on the skin—may simulate a parietal “cortical” lesion, but differs in that vibratory sense is also lost in spinal cord syndromes. In several cases on record, interruption of the posterior columns by surgical incision or other type of injury did not cause a permanent loss of the sensory modalities thought to be subserved by these pathways (Cook and Browder, Wall and Noordenbos). Because postmortem studies of these cases were not performed, it is possible that some of the posterior column fibers had been spared. Also, it should be realized that not all proprioceptive fibers ascend to the gracile and cuneate nuclei; some proprioceptive fibers leave the posterior columns in the lumbar region and synapse with secondary neurons in the spinal gray matter and ascend in the ipsilateral posterolateral funiculus.

Only cutaneous fibers continue to the gracile and cuneate nuclei.

The usual causes of the posterior column syndrome are multiple sclerosis, vitamin B₁₂ deficiency, copper deficiency, tabes dorsalis, and HIV and human T-lymphotropic virus (HTLV) type 1 infection.

Anterior Myelopathy (Anterior Spinal Artery Syndrome)

With infarction of the spinal cord in the territory of supply of the anterior spinal artery or with other lesions that affect the ventral portion of the cord predominantly, as in some cases of myelitis, one finds a loss of pain and temperature sensation below the level of the lesion but with relative or absolute sparing of proprioceptive sensation. Because the corticospinal tracts and the ventral gray matter also lie within the area of distribution of the anterior spinal artery, spastic paralysis is a prominent feature (Fig. 9-7).

Disturbances of Sensation from Lesions of the Brainstem

A characteristic feature of medullary lesions is the occurrence, in many instances, of a crossed sensory disturbance, i.e., a loss of pain and temperature sensation on one side of the face and on the opposite side of the body. This is accounted for by involvement of the descending spinal trigeminal tract or its nucleus and the crossed lateral spinothalamic tract on one side of the brainstem and is nearly always caused by a lateral medullary infarction (Wallenberg syndrome). In the upper medulla, pons, and midbrain, the crossed trigeminothalamic and lateral spinothalamic tracts run together; a lesion at these levels causes loss of pain and temperature sense on the opposite half of the face and body. There are no tactile paresthesias, only thermal or painful dysesthesias. In the upper brainstem, the spinothalamic tract and the medial lemniscus become confluent, so that an appropriately placed lesion causes a contralateral loss of all superficial and deep sensation. Cranial nerve palsies, cerebellar ataxia, and motor paralysis are almost invariably associated, as indicated in the discussion of strokes in this region (Chap. 34). In other words, a lesion in the brainstem at any level is unlikely to cause an isolated sensory disturbance.

Hemisensory Loss Caused by a Lesion of the Thalamus (Syndrome of Dejerine-Roussy)

Involvement of the VPL and VPM nuclei of the thalamus, usually because of a vascular lesion, causes loss or diminution of all forms of sensation on the opposite side of the body. Position sense is affected more frequently than any other sensory function and is usually, but not always, more profoundly reduced than loss of touch and pinprick. With partial recovery of sensation, or with an acute but incomplete lesion, spontaneous pain or discomfort (thalamic pain), sometimes of the most distressing type, may appear on the affected side of the body and any stimulus may then have a diffuse, unpleasant, lingering quality (anterior and proximal syndromes). Thermal—especially cold—stimuli, emotional disturbance, loud sounds, and

even certain types of music may aggravate the painful state. In spite of this overresponse to stimuli, the patient usually shows an elevated pain threshold, i.e., a stronger stimulus than normal is necessary to produce a sensation of pain (hypalgesia with hyperpathia). The same type of pain syndrome may occasionally accompany lesions of the white matter of the parietal lobe, the medial lemniscus, or even the posterior columns of the spinal cord.

It should be pointed out that a symptomatic hemisensory syndrome, usually with few objective changes, occurs frequently without manifest evidence of thalamic or spinal cord damage. This particularly occurs in young women, as pointed out by Toth. A number of our patients with this benign condition have had migraine, and one, as in Toth's series, had the antiphospholipid syndrome, but the connections between all these entities is tenuous and many cases are considered to be psychogenic.

Sensory Loss Caused by Lesions of the Parietal Lobe

In the anterior parietal lobe syndrome (Verger-Dejerine syndrome), there are disturbances mainly of discriminative sensory functions of the opposite arm, leg, and side of the face without impairment of the primary modalities of sensation (unless the lesion is extensive and deep). Loss of position sense and sense of movement, impaired ability to localize touch and pain stimuli (topagnosia), widening of two-point threshold, and astereognosis are the most prominent findings, as described earlier in this chapter and in Chap. 22, "Clinical Effects of Parietal Lobe Lesions."

Another characteristic manifestation of parietal lobe lesions is *sensory inattention, extinction, or neglect*. In response to bilateral simultaneous testing of symmetrical parts, using either tactile or painful stimuli, the patient may acknowledge only the stimulus on the sound side; or, if the face and hand or foot on the affected side is touched or pricked, only the stimulus to the face may be noticed. Apparently cranial structures command more attention than other less richly innervated parts. Yet each stimulus, when applied separately to each side or to each part of the affected side, is properly perceived and localized. In the case of sensory neglect, the patient ignores one side of the body and extrapersonal space contralateral to the parietal lesion, which is usually in the nondominant hemisphere. Left parietal lesions may also cause (right) sensory neglect, but less frequently and less profoundly. Sensory neglect or extinction, which may also occur occasionally with posterior column and medial lemniscus lesions, may be detected in persons who disclaim any sensory symptoms. These phenomena and other features of parietal lobe lesions are considered further in Chap. 22.

Yet another parietal lobe syndrome, Dejerine-Mouzon, is featured by a severe impairment of the primary modalities of sensation (pain, thermal, tactile, and vibratory sense) over half of the body. Motor paralysis is variable; with partial recovery, there may be a clumsiness that resembles cerebellar ataxia. Because the sensory disorder simulates that caused by a thalamic lesion, it was called *pseudothalamic* by Foix and coworkers. Hyperpathia, much like that of

the Dejerine-Roussy syndrome (see above), has also been observed in patients with cortical-subcortical parietal lesions. The pseudothalamic syndrome was related by Foix and colleagues to a sylvian infarct; Bogousslavsky and associates traced it to a parietal infarct caused by occlusion of the ascending parietal branch of the middle cerebral artery. In each of the aforementioned parietal lobe syndromes, if the dominant hemisphere is involved, there may be an aphasia, a bimanual tactile agnosia, or a Gerstmann syndrome; with nondominant lesions, there may be anosognosia (see Chap. 22).

Often with parietal lesions, the patient's responses to sensory stimuli are variable. A common mistake, as emphasized by Critchley, is to attribute this abnormality to hysteria (see also below). A lesion confined to only a part of the parietal cortex (the best examples have been caused by glancing bullet or shrapnel wounds of the skull) may result in a circumscribed loss of superficial sensation in an opposite limb, mimicking a root or peripheral nerve lesion.

Sensory Loss Due to Suggestibility and Hysteria (See also Chap. 51)

The possibility of suggesting sensory loss to a patient is a very real one, as has already been indicated. Hysterical patients may complain of a complete hemianesthesia—sometimes with the overtly hysterical findings of reduced hearing, sight, smell, and taste on one side—as well as impaired vibration sense over only half the skull and sternum, most of these being anatomic impossibilities. A frequently used test to disclose this feature is performed by placing a vibrating tuning fork on each side adjacent to the middle of the forehead. The transmission of vibration through the bone assures that loss of sensation on one side of the midline is not possible. Anesthesia of an entire limb or a sharply defined sensory loss over part of a limb, not conforming to the distribution of a root or cutaneous nerve, may also be observed. The diagnosis of hysterical hemianesthesia is best made by eliciting the other relevant symptoms of hysteria or, if this is not possible, by noting the discrepancies between the sensory loss displayed by the patient and that which occurs as part of the known, anatomically verified sensory syndromes.

Sometimes, in a patient with no other neurologic abnormality or in one with a definite neurologic syndrome, one is dismayed by sensory findings that are completely inexplicable and discordant. In such cases, one must try to reason through to the diagnosis by disregarding the sensory findings or approach the finding as revealing a second disorder such as a neurofibroma of a nerve root.

Laboratory Diagnosis of Somatosensory Syndromes

Affirmation of the clinical sensory syndromes is often possible by the application of electrophysiologic testing. Slowing and reduced amplitude of sensory nerve conduction is found with lesions of nerve, but only if the lesion lies distal to (or within) the sensory ganglion. Severe sensory loss in a neuropathic pattern with preserved

sensory nerve action potentials therefore indicates a radiculopathy. Loss or slowing of the H reflex and F responses corroborates the presence of lesions in proximal parts of nerves, plexuses, and roots. By the use of somatosensory evoked potentials, it is possible to demonstrate slowing of conduction in the peripheral nerves or roots, in the pathways from spinal cord to a point in the lower medulla, in the medial lemniscus to the thalamus, and in the pathway from the thalamus to the cerebral cortex. In the context of regional sensory loss, evoked potentials find their greatest utility in demonstrating root disease when sensory nerve conduction studies are normal; otherwise, they are used most frequently to support the diagnosis of multiple sclerosis, in which case there

may or may not be corresponding sensory features. (See Chap. 2 for discussion of evoked potential testing.)

In practice, it is seldom necessary to examine all modalities of sensation and perception. With single peripheral nerve lesions, touch and pinprick testing are the most informative. With spinal cord disease, pinprick and thermal stimuli are most revealing of lateral column lesions; testing the senses of vibration, position, and movement, and particularly the sense of direction of a dermal stimulus, reliably indicates posterior column lesions. Touch is the least useful. In brainstem lesions, all modes of sensation, including touch, may be affected, and this applies in general to thalamic lesions. Thus, one is guided in the selection of tests by the suspected locale of the disease.

Headache and Other Craniofacial Pains

Of all the painful states that afflict humans, headache is undoubtedly the most frequent and rivals backache as the most common reason for seeking medical help. In fact, there are so many cases of headache that special headache clinics have been established in many medical centers. In addition to its frequency in general practice, many headaches are caused by general medical rather than neurologic diseases, and the subject is the legitimate concern of the general physician. Yet there is always the question of intracranial disease, so that it is difficult to approach the subject without a knowledge of neurologic medicine.

Why so many pains are centered in the head is a question of some interest. Several explanations come to mind. For one thing, the face and scalp are more richly supplied with pain receptors than many other parts of the body, perhaps to protect the precious contents of the skull. Also, the nasal and oral passages, the eye, and the ear—all delicate and highly sensitive structures—reside here and must be protected; when affected by disease, each is capable of inducing pain in its own way. Finally, there is greater concern about what happens to the head than to other parts of the body, since the former houses the brain, and headache frequently raises the specter of brain tumor or other cerebral disease.

Semantically, the term *headache* encompasses all aches and pains located in the head, but in practice, its application is restricted to discomfort in the region of the cranial vault. Facial, lingual, and pharyngeal pains are put aside as something different and are discussed separately in the latter part of this chapter and in Chap. 47, on the cranial nerves.

GENERAL CONSIDERATIONS

In the introductory chapter on pain, reference was made to the necessity, in dealing with any painful state, of determining its quality, severity, location, duration, and time course as well as the conditions that produce, exacerbate, or relieve it. In the case of headache, a detailed history following these lines will determine the diagnosis more often than will the physical examination or imaging. Although the examination is unlikely to be revealing,

a few aspects are worth emphasis. Auscultation of the skull may disclose a bruit (with large arteriovenous malformations), and palpation may disclose the tender, hardened or elevated arteries of temporal arteritis, sensitive areas overlying a cranial metastasis, an inflamed paranasal sinus, or a tender occipital nerve, examination of neck flexion may reveal meningitis; however, apart from such special instances, examination of the head itself, although necessary, seldom discloses the diagnosis.

As to the *quality* of cephalic pain, the patient's description may or may not be helpful. When asked to compare the pain to some other sensory experience, the patient may allude to tightness, aching, pressure, bursting, sharpness, or stabbing. The most important information to be obtained is whether the headache is pulsatile, but one must keep in mind that patients sometimes use the word *throbbing* to refer to a waxing and waning of the headache without any relation to the pulse, or simply use the term to transmit the severity of pain, whereas authentic pulsatile throbbing, is characteristic of migraine.

Similarly, statements about *the intensity of the pain* must be accepted with caution, as they reflect as much the patient's temperament, attitudes and customary ways of experiencing and reacting to pain as its true severity. A better index of severity is the degree to which the pain has incapacitated the patient, especially if he is not prone to illness. A severe migraine attack seldom allows the migraineur to perform the day's work. Another rough index of the severity of headache is its propensity to awaken the patient from sleep or to prevent sleep. The most intense cranial pains are those associated with meningitis and subarachnoid hemorrhage, which have grave implications, and with migraine, cluster headache, or tic douloureux, which do not.

Data regarding the *location* of a headache are apt to be more informative. Migraine headache is unilateral in two-thirds of attacks and is commonly associated with nausea, vomiting, and sensitivity to light, sound, and smells. Inflammation of an extracranial artery causes pain localized to the site of the vessel. Lesions of the paranasal sinuses, teeth, eyes, and upper cervical vertebrae induce a less sharply localized pain but still one that is referred to a certain region, usually the forehead or maxilla or around the eyes. Intracranial lesions in the posterior fossa generally cause pain in the occipitotemporal region

and usually are homolateral if the lesion is one-sided. Supratentorial lesions induce frontotemporal pain, or approximate the site of the lesion. Localization, however, may also be deceiving. Pain in the frontal regions may be caused by such diverse lesions and mechanisms as glaucoma, sinusitis, thrombosis of the vertebral or basilar artery, pressure on the tentorium, and increased intracranial pressure. Similarly, ear pain may signify disease of the ear itself, but as often, it is referred from other regions, such as the throat, cervical muscles, spine, or structures in the posterior fossa. Periorbital and supraorbital pain, while usually indicative of local disease, may reflect dissection of the cervical portion of the internal carotid artery. Headaches localized to the vertex or biparietal regions are infrequent and should raise the suspicion of sphenoid or ethmoid sinus disease or thrombosis of the superior sagittal venous sinus.

The *mode of onset*, the *variation of the pain over time*, and *duration* of the headache, with respect both to a single attack and to the profile of the headache over a period of years, are also useful data. At one extreme, the headache of subarachnoid hemorrhage (caused by a ruptured aneurysm) occurs as an abrupt attack that attains its maximal severity in a matter of seconds or minutes, or, in the case of meningitis, it may come on more gradually, over several hours or days. Simulating the rapid onset, severe headache of subarachnoid hemorrhage are a group of “thunderclap headaches” of diverse causes but principally cerebral venous thrombosis and vasospasm syndromes. Brief sharp pain, lasting a few seconds, in the eyeball (ophthalmodynia) or cranium (“ice-pick” pain) and “ice-cream headache” caused by pharyngeal cooling is more common in migraineurs, with or without the characteristic headache, but otherwise cannot be interpreted and is significant only by reason of its benignity.

Migraine of the classic type usually has its onset in the early morning hours or in the daytime, reaches its peak of severity typically over several to 30 min, and lasts, unless treated, for 4 to 24 h, occasionally for as long as 72 h or more. Often, it is terminated by sleep. A migrainous patient having several attacks per week usually proves to have a combination of migraine and tension headaches, an analgesic “rebound headache,” or, rarely, some unexpected intracranial lesion. By contrast, the occurrence of unbearably severe unilateral orbitotemporal pain coming on within an hour or two after falling asleep or at predictable times during the day and recurring nightly or daily for a period of several weeks to months is typical of cluster headache; usually an individual attack of “cluster” dissipates in 30 to 45 min but some blend into more prolonged migraine. The headache of intracranial tumor may appear at any time of the day or night; it will interrupt sleep, vary in intensity, and last a few minutes to hours as the tumor raises intracranial pressure. With posterior fossa masses, the headache tends to be worse in the morning, on awakening. Tension headaches, described further on, may persist with varying intensity for weeks to months or even longer; when such headaches are protracted, there is usually an associated depressive illness. In general, headaches that have recurred regularly for many years prove to be migraine or tension in type.

The more or less constant *relationship of headache to certain biologic events and also to certain precipitating or aggravating (or relieving) factors* can be of great significance in diagnosis. Headaches that occur regularly in the premenstrual period are usually generalized and mild in degree, but attacks of migraine may also occur at this time (catamenial migraine). Headaches that have their origin in cervical spine disease are most typically intense after a period of inactivity, such as a night's sleep, and the first movements of the neck are stiff and painful. Headache, or more often face ache, from infection of the nasal sinuses may appear, with clock-like regularity, upon awakening or in midmorning and is characteristically worsened by stooping and changes in atmospheric pressure; there is associated midfrontal or maxillary tenderness. On the other hand, the regular recurrence of migraine headache is often misdiagnosed as chronic sinusitis. Eyestrain headaches, of course, follow prolonged use of the eyes, as after long-sustained periods of reading, or exposure to the glare of video displays, but the pain is transient. In certain individuals, alcohol, intense exercise (such as weight lifting), stooping, straining, coughing, and sexual intercourse are known to initiate a special type of bursting headache, lasting a few seconds to minutes. If a headache is made worse by sudden movement or by coughing or straining, an intracranial source is tentatively suggested. Migraine often occurs several hours or a day following a period of intense activity and stress (“weekend”, or “letdown” migraine). Some patients have discovered that their migraine is relieved momentarily by gentle compression of the carotid or superficial temporal artery on the painful side, and others report that the carotid near the angle of the jaw is tender during the headache. Pain that is noticed when the scalp is stroked in combing or fixing the hair (allodynia) is common in migraine but could be a symptom of inflammation of the temporal arteries (temporal arteritis).

Pain-Sensitive Cranial Structures

Our understanding of headache has been augmented by observations made during operations on the brain (Ray and Wolff). These observations have informed us that only certain cranial structures are sensitive to noxious stimuli: (1) skin, subcutaneous tissue, muscles, extracranial arteries, and external periosteum of the skull; (2) the delicate structures of the eye, ear, nasal cavities, and paranasal sinuses; (3) intracranial venous sinuses and their large tributaries because they are intradural; (4) parts of the dura at the base of the brain and the arteries within the dura, particularly the proximal parts of the anterior and middle cerebral arteries and the intracranial segment of the internal carotid artery; (5) the middle meningeal and superficial temporal arteries; and (6) the first three cervical nerves and cranial nerves as they pass through the dura. Interestingly, pain is practically the only sensation produced by stimulation of these structures; the pain arises in the walls of blood vessels containing pain fibers (the nature of vascular pain is discussed further on). Much of the pia-arachnoid, the parenchyma of the brain, and the pependyma and choroid plexuses lack sensitivity.

The reference sites of pain from the aforementioned structures are important in understanding the genesis of cranial pain. Pain that arises from distention of the middle meningeal artery is projected to the back of the eye and temporal area. Pain from the intracranial segment of the internal carotid artery and proximal parts of the middle and anterior cerebral arteries is felt in the eye and orbitotemporal regions. The pathways whereby cephalic sensory stimuli are transmitted to the central nervous system (CNS) are the trigeminal nerves, particularly their first and, to some extent, second divisions, which convey impulses from the forehead, orbit, anterior and middle fossae of the skull, and the upper surface of the tentorium. The sphenopalatine branches of the facial nerve convey impulses from the naso-orbital region. The ninth and tenth cranial nerves and the first three cervical nerves transmit impulses from the inferior surface of the tentorium and all of the posterior fossa. Sympathetic fibers from the three cervical ganglia and parasympathetic fibers from the sphenopalatine and otic ganglia are mixed with the trigeminal and other sensory fibers. The tentorium roughly demarcates the trigeminal from the cervical-vagal-glossopharyngeal innervation zones. The central sensory connections, which ascend through the brainstem or the cervical spinal cord and brainstem to the thalamus, are described in Chaps. 8 and 9.

To summarize, pain from supratentorial structures is referred to the anterior two-thirds of the head, i.e., to the territory of sensory supply of the first and second divisions of the trigeminal nerve; pain from infratentorial structures is referred to the vertex and back of the head and neck predominantly by the second cervical roots. Trigeminal and cervical sensory inputs converge on the second order neurons at the C2 level, permitting pain from the neck and occipital regions to be referred to the forehead, and vice versa. The seventh, ninth, and tenth cranial nerves refer pain to the naso-orbital region, ear, and throat. There may be local tenderness of the scalp at the site of the referred pain. Dental or temporomandibular joint pain impulses are carried by the second and third divisions of the trigeminal nerve. With the exception of the cervical portion of the internal carotid artery, from which pain is referred to the eyebrow and supra-orbital region, and the upper cervical spine, from which pain may be referred to the occiput, pain because of disease in extracranial parts of the body is not referred to the head. There are, however, rare instances of angina pectoris that may produce discomfort at the cranial vertex or adjacent sites and, of course, in the jaw.

Mechanisms of Cranial Pain

The studies of Ray and Wolff demonstrated that relatively few mechanisms are operative in the genesis of cranial pain. More specifically, *intracranial mass lesions* cause headache only if they deform, displace, or exert traction on vessels and dural structures at the base of the brain, and this may happen long before intracranial pressure rises. In fact, artificially raising the intraspinal and intracranial pressure by the subarachnoid or intraventricular injection of sterile saline solution does not consistently

result in headache. This has been interpreted to mean that raised intracranial pressure does not cause headache—a questionable conclusion when one considers the relief of headache in some patients that follows lumbar puncture and lowering of the cerebrospinal fluid (CSF) pressure, particularly after subarachnoid hemorrhage. Actually, most patients with high intracranial pressure complain of bioccipital and bifrontal headaches that fluctuate in severity, probably because of traction on vessels or dura.

Dilatation of intracranial or extracranial arteries (and possibly sensitization of these vessels), of whatever cause, is likely to produce headache. The headaches that follow seizures and ingestion of alcohol are probably all caused by cerebral vasodilatation. Nitroglycerin, nitrites in cured meats (“hot-dog headache”), and monosodium glutamate in Chinese food may cause headache by the same mechanism. It is possible that the throbbing or steady headache that accompanies febrile illnesses has a vascular origin as well; it is likely that the increased pulsation of meningeal vessels activates pain-sensitive structures within their walls or around the base of the brain. Febrile headache may be generalized or predominate in the frontal or occipital regions and is relieved on one side by carotid or superficial temporal artery compression and on both sides by jugular vein compression. Like migraine, it is also increased by shaking the head. Certain systemic infectious agents, enumerated further on, have a tendency to cause severe headache.

A similar mechanism may be operative in the severe, bilateral, throbbing headaches associated with extremely rapid rises in blood pressure, as occurs with pheochromocytoma, malignant hypertension, sexual activity, and in patients being treated with monoamine oxidase inhibitors. Mild to moderate degrees of chronic hypertension, however, do not cause headaches despite a popular notion to the contrary. So-called cough and exertional headaches may also have their basis in the distention of intracranial vessels.

For many years, following the investigations of Harold Wolff, the headache of migraine was attributed to dilatation of the extracranial arteries. Now, it appears that this is not a constant relationship and that the headache is of complex intracranial as much as extracranial origin, perhaps related to the sensitization of blood vessels and their surrounding structures. Activation of the trigeminovascular system (the trigeminal nerves and the blood vessels they supply), leading to an inflammatory response that is generated by local neural mechanisms, “neurogenic inflammation,” has also been assigned a role in migraine headache. These and other theories of causation are summarized by Cutrer and discussed further on in this chapter in the section on migraine.

With regard to cerebrovascular diseases causing head pain, the extracranial temporal and occipital arteries, when involved in giant cell arteritis (cranial or “temporal” arteritis), give rise to severe, persistent headache, at first localized on the scalp and then more diffuse. Most strokes caused by vascular occlusion do not cause head pain. However, with occlusion or dissection of the vertebral artery, there may be pain in the upper neck or

postauricular area; basilar artery thrombosis causes pain to be projected to the occiput and sometimes to the forehead; and the ipsilateral eye and brow, and the forehead above it are the most common sites of projected pain from dissection of the carotid artery and occlusion of the stem of the middle cerebral arteries. Expanding or ruptured intracranial aneurysms of the posterior communicating or distal internal carotid arteries very often cause pain projected to the eye.

Infection or blockage of paranasal sinuses is accompanied by pain over the affected maxillary or frontal sinuses. Usually it is associated with tenderness of the skin and cranium in the same distribution. Pain from the ethmoid and sphenoid sinuses is localized deep in the midline behind the root of the nose or occasionally at the vertex (especially with disease of the sphenoid sinus). The mechanism in these cases involves changes in pressure and irritation of pain-sensitive sinus walls.

With frontal and ethmoidal sinusitis, the pain tends to be worse on awakening and gradually subsides when the patient is upright; the opposite pertains with maxillary and sphenoidal sinusitis. These relationships are believed to disclose their mechanism; pain is ascribed to filling of the sinuses and its relief to their emptying, induced by the dependent position of the ostia. Bending over intensifies the pain by causing changes in pressure, as does blowing the nose and air travel, especially on descent, when the relative pressure in the blocked sinus rises. Sympathomimetic drugs, such as phenylephrine hydrochloride, which reduce swelling and congestion, tend to relieve the pain. However, the pain may persist after all purulent secretions have disappeared, probably because of blockage of the orifice by boggy membranes and absorption of air from the blocked sinus, so called *vacuum sinus headaches*.

Headache of ocular origin, located as a rule in the orbit, forehead, or temple, is of the steady, aching type and tends to follow prolonged use of the eyes in close work. The main faults are hypermetropia and astigmatism (rarely myopia), which result in sustained contraction of extraocular as well as frontal, temporal, and even occipital muscles. In the uncommon and overemphasized circumstance of a refractive error causing headache, correction rapidly ameliorates the headache. Traction on the extraocular muscles or the iris during eye surgery will evoke pain. Patients who develop diplopia from neurologic causes or are forced to use one eye because the other has been occluded by a patch often complain of frontal headache. Another mechanism is involved in *iridocyclitis* and in *acute angle closure glaucoma*, in which raised intraocular pressure causes steady, aching pain in the region of the eye, radiating to the forehead. When acute angle closure glaucoma causes headache, the sclera is invariably red. Dilating the pupil risks precipitating angle closure glaucoma, a situation that can be reversed by the administration of pilocarpine 1 percent drops.

Headaches that accompany disease of ligaments, muscles, and apophysial joints in the upper part of the cervical spine are referred to the occiput and nape of the neck on the same side and sometimes to the temple and forehead.

These headaches have been reproduced by the injection of hypertonic saline solution into the affected ligaments, muscles, and facet joints and are comparable to the regions of sclerotogenous referred pain that is discussed in Chap. 8. Such pains are especially frequent in late life because of the prevalence of degenerative changes in the cervical spine and tend also to occur after whiplash injuries or other forms of sudden flexion, extension, or torsion of the head on the neck. If the pain is arthritic in origin, the first movements after the individual has been still for some hours are stiff and painful. The pain of fibromyalgia, a controversial entity, is characterized by tender areas near the cranial insertion of cervical and other muscles. There are no pathologic data as to the nature of these vaguely palpable and tender regions, and it is uncertain whether the pain actually arises in them. They may represent only the deep tenderness felt in the region of referred pain or the involuntary secondary protective spasm of muscles. Massage of muscles, heat, and injection of the tender spots with local anesthetic has unpredictable effects but relieves the pain in some cases. Unilateral occipital headache is often misinterpreted as occipital neuralgia (see further on).

The headache of meningeal irritation (usually due to infection or hemorrhage) is typically acute in onset, usually severe, generalized, deep seated, constant, and associated with stiffness of the neck, particularly on forward bending. It has been ascribed to increased intracranial pressure; indeed, the withdrawal of CSF may afford some relief. However, dilatation and inflammation of meningeal vessels and the chemical irritation of pain receptors in the large vessels and meninges by endogenous chemical agents, particularly serotonin and plasma kinins, are probably more important factors in the production of pain and spasm of the neck extensors. In the chemically induced meningitis from rupture of an epidermoid cyst, for example, the spinal fluid pressure is usually normal, but the headache is severe. Meningeal irritation or inflammation may also be chronic and have as its main feature a concurrently ongoing headache.

A distinctive type of headache is produced by subarachnoid hemorrhage; it is very intense and very sudden in onset and is usually associated with vomiting and neck stiffness. It is not uncommon for the rupture of an aneurysm that gives rise to subarachnoid hemorrhage to be precipitated by exertion, even of minor degree. Other causes of what has been called "thunderclap headache" discussed further on simulate this disease (see Chap. 34). Among them is a type of diffuse cerebrovascular spasm that may be spontaneous, the result of sympathomimetic drugs, and extracranial vascular dissection of the carotid or vertebral arteries. Another cause is cerebral venous thrombosis.

Lumbar puncture (LP) or spontaneous low CSF pressure headache, as elaborated in Chap. 2, is characterized by a steady occipitonal and frontal pain coming on within a few minutes after arising from a recumbent position (orthostatic headache) and is relieved within a minute or two by lying down. Its cause is a persistent leakage of CSF into the lumbar tissues through the needle track,

or a tear of the meninges that may be spontaneous or induced by spinal trauma. The CSF pressure is low (often zero in the lateral decubitus position), and installation of an epidural “blood patch” relieves the headache. Usually this type of headache is increased by compression of the jugular veins but is unaffected by digital obliteration of the carotid artery. It is likely that, in the upright position, a low intraspinal and negative intracranial pressure permits caudal displacement of the brain, with traction on dural attachments and dural sinuses. Pannullo and colleagues, with MRI, have demonstrated this downward displacement of the cranial contents. “Spontaneous” low-pressure headache may follow a cough, sneeze, strain, or athletic injury, sometimes as a result of rupture of the arachnoid sleeve along a nerve root (see “Spontaneous Intracranial Hypotension” in Chap. 30). Less frequently, LP is complicated by severe stiffness of the neck and pain over the back of the neck and occiput (see “Lumbar Puncture Headache” in Chap. 2); a second spinal tap in some instances discloses slight pleocytosis but no decrease in glucose—a sterile meningitis. This benign reaction must be distinguished from the rare occurrence of meningitis caused by introduction of bacteria through a rent in the meninges that has allowed both escape of spinal fluid and ingress of bacteria.

Headaches that are aggravated by lying down or lying on one side occur with acute and chronic subdural hematoma and with some brain masses, particularly those in the posterior fossa. The headache of subdural hematoma, when it occurs, is dull and unilateral, perceived over most of the affected side of the head. The global and nuchal headaches of idiopathic intracranial hypertension (pseudotumor cerebri) are also generally worse in the supine position (Chap. 31). In all these states of raised intracranial pressure, headaches are typically worse in the early morning hours after a long period of recumbency. Further on, we discuss the relative infrequency of headache as a result of brain tumor.

Exertional headaches are usually benign, but they are sometimes related to pheochromocytoma, arteriovenous malformation, or other intracranial lesions, in addition to the aforementioned subarachnoid hemorrhage from ruptured aneurysm. The same applies to headaches induced by stooping, most of which are benign or, at worst, are accounted for by sinus infection but there are exceptions and subdural hematoma is a known cause (see further on).

PRINCIPAL VARIETIES OF HEADACHE

The clinician’s first goal when confronted with a patient with cranial pain is to determine if the headache is primary or secondary. The main primary headache syndromes are migraine, tension-type headache, cluster headache, or one of the trigeminal–sympathetic migraine variants of migraine or cluster. These tend to be chronic, recurrent, and unattended by other symptoms and signs of neurologic disease. Familiarity with the variety of symptoms, temporal profiles, and accompanying features of the primary headache disorders, and the proclivity

for most of them to be familial, assist in identifying them from the patient’s description. There should be little difficulty in recognizing the secondary headaches of diseases such as glaucoma, purulent sinusitis, subarachnoid hemorrhage, and bacterial or viral meningitis provided that these sources of headache are kept in mind. A fuller account of these types of “secondary” headache syndromes is given in later chapters of the book, where the underlying diseases are described. All other headaches that by their localization, quality of pain, and precipitating characteristics do not conform to one of the primary types should be suspected of being symptomatic of a cranial, cervical, or systemic disorder. Nonetheless, in many instances no such underlying cause will be found after investigation.

The following broad categories of headaches should be considered (Table 10-1). In general, the classification of these headaches and other types of craniofacial pain follow the plan outlined by the International Headache Society (see Olesen and <http://ihs-classification.org/en/>).

Migraine

Migraine is a highly prevalent and largely familial disorder characterized by periodic, commonly unilateral, often pulsatile headaches that begin in childhood, adolescence, or early adult life and recur with diminishing frequency during advancing years.

Two closely related clinical syndromes have been identified, the first called *migraine with aura* and the second, *migraine without aura* (terminology of the International Headache Society). For many years, the first syndrome was referred to as *classic* or *neurologic* migraine and the second as *common* migraine. The ratio of classic to common migraine is 1:5. Either type may be preceded by vague premonitory changes in mood and appetite. *Migraine with aura* is ushered in by a disturbance of nervous function, most often visual, followed in a few minutes to hours by hemicranial (or, in about one-third of cases, bilateral) headache, nausea, and sometimes vomiting, all of which last for hours or as long as a day or more. Migraine without aura is characterized by an unheralded onset over minutes or longer of increasing hemicranial headache or, less often, by generalized headache with or without nausea and vomiting, which then follows the same temporal pattern as the migraine with aura. Sensitivity to light, noise, and often smells (photophobia, phono- or sonophobia, and osmophobia) attends both types, and intensification with movement of the head is common. If the pain is severe, the patient prefers to lie down in a quiet, darkened room and tries to sleep. The *hemicranial* and the *throbbing* (pulsating) aspects of migraine are its most characteristic features in comparison to other headache types. Each patient displays a proclivity for the pain to affect one side or the other of the cranium, but not exclusively, so that some bouts are on the other side.

The heritable nature of classic migraine is apparent from its occurrence in several members of the family of the same and successive generations in 60 to 80 percent of cases; the familial frequency of common migraine is slightly lower. Twin and sibling studies have not revealed

Table 10-1

COMMON TYPES OF HEADACHE

TYPE	SITE	AGE AND SEX	CLINICAL CHARACTERISTICS	DIURNAL PATTERN	LIFE PROFILE	PROVOKING FACTORS	ASSOCIATED FEATURES	TREATMENT			
Migraine without aura (common migraine)	Frontotemporal	Adolescents, young to middle-aged adults, sometimes children, more common in women	Throbbing (pulsatile); worse behind one eye or ear	Upon awakening or later in day	Irregular intervals, weeks to months	Bright light, noise, tension, alcohol	Nausea and vomiting in some cases	Triptans, ergotamine, nonsteroidal anti-inflammatory agents			
	Uni- or bilateral		Becomes dull ache and generalized	Duration: 4–24 h in most cases, sometimes longer	Tends to decrease in middle age and during pregnancy			Relieved by darkness and sleep	Propranolol or amitriptyline for prevention		
Migraine with aura (neurologic migraine)	Same as above	Same as above	Scalp sensitive Same as above	Same as above	Same as above	Same as above	Scintillating lights, visual loss, and scotomas	Same as above			
			Family history frequent						Unilateral paresthesias, weakness, dysphasia, vertigo, rarely confusion		
Cluster (histamine headache, migrainous neuralgia)	Orbitotemporal	Adolescent and adult males (90%)	Intense, nonthrobbing	Usually nocturnal, 1–2 h after falling asleep	Nightly or daily for several weeks to months	Alcohol in some	Lacrimation	O ₂ , sumatriptan, ergotamine before anticipated attack			
	Unilateral						Occasionally diurnal		Recurrence after many months or years	Stuffed nostril	Corticosteroids, verapamil, valproate, and lithium in recalcitrant cases
											Rhinorrhea Injected conjunctivum Ptosis
Tension headaches	Generalized	Mainly adults, both sexes, more common in women	Pressure (nonthrobbing), tightness, aching	Continuous, variable intensity, for days, weeks, or months	One or more periods of months to years	Fatigue and nervous strain	Depression, worry, anxiety	Antianxiety and antidepressant drugs

Table 10-1

COMMON TYPES OF HEADACHE (CONTINUED)

TYPE	SITE	AGE AND SEX	CLINICAL CHARACTERISTICS	DIURNAL PATTERN	LIFE PROFILE	PROVOKING FACTORS	ASSOCIATED FEATURES	TREATMENT
Meningeal irritation (meningitis, subarachnoid hemorrhage)	Generalized, or bioccipital, or bifrontal	Any age, both sexes	Intense, steady deep pain, may be worse in neck	Rapid evolution—minutes to hours	Single episode	None	Neck stiff on forward bending Kernig and Brudzinski signs	For meningitis or bleeding (see text)
Brain tumor	Unilateral or generalized	Any age, both sexes	Variable intensity May awaken patient Steady pain	Lasts minutes to hours; worse in early A.M., increasing severity	Once in a lifetime: weeks to months	None Sometimes position	Papilledema Vomiting Impaired mentation Seizures Focal signs Loss of vision	Corticosteroids Mannitol Treatment of tumor
Temporal arteritis	Unilateral or bilateral, usually temporal	Older than 50 years, either sex	Throbbing, then persistent aching and burning, arteries thickened and tender	Intermittent, then continuous	Persists for weeks to months	None	Polymyalgia rheumatica Fever, weight loss, increased sedimentation rate, jaw claudication	Corticosteroids

a consistent mendelian pattern in either the classic or common form. Certain special forms of migraine, such as familial hemiplegic migraine, appear to be monogenic disorders but the role of these genes, most of which code for ion channels, in classic and common migraine is speculative.

Migraine, with or without aura, is a remarkably common condition. A study by Stewart and colleagues in the United States showed differences in the prevalence of migraine between individuals of white, African, and Asian origin of approximately 20, 16, and 9 percent, respectively, among women, and 9, 7, and 4 percent for men (see also Lipton et al). One-third of migraineurs have more than three attacks monthly if untreated and many require bed rest or severe curtailment of daily activities. Migraine may have its onset in childhood but usually begins in adolescence or young adulthood; in more than 80 percent of patients, the onset is before 30 years of age, and the physician should be cautious in attributing headaches that appear for the first time after this age to migraine, although there are exceptions.

In younger women, the headaches often tend to occur during the premenstrual period; in approximately 15 percent of such migraineurs, the attacks are exclusively perimenstrual (also termed "catamenial migraine"). *Menstrual migraine*, discussed further on, had been considered to be solely related to the withdrawal of estradiol (based on the work of Somerville). It is now acknowledged that the influence of sex hormones on headache is more complex. Migraine tends to cease during the second and third trimesters of pregnancy in 75 to 80 percent of women, and in others they continue at a reduced frequency; less often, attacks of migraine or the associated neurologic symptoms first appear during pregnancy, usually in the first trimester.

Although migraine commonly diminishes in severity and frequency with age, it may actually worsen in some postmenopausal women, and estrogen therapy may either increase or, paradoxically, diminish the incidence of headaches. The use of birth control pills is associated with an increased frequency and severity of migraine and in rare instances has resulted in a permanent neurologic deficit (see further on and Chap 34).

Some patients link their attacks to certain dietary items—particularly chocolate, cheese, fatty foods, oranges, tomatoes, and onions—but these connections have proved invalid in controlled trials and, except in the occasional persuasive instance, they seem to us to be overrated. Some of these foods are rich in tyramine, which has been incriminated as a provocative factor in migraine. Alcohol, particularly red wine or port, regularly provokes an attack in some persons; in others, headaches are fairly consistently induced by exposure to glare or other strong sensory stimuli, sudden jarring of the head ("footballer's migraine"), or by rapid changes in barometric pressure. A common trigger is excess caffeine intake or withdrawal of caffeine.

Migraine with aura frequently has its onset soon after awakening, but it may occur at any time of day. During the preceding day or so, there may have been

mild changes in mood (sometimes a surge of energy or a feeling of well-being), hunger or anorexia, drowsiness, or frequent yawning. Then, abruptly, there is a disturbance of vision consisting usually of unformed flashes of white, or silver, or, rarely, of multicolored lights (photopsia). This may be followed by an enlarging blind spot with a shimmering edge (*scintillating scotoma*), or formations of dazzling zigzag lines (arranged like the battlements of a castle, hence the term *fortification spectra*, or *teichopsia*). Other patients complain instead of blurred or shimmering or cloudy vision, as though they were looking through thick or smoked glass or the wavy distortions produced by heat rising from asphalt. These luminous hallucinations move slowly across the visual field for several minutes and may leave an island of visual loss in their wake (scotoma); the latter is usually homonymous (involving corresponding parts of the field of vision of each eye), pointing to its origin in the visual cortex. Patients often attribute these visual symptoms to one eye rather than to parts of both fields. Ophthalmologic abnormalities of retinal and optic nerve vessels have been described in some cases but are not typical.

Other focal neurologic symptoms, much less common than visual ones, include numbness and tingling of the lips, face, and hand (on one or both sides); slight confusion of thinking; weakness of an arm or leg; mild aphasia or dysarthria, dizziness, and uncertainty of gait or drowsiness. Only one or a few neurologic phenomena are present in any given patient and they tend to occur in more or less the same combination in each attack. If weakness or paresthetic numbness spreads from one part of the body to another, or if one neurologic symptom follows another, this occurs relatively slowly over a period of minutes (not over seconds, as in a seizure, or simultaneously in all affected parts as in a transient ischemic attack).

The visual or neurologic symptoms usually last for less than 30 min, sometimes longer. As they recede, a unilateral dull pain develops of slowly increasing intensity that progresses to a throbbing headache (usually but not always on the side of the cerebral disturbance). At the peak of the pain, within minutes to an hour, the patient may be forced to lie down and to shun light (photophobia) and noise (phonophobia). Light is irritating and may be painful to the globes, or it is perceived as overly bright (dazzle) and strong odors are disagreeable. Nausea and, less often, vomiting may occur. The headache lasts for hours and sometimes for a day or even longer and is always the most unpleasant feature of the illness. The temporal scalp vessels may be tender and the headache is worsened by strain or jarring of the body or head. Pressure on the scalp vessels or carotid artery may momentarily reduce the pain and releasing pressure accentuates it.

Between attacks, the migrainous patient is normal. In the past, it was believed that a migrainous personality existed, characterized by tenseness, rigidity of attitudes and thinking, meticulousness, and perfectionism. Further analyses, however, have not established a particular personality type in the migraineur. A relationship of migraine to epilepsy in general is also tenuous; however, the incidence of seizures is slightly higher in

migrainous patients and their relatives than in the general population, and there are syndromes that encompass both disorders.

Some patients note that their attacks of migraine tend to occur during the “let-down period,” after many days of hard work or tension. There is an overrepresentation of motion sickness or a vague instability of vision or accommodation, sensitivity to striped patterns, fainting, and of fleeting sensory symptoms on one side of the body in migraineurs. Moreover, as appreciated by Graham, migraine has a lifetime profile and is a familial disease that includes some or many of the following: colic in infancy, motion sickness, episodic abdominal pain, fainting, alcohol sensitivity, exercise-induced headaches, “sinus headaches,” “tension headaches,” and menstrual headaches. These are fairly dependable markers of the disease, and their absence in the patient or family members should at least cause the consideration of alternative explanations for cranial pain.

Migraine Variants

Much variation occurs in migraine. The headache may be exceptionally severe and abrupt in onset (“crash migraine” or “thunderclap headache”), raising the specter of subarachnoid hemorrhage. Careful questioning in these cases sometimes reveals that the headache did not truly attain its peak rapidly but evolved over several minutes. Nonetheless, the distinction of this type of “thunderclap headache” from subarachnoid hemorrhage can be made only by examination of the CSF and imaging of the brain (see further on, under “Special Varieties of Headache”).

A headache may at times precede or accompany, rather than follow, the neurologic abnormalities of migraine with aura. Although typically hemicranial (the French word *migraine* is said to be derived from *megrin*, which, in turn, is from the Latin *hemicrania*, and its corrupted forms *hemigranea* and *migranea*), the pain may be frontal, temporal, or, quite often, generalized.

Any two of the three principal components—neurologic abnormality, headache, and gastrointestinal upset—may be absent. With advancing age, for example, there is a tendency for the headache and nausea to become less severe, finally leaving only the neurologic abnormality, which itself recurs with decreasing frequency. This is also subject to great variation. One common configuration is a full-blown visual aura without subsequent headache (migraine without headache, or migraine dissocié). Visual disturbances differ in detail from patient to patient; numbness and tingling of the lips and the fingers of one hand are probably next in frequency, followed by transient dysphasia or a thickness of speech and hemiparesis as mentioned earlier. Rarely, there is sudden but transient blindness or a hemianopia at the onset of a migraine attack, accompanied by only a mild headache.

Basilar Migraine

A less-common form of the migraine syndrome with prominent brainstem symptoms was described by Bickerstaff. The patients, usually children with a family

history of migraine, first develop visual phenomena like those of typical migraine except that they occupy much or the whole of both visual fields (temporary cortical blindness may occur). There may be associated vertigo, staggering, incoordination of the limbs, dysarthria, and tingling in both hands and feet, and sometimes around both sides of the mouth. These symptoms last 10 to 30 min and are followed by headache, which is usually occipital. Some patients, at the stage when the headache would have been likely to begin, may faint, and others become confused or stuporous, a state that may persist for several hours or longer. Exceptionally, there is an alarming period of coma or quadriplegia. The symptoms closely resemble those caused by ischemia in the territory of the basilar-posterior cerebral arteries—hence the name *basilar artery* or *vertebrobasilar migraine*. Subsequent studies have indicated that basilar migraine, although more common in children and adolescents, affects men and women more or less equally over a wide age range, and that the condition is not always benign and transient.

Ophthalmoplegic and Retinal Migraine

The ophthalmoplegic migraines are recurrent unilateral headaches associated with weakness of extraocular muscles. A transient third-nerve palsy with ptosis, with or without involvement of the pupil, is the usual picture; rarely, the sixth nerve is affected. This disorder is more common in children. The ocular paresis often outlasts the headache by days or weeks; after many attacks, a slight mydriasis and, rarely, ophthalmoparesis may remain permanently.

In some cases of unioocular visual disturbance with scotoma, the retinal arterioles have been reported to be attenuated and, rarely, there are retinal hemorrhages as described by Berger and colleagues. More often, there are no funduscopic changes. Such events are referred to as *retinal migraine*, or, more accurately, *ocular migraine*, as either the retinal or the ciliary circulation may be involved. However, in adults the syndrome of headache, unilateral ophthalmoparesis, and loss of vision may have more serious causes, including temporal (cranial) arteritis.

Migraine following Head Injury

Cranial trauma of almost any degree may precipitate a migraine headache in persons prone to the condition. A particularly troublesome migraine variant occurs in a child or adolescent who, after a trivial or mild head injury, may lose vision, suffer severe headache or be plunged into a state of confusion, with belligerent and irrational behavior that lasts for hours or several days before clearing. In yet another variant, there is an abrupt onset of either one-sided paralysis or aphasia after virtually every minor head injury (we have seen this condition several times in college athletes) but without visual symptoms and little or no headache. Although a family history of migraine is frequent in such cases, there has been no history of hemiplegia in other family members.

Migraine in Young Children

This may present special difficulties in diagnosis, as a young child's capacity for accurate description is limited.

Instead of complaining of headache, the child appears limp and pale and complains of abdominal pain; vomiting is more frequent than in the adult, and there may be slight fever. Recurrent attacks were referred to in the past by pediatricians as the “periodic syndrome.” Another variant in the child is episodic vertigo and staggering (paroxysmal disequilibrium) followed by headache, probably a type of basilar migraine (see Watson and Steele). Also, there are puzzling patients with bouts of fever or transient disturbances in mood (“psychic equivalents”) and abdominal pain (*abdominal migraine*), that had been attributed to migraine but are dubious entities at best. We have seen several infants and young children who have had attacks of hemiplegia (without headache), first on one side then the other, every few weeks. Recovery was complete, and arteriography in one child, after more than 70 attacks, was normal. Alternating hemiplegia of childhood may terminate in a dystonic state. The relationship of this condition to familial hemiplegic migraine (see below) remains uncertain. The only advantage of considering such attacks as migrainous is that it may protect some patients from unnecessary diagnostic procedures and surgical intervention; but, by the same token, it may delay appropriate investigation and treatment.

Familial Hemiplegic Migraine

In a related disorder, known as a *hemiplegic migraine*, a condition mostly of infants and children (rarely adults), there are episodes of unilateral paralysis that may long outlast the headache. Several families have been described in which this condition is the result of a mutation in an ion channel (*familial hemiplegic migraine; alternating hemiplegia of childhood*). Of the known loci, which together account for approximately 50 percent of cases, the most common one is in the gene coding for the P/Q-type calcium channel α subunit (CACNA1A). A second locus is in the gene for the Na⁺/K⁺-adenosine triphosphatase (ATPase) channel and a rarer subtype is caused by mutations in a sodium channel α -subunit gene, SCN1A. These do not account for all cases, indicating that there are other mutations that will inevitably be discovered. It is reasonable to surmise that many of the nonfamilial cases of hemiplegic migraine are also caused by these mutations. By their nature, these channelopathies would be expected to have clinical and genetic overlap with other neurologic diseases. Indeed, there are shared traits between some of the genetic forms of familial hemiplegic migraine and both episodic and degenerative cerebellar diseases (Goadsby, 2007). Ducros and colleagues have found a variety of other neurologic features in these families, including persistent cerebellar ataxia and nystagmus in 20 percent; others had attacks of coma and hemiplegia from which they recovered.

Complicating the situation is the undoubted existence of sporadic migraine with transient hemiplegia that has no familial trait. Neurologic symptoms lasting more than an hour or so should prompt investigation for alternative causes, but none may be found. Instances of hemiplegic migraine may account for some of the inexplicable strokes in young women and older adults of both sexes, as discussed below.

Transient Ischemic Attacks and Stroke with Migraine (See also Chap. 34.)

Attacks of migraine, instead of beginning in childhood, may have their onset later in life, and Fisher provided support for the hypothesis that some of the transient aphasic, hemianesthetic, or hemiplegic attacks of later life may be of migrainous origin (“transient migrainous accompaniment”).

Rarely, migrainous neurologic symptoms, instead of being transitory, leave a prolonged or even permanent deficit (e.g., homonymous hemianopia), indicative of an ischemic stroke. This has been called *complicated migraine* and a small number of these prove to be *migrainous infarctions*. Platelet aggregation, edema of the arterial wall, increased coagulability, dehydration from vomiting, and intense, prolonged spasms of vessels have all been implicated (on rather uncertain grounds) in the pathogenesis of arterial occlusion and strokes that complicate migraine (Rascol et al).

The reported incidence of this complication has varied. At the Mayo Clinic, in a group of 4,874 patients ages 50 years or younger with a diagnosis of migraine, migraine equivalent, or vascular headache, 20 patients had migraine-associated infarctions (Broderick and Swanson). Caplan described 7 patients in whom attacks of migraine were complicated by strokes in the vertebrobasilar territory. A more recent study by Wolf and colleagues collected 17 instances of stroke and migraine. Most had a prolonged aura, either visual, sensory or aphasic and over two-thirds of the strokes, demonstrated by diffusion restriction on MRI, were in the posterior circulation territory and occurred in younger women. There is, nonetheless, a paucity of useful pathology by which to interpret the mechanism of migraine-associated stroke. The uncertain but potential role of antimigraine medications in producing stroke is discussed further on in the section on treatment. Estrogen medications have also been implicated in stroke in some women migraineurs.

In children and young adults with the mitochondrial disease MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) and in adults with the rare cerebral vasculopathy CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), migraine may be a prominent feature. Chap. 34 addresses these issues further.

The special problem of focal cerebral disorders associated with segmental or diffuse vasospasm, including the form that follows treatment with the “triptan” (serotonin agonist) drugs and Call-Fleming syndrome, is discussed further on in the section on treatment and under “Diffuse and Focal Cerebral Vasospasm” in Chap. 34.

A separate set of observations, mainly epidemiologic, pertain to the risk of mundane strokes in women with both migraine and cardiovascular disease later in life, and the related issue of imaging changes in migraineurs that are suggestive of small ischemic lesions. Regarding the last problem, a number of cross-sectional population studies, such as the ones by Kurth and colleagues, Scher et al, and Kruit and coworkers, indicated that MRI

changes in both the deep and subcortical white matter were more frequent in women migraine patients who experienced auras than in those without auras and in the general population. A high frequency of migraine headaches was also associated in some studies with an increased number of white matter lesions. Some series have emphasized lesions in the cerebellar white matter.

In contrast, a meta-analysis of case control and cohort studies conducted by Schurks and colleagues were unable to demonstrate an increased risk for cardiovascular events. Other investigators, again depending on various population databases and few patient level studies, have come to the opposite conclusion (Bigal et al) and suggested that all cause mortality is increased in migraine patients (Gudmundsson et al).

The implications of the ubiquitous small white matter lesions in MRI that are now familiar to neurologists are unclear. Several studies indicate that migraineurs with these changes have no greater cognitive decline over time than those in the general population. The lesions are a frequent cause for neurological consultation, sometimes with the question of multiple sclerosis having been raised. We tend to underemphasize these lesions and the risk of stroke in discussion with patients but point out that the usual stroke risk factors, smoking, hypertension, hyperlipidemia, and cardiac rhythm abnormalities should be attended to assiduously.

The issue of oral contraceptives as a risk for stroke is a more complicated matter that has not been resolved. All that can be said at the moment is that this factor did not appear to be consistent in the above discussed epidemiologic surveys, and it is the population of young women who are likely to have both exposures. The pills are not interdicted in migraineurs but perhaps lower estrogen compounds are advisable as formulations with high estrogen concentrations have been associated with clotting in the venous circulation.

Patent foramen ovale and migraine Finally, there has long been discussion of an association between migraine and patent foramen ovale. A few physicians continue to favor a causal role and have advocated closure of the foramen in an attempt to alleviate migraine. Migraine with aura has been especially associated with an open foramen. However, the largest cross-sectional (Rundek et al) and case-control (Garg et al) studies have not affirmed these associations and the issue, while still under discussion, has been of waning interest.

Status Migrainosus

In some individuals, migraine attacks, for unaccountable reasons, may increase in frequency for several months. As many as three or four attacks may occur each week, leaving the scalp on one side continuously tender. An even more difficult clinical problem is posed by migraine that lapses into a condition of daily or virtually severe continuous headache (*status migrainosus*). The pain is initially unilateral, later more generalized, more or less throbbing, but with a constant superimposed ache and is disabling; vomiting or nausea is common at the outset but abates. Almost without exception, there is a preceding history compatible with migraine; in fact, the absence of prior

headaches should raise concern about a more serious cause. Status migrainosus sometimes follows a head injury or a viral infection, but most cases have no explanation. Relief is sought by increasing the intake of ergot or serotonin agonist preparations or even opiates, often to an alarming degree, but with only temporary relief, serving at times to perpetuate the condition through a rebound mechanism.

In the diagnosis of such cases, the possibility should be considered that migraine has been combined with tension headache (migraine-tension or mixed-pattern headache) or transformed to so-called analgesia-rebound headache, or ergotamine, or serotonin agonist-dependency headache, as described by Taimi and colleagues. Narcotic addiction is another consideration. Although not generally popular, it is our practice to admit such patients to the hospital, discontinue all narcotic medications, and administer intravenous hydration, corticosteroids, one of the serotonin agonist medications, or dihydroergotamine intravenous infusion in selected patients (see further on for details of treatment). When admission is not possible or practical, the same therapeutic plan may be pursued in an ambulatory infusion center.

Migraine with CSF Pleocytosis (HaNDL)

An intriguing problem arises in the patient with migraine who is found to have a lymphocytic pleocytosis in the spinal fluid. Most of these cases in our experience have turned out to be simply instances of aseptic meningitis that have precipitated migraine in susceptible individuals. In others, a few cells are found in the spinal fluid during an attack of migraine without obvious explanation; probably a minor cellular reaction of 3 to 10 white blood cells (WBCs)/mL can be ignored if there is no fever or meningismus.

A more extensive syndrome was originally described by Bartleson, Swanson, and Whisnant under the title "A migrainous syndrome with cerebrospinal fluid pleocytosis". A series reported by Gomez-Aranda and colleagues gave the syndrome the name, "Pseudomigrainewith Temporary Neurological Symptoms and Lymphocytic Pleocytosis", also called HaNDL (Headache with Neurological Deficits and CSF Lymphocytosis) by Berg and Williams, together describing what is probably yet another migraine variant. Gomez-Aranda's series comprised 50 adolescents and young adults, predominantly males, who developed several separate episodes of transient neurologic deficits lasting hours, accompanied by migraine-like headaches, sometimes with slight fever but no stiff neck. One-quarter of this group had a history of past migraine and a similar number had a viral-like illness within 3 weeks of the neurologic problem. The CSF contained from 10 to 760 lymphocytes per cubic millimeter, and the total protein was elevated. The transient neurologic deficits were mainly sensorimotor and aphasic; only 6 patients had visual symptoms. The patients were asymptomatic between attacks and in none did the entire illness persist beyond 7 weeks.

The causation and pathophysiology of this syndrome and its relation to migraine are obscure. We have observed several cases, all in otherwise healthy middle-aged men,

none related to the use of nonsteroidal medications, which may cause an aseptic meningial reaction, and we found corticosteroids to be helpful. The distinction between this syndrome and the recurrent aseptic meningitis of Mollaret and other chronic meningitic syndromes as well as cerebral vasospasm or vasculitis is difficult (see "Chronic Persistent and Recurrent Meningitis" in Chap. 32).

Cause and Pathogenesis of Migraine

So far, it has not been possible to determine from the many clinical observations and investigations, a unifying theory as to the cause and pathogenesis of migraine. Tension and other emotional states, which are claimed by some migraineurs to precede their attacks, are so inconsistent as to be no more than potential aggravating factors. Clearly, an underlying genetic factor is implicated, although it is expressed in a recognizable mendelian pattern in only a small number of families (see above). The puzzle is how this genetic predisposition is translated periodically into a regional neurologic deficit, unilateral headache, or both. For many years, our thinking about the pathogenesis of migraine was dominated by the views of Harold Wolff and others—that the headache was caused by the distention and excessive pulsation of branches of the external carotid artery. Certainly, the throbbing, pulsating quality of the headache and its relief by compression of the common carotid artery supported this view, as did the early observation of Graham and Wolff that the headache and amplitude of pulsation of the extracranial arteries diminished after the intravenous administration of ergotamine.

The importance of vascular factors continues to be emphasized by more recent findings but not in the way envisaged by Wolff. For example, in a group of 11 patients with classic migraine, Olsen and colleagues, using the xenon inhalation method, noted a regional reduction in cerebral circulation spreading forward from the occipital region during the period when neurologic symptoms appear. They concluded that the reduction in blood flow was consistent with the cortical spreading depression syndrome described below. In a subsequent study, Woods and colleagues described a patient who, during positron emission tomography (PET), fortuitously had an attack of common migraine with blurred vision. Sophisticated measurements showed a reduction in blood flow that started in the occipital cortex and spread slowly forward on both sides, in a manner much like that of the spreading cortical depression of Leão (see below) and Cutter and colleagues, using perfusion-weighted MRI, corroborated the finding of diminished occipital cerebral blood flow during the aura. However, a study using single-photon emission computed tomography (SPECT) in 20 patients during and after attacks of migraine without aura disclosed no focal changes of cerebral blood flow; also, no changes occurred after treatment of the attacks with 6 mg of subcutaneous sumatriptan (Ferrari et al, 1995).

In reference to the extracranial vessels, Iversen and associates, by means of ultrasonography, documented a dilatation of the superior temporal artery on the side of the migraine during the headache period. The same

dilatation in the middle cerebral arteries has been inferred from observations with transcranial Doppler insonation. The complication of cerebral infarction is also in keeping with a vascular hypothesis, but it involves only a tiny proportion of migraineurs. The vascular hypothesis must be regarded as uncertain, but, clearly, there is frequently a reduction in posterior cortical blood flow during an aura. What is not established is whether the blood flow changes are fundamental or simply the result in a reduction in cortical activity. The original opinion expressed by Wolff that a vascular element is responsible for the cranial pain of migraine is also unconfirmed.

The relationship between the vascular changes and evolving neurologic symptoms of migraine are noteworthy. Lashley, who plotted his own visual aura, calculated that the cortical impairment progressed at a rate of 2 to 3 mm/min over the surface of the brain. Similarly, during the aura, there is a regional reduction in blood flow, as noted above. It begins in one occipital lobe and extends forward slowly (2.2 mm/min) as a wave of "spreading oligemia" that does not respect arterial boundaries (Lauritzen and Olesen). Both of these events are intriguingly similar to the above-mentioned phenomenon of "spreading cortical depression," first observed by Leão in experimental animals. He demonstrated that a noxious stimulus applied to the rat cortex was followed by vasoconstriction and slowly spreading waves of inhibition of the electrical activity of cortical neurons, moving at a rate of approximately 3 mm/min. Lauritzen and Olesen attribute both the aura and spreading oligemia to the spreading cortical depression, and considerable work since then has corroborated this idea. These observations, however, apply only to the aura.

An alternative, but not necessarily exclusive hypothesis links the aura and the painful phase of migraine through a neural mechanism originating in the trigeminal nerve as proposed by Moskowitz. This is based on the innervation of extracranial and intracranial vessels by small unmyelinated fibers of the trigeminal nerve that subserve both pain and autonomic functions (the "trigeminovascular" complex). This model provides an explanation for migraine pain in the trigeminal ganglion. Activation of these fibers releases substance P, calcitonin gene-related peptide (CGRP), and other peptides into the vessel wall, which serves to sensitize the trigeminal system to the pulsatility of cranial vessels, and to increase their permeability, thereby promoting an inflammatory response. The small molecules released from nerve endings adjacent to the cortex would then incite spreading depression in this model. Against this hypothesis is the occurrence of headache as often as not on the side opposite the side of generation of the aura and the lack of clinical effect of drugs that work in this experimental model. Most likely, both neural and vascular mechanisms are operative and they interact.

In part to address the action of the serotonin agonist drugs on migraine (see below), a body of evidence has been assembled that serotonin (5-HT) acts as a humoral mediator in the neural and vascular components of migraine headache. Serotonin is discharged from platelets at the onset of headache and the headache is reduced

by the injection of 5-HT. This led to the development by Humphrey of sumatriptan, which acted selectively on 5-HT_{1B/D} receptors so as to reduce side effects. This was the forerunner of the large group of "triptans." More recently, nitric oxide generated by endothelial cells has been implicated as the cause of the pain of migraine headache, but the reason for its release and the relationship to changes in blood flow is unclear.

Blau and Dexter and Drummond and Lance are confident that the presence or absence of headache does not depend solely on extracranial vascular factors. These authors point to their findings that occlusion of blood flow through the scalp or common carotid circulation fails to alleviate the pain of migraine in one-third to one-half the patients. Lance (1998) has suggested that the trigeminal pathways are in a state of persistent hyperexcitability in the migraine patient and that they discharge periodically, perhaps in response to hypothalamic stimulus acting on the endogenous pain control pathways. This is in keeping with current theories regarding the trigemino-vascular complex discussed above, as well as with evolving ideas on central sensitization to pain because of repeated noxious stimulation from one body region that may produce a type of centrally mediated allodynia. The role of alternative factors in migraine has been reviewed by Lance and Goadsby and in a pictorial representation by Goadsby and colleagues.

The foregoing observations leave a number of questions unanswered. Is one to conclude that migraine with and without aura are different diseases, involving extracranial arteries in one instance and intracranial ones in another? Is the circulatory change the primary cause of headache, or is it a secondary or coincidental phenomenon? Is diminished neuronal activity (spreading depression) the primary cause of neurologic symptoms (it seems so) and headache (unclear), and is the diminished regional blood flow secondary to reduced metabolic demand? Why are the posterior portions of the brain (visual auras) so often implicated (perhaps because of richer trigeminal innervation of the posterior vessels)? The neural mechanisms that underlie these changes and precisely what is altered by the genetic predisposition to migraine are unresolved. No final reconciliation of all these data is possible and migraine remains incompletely explained.

Diagnosis

Migraine with aura should occasion no difficulty in diagnosis if a proper history is obtained. Most often, the symptoms begin as "positive," i.e., scintillation, paresthesia, as opposed to the later "negative" scotoma, numbness, aphasia, or paresis. The difficulties come from a lack of awareness that a progressively unfolding neurologic syndrome may be migrainous in origin and may occur without headache. Furthermore, recurrent migraine headaches take many forms, some of which may prove difficult to distinguish from the other common types of headache, and it is not generally recognized that migraine headaches need not be severe or disabling. Some of these problems merit elaboration because of their practical importance.

The neurologic part of the migraine syndrome may resemble a transient ischemic attack, focal epilepsy, the clinical effects of a slowly evolving hemorrhage from an arteriovenous malformation, or a thrombotic or embolic stroke. It is the pace of the neurologic symptoms of migraine that distinguish it from epilepsy and most cases of stroke. Furthermore, the positive rather than ablative nature of the symptoms assists in distinguishing it from the usual stroke syndromes.

Ophthalmoplegic migraine may suggest a carotid-cavernous or supraclinoid aneurysm. Transient monocular blindness from carotid stenosis is infrequent in the age group affected most by migraine, but the antiphospholipid syndrome, which has some ill-defined relationship to migraine, does cause episodic unilateral visual loss in this group and should be sought as the explanation for transient monocular blindness with or without headache. The invariant occurrence of migraine on the same side of the head increases the likelihood of an underlying arteriovenous malformation (AVM) or other structural lesion. R.D. Adams, who studied more than 1,200 patients with AVM, also found that the headaches, which occurred in more than 30 percent of these individuals, usually did not include the other features of either migraine or cluster headache. However, in about 5 percent, the headaches were associated with visual aura, making them indistinguishable from neurologic migraine. In most, the AVM was in the occipital region and on the side of the headache. Approximately half of the patients with AVM and migraine had a family history of migraine. It is unclear to us if AVM can be regarded as an acknowledged cause of recurrent migraine-like headache. It is, of course, possible that given the ubiquity of migraine in the population, that the association is coincidental.

Treatment of Migraine

This topic may be divided into two parts—control of the individual acute attack, and prevention that includes both medications and lifestyle modifications. The time to initiate treatment of an attack is during the neurologic (visual) prodrome or at the very onset of the headache (see below). If the headaches are mild, the patient may already have learned that aspirin, acetaminophen, or another nonsteroidal anti-inflammatory drug (NSAID) will suffice to control the pain. Insofar as a good response may be obtained from one type of NSAID and not another, it may be advisable to try two or three preparations in several successive attacks of headache and to use moderately high doses if necessary. Some of our colleagues state that reliable patients can be given small amounts of codeine or oxycodone, usually combined with aspirin or acetaminophen, for limited periods. The combination of aspirin or acetaminophen, caffeine, and butalbital, although popular with some patients, is usually incompletely effective if the headache is severe and is also capable of causing drug dependence. Numerous other medications have proved effective and each has had a period of popularity among neurologists and patients.

For severe attacks of migraine headache, sumatriptan or one of the other serotonin agonist "triptans" in this class (e.g., zolmitriptan, rizatriptan, naratriptan, almotriptan, eletriptan, and frovatriptan), or the ergot alkaloids, ergotamine tartrate, and particularly dihydroergotamine (DHE), are the most effective forms of treatment and are best administered early in the attack, ideally just after an aura or at the onset of headache.

Patients with waning visual auras should be advised to wait to self-administer subcutaneous serotonin agonists until the headache begins. Clinical experience and the study by Bates and colleagues suggests that the triptans are ineffective in preventing headache if given during the aura; they are albeit, safe (see below). In contrast, the slower acting nasal spray or oral formulations are often ineffective if given too long after the start of headache and patients have learned to administer them during the aura and, again, this seems safe.

A single 6-mg dose of sumatriptan or its equivalent, given subcutaneously, is an effective and well-tolerated treatment for migraine attacks. When successful, it eliminates or reduces the accompanying symptoms of nausea, vomiting, photophobia, and phonophobia. An advantage of the serotonin agonist drugs, aside from their relative safety, is the ease of self-administration using prepackaged injection kits, thus avoiding frequent and inconvenient visits to the emergency department. For example, sumatriptan can also be given orally in a 25- or 50-mg tablet and as a nasal spray (20 mg per spray), zolmitriptan in a 2.5- or 5-mg tablet, and rizatriptan in a 5- or 10-mg dose tablet, repeated, if needed, in 2 h. For these oral preparations, latency for headache relief is longer than with subcutaneous injection or inhalation. If one serotonin agonist is found to be ineffective, another drug or an alternative route of administration, such as intranasal, may be tried. These medications are summarized in Table 10-2.

A large and often cited meta-analysis of the available drugs in 53 separate trials conducted by Ferrari and colleagues (2001) found modest differences in overall efficacy between drugs. Loder has given a tabulated comparison of the main drugs for migraine and a review of their use in routine situations. Others in this class are sure to be developed in the future and subtle, but usually clinically minor, differences between them undoubtedly

will be highlighted. Sumatriptan is available as a nasal spray, which is useful in patients with nausea and vomiting. The response rate after 2 h is similar to that of the orally administered drug, and the nasal spray acts more rapidly.

Ergotamine is an equally effective agent, but its peripheral and coronary vasoconstricting side effects have reduced its use. This is an alpha-adrenergic agonist with strong serotonin receptor affinity and vasoconstrictive action. The drug is taken as an uncoated 1- to 2-mg tablet of ergotamine tartrate, held under the tongue until dissolved (or swallowed), or in combination with caffeine. Repeat use is not advisable as it may lead to prolonged or daily headache. A single oral dose of promethazine 50 mg, or of metoclopramide 20 mg, given with the ergotamine, relaxes the patient and allays the potential nausea and vomiting from ergotamine. Patients in whom vomiting prevents oral administration may be given ergotamine by rectal suppository or DHE by nasal spray or inhaler (one puff at onset and another at 30 min) or can learn to give themselves a subcutaneous injection of DHE (usual dosage, 1 mg). Caffeine, 100 mg, is thought, on slim evidence, to potentiate the effects of ergotamine and other medications for migraine. When ergotamine is administered early in the attack, the headache will be abolished or reduced in severity and duration in 70 to 75 percent of patients.

An important problem pertains to the magnitude of risk of stroke from serotonin agonists in patients with prolonged visual aura or other neurologic symptoms that persist during the period of headache, or focal neurologic symptoms that are possibly attributable to migraine because of a past history of migraine with or without aura. As a matter of course, serotonin agonists and ergots are generally avoided if there is an ongoing and prolonged aura of any type, including visual, but particularly with hemiparesis, aphasia, or features such as vertigo, drowsiness, or diplopia, referable to the basilar artery. Not all experts agree with this proscription and some small series, among them 13 patients reported by Klapper and colleagues, have found triptans safe to use if a headache with neurologic signs has commenced, but this issue has not been resolved. As previously noted, although this class of drugs may not be helpful during the visual aura, they also seem to do no harm (see Bates et al).

Table 10-2

TRIPTANS FOR ORAL USE

TRIPTANS	TABLET SIZES, MG	OPTIMUM DOSES, MG	MAXIMUM SINGLE DOSES, MG	MAXIMUM DAILY DOSES, MG
Almotriptan	6.25 and 12.5	12.5	12.5	25
Eletriptan	20 and 40	20	40	80
Frovatriptan	2.5	2.5	2.5	7.5
Naratriptan	1 and 2.5	2.5	2.5	5
Rizatriptan	5 and 10	10*	10*	30*
Zolmitriptan	2.5 and 5	2.5	5	10
Sumatriptan*	25, 50, and 100	50	100	200

*Also available as 20 mg nasal spray and 6 mg subcutaneous injection.

Ergot drugs and triptans are contraindicated in symptomatic and asymptomatic coronary artery disease and poorly controlled hypertension. Rare cases of severe but reversible cerebral vasospasm have been reported after the use of ergotamine or a serotonin agonist drug, but most of these patients in fact had not had neurologic features as part of their initial headache syndrome. Of particular danger, however, is the often unnoticed, concurrent use of other sympathomimetic drugs such as phenylpropanolamine as in one of the cases described by Singhal and colleagues and by Meschia and associates (see discussion of Call-Fleming syndrome, "Diffuse Vasoconstriction," "Diffuse and Focal Cerebral Vasospasm" in Chap. 34). Cerebral hemorrhage is another rare complication of serotonin agonist use that possibly relates to hypertension induced by triptans or ergots.

For severely ill patients who arrive in the emergency department or physician's office, having failed to obtain relief from a prolonged headache with the above medications, Raskin (1986) has found metoclopramide 10 mg IV, followed by DHE 0.5 to 1 mg IV every 8 h for 2 days, to be effective. We also use this approach in cases of status migrainosus. The administration of intravenous DHE can be combined with a lidocaine infusion. The potential success of metoclopramide alone should not be dismissed, as we and others have occasionally found that the headache abates after this initial injection. The sympathomimetic drug isometheptene combined with a sedative, and acetaminophen (Midrin) has been useful for some patients and probably acts in a similar way to ergotamine and sumatriptan. A wide array of other drugs including almost all of the conventional nonsteroidal anti-inflammatory medications has been recommended as adjunctive therapy, e.g., prochlorperazine, chlorpromazine, ketorolac, and intranasal lidocaine. Each of these drugs, given alone, is effective in alleviating the headache in about half of patients, emphasizing the need for blinded placebo-controlled trials for any new drug that is introduced for the treatment of headache.

Intravenous and oral corticosteroids have been found anecdotally to be useful in refractory cases and as a means of terminating migraine status, but they should not be given continuously. In a randomized trial of intravenous dexamethasone 10 mg in an emergency department setting, Friedman et al found no benefit. As an alternative to steroids and more commonly used non-steroidal agents, Weatherall and colleagues used intravenous aspirin (lysine acetylsalicylate, 1 g, repeated up to five times) with reasonably good effect in inpatient management of migraine and other headache disorders. We have determined that this agent is difficult to obtain from hospital pharmacies.

If, in an individual attack, all of the foregoing measures fail, it is probably best to resort briefly to narcotics, which usually give the patient a restful, pain-free sleep. Halfway measures at this point are usually futile. However, the use of narcotics as the mainstay of acute or prophylactic therapy is to be avoided. As mentioned above, if the pain does not abate in 12 to 24 h, corticosteroids in any of several regimens may be added and continued for several days.

Based on the action of certain peptides in the trigemino-vascular complex, novel antagonists of CGRP have been used with some success (Olesen et al). Drugs of this type as well as inducible nitric oxide synthase (iNOS) inhibitors and receptor blockers that work by a different mechanism than do the serotonin agonists may be alternatives in the future. So far, these have not been effective as prophylactic drugs but are currently being studied for acute treatment of migraine.

Preventive Treatment

In individuals with frequent migrainous attacks, efforts at prevention are worthwhile. The survey by Lipton and colleagues, found approximately one-fourth of patients were appropriate for some form of prophylactic treatment on the basis of the frequency and severity of their headaches, usually more than one severe episode per week. The most effective agents have been beta-adrenergic blockers, certain antiepileptic drugs, and tricyclic antidepressants. Often, comorbidities such as depression, hypertension, epilepsy or coronary artery disease guide the choice among these three classes of drugs. Some headache specialists have expressed the opinion that amitriptyline may be more effective than the others if headaches are very frequent and that propranolol is more effective if severity of headaches is the prime concern.

Considerable success has been obtained with propranolol, beginning with 10 to 20 mg two to three times daily and increasing the dosage gradually to as much as 240 mg daily, probably best given as a long-acting preparation in the higher dosage ranges. Under-dosing is a major reason for ineffectiveness. If propranolol is unsuccessful or not tolerated, one of the other beta blockers, specifically those that lack agonist properties—atenolol (40 to 160 mg/d), timolol (20 to 40 mg/d), or metoprolol (100 to 200 mg/d)—may prove to be effective. In patients who do not respond to these drugs over a period of 4 to 6 weeks, valproic acid 250 mg taken three to four times daily, other antiepileptic drug such as topiramate, or amitriptyline, 25 to 125 mg nightly may be tried. The newer antidepressants (e.g., specific serotonin reuptake inhibitors) are not as effective and may even cause headache in our experience. Calcium channel blockers (e.g., verapamil, 320 to 480 mg/d; nifedipine, 90 to 360 mg/d) are also reportedly effective in decreasing the frequency and severity of migraine attacks in some patients, but there is typically a lag of several weeks before benefit is attained and our success with them has been limited. Isometheptene (Midrin) as already mentioned; indomethacin, 150 to 200 mg/d; and cyproheptadine (Periactin), 4 to 16 mg/nightly are found to be helpful in some patients and may be particularly useful in preventing predictable attacks of perimenstrual migraine. A typical experience is for one of these medications to reduce the number and severity of headaches for several months and then to become less effective, whereupon an increase in the dosage, if tolerated, may help; or one of the many alternatives can be tried. The newest putative treatment for chronic or frequently repeating headaches, both migraine and tension, is the injection of botulinum toxin (Botox) into sensitive temporalis and other cranial

muscles. Elimination of headaches for 2 to 4 months has been reported—a claim that justifies further study. Whether these injections are of value during an acute attack is uncertain. Surgical decompression of sensory nerves in the scalp and related techniques have also been advocated but require rigorous study.

Methysergide (Sansert), an ergot derivative that was more widely used in the past, in doses of 2 to 6 mg daily for several weeks or months is effective in the prevention of migraine. Retroperitoneal and pulmonary fibrosis are rare but serious complications that can be avoided by discontinuing the medication for 3 to 4 weeks after every 5-month course of treatment. Its use has virtually ceased.

Some patients allege that certain items of food induce attacks (chocolate, peanuts, hot dogs, smoked meats, oranges, and red wine are the ones most commonly mentioned), and it is obvious enough that they should avoid these foods if possible. Limiting caffeinated beverages may be helpful. In certain cases, the correction of a refractive error, an elimination diet, or behavioral modification is said to have reduced the frequency and severity of migraine and of tension headaches. However, the methods of study and the results have been so poorly controlled that it is difficult to evaluate them. All experienced physicians appreciate the importance of helping patients rearrange their schedules with a view to controlling tensions and hard-driving lifestyles. There is no single program to accomplish this. Psychotherapy has not been helpful, or at least one can say that there is no evidence of its value. The claims for sustained improvement of migraine with chiropractic manipulation are similarly unsubstantiated and do not accord with our experience. Meditation, acupuncture, and biofeedback techniques all have their advocates, but again, the results, while not to be entirely discounted, are uninterpretable.

Indomethacin Responsive Headaches

This is a group of relatively uncommon syndromes that may be allied with migraine but respond very well and specifically to indomethacin both acutely and as prophylaxis, so much so that some authors have defined a category of *indomethacin-responsive headaches*. These include orgasmic migraine, chronic paroxysmal hemicrania (see further on), hemicrania continua, exertional headache, hypnic headache, brief head pains (jabs and jolts and “ice-pick” headaches), and some instances of premenstrual migraine. These are summarized in Table 10-3.

Cluster Headache

This type of headache has been described in the past under a variety of names, including *paroxysmal nocturnal cephalalgia*, *migrainous neuralgia*, *histamine cephalalgia* (Horton’s headache), and others. Kunkle and colleagues, who were impressed with the characteristic temporal “cluster pattern” of the attacks, coined the term in current use—*cluster headache*. This headache pattern occurs predominantly in adult men (age range: 20 to 50 years; male-to-female ratio approximately 5:1) and is characterized by a severe consistent unilateral orbital localization. The pain is felt deep in and around the eye, is very intense

Table 10-3

INDOMETHACIN RESPONSIVE HEADACHES

Valsalva related headaches
Primary headache associated with sexual activity*
Primary exertional (exercise induced, weight lifters) headache*
Primary cough headache
Trigeminal-autonomic cephalgias
Chronic paroxysmal hemicrania
Episodic paroxysmal hemicrania
Hemicrania continua*
SUNCT (short-lasting unilateral neuralgiform attacks with conjunctival injection and tearing)
Stabbing headaches
“Jabs and jolts”
Idiopathic stabbing (ice pick) headache

*These headache syndromes may improve with drugs other than Indomethacin.

and nonthrobbing as a rule, and often radiates into the forehead, temple, and cheek—less often to the ear, occiput, and neck. Its denominative feature is the nightly recurrence, between 1 and 2 h after the onset of sleep, or several times during the night for several or more consecutive days; thus “cluster”. Less often, it occurs during the day or early evening, unattended by aura or vomiting. The headache has been called the “alarm clock headache” because it may recur with remarkable regularity each night for periods extending as long as many weeks, followed thereafter by complete freedom for many months or even years. However, in approximately 10 percent of patients, the headache becomes chronic, persisting over days, months, or even years.

There are several associated vasomotor phenomena by which cluster headache can be identified: a blocked nostril, rhinorrhea, injected conjunctivum, lacrimation, miosis, and a flush and edema of the cheek, all lasting on average for 45 min (range: 15 to 180 min). Some of our patients, when alerted to the sign, also report a slight ptosis on the side of the orbital pain; in a few, the ptosis has become permanent after repeated attacks. The homolateral temporal artery may become prominent and tender during an attack, and the skin over the scalp and face may be hyperalgesic.

Most patients arise from bed during an attack and sit in a chair and rock or pace the floor, holding a hand to the side of the head. The pain of a given attack may leave as rapidly as it began or may fade away gradually. Almost always the same orbit is involved during a cluster of headaches as well as in recurring bouts. During the period of freedom from pain, alcohol, which commonly precipitates headaches during a cluster, no longer has the capacity to do so. The picture of cluster headache, including the patient’s nocturnal behavior in response to it, is usually so characteristic that it cannot be confused with any other disease, although those unfamiliar with it may entertain a diagnosis of migraine, trigeminal neuralgia, carotid aneurysm, or temporal arteritis.

A somewhat similar syndrome is produced by the *Tolosa-Hunt syndrome* of eye pain and ocular motor

paralysis caused by dural granuloma at the orbital apex (see further on) and the *paratrigeminal syndrome of Raeder*, which consists of paroxysms of pain somewhat like that of tic douloureux in the distribution of the ophthalmic and maxillary divisions of the fifth nerve, in association with unilateral Horner syndrome (ptosis and miosis but with preservation of facial sweating). Loss of sensation in a trigeminal nerve distribution and mild weakness of muscles innervated by the fifth nerve are often added. Raeder syndrome is now recognized as a heterogeneous syndrome, some cases being cluster and others caused by a structural lesion in or near the carotid siphon.

Trigeminal Autonomic Cephalgias (Cluster Variants)

Cases of paroxysmal pain behind the eye or nose or in the upper jaw or temple—associated with blocking of the nostril or lacrimation and described in the past under the titles of *sphenopalatine* (Sluder), *petrosal*, *vidian*, and *ciliary neuralgia* (Charlin or Harris)—probably represent variants of cluster headache. A similar head pain may occasionally be confined to the lower facial, postauricular, or occipital areas. Ekblom distinguished yet another “lower cluster headache” syndrome with infraorbital radiation of the pain, an ipsilateral partial Horner syndrome, and ipsilateral hyperhidrosis. There is no evidence to support the separation of these neuralgias as distinct entities, and they have collectively been called *trigeminal autonomic cephalgias*. They are important, however, because of the high frequency of underlying intracranial lesions. Favier and colleagues collected 4 of their own cases and 27 from the literature to emphasize the range of underlying diseases, including intracranial aneurysms, peritentorial or parasellar meningiomas, or other tumors and nasopharyngeal cancers surrounding the carotid artery. We have encountered a case of Wegener granulomatosis of the soft palate that presented as a paroxysmal trigeminal autonomic neuralgia. The headache syndrome disappeared with cyclophosphamide treatment of the underlying granulomatous disorder.

Chronic paroxysmal hemicrania was the name given by Sjaastad and Dale to a rapidly repetitive unilateral form of headache that resembles cluster headache in many respects but has several distinctive features. These are of much shorter duration (2 to 45 min) than cluster and usually affect the temporoorbital region of one side, accompanied by conjunctival hyperemia, rhinorrhea, and in some cases a partial Horner syndrome. Even periorbital ecchymosis may accompany a severe attack. Unlike cluster headache, however, the paroxysms occur many times each day, recur daily for long periods (the patient of Price and Posner had an average of 16 attacks daily for more than 40 years), and, most important, respond dramatically to the administration of indomethacin, 25 to 50 mg tid. Unlike cluster headache, chronic paroxysmal hemicrania is more common in women than in men (ratio of 3:1).

The acronym SUNCT (short-lasting unilateral neuralgiform attacks with conjunctival injection and tearing) has been applied to an episodic condition with attacks

of even briefer duration, but otherwise similar to paroxysmal hemicrania in which the supraorbital or temporal pain lasts up to 4 min or so and frequent; it does not usually respond to indomethacin.

A similar hemicrania but without autonomic features, may be symptomatic of lesions near the cavernous sinus (mainly pituitary adenoma) or in the posterior fossa, but most cases are idiopathic. The typical episode of pain lasts approximately 20 min. Also known is a recurrent nocturnal headache in elderly individuals (“hypnic headache”), as described further on.

The relationship of cluster headache and all of its variants to migraine remains conjectural. No doubt the headaches in some persons have some of the characteristics of both, hence the terms *migrainous neuralgia* and *cluster migraine* (Kudrow). Lance and others, however, have pointed out differences that seem important to us: flushing of the face on the side of a cluster headache and pallor in migraine; increased intraocular pressure in cluster headache, normal pressure in migraine; increased skin temperature over the forehead, temple, and cheek in cluster headache, decreased temperature in migraine; and notable distinctions in sex distribution, age of onset, rhythmicity, and other clinical features, but prominently by differences among them in response to specific treatments. Cluster may be triggered in sensitive patients by the use of nitroglycerin and, as mentioned, by alcohol.

The cause and mechanism of the cluster headache syndrome are unknown. Gardner and coworkers originally postulated a paroxysmal parasympathetic discharge mediated through the greater superficial petrosal nerve and sphenopalatine ganglion. These authors obtained inconsistent results by cutting the nerve, but others (Kittrelle et al) reported that application of cocaine or lidocaine to the region of the sphenopalatine fossa (via the nostril) consistently aborts attacks of cluster headache. Capsaicin, applied over the affected region of the forehead and scalp, may have the same effect. Stimulation of the ganglion is said to reproduce the syndrome. Kunkle, on the basis of a large personal experience, concluded that the pain arises from the internal carotid artery, in the canal through which it ascends in the petrous portion of the temporal bone. In the course of an arteriogram, during which a patient with cluster headaches fortuitously developed an attack, Ekblom and Greitz noted a narrowing of the artery that was interpreted as being caused by swelling of the arterial wall, which, in turn, compromised the pericarotid sympathetic plexus and caused the Horner syndrome. This remains to be confirmed.

The cyclic nature of the attacks has been linked to a hypothalamic mechanism that governs the circadian rhythm. At the onset of the headache, the region of the suprachiasmatic nucleus appears to be active on PET (May et al). Hypothalamic activation has also been found in migraine, SUNCT, chronic paroxysmal hemicrania, and hemicrania continua. Moreover, stimulation of the hypothalamus has proved effective, although highly experimental, in stopping chronic cluster headache and SUNCT (see Leone et al and Bartsch et al).

Much was made in the past of the fact that cluster headaches could be reproduced by the intravenous injection

of 0.1 mg histamine, but the effect was probably nonspecific. Goadsby has reviewed the pathophysiology of the cluster headache syndrome.

Treatment of Cluster Headache

Inhalation of 100 percent oxygen via mask for 10 to 15 min at the onset of cluster headache may abort the attack, but this is not always practical. Termination of a cycle of cluster can also be achieved with verapamil, starting with 80 mg qid and increasing the dose over days, but electrocardiogram (ECG) monitoring is recommended in the older individual. The usual nocturnal attacks of cluster headache can be treated with a single anticipatory dose of ergotamine at bedtime (2 mg orally) or with possibly lesser efficacy, an equivalent dose of serotonin agonist. Intranasal lidocaine or sumatriptan (or zolmitriptan as for migraine, see above) can also be used to abort an acute attack. In other patients, ergotamine given once or twice during the day, before an attack of pain is expected, has been helpful.

With regard to prevention of cluster headache, if ergotamine and sumatriptan are ineffective or become ineffective in subsequent bouts, many headache experts prefer to use verapamil, up to 480 mg per day. Ekblom introduced lithium therapy for cluster headache (600 mg, up to 900 mg daily), and Kudrow has confirmed its efficacy in chronic cases. Lithium and verapamil may be given together, but lithium toxicity is a frequent problem. A course of prednisone, beginning with 75 mg daily for 3 days and then reducing the dose at 3-day intervals, has been beneficial in many patients. Usually, it can be decided within a week if any one of these medications is effective. In brief, no method is effective in all cases, but the best initial approach probably involves the use of one of the triptan compounds. Rare cases of intractable cluster headache, in which the syndrome persists for weeks or longer without remission, have been treated by partial section of the trigeminal nerve, as described by Jarrar and colleagues, but these ablative measures are now always a last resort, especially when hypothalamic stimulation has been shown to be possibly effective, as mentioned earlier.

Tension Headache

This, said to be the most common variety of headache, is usually bilateral, with occipitonal, temporal, or frontal predominance, or diffuse extension over the top of the cranium. The pain is usually described as dull and aching, but questioning often uncovers other sensations, such as fullness, tightness, or pressure (as though the head were surrounded by a band or clamped in a vise) or a feeling that the head is swollen and may burst. On these sensations, waves of aching pain are superimposed. These may be interpreted as paroxysmal or throbbing and, if the pain is slightly more on one side, the headache may suggest a migraine without aura. However, absent in tension headache are the persistent throbbing quality, nausea, photophobia, phonophobia, and clear lateralization of migraine. Nor do most tension headaches seriously interfere with daily activities, as migraine does. The onset is more gradual than that of migraine, and the

headache, once established, may persist with only mild fluctuations for days, weeks, months, or even years. In fact, this is the only type of headache that exhibits the peculiarity of being present throughout the day, day after day, for long periods of time for which the term *chronic tension-type headache* is used. There is often self-acknowledged anxiety and depression, as noted below. Although sleep is usually undisturbed, the headache develops soon after awakening, and the common analgesic remedies have limited effect if the pain is of more than mild to moderate severity.

The incidence of tension headache is certainly greater than that of migraine. However, most patients treat tension headaches themselves and do not seek medical advice. Like migraine, tension headaches are more common in women than in men. Unlike migraine, they infrequently begin in childhood or adolescence but are more likely to arise in middle age and to coincide with anxiety, fatigue, and depression in the trying times of life. In the large series reported by Lance and Curran, about one-third of patients with persistent tension headaches had readily recognized symptoms of depression. They carried out a controlled and blinded trial that demonstrated benefit from amitriptyline even in those patients who were not depressed. In our experience, chronic anxiety or depression of varying degrees of severity is present in the majority of patients with protracted headaches. Migraine and traumatic headaches may, of course, be complicated by tension headache, which, because of its persistence, often arouses fears of a brain tumor or other intracranial disease. However, as Patten points out, not more than one or two patients out of every thousand with tension headaches will be found to harbor an intracranial tumor, and its discovery has been most often incidental (see further on).

In a substantial group of patients with chronic daily headache, the pain, when severe, develops a pulsating quality, to which the term *tension-migraine* or *tension-vascular* headache has been applied (Lance and Curran). Observations such as these have tended to blur the sharp distinctions between migrainous and tension headaches in some cases.

For many years, it was thought that tension headaches were a result of excessive contraction of craniocervical muscles and an associated constriction of the scalp arteries. However, it is not clear that either of these mechanisms contributes to the genesis of tension headache, at least in its chronic form. In most patients with tension headache, the craniocervical muscles are quite relaxed (by palpation) and show no evidence of persistent contraction when measured by surface electromyographic (EMG) recordings. Anderson and Frank found no difference in the degree of muscle contraction between migraine and tension headache. However, using an ingenious laser device, Sakai and associates have reported that the pericranial and trapezius muscles are hardened in patients with tension headaches. Recently, nitric oxide has been implicated in the genesis of tension-type headaches, specifically by creating a central sensitization to sensory stimulation from cranial structures. The strongest support for this concept comes from several reports that an

inhibitor of nitric oxide reduces muscle hardness and pain in patients with chronic tension headache (Ashina et al). At present, these are interesting but speculative ideas.

Treatment of Tension Headache

Simple analgesics, such as aspirin or acetaminophen or other NSAIDs, may be helpful, if only for brief periods. Persistent or frequent tension headaches respond best to the cautious use of one of several drugs that relieve anxiety or depression such as amitriptyline given as a single dose at night, especially when symptoms of these conditions are present. Stronger analgesic medication should be avoided. Raskin reports success with calcium channel blockers, phenelzine, and cyproheptadine. Ergotamine and propranolol are ineffective unless there are symptoms of both migraine and tension headache. Some patients respond to ancillary measures such as massage, meditation, and biofeedback techniques. Relaxation techniques may be helpful in teaching patients how to deal with underlying anxiety and stress. Gradual withdrawal of daily doses of analgesics, ergotamines, or triptan medications is an important aspect of treating chronic daily headache.

Headaches in the Elderly

In several surveys, headache with onset in the elderly age period was found to be a prominent problem in as many as 1 of 6 persons, and more often to have serious import than headache in a younger population. In a series reported by Pascual and Berciano, more than 40 percent were classified as having tension headaches (women more than men), and there was a wide variety of diseases in the others (posttraumatic headaches, cerebrovascular disease, intracranial tumors, cranial arteritis, severe hypertension). Cough-induced headaches and cluster headaches were present in some of the men. New-onset migraine in this age group was a rarity.

Raskin described a headache syndrome in older patients that shares with cluster headache a nocturnal occurrence (*hypnic headache*). It also may occur with daytime naps. However, it differs in being bilateral and unaccompanied by lacrimation and rhinorrhea. He has successfully treated a number of his patients with 300 mg of lithium carbonate or 75 mg of sustained-release indomethacin at bedtime. The nosologic position of this hypnic headache syndrome is undetermined.

Despite these considerations, the most treacherous and neglected cause of headache in the elderly is temporal (cranial) arteritis with or without polymyalgia rheumatica, as discussed further on.

Headache and Other Craniofacial Pain with Psychiatric Disease

The most common cause of generalized persistent headache, both in adolescents and adults, is probably mild depression or anxiety in one of its several forms. A small group of older patients has delusional symptoms involving pain and physical distortion of cranial structures. As

the psychiatric symptoms subside, the headaches usually disappear. Odd cephalic pains, e.g., a sensation of having a nail driven into the head (*clavus hystericus*), may occur in hysteria or psychosis and raise perplexing problems in diagnosis. The bizarre character of these pains, their persistence in the face of every known therapy, the absence of other signs of disease, and the presence of other manifestations of psychiatric disease provide the basis for correct diagnosis. Older children and adolescents sometimes have peculiar behavioral reactions to headache: screaming, looking dazed, clutching the head with an agonized look. Usually, migraine is the underlying disorder in these cases, the additional manifestations responding to therapeutic support and suggestion.

Posttraumatic Headache

Severe, chronic, continuous, or intermittent headaches lasting several days or weeks appear as the cardinal symptom of several posttraumatic syndromes, separable in each instance from the headache that immediately follows head injury (i.e., scalp laceration and cerebral contusion with blood in the CSF or increased intracranial pressure).

The *headache of chronic subdural hematoma* is deep seated, dull, steady, mainly unilateral and may be accompanied or followed by drowsiness, confusion, and fluctuating hemiparesis. In more *acute subdural hematomas*, we have been impressed with the positional worsening of pain in some patients after lying down or leaning the head to one side. Tentorial hematomas produce the additional feature of pain in the eye. The head injury that gives rise to a subdural hematoma may have been minor, as described in Chap. 35, and forgotten by the patient and family. Typically, the headache increases in frequency and severity over several weeks or months. Patients who have received anticoagulation are particularly at risk. Diagnosis is established by CT or MRI.

Chronic headache is certainly a prominent feature of the postconcussion syndrome, comprising dizziness, fatigability, insomnia, nervousness, irritability, and inability to concentrate (a syndrome that we have also called *posttraumatic nervous instability*). This type of headache and associated symptoms, which resemble the tension headache syndrome, are described fully in Chap. 35, "Cranio-cerebral Trauma." The International Headache Society has classified persistence in this context as headache for longer than 3 months after injury. The patient with postconcussion syndrome requires supportive therapy in the form of repeated reassurance and explanations of the benign nature of the symptoms, a program of increasing physical activity, and the use of drugs that allay anxiety and depression. The early settlement of litigation, which is often an issue, works to the patient's advantage.

Tenderness and aching pain sharply localized to the scar of a long previous scalp laceration or surgical incision represent in a different problem and raise the question of a traumatic neuralgia or neuroma. Tender scars from scalp lacerations may be treated by repeated subcutaneous injections of local anesthetics, such as 5 mL of 1 percent procaine, which also acts as a diagnostic test.

With *whiplash injuries* of the neck, there may be unilateral or bilateral retroauricular or occipital pain, probably as a result of stretching or tearing of ligaments and muscles at the occipitounuchal junction or of a worsening of a preexisting cervical arthropathy. Much less frequently, cervical intervertebral discs and nerve roots are involved. However, it is questionable if chronic headache and vague neuropsychiatric symptoms can be attributed to whiplash (see Maleson).

One should also be alert to headache as a sign of carotid artery dissection after head or neck injury.

Headaches of Brain Tumor

It remains a popular notion that headache is a significant symptom in many patients with brain tumor, but it is actually infrequent, particularly as the heralding symptom of a tumor in an adult. While headache is sometimes stated to occur in one-third of brain tumor cases, this is certainly the result of the high frequency of cranial imaging in headache patients. Headache probably only arises if the tumor displaces major cerebral vessels or blocks the flow of CSF, but we have seen exceptions. The pain has no specific features; it tends to be deep seated, usually nonthrobbing (occasionally throbbing), and is described as aching or bursting. However, a major change in the pattern of an accustomed headache syndrome should raise suspicion of a structural lesion in the cranium. Physical activity and changes in position of the head may provoke pain, whereas rest sometimes diminishes it. Nocturnal awakening because of pain occurs in only a small proportion of brain tumor patients and is by no means diagnostic. Most headaches that awaken people at night are cluster-like headaches, hypnic headaches in the elderly, or those caused by caffeine withdrawal. Unexpected forceful (projectile) vomiting may punctuate brain tumor headache in its later stages, particularly in children, or occur early if the mass is in the posterior fossa.

If unilateral, the headache is nearly always on the same side as the tumor. Pain from supratentorial tumors is felt anterior to the interauricular circumference of the skull; from posterior fossa tumors, it is felt behind this line. Bifrontal and bioccipital headaches from tumor coming on after unilateral headaches probably signify the development of increased intracranial pressure or hydrocephalus.

Having stated that headache is not to be equated with brain tumor, one cannot help but be impressed with its frequency as a manifestation of *colloid cysts*, and we have several times stumbled on the correct diagnosis when an odd, unexplained bilateral headache led to brain imaging. The mechanism of headache in cases of colloid cyst, if such a relationship is valid, is not simply one of blocking the flow of CSF at the foramina of Monro, as it is not predicated on the development of hydrocephalus. Additionally, Harris described headaches of paroxysmal type with intra- and periventricular brain tumors, and many others have commented on the same type of headache with parenchymal tumors. These are severe headaches that reach their peak intensity in a few seconds, last for several minutes or as

long as an hour, and then subside quickly. When they are associated with vomiting, transient blindness, leg weakness causing "drop attacks," and loss of consciousness, there is a possibility of brain tumor with greatly elevated intracranial pressure. With respect to its onset, this headache almost resembles that of subarachnoid hemorrhage, but the latter is far longer-lasting and even more abrupt in onset. In its entirety, this paroxysmal headache is most typical of the aforementioned colloid cyst of the third ventricle, but it can occur with other tumors as well, including craniopharyngiomas, pinealomas, and cerebellar masses.

Headaches of Temporal Arteritis (Giant Cell Arteritis) (See also Chap. 34)

This type of inflammatory disease of cranial arteries is an important cause of headache in older persons. All of our patients have been older than 55 years of age, most of them older than age 65. From a state of normal health, the patient develops an increasingly intense throbbing or nonthrobbing headache, often with superimposed sharp, stabbing pains. In a few patients the headache has had an almost explosive onset. The pain is usually unilateral, sometimes bilateral, and often localized to the site of the affected arteries in the scalp. The pain persists to some degree throughout the day and is particularly severe at night. It lasts for many months if untreated. The superficial temporal and other scalp arteries are frequently thickened and tender and without pulsation. Jaw claudication and ischemic nodules on the scalp, with ulceration of the overlying skin, have been described in severe cases.

Many of the patients feel generally unwell and have lost weight; some have a low-grade fever and anemia. Usually the sedimentation rate is greatly elevated (>50 mm/h and typically >75 mm/h) but elevation of the C-reactive protein (CRP) level is a more sensitive indicator of this inflammatory condition and is particularly helpful when the sedimentation rate is only mildly elevated. A few patients have a peripheral neutrophilic leukocytosis. As many as 50 percent of patients have generalized aching of proximal limb muscles, reflecting the presence of polymyalgia rheumatica (see Chap. 55, "Polymyalgia Rheumatica").

The importance of early diagnosis relates to the threat of blindness from thrombosis of the ophthalmic or posterior ciliary arteries. This may be preceded by several episodes of amaurosis fugax (transient monocular blindness). Ophthalmoplegia may also occur but is less frequent, and its cause, whether neural or muscular, is not settled. Masticatory claudication is a specific but not particularly sensitive symptom of cranial arteritis. The large intracranial vessels are occasionally affected, thereby causing stroke. Once vision is lost, it is seldom recoverable. For this reason, *the earliest suspicion* of cranial arteritis should lead to the administration of corticosteroids and then to biopsy of the appropriate scalp artery. Microscopic examination discloses an intense granulomatous or "giant cell" arteritis. If biopsy on one

side fails to clarify the situation and there are sound clinical reasons for suspecting the diagnosis, the other side should be sampled. Arteriography of the external carotid artery branches is probably the most sensitive test but is seldom used, because of its relatively higher risk. Ultrasonographic examination of the temporal arteries may display a dark halo and irregularly thickened vessel walls. This technique has not yet been incorporated into the routine evaluation because its sensitivity has not been established; our own experience suggests that it may miss cases, but it could be useful in choosing the site for biopsy of the temporal artery.

Treatment

The administration of prednisone, 45 to 60 mg/d in single or divided doses over a period of several weeks, is indicated in all cases, with gradual reduction to 10 to 20 mg/d and maintenance at this dosage for several months or years, if necessary, to prevent relapse. The headache can be expected to improve within a day or two of beginning treatment; failure to do so brings the diagnosis into question. When the sedimentation rate or CRP is elevated, its return to normal, usually over months, is a reliable index of therapeutic response. Whether symptoms or the blood tests are a better guide to reducing the steroid dose is unclear, one should probably be cautious in lowering the medication if the erythrocyte sedimentation rate (ESR) and CRP remain high.

Headaches of Pseudotumor Cerebri (Benign or Idiopathic Intracranial Hypertension)

(See Chap. 30)

The headache of pseudotumor cerebri assumes a variety of forms. Most typical is a feeling of occipital pressure that is greatly worsened by lying down, but many patients have—in addition, or only—headaches of migraine or tension type. Indeed, some of them respond to medications such as propranolol and ergot compounds. None of the proposed mechanisms for pain in pseudotumor cerebri seems to be adequate as an explanation, particularly the idea that cerebral vessels are displaced or compressed, as neither has been demonstrated. It is worth noting that facial pain may also be a feature of the illness, albeit rare. Chapter 30 has a more complete description of the clinical features and treatment.

After successful treatment for pseudotumor, some patients have persistent headaches that have the flavor of migraine.

SPECIAL VARIETIES OF HEADACHE

Low-Pressure and Spinal Puncture Headache

These are commonly known to neurologists, as noted earlier in this chapter. It occurs after lumbar punctures in approximately 5 percent of cases. The headache is associated with the greatly reduced pressure of the CSF compartment and probably caused by vertical traction

or cranial blood vessels. Assuming the supine position almost immediately relieves the cranial pain and eliminates vomiting, but a blood-patch procedure may be required in persistent cases. In a limited number of cases, success has been obtained by the use of intravenous caffeine injections. The condition and its treatment are discussed in Chap. 30 “Lumbar Puncture Headache” and “Spontaneous Intracranial Hypertension.”

Menstrual (Catamenial) Migraine and Other Headaches Linked to the Hormonal Cycle

The relation of headache to a drop in estradiol levels during the late luteal phase was mentioned in “Migraine” above. There it was also indicated that the mechanism is probably more complex. In practice, factors such as sleep deprivation are at least as important in triggering perimenstrual headaches. Premenstrual headache, taking the form of migraine or a combined tension-migraine headache, usually responds to the administration of an NSAID begun 3 days before the anticipated onset of the menstrual period; oral sumatriptan (25 to 50 mg qid) and zolmitriptan (2.5 to 5 mg bid) are also equally effective. Manipulation of the hormonal cycle with danazol (a testosterone derivative) or estradiol has also been effective but is rarely necessary.

The management of migraine during pregnancy poses special problems because one wants to restrict exposure of the fetus to medications. It can be stated that beta-adrenergic compounds and tricyclic antidepressants may be used safely in the small proportion of women whose headaches persist or intensify during pregnancy. From a limited registry of patients who were given sumatriptan during pregnancy, and from several small trials summarized by Fox and colleagues, no teratogenic effects or adverse effects on pregnancy arose, but serotonin agonist drugs should be used advisedly until their safety is further confirmed. For those women who use antiepileptic drugs as a means of headache prevention, it is recommended that the drugs be stopped prior to pregnancy or as soon as it is known that pregnancy has begun.

Cough and Exertional Headache

A patient may complain of very severe, transient cranial pain on coughing, sneezing, laughing heartily, lifting heavy objects, stooping, and straining at stool. Pain is usually felt in the front of the head, sometimes occipitally, and may be unilateral or bilateral. As a rule, it follows the initiating action within a second or two and lasts a few seconds to a few minutes. The pain is often described as having a bursting quality and may be of such severity as to cause the patient to cradle his head in his hands, thereby simulating the headache of acute subarachnoid hemorrhage.

Most often this syndrome is a benign idiopathic state that recurs over a period of several months to a year or two and then disappears. Many decades ago, Symonds emphasized the benignity of the condition. In a report

of 103 patients followed for 3 years or longer, Rooke found that additional symptoms of neurologic disease developed in only 10. The cause and mechanism have not been determined. During the headache, the CSF pressure is normal. Bilateral jugular compression may induce an attack, possibly because of traction on the walls of large veins and dural sinuses. In a few instances, we have observed this type of headache after lumbar puncture or after a hemorrhage from an arteriovenous malformation.

Patients with cough or strain headache will only occasionally be found to have serious intracranial disease; when present, it has been traced to lesions of the posterior fossa and foramen magnum, arteriovenous malformation, subdural hematoma, Chiari malformation, basilar impression, or tumor. It may be necessary, therefore, to supplement the neurologic examination by appropriate CT and MRI. Far more common, of course, are the temporal and maxillary pains that are caused by dental or sinus disease, which may also be worsened by coughing.

All manner of headache has been attributed to Chiari type 1 malformation (with tonsils descended at least 3 mm below the lip of the foramen magnum) with little justification. However, some instances of exertional and Valsalva-induced suboccipital pain can be attributed to this disease. Some patients report radiating pain across the base of the neck and shoulders with straining and headache. In the survey by Pascual and colleagues of 50 patients with Chiari type 1 malformations, the incidence of migraine and tension-type headache was found to be appropriate to the population at large and only the degree of tonsillar descent correlated with the presence of exertional headache. It follows that suboccipital decompressive operations should be undertaken only selectively. Chiari malformation is discussed further in Chap. 38.

A special variant of exertional headache is “weightlifter’s headache.” It occurs either as a single event or repeatedly over a period of several months, but each episode of headache may last many hours or days, again raising the suspicion of subarachnoid hemorrhage. The pain begins immediately or within minutes of heavy lifting. If the pain resolves in an hour or less and there is no meningismus or sign of bleeding on the CT, we have foregone lumbar puncture and angiography but have suggested that weight lifting not be resumed for several weeks. Athletes and runners in general seem to suffer exertional headaches quite often in our experience, and the episodes usually have migrainous features.

Indomethacin is usually effective in controlling exertional headaches; this has been confirmed in controlled trials. Useful alternatives are NSAIDs, ergot preparations, and propranolol. In a few of our patients, lumbar puncture appeared to immediately resolve the problem in some inexplicable way.

Headaches Related to Sexual Activity

Lance (1976) described 21 cases of this type of headache, 16 in males and 5 in females. The headache took one of two forms: one in which pain typical of tension headache developed as sexual excitement increased, and another in which a severe, throbbing, “explosive”

headache occurred at the time of orgasm and persisted for several minutes or hours (orgasmic headache). The latter headaches were of such abruptness and severity as to suggest a ruptured aneurysm but the neurologic examination was negative in every instance, as was arteriography in 7 patients who were subjected to this procedure. In 18 patients who were followed for a period of 2 to 7 years, no other neurologic symptoms developed. Characteristically, the headache occurred on several consecutive occasions and then disappeared. In cases of repeated coital headache, indomethacin has been effective. Of course, so-called orgasmic headache is not always benign; a hypertensive hemorrhage, rupture of an aneurysm or vascular malformation, carotid artery dissection, or myocardial infarction may occur during the exertion of sexual intercourse. While there is no authoritative direction, it is justified to perform a spinal tap if a sexual-related headache is the first occurrence of headache in a patient’s history.

Thunderclap Headache

The headache of subarachnoid hemorrhage caused by rupture of a berry aneurysm is among the most abrupt and dramatic of cranial pains (see Chap. 34). There are several reports regarding such pains as a “warning leak” of rupture and even reports suggesting that acute severe headaches occur as a consequence of unruptured aneurysms (although subsequent studies suggest that this is infrequent). It was in relation to an exceptional case of this nature that the term *thunderclap* was introduced by Day and Raskin. Patients in our services have offered colorful descriptions, such as “being kicked in the back of the head.” Thunderclap headache, as pointed out by Dodick, has also been a symptom of pituitary apoplexy, cerebral venous thrombosis, cervical arterial dissection, non-aneurysmal perimesencephalic hemorrhage, or hypertensive crisis (Table 10-4). To this list we would add diffuse idiopathic arterial spasm (Call-Fleming syndrome; see “Diffuse and Focal Cerebral Vasospasm” in Chap. 34) and cerebral vasospasm as the result of the administration of sympathomimetic or serotonergic drugs, including cocaine and the triptan group of medications for the treatment of migraine. Recurrent thunderclap pain may be particularly indicative of multifocal or diffuse vasospasm, as pointed out by Chen and colleagues, who found this vasculopathy in 39 percent of their patients with recurrent thunderclap pain.

Table 10-4

CAUSES OF THUNDERCLAP HEADACHE

Migraine
Subarachnoid hemorrhage
Cerebral venous thrombosis
Diffuse cerebral vasospasm (Call-Fleming syndrome)
Accelerated hypertension
Pituitary apoplexy
Cocaine and adrenergically active drugs
Perimesencephalic non-aneurysmal subarachnoid hemorrhage

Nevertheless, in a large proportion of patients with thunderclap headache the pain is indistinguishable from that caused by subarachnoid hemorrhage, even to the extent of being accompanied by vomiting and acute hypertension. The diagnosis is clarified after lumbar puncture and cerebral imaging exclude bleeding and aneurysm, and the pain resolves in hours or less. Most cases turn out to be idiopathic. Wijdicks and colleagues confirmed that thunderclap headache is usually a benign condition; among 71 patients followed for more than 3 years they found no serious cerebrovascular lesions. For this reason, these idiopathic thunderclap headaches have been presumed to be a form of migraine ("crash migraine"). This opinion is based in part on a history of preceding or of subsequent headaches and migrainous episodes in affected individuals; however, in our experience not all of such patients have had migraine in the past. There is a notable tendency for thunderclap headaches to recur.

Erythrocyanotic Headache

An intense, generalized, throbbing headache may occur in conjunction with flushing of the face and hands and numbness of the fingers (erythromelalgia). Episodes tend to be present on awakening from sound sleep. This condition, called erythrocyanotic, has been reported in a number of unusual settings: (1) in mastocytosis (infiltration of tissues by mast cells, which elaborate histamine, heparin, and serotonin); (2) with carcinoid tumors; (3) with serotonin-secreting tumors; (4) with some tumors of the pancreatic islets; and (5) with pheochromocytoma. Seventy-five percent of patients with pheochromocytoma reportedly have vascular-type headaches coincident with paroxysms of hypertension and release of catecholamines (Lance and Hinterberger) but the flushing phenomenon has been rare in our experience.

Headache Related to Medical Diseases

A cardinal feature of meningitis of varied causes is headache. When accompanied by fever and stiff neck, the diagnosis is almost assured. However, severe headache may occur with a number of infectious illnesses caused by banal viral infections, by organisms such as *Mycoplasma*, and particularly by influenza. There is often accompanying neck pain and slight stiffness. The suspicion of meningitis is raised, even subarachnoid hemorrhage, but there is no reaction in the CSF ("meningism"). The mild aseptic meningitis that accompanies HIV seroconversion may also be accompanied by headache.

Approximately 50 percent of patients with hypertension complain of headache, but the relationship of one to the other is not clear. Minor elevations of blood pressure may be a result rather than the cause of tension headaches. Severe (accelerated) hypertension, with diastolic pressures of more than 120 mm Hg, is regularly associated with headache, and measures that reduce the blood pressure relieve it. In preeclampsia, the headaches occur at lower levels of blood pressure. Abrupt

elevations of blood pressure, as occur in patients who take monoamine oxidase inhibitors and then ingest tyramine-containing food, can cause headaches that are abrupt and severe enough to simulate subarachnoid hemorrhage. However, it is the individual with moderately severe hypertension and frequent severe headaches that typically confronts the practitioner. In some of these patients, the headaches are of the common migrainous or tension type, but in others, they defy classification. According to Wolff, the mechanism of the hypertensive headache is similar to that of migraine. The headaches, however, bear no clear relation to even modest peaks in blood pressure. The acute headache of pheochromocytoma correlates with the rate of increase of blood pressure rather than its absolute value. Curiously, headaches that occur toward the end of renal dialysis or soon after its completion are associated with a fall in blood pressure (as well as a decrease in blood sodium levels and osmolality).

Headaches frequently follow a seizure, having been recorded in half of one large series of epileptic patients analyzed in a Great Britain study but the pain is infrequently severe. In migraineurs, the postictal headache may reproduce a typical migraine attack. Experienced physicians are aware of many other conditions in which headache may be a principal symptom. These include fevers of any cause, carbon monoxide exposure, chronic lung disease with hypercapnia (headaches often nocturnal or early morning), sleep apnea, hypothyroidism, Cushing disease, withdrawal from corticosteroid medication or alcohol, mountain (altitude) sickness, exposure to nitrates, occasionally in adrenal insufficiency, and acute anemia with hemoglobin below 10 g.

No attempt is made here to discuss the symptomatic treatment of headache that may accompany these many medical conditions. Obviously, the guiding principle is to address the underlying disease.

Headache Related to Diseases of the Cervical Spine

Headaches that accompany diseases of the upper cervical spine are well recognized, but their mechanism is obscure and their frequency possibly overestimated. Recent writings have focused on a wide range of causative lesions, such as zygapophyseal (facet) arthropathy, C2 dorsal root entrapment, calcified ligamentum flavum, hypertrophied posterior longitudinal ligament, and rheumatoid arthritis of the atlantoaxial region. As summarized by Bogduk and Govind, the most credible evidence for this group of disorders comes from systematic injection of anesthetics into cervical structures and effecting complete relief of headache. Even this is not uniformly successful in patients whose cranial pain has been attributed to a cervicogenic mechanism. CT and MRI have divulged a number of these abnormalities. One special variety is discussed further below, under "Third Occipital Nerve' Headache," and further in Chap. 11.

OTHER CRANIOFACIAL PAINS

(See Chap. 47)

Trigeminal Neuralgia (Tic Douloureux)

This is a common disorder of middle age and later life, consisting of paroxysms of intense, stabbing pain in the distribution of the mandibular and maxillary divisions (rarely the ophthalmic division) of the fifth cranial nerve. The pain seldom lasts more than a few seconds or rarely a minute or two, but it is often so intense that the patient winces involuntarily; hence the term *tic*. It is uncertain whether the tic is reflexive or quasivoluntary. The paroxysms recur frequently, both day and night, for several weeks or months at a time. Another characteristic feature is the initiation of a jab or a series of jabs of pain by stimulation of certain areas of the face, lips, or gums, as in shaving or brushing the teeth, or by movement of these parts in chewing, talking, or yawning, or even by a breeze—the so-called trigger factors. Sensory or motor loss in the distribution of the fifth nerve cannot be demonstrated, though there are minor exceptions to this rule. In addition to the paroxysmal pain, some patients complain of a more or less continuous discomfort, itching, or sensitivity of restricted areas of the face, features regarded as atypical even though not infrequent.

In studying the relationship between stimuli applied to the trigger zones and the paroxysms of pain, touch and possibly tickle are more likely to be precipitants rather than painful or thermal stimulus. Usually a spatial and temporal summation of impulses is necessary to trigger a paroxysm of pain, which is followed by a refractory period of up to 2 or 3 min.

The *diagnosis* of tic douloureux must rest on the strict clinical criteria enumerated above, so that the condition can be distinguished from other forms of facial and cephalic neuralgia and pain arising from diseases of the jaw, teeth, or sinuses. Most cases of trigeminal neuralgia are without obvious cause (idiopathic), in contrast to *symptomatic trigeminal neuralgia*, in which paroxysmal facial pain is because of involvement of the fifth nerve by some other disease: multiple sclerosis (may be bilateral), aneurysm of the basilar artery, or tumor (acoustic or trigeminal schwannoma, meningioma, epidermoid) in the cerebellopontine angle. Each of the forms of symptomatic trigeminal neuralgia may give rise only to pain in the distribution of the trigeminal nerve, or it may produce a loss of sensation as well.

Vascular loop as a cause of trigeminal neuralgia It has also become apparent that a proportion of ostensibly idiopathic cases are caused by compression of the trigeminal roots by a small tortuous branch of the basilar artery, as originally pointed out by Dandy and brought to greater attention by Jannetta, who has observed it frequently and has relieved the pain by surgical decompression of the trigeminal root. In this procedure, the offending small vessel is removed from contact with the proximal portion of the nerve (see below). Others have declared a vascular compressive causation to be infrequent, but modern

imaging has increasingly revealed a putative association. This and other disorders of the fifth nerve, some of which give rise to facial pain, are discussed in Chap. 47.

Treatment Carbamazepine is effective in 70 to 80 percent of patients, but half become tolerant over a period of several years. Other antiepileptic drugs such as phenytoin (300 to 400 mg/d), valproic acid (800 to 1,200 mg/d), clonazepam (2 to 6 mg/d), gabapentin (300 to 900 mg/d or more), pregabalin (150 to 300 mg/d), and carbamazepine (600 to 1,200 mg/d), alone or in combination, suppress or shorten the duration and severity of the attacks in most patients for varying times. Baclofen may be useful in patients who cannot tolerate carbamazepine or gabapentin, but it is most effective as an adjunct to one of the anticonvulsant drugs. Capsaicin applied locally to the trigger zones or the topical instillation in the eye of an anesthetic has been helpful in some patients. By temporizing and using these drugs, one may permit a spontaneous remission to occur in perhaps 1 in 5 patients over a year or two.

Most of the patients with intractable pain, however, come to vascular surgery or a surgical form of root destruction. The procedure of vascular decompression, popularized by Jannetta, which requires a posterior fossa craniotomy but leaves no sensory loss, has been the most popular. Barker and colleagues reported that 70 percent of 1,185 patients were relieved of pain by repositioning a small branch of the basilar artery that was found to compress the fifth nerve, and this benefit persisted with a recurrence rate of less than 1 percent annually for 10 years. It is not clear if conventional or CT arteriography is useful in identifying an aberrant blood vessel prior to surgery but most neurosurgeons obtain these studies before committing a patient to surgery.

A procedure used more in the past, was stereotactically controlled thermocoagulation of the trigeminal roots (Sweet and Wepsic). The therapeutic efficacy of the two surgical approaches is roughly equivalent; in recent years, there has been a preference for microvascular decompression on the basis of its sparing of sensation, especially late in the course of the illness (Fields). Gamma Knife and other forms of focused radiation are emerging as less intrusive alternatives to destroying the ganglion, but its full effect is not evident for months. In practice, an antiepileptic medication is often required for some period of time after any of these procedures, and it must be reinstated when symptoms reoccur, as they often do in our experience.

Glossopharyngeal Neuralgia

This syndrome is much less common than trigeminal neuralgia but resembles the latter in many respects. The pain is intense and paroxysmal; it originates in the throat, approximately in the tonsillar fossa, and is provoked most commonly by swallowing but also by talking, chewing, yawning, laughing, etc. The pain may be localized in the ear or radiate from the throat to the ear, implicating the auricular branch of the vagus nerve. For this reason, White and Sweet suggested the term *vaguglossopharyngeal neuralgia*. This is the main craniofacial neuralgia that may

be accompanied by bradycardia and even by syncope, presumably because of the triggering of cardioinhibitory reflexes by afferent vagal pain impulses. There is no demonstrable sensory or motor deficit.

Rarely, tumors, including carcinoma, lymphoma or epithelioma of the oropharyngeal-infracranial region or peritonsillar abscess may give rise to pain that is clinically indistinguishable from glossopharyngeal neuralgia.

Treatment For idiopathic glossopharyngeal neuralgia, a trial of carbamazepine, gabapentin, pregabalin, or baclofen may be useful. If these are unsuccessful, the conventional surgical procedure had been to interrupt the glossopharyngeal nerve and upper rootlets of the vagus nerve near the medulla but recent observations suggest that a vascular decompression procedure similar to the one used for tic and directed to a small vascular loop under the ninth nerve relieves the pain in a proportion of patients.

Acute Herpes Zoster and Postherpetic Neuralgia

Neuralgia associated with a vesicular eruption caused by the herpes zoster virus may affect cranial as well as peripheral nerves. Two syndromes are frequent: herpes zoster auricularis and herpes zoster ophthalmicus. Both may be exceedingly painful in the acute phase of the infection. In the auricular form, herpes of the external auditory meatus and pinna and sometimes of the palate and occipital region—with or without deafness, tinnitus, and vertigo—is combined with facial paralysis. This syndrome, since its original description by Ramsay Hunt, has been known as geniculate herpes, and also Ramsay-Hunt syndrome (see also Chap. 47). However, it has never been clear to us how there is a connection between the geniculate ganglion and the skin of the external ear canal and tympanic membrane and a careful pathologic study of the ganglion by Denny-Brown and Adams in one case showed no lesion there. The facial nerve, however, was heavily infiltrated with inflammatory cells, at least explaining the facial palsy.

The more common pain and herpetic eruption caused by herpes zoster infection of the gasserian ganglion are practically always limited to the first division (herpes zoster ophthalmicus). Ordinarily, the rash appears within 4 to 5 days or less after the onset of the pain, thereby making the clinical diagnosis difficult; however, treatment should be instituted (see below) based on the clinical likelihood of zoster infection. If the eruption does not appear, some cause other than herpes zoster will almost invariably declare itself; nevertheless, a few cases have been reported in which the characteristic location of pain with serologic evidence of herpes zoster infection was not accompanied by skin lesions.

The acute discomfort associated with the herpetic eruption usually subsides after several days or weeks, or it may linger for several months. It is mostly in the elderly that the pain becomes chronic and intractable. Usually it is described as a constant burning, with superimposed waves of stabbing pain, and the skin in the territory of the preceding eruption is exquisitely sensitive to the slightest

tactile stimuli, even though the threshold of pain and thermal perception is elevated. This unremitting *postherpetic neuralgia* of long duration represents one of the most difficult pain problems with which the physician must deal. Some relief may be provided by application of capsaicin cream, use of a mechanical or electrical cutaneous stimulator, or administration of one of the antiepileptic drugs.

Treatment Treatment with acyclovir, along the lines indicated in Chap. 33, will shorten the period of eruption and pain, but the drug does not prevent its persistence as a chronic pain.

Antidepressants such as amitriptyline and fluoxetine are helpful in some patients, and Bowsher has suggested, on the basis of a small placebo-controlled trial, that treatment with amitriptyline during the early acute phase may prevent persistent pain. The use of preemptive measures, such as gabapentin or pregabalin administered at the outset, may be effective but a properly performed clinical trial is lacking. The addition of amitriptyline 75 mg at bedtime has proved to be a useful measure. Probably equivalent results are obtained by a combination of valproic acid and an antidepressant, as reported by Raftery. King has reported that two 325-mg aspirin tablets crushed and mixed with cold cream or chloroform (15 mL) and spread over the painful zone on the face or trunk relieved the pain for several hours in most patients with postzoster neuralgia. Ketamine cream has been suggested as an alternative. Extensive trigeminal rhizotomy or other destructive procedures should be avoided, as these surgical measures are not for long successful and may lead to a superimposed diffuse refractory dysesthetic component on the original neuralgia (*anesthesia dolorosa*).

Trochlear Headache

Under the heading of "primary trochlear headache," Yanguela and colleagues have described a periorbital pain that emanates from the superomedial orbit in the region of the trochlea (the pulley of the superior oblique muscle). Most of their patients were women. The pain was worsened by adduction and (paradoxically for the superior oblique) upgaze of the globe on the affected side, in the direction of action of the superior oblique muscle. The authors describe a diagnostic method of examination that begins by having the patient look downward so that the trochlea can be palpated and compressed; the patient then looks upward, eliciting or exaggerating the pain, while the examiner continues compression. Injection of the trochlea with corticosteroids relieved the pain in almost all of these patients. The authors made a distinction between primary trochlear headache and "trochleitis," which seems to us an ambiguous difference. There is no limitation of ocular movement or autonomic change and imaging of the orbit is normal. This syndrome, with which we have no experience, brings to mind the entity of the Brown syndrome of trochlear entrapment with diplopia and pain (Chap. 13). The above authors were also of the opinion that the trochlea may be a trigger point for migraine.

Otalgia

Pain localized in and around one ear is occasionally a primary complaint. It is commonly the incipient symptom of Bell's palsy but there are a number of different causes and mechanisms. During neurosurgical operations in awake patients, stimulation of cranial nerves V, VII, IX, and X causes ear pain, yet interruption of these nerves usually causes no or limited demonstrable loss of sensation in the ear canal or the ear itself (superficial sensation in this region is supplied by the great auricular nerve, which is derived from the C2 and C3 roots). The neurosurgical literature cites examples of otalgia that were relieved by section of the nervus intermedius (sensory part of VII) or of nerves IX and X. In otalgic cases, one is prompted to search for a nasopharyngeal tumor, vertebral artery aneurysm or to anticipate an outbreak of zoster. Formerly, lateral sinus thrombosis was a common cause in children. When these possibilities are eliminated by appropriate studies, there always remain examples of primary idiopathic otalgia, lower cluster headache, and glossopharyngeal neuralgia. Some patients with migraine have pain centered in the ear region and occiput, but we have never observed a trigeminal neuralgia in which the ear was the predominant site of pain. Occasionally, temporomandibular joint disease is the cause (see below).

Occipital Neuralgia

Paroxysmal pain may occasionally occur in the distribution of the greater or lesser occipital nerves (suboccipital, occipital, and posterior parietal areas). While tenderness may be localized to the region where these nerves cross the superior nuchal line, there is only questionable evidence of an occipital nerve lesion at this site. The finding of hypesthesia in the distribution of the occipital nerves makes the possibility of an entrapment neuropathy more convincing. Carbamazepine or gabapentin may provide some relief. Blocking the nerves with lidocaine may abolish the pain and encourage attempts to section one or more occipital nerves or the second or third cervical dorsal root, but the results have rarely been successful, and several such patients who had these procedures were later referred to us with disabling anesthesia dolorosa. We have advised repeated injections of local anesthetic agents and the use of steroids, traction, local heat, and analgesic and anti-inflammatory drugs. The pain at times may be difficult to distinguish from that arising in the upper three cervical facet joints, one type of which is discussed below. The approach of treating migraine by injection of the occipital nerves is controversial.

"Third Occipital Nerve" Headache

This condition, a unilateral occipital and suboccipital ache, may be a prominent symptom in patients with neck pain, particularly after neck injuries (a prevalence of 27 percent, according to Lord et al). Bogduk and Marsland attribute it to a degenerative or traumatic arthropathy

involving the C2 and C3 apophysial joints with impingement on the "third occipital nerve" (a branch of the C3 dorsal ramus that crosses the dorsolateral aspect of the apophysial [facet] joint). Elimination of the neck pain and headache by percutaneous blocking of the third occipital nerve near the facet joint under fluoroscopic control is diagnostic and temporarily therapeutic. More sustained relief (weeks to months) has been obtained by radiofrequency coagulation of the nerve or steroid injections in and around the joint. NSAIDs also provide some relief.

Carotidynia and Extracranial Artery Dissection

Carotidynia was coined by Temple Fay in 1927 to designate a special type of cervicofacial pain that could be elicited by pressure on the common carotid arteries of patients with atypical facial neuralgia. Compression of the artery in the neck in these patients, or mild electrical stimulation at or near the bifurcation, produced a dull ache that was referred to the ipsilateral face, ear, jaws, and teeth or down the neck. This type of carotid sensitivity occurs as part of cranial (giant cell) arteritis and of the rare condition known as Takayasu arteritis (Chap. 34), and during attacks of migraine or cluster headache. It has also been described with displacement of the carotid artery by tumor and dissecting aneurysm of its wall; among these causes, the last is of greatest concern. The idiopathic variety of carotidynia may have to do with a swelling or inflammation of the tissue surrounding the carotid bifurcation, a change that has been demonstrated on MRI by Burton and colleagues, but the problem has been seen most frequently in migraineurs.

Roseman has described a variant of carotidynia that has a predilection for young adults. This syndrome takes the form of recurrent, self-limited attacks of pain and tenderness at the carotid bifurcation lasting a week or two. During the attack, aggravation of the pain by head movement, chewing, and swallowing is characteristic. This condition is treated with simple analgesics. Yet another possible variety of carotidynia appears at any stage of adult life and recurs in attacks lasting minutes to hours in association with throbbing headaches indistinguishable from common migraine (Raskin and Prusiner). This form responds favorably to the administration of ergotamine, methysergide, and other drugs that are effective in the treatment of migraine.

Although most pain of carotid or vertebral artery dissection is localized to the site of injury in the anterior or posterior neck, Arnold and colleagues have emphasized the frequency with which headache, and not neck pain, was the sole feature. Some had a paroxysmal ("thunderclap") onset but most had throbbing and progressive pain over days, sometimes bilaterally. The combination of focal neck pain and localized headache over an eye is particularly suggestive and, of course, if there are corresponding symptoms of fluctuating or static regional brain ischemia, Horner syndrome, or lower cranial nerve palsies, the diagnosis is likely.

Temporomandibular Joint Pain (Costen Syndrome)

This is a form of craniofacial pain from dysfunction of one temporomandibular joint. Malocclusion because of ill-fitting dentures or loss of molar teeth on one side with alteration of the normal bite may lead to distortion of and ultimately degenerative changes in the joint and to pain in front of the ear, with radiation to the temple and over the face (see Guralnick et al). Most patients, according to Scrivani and colleagues report deviation of the mandible to the affected side on jaw opening and clicking noises emanating from the joint. Locking of the jaw in either the open or closed position is another feature. The diagnosis is supported by the findings of tenderness over the joint, crepitus on opening the mouth, and limitation of jaw opening. The favored diagnostic maneuver involves palpating the joint from its posterior aspect by placing a finger in the external auditory meatus and pressing forward. The diagnosis can be made with some confidence only if this entirely reproduces the patient's pain. CT and plain films are rarely helpful, but effusions have been shown in the joints by MRI. Management consists of careful adjustment of the bite by a dental specialist. Small doses of amitriptyline at bedtime may be helpful. In our experience, most of the putative diagnoses of Costen syndrome that reach the neurologist have been erroneous, and the number of headaches and facial pains that are attributed to "temporomandibular joint dysfunction" is excessive, especially if judged by the response to treatment. The temporomandibular joint may also be the source of pain when involved with rheumatoid arthritis and other connective tissue diseases.

Facial Pain of Dental or Sinus Origin

Maxillary and mandibular discomfort is a common effect of nerve irritation from deep caries, abscess, dental pulp degeneration, or periodontal disease. The pain of dental nerve origin is usually most severe at night, slightly pulsating, and often associated with local tenderness at the root of the tooth in response to heat, cold, or pressure. The diagnosis can be confirmed by infiltrating the base of the tooth with lidocaine, and the pain is eradicated by proper dental management.

Trigeminal neuritis following dental extractions or oral surgery is another vexing problem. There may be sensory loss in the tongue or lower lip and weakness of the masseter or pterygoid muscle.

Sometimes the onset of "atypical facial pain" (see below) can be dated to a dental procedure such as tooth extraction, and, as usually happens, neither the dentist nor the neurologist is able to find a source for the pain or any malfunction of the trigeminal nerve. Roberts and coworkers, as well as Ratner and associates, have pointed out that residual microabscesses and subacute bone infection account for some of these cases. They isolated the affected region by using local anesthetic blocks, curetted the bone, and administered antibiotics, following which the pain resolved. The removed bone fragments showed vascular and inflammatory changes and infection with oral bacterial flora, but there was no control material.

Facial Pain of Uncertain Origin (Idiopathic, "Atypical" Facial Pain)

There remains—after all the aforementioned facial pain syndromes a fair number of patients with pain in the face for which no cause can be found. These patients are most often young women, who describe the pain as constant and unbearably severe, deep in the face, or at the angle of cheek and nose, and unresponsive to all varieties of analgesic medication. Because of the failure to identify an organic basis for the pain, one is tempted to attribute it to psychologic or emotional factors. Depression of varying severity is found in some. Some such patients, with or without depression, respond to tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRI) medications. Differentiated from this group is the condition of trigeminal neuropathy with facial numbness, described in Chap. 47.

Facial pain of the "atypical type," like other chronic pain of indeterminate cause, requires close observation of the patient, looking for lesions such as nasopharyngeal carcinoma or apical lung carcinoma to declare themselves. The pain should be managed by the conservative methods outlined in the preceding chapter and not by destructive surgery. Antidepressants may be helpful, especially if the patient displays obsessive characteristics in relation to the pain; some European neurologists favor clomipramine for various facial and scalp pains.

Other Rare Types of Facial Pain

Neuralgia may arise in the terminal branches of the trigeminal, ciliary, nasociliary, and supraorbital nerves; some of which have already been mentioned. Some of these are vague entities at best and merely descriptive terms given to pains localized around the eye and nose. The Tolosa-Hunt syndrome of pain behind the eye and granulomatous involvement of some combination of cranial nerves III, IV, VI, and ophthalmic V, responsive to steroids, is discussed in Chap. 47.

A kind of *reflex sympathetic dystrophy of the face* is postulated as another rare form of persistent facial pain that may follow dental surgery or penetrating injuries to the face. It is characterized by severe burning pain and hyperpathia in response to all types of stimuli. Sudomotor, vasomotor, and trophic changes are lacking, unlike causalgia that affects the limbs. Nevertheless, this form of facial pain is said to respond to repeated blockade or resection of the stellate ganglion.

Under the title of *neck-tongue syndrome*, Lance and Anthony have described the occurrence of a sharp pain and tingling in the upper neck or occiput with numbness of the ipsilateral half of the tongue on sudden rotation of the neck. They attribute the syndrome to stretching of the C2 ventral ramus, which contains proprioceptive fibers from the tongue; these fibers run from the lingual nerve to the hypoglossal nerve and thence to the second cervical root.

A problem that has gone by the self-evident name *burning mouth syndrome (stomatodynia)* occurs mainly in middle-aged and older women, as commented in Chap. 12.

The tongue or other oral sites may be most affected or the entire oral mucosa may burn. A few patients are found to have diabetes, vitamin B₁₂ deficiency, or Sjögren syndrome as possible causes. A hint to the last diagnosis is the inability to feel food in the mouth. The oral mucosa is normal when inspected, and no one treatment has been

consistently effective, but gabapentin combined with antidepressants or clonazepam may be tried (see the review by Grushka et al). One of our patients with a limited form of this condition, which affected only the upper palate and gums, benefited from dental nerve blocks with lidocaine.

Pain in the Back, Neck, and Extremities

We include an extensive chapter on this subject in recognition of the fact that back pain is among the most frequent of medical complaints. Up to 80 percent of adults have low back pain at some time in their lives and, according to Kelsey and White, an even larger percentage will be found at autopsy to have degenerative spine disease. One task of the neurologist is to determine whether a disease of the spine has compressed the spinal cord or the spinal roots. To do this effectively, a clear understanding of the structures involved and some knowledge of orthopedics and rheumatology is necessary.

Pains in the lower part of the spine and legs are caused by somewhat different types of disease than those in the neck, shoulder, and arms; therefore, these two categories are considered separately.

PAIN IN THE LOWER BACK AND LIMBS

The lower parts of the spine and pelvis, with their massive muscular attachments, are relatively inaccessible to palpation and inspection. Although some physical signs and imaging studies are helpful, diagnosis often depends on the patient's description of the pain and his behavior in different positions and during the execution of certain maneuvers. Seasoned clinicians appreciate the need for a systematic inquiry and method of examination, the descriptions of which are preceded here by a brief consideration of the anatomy and physiology of the spine.

Anatomy and Physiology of the Lower Part of the Back

The bony spine is a complex structure, roughly divisible into an anterior and a posterior part. The anterior component consists of the cylindrical vertebral bodies, articulated by the intervertebral discs and held together by the anterior and posterior longitudinal ligaments. The posterior elements are more delicate and extend from the vertebral bodies as pedicles and laminae, which encircle the *spinal canal*. Large transverse and spinous processes project laterally and posteriorly, respectively, and serve as the origins and insertions of the muscles that support and protect the spinal column. The bony processes are also held together by sturdy ligaments, the most important

being the ligamentum flavum, which runs along the ventral surfaces of the laminae. The posterior longitudinal ligament lies opposite it—on the dorsal surfaces of the vertebral bodies. These two ligaments define the posterior and anterior margins of the spinal canal, respectively.

The posterior parts of the vertebrae articulate with one another at the diarthrodial *facet joints* (also called apophysial or zygapophysial joints), each of which is composed of the inferior facet of the vertebra above and the superior facet of the one below. Figure 11-1 illustrates these anatomic features. The configuration and orientation of the facet joints differs in the cervical, thoracic and lumbosacral parts of the spine. The facet and sacroiliac joints, which are covered by synovia, the compressible intervertebral discs, and the collagenous and elastic ligaments, permit a limited degree of flexion, extension, rotation, and lateral motion of the spine.

The stability of the spine depends on the integrity of the vertebral bodies, pedicles and intervertebral discs and on two types of supporting structures, ligamentous (passive) and muscular (active). Although the ligamentous structures are quite strong, neither they nor the vertebral body–disc complexes have sufficient integral strength alone to resist the enormous forces that may act on the spinal column. Consequently, the stability of the lower back is also largely dependent on the voluntary and reflex activity of the paraspinal, sacrospinal, abdominal, gluteus maximus, and hamstring muscles.

The vertebral and paravertebral structures derive their innervation from the meningeal branches of the spinal nerves (also known as recurrent meningeal or sinuvertebral nerves). These meningeal branches spring from the posterior divisions of the spinal nerves just distal to the dorsal root ganglia, reenter the spinal canal through the intervertebral foramina, and supply pain fibers to the intraspinal ligaments, periosteum of bone, outer layers of the annulus fibrosus (which enclose the disc), and the capsule of the articular facets. Coppes and associates have found A- δ and C pain fibers extending into the inner layers of the annulus, and even into the nucleus pulposus.

Although the spinal cord itself is insensitive, many of the conditions that affect it produce pain by involving these adjacent structures. For example, the sensory fibers from the lumbosacral and sacroiliac joints enter the spinal cord via the fifth lumbar and first sacral roots. Motor

Figure 11-1. A. The lumbar vertebrae viewed from above from B. the side and C. mid-sagittally. A and B show the bony structures and their relationships to the disc space, facet joints and intervertebral foramina. C demonstrates in a cutaway mid-sagittal view, the main ligamentous structures of the spine in relation to the bones and discs. The ligaments and articulations are critical to the mechanical integrity of the spinal column.

fibers exit through the corresponding anterior roots and form the efferent limb of segmental reflexes.

The spinal roots in the lumbar region, after exiting from the spinal cord, course downward in the subarachnoid space of the spinal canal and are gradually displaced

laterally until they angulate and exit at the intervertebral foramina. Prior to entering the proximal foraminal canal, the spinal root lies in a shallow furrow along the inner surface of the pedicle, the *lateral recess*. The lumbar nerve roots traverse this lateral recess one level superior to their exit through the foramen. The lateral recess is a common site of entrapment of the traversing root by posterolaterally herniated disc material and bony overgrowth.

The parts of the back that possess the greatest freedom of movement, and hence are most frequently subject to injury, are the lumbar, lumbosacral, and cervical. In addition to bending, twisting, and other voluntary movements, many actions of the spine are reflexive in nature and are the basis of erect posture.

Agging Changes in Spinal Structures

Degeneration in the intervertebral discs and ligaments is a consequence of aging and the succession of inevitable minor traumas to the spine. Deposition of collagen and elastin and alterations of glycosaminoglycans combine to decrease the water content of the nucleus pulposus; concomitantly, the cartilaginous endplate becomes less vascular (Hassler). The dehydrated disc thins out and becomes more fragile. Similar changes occur in the annulus of the disc, which frays to an increasing degree with the passage of time, permitting the nucleus pulposus to bulge and, sometimes with injury to the surrounding annulus, to extrude. This process can be observed by MRI, which shows a gradual reduction in the high T2 signal of the nucleus pulposus with the passage of time. In women who had MRI for gynecologic reasons, Powell and coworkers found an increasing frequency of lumbar disc degeneration and bulging, approaching 70 percent by the fiftieth year. Jensen and colleagues recorded similar abnormalities with aging in asymptomatic men and women (see further on).

The problem of degenerative spinal disease has been conceptualized as a series of events having its genesis in shrinkage of the disc that subsequently alters the alignment of the articular facets and vertebral bodies, leading to facet arthropathy and bony spur formation. These reactive changes contribute to stenosis of the spinal canal and directly compromise the lateral recesses of the canal and the intervertebral foramina, where they impinge on nerve roots. Osteoporosis, especially in older women, is a further important cause of vertebral flattening or collapse, additionally narrowing the spinal canal. All of these changes may further conspire to weaken ligaments and allow slippage of one vertebral body on adjacent ones, termed spondylolisthesis.

General Clinical Features of Low Back Pain

Types of Low Back Pain

Of the several symptoms of spinal disease (pain, stiffness, limitation of movement, and deformity), pain is foremost. Four types of pain may be distinguished: local, referred, radicular, and that arising from secondary muscular spasm. These several types of pain can often be discerned from the patient's description; reliance is placed mainly

on the character of the pain, its location, and conditions that modify it.

Local pain is caused by any pathologic process that impinges on structures containing sensory endings, including the periosteum of the vertebral body, capsule of apophysial joints, annulus fibrosus, and ligaments. Destruction of the nucleus pulposus alone produces little or no pain but the annulus is innervated with small nerve fibers and, when subject to disruption, may produce considerable pain. This pain is steady and aching, but it may be intermittent and sharp, and, although not well circumscribed, is felt in or near the affected part of the spine. Pathologic change arising in spinal structures may also evoke discomfort in regions that share common innervation and thereby vaguely simulate the pain of radicular disease. These areas of projection may be considered similarly to the referred pain of the “sclerotomes” discussed in Chap. 8 and just below.

Referred pain in reference to the spine is of two types: one that is projected from the spine to viscera and other structures lying within the territory of the lumbar and upper sacral dermatomes, and another that is projected from pelvic and abdominal viscera to the spine. Pain caused by disease of the upper part of the lumbar spine may be referred to the medial flank, lateral hip, groin, and anterior thigh (sclerotomes; see Chap. 8). This has been attributed to irritation of the superior cluneal nerves, which are derived from the posterior divisions of the first three lumbar spinal nerves and innervate the superior portions of the buttocks. Pain from the lower part of the lumbar spine is usually referred to the lower buttocks and posterior thighs and is a result of irritation of lower spinal nerves, which activate the same pool of intraspinal neurons as the nerves that innervate the posterior thighs. Pain of this type is usually diffuse and has a deep, aching quality, but it tends at times to be more superficially projected. In general, the intensity of the referred pain parallels that of the local pain. Maneuvers that alter local pain have a similar effect on referred pain. McCall and colleagues and Kellgren have verified these areas of reference by the injection of hypertonic saline into the facet joints and the “sclerotomes” they determined are discussed in Chap. 8. But, as Sinclair and coworkers have pointed out, the sites of reference are inexact and cannot be relied on for precise anatomic localization.

In contrast to the movement-altered referred pain that originates in the spine, pain from visceral diseases felt within the abdomen, flanks, or lumbar region, is modified by the state of activity of the viscera and sometimes by assuming an upright or supine posture. In other words, its character and temporal relationships have little relationship to movement of the back.

Radicular or “root” pain has some of the characteristics of referred pain but differs in its greater intensity, distal radiation, circumscription to the territory of a root, and factors that excite it. The mechanism is stretching, irritation, or compression of a spinal root within or central to the intervertebral foramen. The pain is sharp, often intense, and usually superimposed on the dull ache of referred pain; it nearly always radiates from a paracentral position near the spine to some part of the lower

limb. Coughing, sneezing, and straining characteristically evoke this sharp radiating pain, although each of these actions may also jar or move the spine and enhance local pain. Any maneuver that stretches the nerve root—e.g., “straight-leg raising” in cases of sciatica—evokes radicular pain. The specific patterns of radicular pain are described in the sections on prolapsed discs further on in the chapter, and the distribution of cutaneous innervation of the spinal roots is shown in Figs. 9-2 and 9-3. The most common pattern is *sciatica*, pain that originates in the buttock and is projected along the posterior or posterolateral thigh. It results from irritation of the L5 or S1 nerve root. Paresthesia or superficial sensory loss, soreness of the skin, and tenderness in certain regions along the nerve usually accompany radicular pain. If the anterior roots are involved as well, there is weakness, atrophy, or muscular twitching.

In patients with severe circumferential constriction of the cauda equina because of spondylosis (*lumbar stenosis*), sensorimotor impairment and referred pain are elicited by standing and walking. The symptoms are projected to the calves and the backs of the thighs thereby simulating the exercise-induced symptoms of iliofemoral arterial insufficiency—hence the term *spinal claudication* has been applied to the activity-induced symptoms of lumbar stenosis (see “Lumbar Stenosis and Spondylotic Caudal Radiculopathy” later in this chapter).

Referred pain from structures of the lower back (sometimes called *pseudoradicular*) does not, as a rule, project below the knees and is not accompanied by neurologic changes other than sometimes a vague numbness without demonstrable sensory impairment. This is quite in contrast to the pain of root compression. Pain resulting from muscular spasm usually occurs in relation to local spinal irritation and may be thought of as a nocifensive reflex for the protection of the diseased parts against injurious motion. Chronic muscular contraction may give rise to a dull, sometimes cramping local ache. One can sometimes feel the tautness of the sacrospinalis and gluteal muscles and demonstrate by palpation that the pain is localized to them. However, except for the most severe degrees of acute injuries of the back, the spasms are difficult to detect and their contribution to back pain has appeared to us to be relatively small.

In addition to assessing the character and location of the pain, one should determine the factors that aggravate and relieve it, its constancy, and its relationship to activity and to rest, posture, forward bending, coughing, sneezing, and straining. Frequently, the most important lead comes from knowledge of the mode of onset and the circumstances that initiated the pain. Inasmuch as many painful conditions of the back are the result of injuries incurred during work or in automobile accidents, the possibility of exaggeration or prolongation of pain for purposes of compensation must always be kept in mind.

Examination of the Lower Back

The main goals of the examination of the back are to differentiate pain that is caused by nerve root compression from those of musculoskeletal strains, metastatic spinal

tumor, and infectious and inflammatory diseases of the spine and hips.

Some information may be gained by inspection of the back, buttocks, and lower limbs in various positions. The normal spine shows a thoracic kyphosis and lumbar lordosis in the sagittal plane, which in some individuals may be exaggerated. In the coronal plane, the spine is normally straight or shows a slight curvature, particularly in women. One should observe the spine for excessive curvature, a list, flattening of the normal lumbar lordosis, presence of a gibbus (a sharp, kyphotic angulation usually indicative of a fracture), pelvic tilt or obliquity (Trendelenburg sign), and asymmetry of the paravertebral or gluteal musculature. A sagging gluteal fold suggests involvement of the S1 root. In sciatica one may observe a flexed posture of the affected leg, presumably to reduce tension on the irritated nerve root. Or, patients in whom a free fragment of lumbar disc material has migrated posterolaterally may be unable to lie down and extend the spine.

The next step in the examination is observation of the spine, hips, and legs during certain motions. No advantage accrues from determining how much pain the patient can tolerate. More important is to determine when and under what conditions the pain begins or worsens. Observation of the patient's gait may disclose a subtle limp, a pelvic tilt, a shortening of step, or a stiffness of bearing—indicative of a disinclination to bear weight on a painful leg—the “antalgic gait”. Analysis of this type of gait is covered in greater detail in Chap. 7. One looks for limitation of motion while the patient is standing, sitting, and reclining. When standing, the motion of forward bending normally produces flattening and reversal of the lumbar lordotic curve and exaggeration of the thoracic curve. With lesions of the lumbosacral region that involve the posterior ligaments, articular facets, or sacrospinalis muscles and with ruptured lumbar discs, protective reflexes prevent flexion, which stretches these structures (“splinting”). As a consequence, the sacrospinalis muscles remain taut and prevent motion in the lumbar part of the spine. Forward bending then occurs at the hips and at the thoracolumbar junction; also, the patient bends in such a way as to avoid tensing the hamstring muscles and putting undue leverage on the pelvis. In the presence of degenerative disc disease, straightening up from a flexed position is performed only with difficulty.

Lateral bending is usually less revealing than forward bending but, in unilateral ligamentous or muscular strain, bending to the opposite side aggravates the pain by stretching the damaged tissues. With unilateral sciatica, the patient lists to one side and strongly resists bending to the opposite side, and the preferred posture in standing is with the leg slightly flexed at the hip and knee. When the herniated disc lies lateral to the nerve root and displaces it medially, tension on the root is reduced and pain is relieved by bending the trunk to the side opposite the lesion; with herniation medial to the root, tension is reduced by inclining the trunk to the side of the lesion.

In the sitting position, flexion of the hips can be performed more easily, even to the point of bringing the knees in contact with the chest. The reason for this is that

knee flexion relaxes tightened hamstring muscles and relieves the stretch on the sciatic nerve. This feature may also be evident in instances of lumbar disc disease, making the maneuver less sensitive than others.

Examination with the patient in the reclining position yields much the same information as in the standing and sitting positions. With lumbosacral disc lesions and sciatica, passive lumbar flexion causes little pain and is not limited as long as the hamstrings are relaxed, and there is no stretching of the sciatic nerve. Thus, with the knees flexed to 90 degrees, sitting up from the reclining position is unimpeded and not painful; with knees extended, there is pain and limited motion (Kraus-Weber test). With vertebral disease, passive flexion of the hips is free, whereas flexion of the lumbar spine may be impeded and painful.

Among the most helpful signs in detecting nerve root compression is passive *straight-leg raising* (possible up to almost 90 degrees in normal individuals) with the patient supine. This places the sciatic nerve and its roots under tension, thereby producing radicular, radiating pain from the buttock through the posterior thigh. This maneuver is the usual way in which compression of the L5 or S1 nerve root is detected (Lasègue sign), however, it may also cause an anterior rotation of the pelvis around a transverse axis, increasing stress on the lumbosacral joint and causing milder radiating pain if this joint is arthritic or otherwise diseased. *Straight raising of the opposite leg* (“crossed straight-leg raising,” Fajersztajn sign) may cause sciatica on the opposite side and is a more specific sign of prolapsed disc than is the Lasègue sign. Several of the many derivatives of the straight-leg raising sign are discussed in the section on lumbar disc disease. Asking the seated patient to extend the leg so that the sole of the foot can be inspected is a way of checking for a feigned Lasègue sign.

A patient with lumbosacral strain or disc disease (except in the acute phase or if the disc fragment has migrated laterally) can usually extend the spine with little or no aggravation of pain. If there is an active inflammatory process or fracture of the vertebral body or posterior elements, hyperextension may be markedly limited. In disease of the upper lumbar roots, hyperextension of the leg with the patient prone is the motion that is most limited and reproduces pain; however, in some cases of lower lumbar disc disease with thickening of the ligamentum flavum, this movement is also painful.

Maneuvers in the *lateral decubitus position* yield less information but are useful in eliciting joint disease. In cases of sacroiliac joint disease, abduction of the upside leg against resistance reproduces pain in the sacroiliac region, sometimes with radiation of the pain to the buttock, posterior thigh, and symphysis pubis. Hyperextension of the upside leg with the downside leg flexed is another test for sacroiliac disease. Rotation and abduction of the leg evoke pain in a diseased hip joint and with *trochanteric bursitis*. A helpful indicator of *hip disease* is the Patrick test: with the patient supine, the heel of the offending leg is placed on the opposite knee, and pain is evoked by depressing the flexed leg and externally rotating the hip.

Gentle palpation and percussion of the spine are the last steps in the examination. It is preferable to first palpate the regions that are the least likely to evoke pain. The examiner should know what structures are being palpated (Fig. 11-2). Localized tenderness is seldom pronounced in disease of the spine because the involved structures are so deep. Nevertheless, tenderness over a spinous process or jarring by gentle percussion may indicate the presence of deeper, local spinal inflammation (as in disc space infection), pathologic fracture, metastasis, epidural abscess, or a disc lesion.

Tenderness over the interspinous ligaments or over the region of the articular facets between the fifth lumbar and first sacral vertebrae is consistent with lumbosacral disc disease (Fig. 11-2, sites 2 and 3). Tenderness in this region and in the sacroiliac joints is also a frequent manifestation of ankylosing spondylitis. Arthritic changes at a facet may cause the same tenderness. Tenderness over the costovertebral angle often indicates genitourinary disease, adrenal disease, or an injury to the transverse process of the first or second lumbar vertebra (Fig. 11-2, site 1).

Tenderness on palpation of the paraspinal muscles may signify a strain of muscle attachments or injury to the underlying transverse processes of the lumbar vertebrae. Focal pain in the same parasagittal line along the thoracic spine points to inflammation of the costovertebral articulation between spine and rib (*costovertebritis*). Other sites of tenderness and the structures implicated by disease are shown in the figure.

In palpating the spinous processes, it is important to note any deviation in the lateral plane (this may be indicative of fracture or arthritis) or in the anteroposterior plane. A “step-off” forward displacement of the spinous process and exaggerated lordosis are important clues to the presence of *spondylolisthesis* (see further on).

Many of the processes discussed above can coexist, especially in the older individual, who may have hip and lumbar spine osteoarthritis. This makes the interpretation of various signs difficult unless the symptoms are first analyzed properly.

On completion of the examination of the back and legs, one turns to a search for motor, reflex, and sensory changes in the lower extremities (see “Herniation of Lumbar Intervertebral Discs,” further on in this chapter).

Diagnostic Procedures

Depending on the circumstances, these may include a blood count, erythrocyte sedimentation rate, and C-reactive protein (especially helpful in screening for spinal osteomyelitis, epidural abscess, or myeloma). Other useful blood tests are calcium, alkaline phosphatase, and prostate-specific antigen (if one suspects metastatic carcinoma of the prostate); a serum protein immunoelectrophoresis (myeloma proteins); in special cases, a tuberculin test or serologic test for *Brucella*; a test for rheumatoid factor; and human leukocyte antigen (HLA) typing (for ankylosing spondylitis), all in the appropriate settings.

Radiographs of the lumbar spine may be useful in the routine evaluation of low back pain and sciatica and can be performed with the patient in flexed and extended positions in the anteroposterior, lateral, and oblique planes. Readily demonstrable in plain films are narrowing of the intervertebral disc spaces, bony facet or vertebral overgrowth, displacement of vertebral bodies (*spondylolisthesis*), and an unsuspected infiltration of bone by cancer. However, in cases of suspected disc herniation or tumor infiltration of the spinal canal, one generally proceeds directly to MRI. Administration of gadolinium at the time of MRI enhances regions of inflammation and tumor but is not particularly helpful in cases of degenerative and disc disease of the spine. T2-weighted MRI performed with elimination of the hyperintense signal of fat (“fat suppression”, i.e., the short T1 inversion recovery or “STIR” sequence), allows inflammation and edema to be visualized in the bone marrow and paravertebral soft tissues that normally contain fat. The current generation of MRI scanners has largely replaced conventional myelography for the examination of spinal disease but the latter, when combined with CT, provides detailed information about the dural sleeves that surround the spinal roots as occur with arachnoiditis, disclosing subtle truncations

Figure 11-2. (1) Costovertebral angle. (2) Spinous process and interspinous ligament. (3) Region of articular facet (fifth lumbar to first sacral). (4) Dorsum of sacrum. (5) Region of iliac crest. (6) Iliolumbar angle. (7) Spinous processes of fifth lumbar and first sacral vertebrae (tenderness = faulty posture or occasionally spina bifida occulta). (8) Region between posterior superior and posteroinferior spines. Sacroiliac ligaments (tenderness = sacroiliac sprain, often tender, with fifth lumbar or first sacral disc). (9) Sacrococcygeal junction (tenderness = sacrococcygeal injury; i.e., sprain or fracture). (10) Region of sacrosiatic notch (tenderness = fourth or fifth lumbar disc rupture and sacroiliac sprain). (11) Sciatic nerve trunk (tenderness = ruptured lumbar disc or sciatic nerve lesion).

caused by laterally situated disc herniations and at times revealing surface abnormalities of the spinal cord, such as arteriovenous malformations. When metallic devices such as a pacemaker preclude the performance of MRI, CT myelography remains very useful for diagnosis.

Nerve conduction studies and electromyography (EMG) are particularly helpful in suspected root and nerve diseases as indicated further on in the discussion of spinal nerve root disease. However, as for all the aforementioned tests, they must be interpreted in the context of the history and clinical examination; otherwise they are subject to over interpretation.

Conditions Giving Rise to Pain in the Lower Back

Congenital Anomalies of the Lumbar Spine

Anatomic variations of the spine are frequent and, though rarely themselves the source of pain and functional derangement, they may predispose an individual to discogenic and spondylotic complications by virtue of altering the mechanics and alignment of the vertebrae or size of the spinal canal.

A common anomaly is fusion of the fifth lumbar vertebral body to the sacrum (“sacralization”) or, conversely, separation of the first sacral segment, giving rise to 6, rather than the usual 5 lumbar vertebrae (“lumbarization”). However, neither of these is consistently associated with any type of back derangement. Another less-common finding is a lack of fusion of the laminae of one or several of the lumbar vertebrae or of the sacrum (spina bifida). Occasionally, a subcutaneous mass, hypertrichosis, or hyperpigmentation in the lumbar or sacral area overlying the bony separation betrays the condition, but in most patients it remains occult until it is disclosed radiologically. The anomaly may be accompanied by malformation of vertebral joints and usually induces pain only when aggravated by injury. The neurologic aspects of defective fusion of the spine (dysraphism) are discussed in Chap. 38, with developmental abnormalities of the nervous system.

Many other congenital variants affect the lower lumbar vertebrae: asymmetrical facet joints, abnormalities of the transverse processes, are seen occasionally in patients with low back symptoms, but apparently with no greater frequency than in asymptomatic individuals. *Spondylolysis* consists of a congenital and probably genetic bony defect in the pars interarticularis (the segment at the junction of pedicle and lamina) of the lower lumbar vertebrae. It is remarkably common, affecting approximately 5 percent of the North American population and mainly a disease of children (peak incidence between 5 and 7 years of age). The defect assumes importance in that it predisposes to subtle fracture of the pars articularis, sometimes precipitated by slight trauma but often in the absence of an appreciated injury. In some young individuals, it is unilateral and may cause unilateral lumbar aching back pain that is accentuated by hyperextension and twisting. In the usual bilateral form, small fractures at the pars interarticularis allow the vertebral body, pedicles,

and superior articular facets to move anteriorly, leaving the posterior elements behind. This leads to an anterior displacement of one vertebral body in relation to the adjacent one, *spondylolisthesis*. Considerable dull, aching back pain can result.

The main cause of spondylolisthesis in older adults is degenerative arthritic disease of the spine as discussed further on. Patients with progressive vertebral displacement and neurologic deficits require surgery. Reduction of displaced vertebral bodies before fusion and direct repair of pars defects are possible in special cases. Back pain is relieved in the majority of cases.

Traumatic Disorders of the Low Back

These constitute by far the most frequent causes of low back pain. In severe acute injuries from direct impact the examiner must be careful to avoid further damage and movements should be kept to a minimum until an approximate diagnosis has been made. If the patient complains of pain in the back and cannot move the legs, the spine may have been fractured and the cord or cauda equina compressed or crushed. (See Chap. 44 for further discussion of spinal cord injury.) Lesser degrees of injury, such as sprains and strains, are ubiquitous and can be handled with less caution because they do not involve compression of neural structures or displacement of spinal elements.

Acute Sprains and Strains The terms *lumbosacral strain*, *sprain*, and *derangement* are used loosely, and it is probably not possible to differentiate them. Furthermore, what was formerly referred to as “sacroiliac strain” or “sprain” is now known to be caused by, in some instances, disc disease. The term *acute low back strain* may be preferable for minor, self-limiting injuries that are usually associated with lifting heavy loads when the back is in a mechanically disadvantaged position, or there may have been a fall, prolonged uncomfortable postures such as in air travel or car rides, or sudden unexpected motion, as may occur in an auto accident.

Nonetheless, the discomfort of acute low back strain can be severe, and the patient may assume unusual postures related to spasm of the lower lumbar and sacrospinalis muscles. The pain is usually confined to the lower part of the back, in the midline, across the posterior waist, or just to one side of the spine. The diagnosis of lumbosacral strain is dependent on the biomechanics of the injury or activity that precipitated the pain. The injured structures are identified by the localization of the pain, the finding of localized tenderness, augmentation of pain by postural changes—e.g., bending forward, twisting, or standing up from a sitting position, and by the absence of signs of radicular involvement. In more than 80 percent of cases of acute low back strain of this type, the pain resolves in a matter of several days or a week, even with no specific treatment.

Sacroiliac joint and ligamentous strain is the most likely diagnosis when there is tenderness over the sacroiliac joint and pain radiating to the buttock and posterior thigh, but this always needs to be distinguished from the sciatica of a herniated intervertebral disc (see further on).

Strain is characteristically worsened by abduction of the thigh against resistance and may produce pain that is also felt in the symphysis pubis or groin.

Treatment of Acute Low Back Strain The pain of muscular and ligamentous strains is usually self-limiting, responding to simple measures in a relatively short period of time. The basic principle of therapy in both disorders is to avoid reinjury and reduce the discomfort of painful parts. As a result of several studies that have failed to demonstrate a benefit of bed rest, the recent practice has been to mobilize patients as soon as they are able and to prescribe exercises designed to stretch and strengthen trunk (especially abdominal) muscles, overcome faulty posture, and increase the mobility of the spinal joints. Despite this approach, the authors can affirm from personal experience that some injuries produce such discomfort that arising from a bed or chair is simply not possible in the early days after injury (see Vroomen et al). Lying on the side with knees and hips flexed, or supine with a pillow under the knees favor relief of pain. With strains of the sacrospinalis muscles and sacroiliac ligaments, the optimal position is hyperextension, which is effected by having the patient lie with a small pillow under the lumbar portion of the spine or by lying prone. Local physical measures—such as application of ice in the acute phase and, later, heat diathermy and massage—often relieve pain temporarily. Nonsteroidal antiinflammatory drugs (NSAIDs) may be given liberally during the first few days. Muscle relaxants (e.g., cyclobenzaprine, carisoprodol, metaxalone, and the diazepam) serve mainly to make bed rest more tolerable but have little primary effect. Traction, formerly a popular treatment, is infrequently used. When weight bearing is resumed, discomfort may be diminished by a light lumbosacral support, but many orthopedists refrain from prescribing this aid.

Spinal manipulation—practiced by chiropractors, osteopaths, and others—has always been a contentious matter partly because of unrealistic therapeutic claims made in treating diseases other than low back derangements. A type of slow muscle stretching and joint distraction (axial traction on a joint) administered by physiatrists and physical therapists is quite similar. It must be recognized that many patients seek chiropractic manipulation for back complaints, often before seeing a physician, and may not disclose this information. When the supporting elements of the spine (pedicles, facets, and ligaments) are not disrupted, chiropractic manipulation of the lumbar spine has provided acute relief to a number of our patients with low back strain or facet pain. At issue is the durability of the effect, particularly the need for repeated spinal adjustments. One randomized British trial has shown manipulation to be faster than analgesics and bed rest in returning patients to work after minor back injury (Meade et al). Some trials have corroborated this finding (Hadler et al), whereas others have not, or, often, the results have been ambiguous. In the study by Cherkin and colleagues comparing chiropractic, physical therapy (McKenzie method), and simple instruction to the patient from a booklet, manipulation yielded a slightly better

outcome at the end of a month. Despite several hypotheses offered by practitioners of spinal manipulation, the mechanism of pain relief is not known. The cracking sound created by rapid distraction of the facet joints (and attributed to gas coming out of solution in the joint fluid) seems not to be necessary for pain relief. It is unlikely that mundane low back pain represents minor subluxation, as claimed by chiropractors. In the authors' clinical experience, chronic low back pain, discussed below, has been less successfully treated by manipulative procedures than has acute pain, but there are some patients who testify to improvement in their clinical state and admittedly, the medical profession has little to offer in most cases of chronic low back pain. The results for acute and chronic back pain with another popular approach, acupuncture, have been even more uncertain, most studies showing it to be no more effective than a sham treatment (Tudler et al). It should be emphasized, however, that the chronic use of NSAIDs or narcotic analgesics is hazardous and is not an appealing alternative.

Chronic and Recurrent Low Back Syndrome Often the symptoms of low back strain are recurrent and more chronic in nature, being regularly exacerbated by bending or lifting, suggesting that postural, muscular, and arthritic factors play a role. This is the most common syndrome seen in spine clinics, more often in men than in women.

Insidiously, or after some unusual activity, raising the question of trauma, especially if it happens in the workplace, the patient develops aching pain in the low back, increased by certain movements and attended by stiffness. The pain may additionally have a restricted radiation into the buttocks and posterior thigh, thereby simulating root compression. There are no motor, sensory, or reflex abnormalities. Radiographs and imaging procedures usually reveal some combination of osteoarthropathy, changes in vertebral discs, osteoarthritic changes in apophysial joints, and sometimes osteoporosis or slight spondylosis, or they may be entirely normal. Treatment with short-duration bed rest, analgesics, and physiotherapy, as outlined for acute strains, helps to relieve the symptoms, and the majority of patients recover within a few weeks, only to have a recurrence of similar pains in the future. Recurrent attacks are typical of degenerative spine disease that affects the vertebrae and facet joints. Usually, the origin of the pain cannot be assigned with certainty to spinal, joint, or muscular injury, but direct percussion tenderness of one vertebral segment always raises concern of metastatic disease as noted above. Quite often, changing the firmness of the mattress (in either direction) is helpful. Compensation relating to injuries at work or to an accident and related legal matters often add to the disability, but there are, of course, many legitimate injuries that occur in these circumstances.

Vertebral Fractures Fractures of lumbar vertebral bodies are usually the result of flexion injuries. Such trauma may occur in a fall or jump from a height (if the patient lands on his feet, the calcanei may also be fractured) or as a result of an auto accident or other violent injury. If the injury is severe, it may cause a fracture dislocation,

a “burst” fracture of one or more vertebral bodies, or an asymmetrical fracture of a pedicle, lamina, or spinous process; most often, however, there is asymmetrical loss of height of a vertebral body (*wedge compression fracture*), which may be extremely painful at the onset. When compression or other fractures occur with minimal trauma (or spontaneously), the bone has presumably been weakened by some pathologic process. Most of the time, particularly in older individuals, osteoporosis is the cause of such an event, but there are many other causes, including osteomalacia, hyperparathyroidism, prolonged use of corticosteroids, myeloma, metastatic carcinoma, and a number of other conditions that are destructive of bone. Spasm of the lower lumbar muscles, limitation of all movements of the lumbar section of the spine, and the radiographic appearance of the damaged lumbar portion (with or without neurologic abnormalities) are the basis of clinical diagnosis. The pain is usually immediate, although occasionally it may be delayed for days.

A fractured transverse process, which is almost always associated with high-impact rotary injury of the spine and causes tearing of the paravertebral muscles and a local hematoma, produces deep tenderness at the site of the injury and limitation of all movements that stretch the lumbar muscles. The imaging findings, particularly MRI, confirm the diagnosis. In some circumstances, tears of the paravertebral musculature may be associated with extensive bleeding into the retroperitoneal space; this produces paraspinal or groin pain and proximal leg weakness with loss of the patellar reflex on the affected side. There may be a delayed subcutaneous hematoma in the flanks (Grey-Turner sign).

A problem not easily classified but having a distinctive clinical profile that should be known to neurologists is that of an osteoid osteoma. These benign tumors characteristically cause severe nocturnal pain located in one region of the parasagittal spine that awakens the patient from a peaceful sleep; also typical is complete relief after aspirin or small doses of other NSAIDs. MRI or CT is required to detect the lesion, as it may not be evident on plain radiographs of the spine. The typical appearance is a well-demarcated lytic lesion surrounded by a rim of bony sclerosis.

TREATMENT OF VERTEBRAL COMPRESSION FRACTURE For the mundane thoracic and lumbar fracture associated with osteoporosis, bed rest, and analgesics are usually adequate. In the past two decades several mechanical approaches to reducing pain have been investigated. The injection of various materials directly into the fracture site within the vertebral body (vertebroplasty) attained popularity because of reports of marked pain relief. Several large trials have addressed the use of vertebroplasty and given conflicting results. The best conducted of these, with a placebo control groups (see Buchbinder et al and Kallmes et al) concluded that there was no durable benefit, however, these two studies included patients with fractures up to a year old. Having witnessed a few patients with almost immediate and remarkable relief of severe pain, we are uncertain of the best course but acknowledge that this is probably not an effective treatment

for the majority of patients. Further discussion can be found in the review by Ensrud and Schousboe.

Herniation of Lumbar Intervertebral Discs (Table 11-1)

This condition is a major cause of severe and chronic or recurrent low back and leg pain. It occurs mainly during the third and fourth decades of life when the nucleus pulposus is still gelatinous. The disc between the fifth lumbar or first sacral vertebrae (L5-S1) is most often involved, and, with decreasing frequency, that between the fourth and fifth (L4-L5), third and fourth (L3-L4), second and third (L2-L3), and—quite infrequently—the first and second (L1-L2) lumbar vertebrae. Relatively rare but well described in the thoracic portion of the spine, disc disease is again frequent in the cervical spine at the fifth and sixth and the sixth and seventh cervical vertebrae (see further on).

The cause of a herniated lumbar disc in any individual case is often not identifiable and flexion injury is often imputed, but a considerable proportion of patients do not recall an inciting episode. Degeneration of the annulus and the posterior longitudinal ligaments, and changes nuclei pulposus itself may have taken place silently or have been manifest by mild, recurrent lumbar ache. A sneeze, lurch, or other trivial movement may then cause the nucleus pulposus to prolapse, pushing the frayed and weakened annulus posteriorly. Fragments of the nucleus pulposus protrude through rents in the annulus, usually to one side or the other (sometimes in the midline), where they impinge on one or more nerve roots and cause the characteristic sciatic or other radicular pains and neurologic signs. In more severe cases of disc disease, a small piece of the nucleus may be entirely extruded as a “free fragment”, sometimes called a sequestered disc fragment, and be mobile enough to affect a root at an adjacent level or to give rise to unusual precipitating features of radicular pain. Large protrusions cause pain by compressing the adjacent root against the articular apophysis or lamina. The protruded material may become reduced in size over time, presumably from desiccation, but often there is continued chronic irritation of the root or a discarthrosis with posterior osteophyte formation.

The Clinical Syndrome of Lumbar Disc Herniation The fully developed syndrome of the common prolapsed intervertebral lower lumbar disc consists of (1) pain in the sacroiliac region, radiating into the buttock, thigh, and the calf, a symptom broadly termed *sciatica*; (2) a stiff or unnatural spinal posture; and often (3) some combination of paresthesia, weakness, and reflex impairment.

The pain of herniated intervertebral disc varies in severity from a mild aching discomfort to severe knife-like stabs that radiate the length of the leg and are superimposed on a constant intense ache. Sciatic pain is usually perceived by the patient as originating deep in the buttock and radiating to the posterolateral thigh; it may progress to the calf and ankle—to the medial malleolus (L4), lateral malleolus (L5), or heel (S1); however, distal radiation to the foot is less frequent. There are variations in the sciatic syndrome. Abortive forms may produce aching discomfort

Table 11-1

FEATURES OF THE MAIN ROOT-COMPRESSIVE SYNDROMES DUE TO CERVICAL AND LUMBAR DISC HERNIATION*

INTERVERTEBRAL DISC SPACE	ROOT AFFECTED	PAIN REFERRAL	WEAKNESS	REFLEX CHANGE	ADDITIONAL FEATURES
C4-C5	C5	Shoulder, trapezius	Supra- and infra-spinatus deltoid, slight biceps weakness	Slightly diminished biceps jerk	
C5-C6	C6	Trapezius ridge and tip of shoulder, radiation to anterior upper arm, thumb, and index finger	Biceps, brachioradialis, extensor carpi radialis	Diminished biceps and supinator jerk	Tenderness over spine or scapula and supra-scapular region; paresthasias in thumb and index finger
C6-C7	C7	Shoulder, axilla, posterolateral arm, elbow, and middle finger	Triceps, wrist extensors	Diminished or absent triceps jerk	Tenderness over medial scapula and supra-clavicular region or triceps. May complain of paresthasias in most of the fingers
C7-T1	C8	Medial forearm	Intrinsic hand muscles	Slight or no decrease in triceps jerk	Mimics ulnar palsy
L2-L3	L3	Anterior thigh, over knee	Thigh adductor, quadriceps	Absent or diminished knee jerk	
L3-L4	L4	Anterolateral thigh, medial foreleg	Anterior tibial, sometimes with partial foot drop	Diminished or normal knee jerk	
L4-L5	L5	Posterolateral gluteal sciatica; lateral thigh, anterolateral foreleg, dorsal foot, lateral malleolus and great or second and third toe	Extensor hallucis longus and extensor digitorum brevis; some weakness of anterior tibialis, sometimes with foot drop	Unaffected (except posterior tibial)	Pain with straight-leg raising and variant tests; tenderness over fourth lumbar lateral process and lateral gluteal region
L5-S1	S1	Midgluteal sciatica; posterior thigh, posterolateral leg, lateral foot, heel, or lateral toes	Plantar-flexor and hamstring weakness	Absent or diminished ankle jerk	Pain with straight-leg raising and variant tests; tenderness over lumbosacral (L5-S1) joint and sciatic notch; discomfort walking on heels

*For pattern of sensory loss, see dermatomal diagram in Figs. 9-3 and 9-4.

only in the lower buttock or proximal thigh and occasionally only in the lower hamstring or upper calf. With the most severe pain, the patient is forced to stay in bed, avoiding the slightest movement; a cough, sneeze, or strain is intolerable. The most comfortable position may be lying on the back with legs flexed at the knees and hips and the shoulders raised on pillows to obliterate the lumbar lordosis. For some patients, a lateral decubitus position is more comfortable. Free fragments of disc that find their way to a lateral and posterior position in the spinal canal may produce the opposite situation, one whereby the patient is unable to extend the spine and lie supine. Sitting and standing up from a sitting position may be particularly painful. It is surprising to patients that a lumbar disc protrusion may cause little or no back pain. If there is back discomfort, it tends to be just paraspinal on the side of sciatica and mainly in the acute stages.

In cases of root compression, pain is also characteristically provoked by pressure along the course of the sciatic nerve at the classic points of Valleix (sciatic notch, retrotrochanteric gutter, posterior surface of thigh, and

head of fibula). Pressure at one point may cause radiation of pain and tingling down the leg. Elongation of the nerve root by straight-leg raising or by flexing the leg at the hip and extending it at the knee (Lasègue maneuver as discussed earlier) is the most consistent of all pain-provoking signs. During straight-leg raising, the patient can distinguish between the discomfort of ordinary tautness of the hamstring and the sharper, less-familiar root pain, particularly when asked to compare the experience with that on the normal side. Many variations of the Lasègue maneuver have been described (with numerous eponyms), the most useful of which is accentuation of the pain by dorsiflexion of the foot (Bragard sign) or of the great toe (Sicard sign). The Lasègue maneuver with the healthy leg may evoke sciatic pain on the contralateral side, but usually of lesser degree (Fajersztajn sign). However, this "crossed straight-leg-raising sign" is highly indicative of a ruptured disc as the cause of sciatica (56 of 58 cases in the series of Hudgkins). With the patient standing, forward bending of the trunk may induce reflexive flexion of the knee on the affected side

(Neri sign). Sciatica may be provoked by forced flexion of the head and neck, coughing, or pressure on both jugular veins, all of which increase intraspinal pressure (Naffziger sign). Marked inconsistencies in response to these tests raise the suspicion of psychological factors or of referred muscular pain.

An antalgic posture, referred to as *sciatic scoliosis*, is maintained by reflex contraction of the paraspinal muscles, which can be both seen and palpated. In walking, the knee is slightly flexed, and weight bearing on the painful leg is brief and cautious on the ball of the foot, giving a limp. It is particularly painful for the patient to go up and down stairs.

The signs of more severe spinal root compression are impairment of sensation, loss or diminution of tendon reflexes, and muscle weakness, as summarized in Table 11-1.

Generally, disc herniation compresses the root on one side, at the level just below the herniation (see below). Hypotonia may be evident on inspection and palpation of the buttock and calf. In a few patients, foot drop (L5 root) or weakness of plantar flexion (S1 root) is a main feature of disc protrusion, and some of these patients have little associated pain. The reflex changes noted below have little relationship to the severity of the pain or sensory loss. Furthermore, compression of the fourth, or sometimes fifth, lumbar root may occur without any change in the tendon reflexes. Bilaterality of symptoms and signs is rare, as is sphincteric paralysis, but they occur with large central protrusions that compress the cauda equina. The cerebrospinal fluid (CSF) protein is often elevated with disc rupture, more predictably with central rupture and then, usually in the range of 55 to 85 mg/dL, sometimes higher.

As emphasized earlier, herniations of the intervertebral lumbar discs occur most often between the fifth lumbar and first sacral vertebrae (compressing the traversing S1 or exiting L5 root; Fig. 11-3) and between the fourth and fifth lumbar vertebrae (compressing the traversing L5 or exiting L4 root).

Lesions of the fifth lumbar root (L5) produce pain in the region of the hip and posterolateral thigh (i.e., sciatica) and, in more than half such cases, lateral calf (to the lateral malleolus), and less often, the dorsal surface of the foot and the first or second and third toes. Pain is elicited by the straight-leg raising test or one of its variants, and protective nocifensive reflexes come into play, limiting further elevation of the leg. Paresthesia may be felt in the entire territory or only in its distal parts. The tenderness is in the lateral gluteal region and near the head of the femur. Weakness, if present, involves the extensors of the big toe and foot and the foot invertors (a distinguishing feature of foot drop originating in peroneal nerve damage). The ankle jerk may be diminished (more often it is normal), but the knee jerk is hardly ever altered.

With *lesions of the first sacral root (S1)*, the pain is felt in the midgluteal region, mid-posterior part of the thigh, posterior region of the calf to the heel, outer plantar surface of the foot, and fourth and fifth toes. Tenderness is

Figure 11-3. Mechanisms of compression of the fifth lumbar and first sacral roots by herniated lumbosacral discs. A lateral disc protrusion at the L4-L5 level usually involves the fifth lumbar root and spares the fourth; a protrusion at L5-S1 involves the first sacral root and spares the fifth lumbar root. Note that a more medially placed disc protrusion at the L4-L5 level (cross-hatched) may involve the fifth lumbar root as well as the first (or second and third) sacral root.

most pronounced over the midgluteal region. Paresthesia and sensory loss are mainly in the lower part of the leg and outer toes, and weakness, if present, involves the plantar flexor muscles of the foot and toes, abductors of the toes, and hamstring muscles. The Achilles reflex is diminished or absent in the majority of cases. In fact, loss of the Achilles reflex may be the only objective sign. Walking on the toes is more difficult and uncomfortable than walking on the heels because of weakness of the plantar flexors.

The less-frequent lesions of the *third (L3) and fourth (L4) lumbar roots* give rise to pain in the anterior part of the thigh and knee and anteromedial part of the leg (fourth lumbar), with corresponding sensory impairment in these dermatomal distributions. The knee jerk is diminished or abolished with compression of either root. Third lumbar (L3) motor root lesions may weaken the quadriceps, thigh adductor, and iliopsoas; L4 root lesions weaken the anterior tibial innervated muscles, sometimes with a mild foot drop. First lumbar (L1) root pain is projected to the groin, and L2, to the lateral hip.

Some patients have a distinctive syndrome associated with extreme lateral disc protrusions, particularly those situated within the proximal portion of the intervertebral spinal foramina. Unremitting radicular pain without back pain and a tendency to worsen with extension of the back and torsion toward the side of the herniation are characteristic. Also, in rare instances of lumbar *intradural* disc rupture, there may not be sciatic

pain because the free fragment in the subarachnoid space does not impinge on the roots of the cauda equina. Both of these configurations may confound clinical and radiologic diagnosis and make surgery more difficult.

Rarer still, and often clinically obscure, are protrusions of *thoracic intervertebral discs* (0.5 percent of all surgically verified disc protrusions, according to Love and Schorn). The four lowermost thoracic interspaces are the most frequently involved. Trauma, particularly hard falls on the heels or buttocks, is an important causative factor. Deep boring spine pain; root pain circling the body or projected to the abdomen or thorax (sometimes simulating visceral disease); paresthesias below the level of the lesion; loss of sensation; both deep and superficial; and paraparesis or paraplegia are the usual clinical manifestations.

A herniated lumbar disc at one interspace may compress more than one root (Fig. 11-3), and it follows that the symptoms will then reflect this. Furthermore, the above descriptions of single root compression refer mainly to signs and symptoms of typical posterolateral disc protrusion. Very large *central disc protrusions* may compress the entire cauda equina with a dramatic syndrome that includes intense low back and bilateral sciatic pain, incomplete paraparesis, loss of both ankle jerks, and, most characteristic, varying degrees of urinary retention and incontinence. This circumstance demands surgical attention.

Anomalies of the lumbosacral roots may lead to errors in localization (see descriptions by Postacchini et al). The combined rupture of two or more discs occurs occasionally and complicates the clinical picture. When both the L5 and S1 roots are compressed by a large herniated disc, the signs of the S1 lesion usually predominate.

Herniation may occur directly into the adjacent vertebral body, giving rise to a Schmorl nodule. In such cases there are no signs of nerve root involvement although back pain may be present, sometimes recurrent and referred to the thigh. Most often, these well-circumscribed rounded radiographic densities adjacent to the endplate of the vertebral body are found incidentally on CT or MRI.

Diagnosis When all components of the lumbar disc syndrome are present, the diagnosis can be made with reasonable confidence. With persistent symptoms, many neurologists prefer to corroborate their clinical impression with MRI of the lumbar spine (Fig. 11-4). In the absence of neurological deficits, imaging generally need not be undertaken until the pain has persisted for several weeks (see Chou and colleagues). This, of course, may not be necessary if the pain is manageable and surgery is not contemplated (see further on). MRI is favored over CT because of the advantages of the distinction that can be made between disc material, annulus, nerves and bones and the clarity of their anatomic relationships. MRI also excludes disc herniations at other sites or an unsuspected tumor. As indicated earlier, in cases in which MRI is not

Figure 11-4. Lumbar disc herniation as shown by T2-weighted MRI. **A.** Sagittal view of a large herniated nucleus pulposus at L5-S1. The posteriorly protruding disc material indents and elevates the anterior thecal sac and narrows the spinal canal. The extruded material has the same signal characteristics of the parent disc. The disc space at this level is narrowed and the disc is less hyperintense than normal because of desiccation and the extruded component. **B.** Axial view showing the focal right paracentral posterior disc herniation (large arrow) protruding into the canal and compressing the traversing nerve root (the right S1 nerve root) at this level. The exiting L5 roots above are not affected and can be seen laterally to the disc (small arrows).

possible or it has been unrevealing, we often turn to CT or CT with myelography for a refined definition of the root sleeves and use the EMG to corroborate subtle findings.

The needle EMG study is abnormal, showing fibrillation potentials in denervated muscles after 1 or 2 weeks, but it may remain normal in 10 percent of cases according to Leyshon and colleagues. Loss or marked asymmetry of the H reflex is another useful indication of S1 radiculopathy, but this simply corroborates the loss of an Achilles reflex. The finding of denervation potentials in the paraspinal muscles (indicating root rather than peripheral nerve lesions) and in muscles that conform to a root distribution is also helpful, but again, some weeks must have elapsed from the onset of root pain for these findings to be present. We emphasize that, while useful information is to be gained from EMG, it is required in only a limited proportion of cases and often provides mainly corroborating data. It is more helpful when the diagnosis is uncertain. An entirely normal study should lead to reconsideration of the diagnosis, particularly if surgery was planned for relief of a compressive radiculopathy.

Many disc abnormalities observed on MRI and loosely referred to as "herniation" are incidental findings, unrelated to the patient's symptoms, or are simply bulges of the annulus. Jensen and colleagues, in an MRI study of the lumbar spine in 98 asymptomatic adults, found that in more than half, there was a symmetrical extension of a disc (or discs) beyond the margins of the interspace (*bulging*). In 27 percent, there was a focal or asymmetrical extension of the disc beyond the margin of the interspace (*protrusion*), and in only 1 percent was there more extreme extension of the disc (*extrusion or sequestration*). These findings emphasize the importance of using precise terms in describing the imaging abnormalities and evaluating them strictly in the context of the patient's symptoms.

Treatment of Ruptured Lumbar Disc

In the treatment of an *acute or chronic rupture of a lumbar disc*, many patients have found it nearly impossible to participate in physical activities and to assume certain positions that cause pain. However, the time-honored tenet of prolonged bed rest has been questioned by the results of several randomized studies (Vroomen et al). It would appear that the main benefit is simply that time has passed and the expected resolution of pain has taken its course in many patients. Traction is probably of little value. Analgesic medications, either NSAIDs or opioids, may be required for a few days. In a few patients with severe sciatica we have been impressed with the temporary relief afforded by administration of oral dexamethasone (4 mg every 8 h) for several days, although this approach has not been studied systematically and several of our colleagues decry it. The treatment of nerve root compression with repeated epidural injections of corticosteroids has enjoyed periods of popularity, but controlled studies have failed to confirm sustained efficacy (White et al; Cuckler et al), and it is not without complications including the rare but widely publicized outbreak

of fungal meningitis from contaminated steroids. As with many similar studies, Carette and colleagues (1997) found only short-term improvement with epidural steroid injection and the ultimate need for surgery was not altered. Nevertheless, some pain specialists have not discarded this form of treatment in view of success in selected patients, even if short-lived.

Surgical Treatment of Lumbar Disc Disease An indication for emergency surgery is an acute compression of the cauda equina by massive disc extrusion, causing bilateral sensorimotor loss and sphincteric paralysis. Although not the recommended course, it should be pointed out that there have been instances in which even a dramatic syndrome of cauda equina compression had resolved spontaneously after several weeks.

If the pain and neurologic findings have not subsided in response to conservative management or the patient has suffered frequent disabling acute episodes, surgical treatment must be considered. Useful information regarding surgery and its timing can be ascertained from a randomized trial conducted by Peul and colleagues and from the Spine Patients Outcomes Research Trial (SPORT) conducted by Weinstein and coworkers (2006). In the first study, a large proportion of patients assigned to treatment with physical therapy and pain medications had enough pain that they required surgery within several months. In addition, patients assigned initially to surgery by microdiscectomy had considerably faster relief of back and sciatic pain, but at the end of a year, both groups had minimal disability and similar degrees of minor pain. The implications of this study are that avoiding surgery initially does not have adverse consequences but if more rapid pain relief and mobilization are the aims, surgery is preferable. In the second cited study there was even greater crossover between conservative and surgically assigned groups and there was a slightly more favorable outcome in those who underwent early surgery.

The surgical procedure most often indicated for lumbar disc disease is one of the variants of a hemilaminectomy with excision of the disc fragment introduced almost a century ago by Mixter and Barr. Questions relating to the relative merits of limited ("microscopic"), or minimally invasive excision of the lamina are often raised by patients and no clear answer can be given except that individual surgeons excel at one or another technique and the outcomes are similar. Eighty-five to 90 percent of cases with sciatic pain because of L4-L5 or L5-S1 disc ruptures are relieved by operation, are home in days or less, and are resuming activities within weeks. Rerupture occurs in approximately 5 percent of operated cases according to Shannon and Paul. Spinal fusion of the involved segments is indicated in cases in which there is instability, usually related to extensive or prior surgery or to an anatomic abnormality.

The features that are predictive of better outcome from decompressive surgery are a clearly delineated radicular leg pain, in contrast to general back pain alone, younger age, an identifiable precipitating event for the back and sciatic pain, clinical features that are restricted to compression of a single nerve root, and the absence

of chronic or frequently recurrent back pain. Curiously, Barzouhi and colleagues found that the presence or absence of disc herniation in the MRI a year after operation had little relationship to the persistence of sciatica.

Other Causes of Sciatica and Low Back Pain

An increasing experience with lumbar back pain and sciatica has impressed the authors with the large number of such cases that have no clear cause. At one time, all these cases were classified as sciatic neuritis or “sacroiliac strain.” After Mixter and Barr popularized the concept of herniated disc, all sciatica and lumbar pains were ascribed to this condition. Operations became somewhat indiscriminately practiced, not only for frank disc protrusion but also for “hard discs” (unruptured) and related pathologies of the spine. In large referral centers, the surgical results became decreasingly satisfactory until recently, as many patients were being seen with unrelieved postlaminectomy pain as with unoperated ruptured discs. This is no longer the case as selection of patients has been refined.

Other cases of chronic sciatic pain are due to one of a number of pathologic entities. Entrapment of lumbar roots may be the consequence not only of disc rupture but also of spondylotic spurs with *stenosis of the lateral recess*, cysts of the synovium derived from degenerative disease of the facet joint, hypertrophy of facets, and, rarely, arachnoiditis. Lateral recess stenosis in particular may be a cause of sciatica not relieved by conventional disc surgery (see below, under “Lumbar Stenosis”). Synovial cysts arising from a facet joint are not uncommon, and even very small ones may be situated in the proximal portion of the foramen, thereby causing sciatica. If pain is intractable, surgical removal of the cyst is indicated. Another surprising finding in the course of imaging the spinal canal is a cyst-like dilatation of the perineurial sheath (Tarlov cysts). One or more sacral roots may be involved at points where they penetrate the dura and may be associated with radicular symptoms. There are reports of relief from opening the cysts and freeing the roots, but the results seem more uncertain to us. Sciatica that is temporally linked to the premenstrual period is usually a result of endometriosis involving the nerve at the sciatic notch (“catamenial sciatica”). We have also observed cases of sciatica that occurred with each pregnancy, presumably from uterine traction on the nerve.

The notion of a pyriformis (piriformis) syndrome, so named by Kopell and Thompson, has arisen as a cause of otherwise unexplained buttock pain or vague sciatica. The muscle overlies or, in a small proportion, embeds the peroneal trunk of the sciatic nerve. Hypertrophy, spasm, or simply the anatomic variation in which the nerve is entrapped in the tendinous origin of the muscle have all putatively caused local and some degree of sciatic pain. Sciatica in these cases is elicited by stretching the muscle through flexion, adduction, and internal rotation of the hip. The validity of this syndrome is uncertain and it has been the subject of polemical discussions in the literature. EMG data are ambiguous but reportedly show

distal denervation, sparing more proximally innervated muscles. Our practice would be to avoid surgery in such cases, but to endorse physical therapy.

Compression of the cauda equina by epidural masses, as described further on, most often begins with back pain or sciatica. The sciatic nerve or the plexus from which it originates may be directly implicated in tumor (lymphoma, neurofibrosarcoma).

Several *inflammatory diseases of the cauda equina* produce back pain and *bilateral sciatica* and may be mistaken for the more usual types of cauda equina compression; cytomegalovirus infection in AIDS patients, Lyme disease (Bannwarth syndrome), herpetic infection (Elsberg syndrome), and neoplastic meningitis at times behave in this fashion. In all of these, the CSF shows a pleocytosis. The Guillain-Barré syndrome may also produce misleading back and radicular pain before weakness is apparent. The caudal roots in these diseases usually enhance with gadolinium on MRI.

An unusual *lumbosacral plexus neuritis* (Wartenberg plexitis) is a unilateral (occasionally bilateral) disorder akin to brachial neuritis, which may cause sciatica, as does occasionally nerve infarction or damage from diabetes, herpes zoster, parvovirus, or a retroperitoneal mass (see Chap. 46).

Again, if one sees enough of these cases, the cause of a number of them, particularly those with bilateral burning along the sciatic nerve, cannot be determined.

Lumbar Spinal Canal Stenosis (“Lumbar Stenosis” and Neurogenic Claudication)

The term spondylosis is often applied to a general constellation of bone, joint and ligamentous changes that narrow the spinal canal and neural foramina. In the lumbar region, these osteoarthritic and related degenerative changes lead to compression of one or more lumbar and sacral roots because of narrowing of the spinal canal. The problem is more likely to occur if there is a congenitally narrow canal. The roots are typically compressed between the posterior surface of the vertebral body anteriorly, the facet joint laterally, and the ligamentum flavum posteriorly. Lateral recess stenosis and foraminal stenosis are common effects of spondylosis (as mentioned above in relation to disc disease) and either or both may be the main cause of individual root compression.

The usual features of lumbar stenosis are of fluctuating aching and sharp pain in the low back, buttock and sciatic distribution, occasionally including femoral areas, and generally elicited by prolonged sitting, standing, or walking and relieved by rest. Some patients have virtually constant pain in these areas but still have relief with rest in one or another body position.

In the distinctive syndrome of “neurogenic claudication”, standing or walking causes a gradual onset of numbness and weakness of the legs, usually with asymmetrical sciatic, calf, or buttock discomfort that forces the patient to sit down. When the condition is more severe, the patient gains relief by squatting or lying with the legs flexed at the hips and knees, or in a forward leaning position with the hips and knees slightly flexed, as if in a

bicyclists position. Often the numbness begins in one leg, spreads to the other, and ascends as standing or walking continues. The ankle tendon reflexes may disappear after walking a distance, only to return on flexing the spine. Pain in the low back and glutei is variable. Disturbances of micturition and impotence are infrequent unless there has been an additional more acute disc herniation. In some patients with lumbar stenosis, neurologic symptoms persist without relation to body position. The process is distinguished from vascular claudication of the legs by its appearance in the standing position, the prominence of numbness in some cases, and, of course, by the preservation of distal leg pulses and loss of ankle reflexes in the neurogenic variety.

This “claudication of the cauda equina” was described by van Gelderen in 1948, and it was shown by Verbiest to not be caused by ischemia but by encroachment on the cauda by hypertrophied joints, thickened ligaments, and protrusions of disc material on a developmentally shallow canal. A spondylolisthesis may contribute to the stenosis in the anteroposterior dimension. Later, the canal is also narrowed from side to side (reduced interpedicular distance).

A prominent feature of many cases of the degenerative spinal disorder is displacement and malalignment of one vertebral body in relation to the adjacent one, or spondylolisthesis. This may cause little difficulty at first but eventually the patient complains of limitation of motion and pain in the low back radiating into the thighs. In the extreme case, examination discloses tenderness near the segment that has “slipped” anteriorly (most often L5, occasionally L4 in middle-aged women) or a palpable “step” of the spinous process forward and shortening of the trunk with protrusion of the lower abdomen (anterior shift of L5 on S1, *spondyloptosis*). Compression of the corresponding spinal roots by the displaced vertebrae causes paresthesia and sensory loss, muscle weakness, and diminished reflexes. These neurologic features, however, tend not to be severe. When *spondylolisthesis* is unstable, new symptoms may appear abruptly in the form of a foot drop, urinary retention, or overflow incontinence. The spinal instability is evidenced on conventional radiographs by a change in the diameter of the spinal canal as the patient moves between the flexed and extended position of the back.

A striking syndrome that has been attached to lumbar stenosis consists of *painful legs–moving toes*, described by Spillane. There is burning leg pain and continuous and complex rhythmic movements of the toes, as the name implies. Symptoms may begin on one side but become bilateral. Lumbar nerve root compression, most often from lumbar stenosis, or other types of peripheral damage underlie most cases.

Treatment of Lumbar Stenosis Decompression of the spinal canal relieves the symptoms of lumbar stenosis in a considerable proportion of cases, but the results have been inconsistent. Patients must be chosen carefully for surgery, and success is likely if the clinical features conform to the typical syndrome, mainly pain that altered in various positions and at least partially relieved by rest,

with definite evidence of root compression by imaging. In perhaps the most careful, controlled trial comparing surgery to conservative treatment for lumbar spinal stenosis, pain and overall function at 2 years was several-fold better in those who had operations (Weinstein et al, 2008). However, interpretation was hampered by a large number of patients who crossed over between arms of the study. Issues pertaining to the methodology of operation, the need for fusion of the lumbar spine to limit mobility, and various forms of “instrumentation” are of great interest, but are best discussed in textbooks of neurosurgery and orthopedics.

Insofar as lumbar stenosis is a cauda equina syndrome, its differential diagnosis is also considered in Chap. 44.

Atherosclerosis of the Distal Aorta (Vascular Claudication)

Atherosclerosis of large and medium-sized arteries often leads to symptoms that are induced by exercise (intermittent claudication) but may also occur at rest (ischemic rest pain) as already mentioned. The diabetic patient is especially susceptible. The muscle pain that is brought on by exercise and promptly relieved by rest most frequently involves the calf and thigh muscles. If the atherosclerotic narrowing or occlusion implicates the aorta and iliac arteries, it may also cause hip and buttock claudication and impotence in the male (Leriche syndrome). Ischemic rest pain—and sometimes attendant ulceration and gangrene—is usually localized to the foot and toes; it is the consequence of multiple sites of vascular occlusion. Pain at rest is characteristically worse at night and totally or partially relieved by dependency.

The examination of such patients will reveal a loss of one or more peripheral pulses, trophic changes in the skin and nails (in advanced cases), and the presence of bruits over or distal to sites of narrowing. The ankle reflexes are often diminished. The similarities to a claudicatory syndrome of lumbar spine stenosis have already been discussed.

Degenerative Osteoarthritis, or Osteoarthropathy

Independent of stenosis of the lumbar canal is chronic and recurring back pain caused by degenerative arthritic disease. It occurs in later life and may involve all or any part of the spine but is most prevalent in the cervical and lumbar regions. The pain is described as a stiffness that is centered in the affected part of the spine. It is increased initially by movement and is associated with limitation of motion but is often worse on arising in the morning. In contrast to the spinal claudicatory syndrome, warming up and progressive mobilization make the pain better. There is a notable absence of systemic symptoms such as fatigue, malaise, or fever, and, more importantly, *there are limited or no features of radicular compression*. Some patients complain of vague and intermittent pains in the upper or posterior legs, but sciatica is not a component and the straight-leg raising tests do not elicit pain. The sitting position is usually comfortable, although stiffness and discomfort are accentuated when the erect posture is resumed.

The severity of the symptoms often bears little relation to the radiologic changes; pain may be present despite minimal radiographic findings; conversely, marked osteophytic overgrowth with spur formation, ridging, bridging of vertebrae, narrowing of disc spaces, subluxation of posterior joints on flexion, and air in the disc spaces can be seen in both symptomatic and asymptomatic persons.

Facet Syndrome

This syndrome has been somewhat clarified in recent years, but its definition and nature remain imprecise. In the typical instance, osteoarthritic degeneration of the facet joint gives rise to a focal parasagittal lumbar back pain, with tenderness over the joint (Fig. 11-2, location 3) but without signs of root compression. The pain can be severe, worse at night, and prevent sleep if no comfortable position can be found. Nonsteroidal drugs are helpful. The diagnosis is confirmed when the pain is relieved for a variable period by injection of the joint with local anesthetic.

Often one is uncertain whether it was the analgesic effect on the joint or the infiltration of the region around the nerve root that relieved the pain. Two controlled studies have provided evidence of the inefficacy, both in the short and long term, of corticosteroid injections into the facet joints (Carette et al, 1991; Lilius et al). Notwithstanding these reports, we have found the injection of analgesics and steroids in and around the facet to be a useful temporizing measure in some patients. Some patients have discovered that they may obtain temporary relief from facet pain by forcefully twisting or stretching the back and creating an audible pop at the affected joint, comparable to chiropractic manipulation. Over time, they acquire a laxity of the supporting structures of the joint, which may actually perpetuate the problem.

If the diagnosis is established by local injection, pain centers offer radiofrequency ablation of the small recurrent sensory nerves that innervate the joint as a means of permanent relief. This has met with some success but has not been studied systematically.

Some writers have used the term facet syndrome to describe a painful state from facet hypertrophy that gives rise to a lumbar monoradiculopathy indistinguishable from that caused by a ruptured disc or spondylosis. Reynolds and coworkers have documented such cases. At operation, the spinal root is compressed against the floor of the intervertebral canal by overgrowth of an inferior or superior facet. Foraminotomy and facetectomy, after exploration of the root from the dural sac to the pedicle, have relieved the pain in many operated cases.

Lumbar Adhesive Arachnoiditis

This is a somewhat vague entity in which the arachnoid membrane is thickened and opaque in the vicinity of the cauda equina. The term is also applied to thickening of the arachnoidal sheaths around roots (normal roots have essentially no epineurium). According to one review, lumbar arachnoiditis is rare, having been seen in only 80 of 7,600 myelograms, and it should virtually vanish as the use of MRI and water-soluble dyes for myelography take

precedence. The usual clinical features are intractable low-back and leg pain and paresthesia, all positionally sensitive, in combination with neurologic abnormalities referable to lumbar spinal roots. In our few patients, multiple previous myelograms with lipid contrast agent (a problem of the past), disc rupture, operative procedures, infections, and subarachnoid bleeding have been causal. Some cases have followed spinal anesthesia and even epidural anesthesia by a period of months or years. The presumption is that the dura had been breached, and often, there were clinical signs of aseptic meningitis soon after the procedure. In the absence of such an acute reaction, the later diagnosis of arachnoiditis rests on less-certain grounds.

The MRI shows eccentrically thickened meninges in the spinal canal with arachnoid adhesions and collections of CSF that displace nerve roots (Fig. 11-5). Abnormalities are even more striking on CT myelographic studies in which the contrast is broken up and fails to outline the roots. Treatment is unsatisfactory. Lysis of adhesions under an operating microscope and administration of intrathecal steroids have been of limited value, although some experienced surgeons claim otherwise. Epidural injection of steroids is occasionally helpful according to some of our orthopedic surgeon colleagues.

Ankylosing Spondylitis

This disorder, referred to in the past as *rheumatoid spondylitis* and as *von Bechterew* or *Marie-Strimpell arthritis*, affects young adult males predominantly. Approximately 95 percent of patients with ankylosing spondylitis are marked by the histocompatibility antigen HLA-B27 (which is present in only 7 percent of nonaffected persons of European extraction). Pain, usually centered in the low back, is the main early complaint. Often it radiates to the back of the thighs and groin. At first, the symptoms are vague (tired back, "catches" up and down the back, sore back), and the diagnosis may be overlooked for many years. Although the pain is recurrent, limitation of movement is constant and progressive and comes to dominate the clinical picture. Early in the course of disease there is only "morning stiffness" or an increase in stiffness after periods of inactivity similar to lumbar osteoarthritis but unusual for the affected age group. In advanced stages, a cauda equina compression syndrome may complicate ankylosing spondylitis, the result apparently of an inflammatory reaction and proliferation of connective tissue (Matthews). Limitation of chest expansion, tenderness over the sternum, decreased motion and tendency to progressive flexion of the hips, and the characteristic immobility and flexion deformity of the spine ("poker spine") may be present early in the course of the disease.

The radiologic hallmarks are destruction and subsequent obliteration of the sacroiliac joints, followed by bony bridging of the vertebral bodies to produce the characteristic "bamboo spine." When this change becomes apparent, the pain usually subsides, but the patient by then has little motion of the back and neck. An unusual additional feature, almost unique to this condition but not present in all cases, is an extreme dilatation of the lumbar thecal sac. Ankylosing spondylitis may also

Figure 11-5. Lumbo-sacral MRI of a patient with lymphoma, with radiation-induced arachnoiditis causing severe back pain and leg weakness. **A.** Sagittal T2-weighted MRI showing clumping of the nerve roots of the cauda equina. **B.** Axial T2-weighted image at the L3 vertebral level showing clumping of the nerve roots. **C.** Axial T2-weighted image at the L5 vertebral level showing lateral displacement of nerve roots by acquired arachnoid cysts. There are bilateral metallic pedicle screws.

be accompanied by the Reiter syndrome, psoriasis, and inflammatory diseases of the intestine (see also Chap. 44). The great risk in this disease is fracture dislocation of the spine from relatively minor trauma, particularly flexion-extension injuries.

Occasionally, ankylosing spondylitis is complicated by destructive vertebral lesions. This complication should be suspected whenever the pain returns after a period of quiescence or becomes localized. The cause of these lesions is not known, but they may represent a response to nonunion of fractures, taking the form of an excessive production of fibrous inflammatory tissue. When it is severe, ankylosing spondylitis may involve both hips, greatly accentuating the back deformity and disability.

Rheumatoid arthritis of the spine may be confined to the cervical region and creates risk of fracture–dislocation; it is considered further on in this chapter.

Neoplastic and Infectious Diseases of the Spine (See also Chap. 44)

Metastatic carcinoma (breast, bronchus, prostate, thyroid, kidney, stomach, uterus), multiple myeloma, and lymphoma are the common malignant tumors that involve the spine. The primary lesion may be small and asymptomatic, and the first manifestation of the tumor may be pain in the back caused by metastatic deposits. The pain is constant and dull; it is often unrelieved by rest and is

generally worse at night, interrupting sleep. Radicular pain may be added if the metastasis extends laterally. A fracture of a vertebral body in an otherwise healthy young or middle-aged person should alert the physician to the possibility of an underlying metastasis. At the time of onset of the back pain, there may be no radiographic changes on plain radiographs; when such changes do appear, they usually take the form of destructive lesions in one or several vertebral bodies with little or no involvement of the disc space, even in the face of a compression fracture. However, the changes are evident on CT and MRI or radioactive isotope scan, including PET, and demonstrate areas of osteoblastic activity caused by neoplastic or inflammatory disease.

Infection of the vertebral column, *osteomyelitis*, is usually caused by staphylococci and less often by coliforms and mycobacteria. The patient complains of subacute or chronic pain in the back, which is exacerbated by movement but not materially relieved by rest. Motion becomes limited, and there is percussion-induced tenderness over the spine in the involved segments and pain with jarring of the spine, as occurs when the heels strike the floor. Often these patients are afebrile and do not have a leukocytosis. The erythrocyte sedimentation rate and C-reactive protein are elevated as a rule. Highly characteristic is the demonstration by CT scanning and MRI of involvement of both the vertebral body and the adjacent intervertebral

disc, and the finding of a breached disc space with involvement of two adjacent vertebral bodies is one of the features that differentiates infectious from neoplastic diseases of the spine. A paravertebral mass is often found, indicating an abscess, which may, in the case of tuberculosis, drain spontaneously at sites quite remote from the vertebral column. In the postoperative setting or following trauma, a disc infection can occur by direct microbial seeding. It should be remembered that the intervertebral disc is an avascular structure, and therefore blood-borne pathogens first infect the bone and then secondarily spread to the adjacent disc. This is not the case in the neonatal period when the discs are directly perfused, for which reason neonates are subject to hematogenously seeded discitis.

We have also encountered a number of patients with bacterial endocarditis who complained of severe midline thoracic and lumbar back pain but had no evident infection of the spine.

Tuberculous spinal infection and the resultant kyphotic deformity (Pott disease) represent a special condition that is common in developing countries (see Chaps. 32 and 44).

Spinal Epidural Abscess Special emphasis is placed on this condition, which usually necessitates urgent surgical treatment. Failure to properly identify this lesion has led to paraplegia or death from sepsis. Most often this is caused by staphylococcal infection, which is carried in the bloodstream from a septic focus (e.g., furuncle) or is introduced into the epidural space from an osteomyelitic lesion. Another important avenue of infection is the intravenous self-administration of drugs and use of contaminated needles. Rarely, the infection is introduced in the course of a lumbar puncture, epidural injection, or laminectomy for disc excision. In some instances, the source of an epidural abscess cannot be ascertained. The main symptoms are low-grade fever, leukocytosis, and persistent and severe localized pain that are intensified by percussion and pressure over the vertebral spines. Additionally, the pain may acquire radicular radiation. These symptoms usually require investigation by MRI or CT myelography and surgical intervention, preferably before the signs of paraplegia, sphincter dysfunction, and sensory loss become manifest. Small abscesses and granulomas that are the residua of previous and partially treated abscesses can be sometimes treated successfully with antibiotics alone as discussed further on.

Intraspinal Hemorrhage (See Chap. 44)

Sudden, excruciating midline back pain (*le coup de poignard* or “the strike of the dagger”)—often with rapidly evolving paraparesis, urinary retention, and numbness of the legs—may announce the occurrence of subarachnoid, subdural, or epidural bleeding. The most common causes of such an event are a coagulopathy (mainly from warfarin), and a spinal arteriovenous malformation (AVM), as discussed in Chap. 44. Spinal arterial aneurysms are much less common underlying lesions. It should be mentioned that focal back pain of comparable intensity may mark the onset of acute myelitis, spinal cord infarction, compression fracture, and occasionally, Guillain-Barré syndrome.

Back Pain from Visceral Disease

Peptic ulcer disease and carcinoma of the stomach and pancreas most typically induce pain in the epigastrium. However, if the posterior stomach wall is involved, particularly if there is retroperitoneal extension, the pain may be felt in the thoracic spine, centrally or to one side, or in both locations. If intense, it may seem to encircle the body. The back pain tends to reflect the temporal characteristics of the pain from the affected organ; e.g., if caused by gastric ulceration, it appears about two hours after a meal and is relieved by food and antacids.

Diseases of the pancreas are apt to cause pain in the back, being more to the right of the spine if the head of the pancreas is involved and to the left if the body and tail are implicated. Retroperitoneal neoplasms—e.g., lymphomas, renal cell tumors, sarcomas, and other malignancies—may evoke pain in the lower thoracic or lumbar spine with a tendency to radiate to the lower part of the abdomen, groins, anterior thighs, or flank. A tumor in the iliopsoas region often produces a unilateral lumbar ache with radiation toward the groin and labia or testicle; there may also be signs of involvement of the upper lumbar spinal roots. An aneurysm of the abdominal aorta may induce pain localized to an analogous region of the spine. The sudden appearance of lumbar pain in a patient receiving anticoagulants should arouse suspicion of retroperitoneal bleeding; this pain may also be referred to the groin.

Inflammatory diseases and neoplasms of the colon cause pain that may be felt in the lower abdomen, the midlumbar region, or both. As with intense pain higher in the spine, it may have a belt-like distribution. Pain from a lesion in the transverse colon or first part of the descending colon may be central or left-sided; its level of reference is to the second and third lumbar vertebrae. If the sigmoid colon is implicated, the pain is lower in the upper sacral spine and anteriorly in the suprapubic region or left lower quadrant of the abdomen. Retroperitoneal appendicitis may have an odd referral of pain to the low flank and back.

Gynecologic disorders often manifest themselves by back pain, and their diagnosis may prove difficult. Thorough abdominal palpation, as well as vaginal and rectal examination by an experienced physician, supplemented by ultrasonography and CT scanning or MRI, usually discloses the source of pain. The uterosacral ligaments are a pelvic source of chronic back pain. Endometriosis or carcinoma of the uterus (body or cervix) may invade these structures, causing pain localized to the sacrum either centrally or more to one side. In endometriosis, the pain begins premenstrually and often merges with menstrual pain, which also may be felt in the sacral region. Rarely, cyclic engorgement of ectopic endometrial tissue may give rise to sciatica and other radicular pain. Changes in posture may also evoke pain here when a fibroma of the uterus pulls on the uterosacral ligaments. Low back pain with radiation into one or both thighs is a common phenomenon during the last weeks of pregnancy.

The pain of neoplastic infiltration of pelvic nerve plexuses may be projected to the low back and is continuous, becoming progressively more severe; it tends to be more intense at night and may have a burning quality.

The primary lesion can be inconspicuous and may be overlooked on pelvic examination.

Coccydynia

This is the name applied to pain localized to the coccyx, the three or four small vestigial bones at the lower-most part of the sacrum. The trauma of childbirth, a fall on the buttocks, avascular necrosis, a neurofibroma or glomus tumor, or one of a variety of other rare tumors and anal disorders, and, of course, pilonidal cyst, can sometimes be established as the cause of pain in this region. Far more often, the source remains obscure. In the past, patients in this latter group were indiscriminately subjected to coccygectomy, but more recent studies have demonstrated that most cases respond favorably to injections of local anesthetic and methylprednisolone or to manipulation of the coccyx under anesthesia (Wray et al).

Obscure Types of Low Back Pain and the Question of Psychiatric Disease

Even after careful examination, there remains a sizable group of patients in whom no basis for the back pain can be found. Two categories can be recognized: one with postural back pain and pain after injury, and another with psychiatric illness, but there are always cases where the diagnosis remains obscure.

Low back pain may be a major symptom in patients with hysteria, malingering, anxiety, depression, and hypochondriasis as well as in many persons whose symptoms do not conform to any of these psychiatric illnesses. It is good practice to assume that pain in the back in such patients may signify disease of the spine or adjacent structures, and this should always be carefully sought. However, even when some organic factors are found, the pain may be exaggerated, prolonged, or woven into a pattern of invalidism because of coexistent primary or secondary factors. This is especially true when there is the possibility of secondary gain (notably workers' compensation or settlement of personal injury claims). Patients seeking compensation for protracted low back pain without obvious structural disease tend, after a time, to become suspicious, uncooperative, and hostile toward their physicians or anyone who might question the authenticity of their illness. One notes in them a tendency to describe their pain vaguely and a preference to discuss the degree of their disability and their mistreatment at the hands of the medical profession. The description of the pain may vary considerably from one examination to another. Often also, the region(s) in which pain is experienced and its radiation are non-physiologic, and the condition fails to respond to rest and inactivity. These features and a negative examination of the back should lead one to suspect a psychologic factor. A few patients, usually frank malingerers, adopt bizarre gaits and attitudes, such as walking with the trunk flexed at almost a right angle (camptocormia), and are unable to straighten up. Or the patient may be unable to bend forward even a few degrees, despite the absence of muscle spasm, and may wince at the slightest pressure, even over the sacrum, which is seldom a site of tenderness unless there is pelvic disease.

The depressed and anxious patient with back pain represents a troublesome problem. The disability seems excessive for the degree of spinal malfunction. Anxiety and depression may become important components of the back syndrome, and the patient may ruminate about an undiagnosed cancer or other serious illness. In these circumstances, common and minor back ailments—e.g., those caused by osteoarthritis and postural ache—are enhanced and rendered intolerable. Such patients are still subjected to unnecessary surgical procedures. It is not clear if one can depend on the diagnostic features of a response to drugs that alleviate depression.

Failed Back Syndrome

Surely among the most difficult patients to manage are those with chronic low back pain who have already had one or more laminectomies and sometimes a fusion without substantial relief. In one perhaps dated but large series of patients operated on for proven disc herniation, 25 percent were left with troublesome symptoms and 10 percent required further surgery (Weir and Jacobs). In such patients our practice has been to repeat the MRI or CT myelography. In a small number it will be found that the disc has reruptured, or that there is unaddressed lateral recess stenosis, that a disc has ruptured at another level, or that there is increased spondylolisthesis with flexion or extension. It may happen that the surgeon did not remove all the herniated disc tissue, in which case another operation to remove the remainder will usually be successful. EMG and nerve conduction studies, searching for evidence of a radiculopathy, are also helpful. If there is evidence of a radiculopathy but no disc material, or only scar tissue is seen on MRI, one cannot know whether the pain is because of injury from the initial rupture or is the aftermath of surgery. Various explanations are then invoked—radiculitis, lateral recess syndrome, facet syndrome, unstable spine, and lumbar arachnoiditis, each described earlier in this chapter (see reviews by Quiles et al and by Long).

Transcutaneous stimulators, posterior column stimulators, intrathecal injections of analgesics, and epidural steroid injections have seldom helped for long in our experience, but we have seen striking exceptions, especially with epidural pumps that administer analgesics. At present, the best that can be offered the patient is weight reduction (in appropriate individuals), stretching and progressive exercise to strengthen abdominal and back muscles, as well as mild nonnarcotic analgesics and antidepressant drugs. A trial of massage and other types of physiotherapy or a limited course of spinal chiropractic manipulation is reasonable.

PAIN IN THE NECK, SHOULDER, AND ARM

General Considerations

It is useful to distinguish three major categories of painful disease of the neck and arms—that originating in the *cervical spine*, in the *brachial plexus*, and in the *shoulder*.

Although the distribution of pain from each of these sources may overlap, the patient can usually indicate its site of origin. Pain arising from the *cervical part of the spine* is felt in the neck or back of the head and is projected to the shoulder and upper arm; it is evoked or enhanced by certain movements or positions of the neck and is accompanied by limitation of motion of the neck and by tenderness to palpation over the cervical spine.

Pain of brachial plexus origin is experienced in the supraclavicular region, or in the axilla and around the shoulder; it may be worsened by certain maneuvers and positions of the arm and neck (extreme rotation). A palpable abnormality above the clavicle may disclose the cause of the plexopathy (aneurysm of the subclavian artery, tumor, and cervical rib). The combination of circulatory abnormalities and signs referable to the medial cord of the brachial plexus is characteristic of the *thoracic outlet syndrome*, described further on.

Pain localized to the shoulder region, worsened by motion, and associated with tenderness and limitation of movement, especially internal and external rotation and abduction, points to a tendonitis, subacromial bursitis, or tear of the rotator cuff or labrum of the shoulder joint, which is made up of the tendons of the muscles surrounding the shoulder joint. The term *bursitis* is often used loosely to designate the first three of these disorders. Shoulder pain, like spine and plexus pain, may radiate vaguely into the arm and rarely into the hand, but sensorimotor and reflex changes—which always indicate disease of nerve roots, plexus, or nerves—are absent. Shoulder pain of this type is very common in middle and late adult life. It may arise spontaneously or after unusual or vigorous use of the arm. Local tenderness over the greater tuberosity of the humerus is characteristic. Plain radiographs of the shoulder may be normal or show a calcium deposit in the supraspinatus tendon or subacromial bursa. MRI is able to demonstrate more subtle abnormalities, such as muscle and tendon tears of the rotator cuff or a labral tear of the joint capsule. In most patients the pain subsides gradually with immobilization and analgesics followed by a program of increasing shoulder mobilization. If it does not, the injection of small amounts of corticosteroids into the bursa, or the site of major pain indicated by passive shoulder movement in the case of rotator cuff injuries, is often temporarily effective and allows the patient to mobilize the shoulder. The more extreme problem of the “frozen shoulder” is addressed further on.

Osteoarthritis and osteophytic spur formation of the cervical spine may cause pain that radiates into the back of the head, shoulders, and arm on one or both sides. Coincident compression of nerve roots is manifest by paresthesia, sensory loss, weakness and atrophy, and tendon reflex changes in the arms and hands. Should bony ridges form in the spinal canal, as described in detail in Chap. 44 (*cervical spondylosis*), the spinal cord may be compressed, with resulting spastic weakness, ataxia, and loss of vibratory and position sense in the legs. The bony changes are evident on plain films but are better seen by CT and MRI. There may be difficulty in distinguishing cervical spondylosis with root and spinal cord compression from a

disc (see further on) or from a primary neurologic disease (syringomyelia, amyotrophic lateral sclerosis, or tumor) with an unrelated cervical osteoarthritis. Here the MRI is of particular value in revealing compression of the spinal cord, but this study is prone to over interpretation when a bony ridge barely comes into contact with the cord but does not deform it or extends laterally to the proximal foramen but does not compress the nerve root (see “Cervical Spondylosis with Myelopathy” in Chap. 44).

Spinal *rheumatoid arthritis* may be restricted to or include the cervical zygapophysial (facet) joints and the atlantoaxial articulation. The usual manifestations are pain, stiffness, and limitation of motion in the neck and pain in the back of the head. In contrast to ankylosing spondylitis, rheumatoid arthritis is rarely confined to the spine. Because of evident disease of other joints, the diagnosis is relatively easy to make, but significant involvement of the cervical spine may be overlooked. In the advanced stages, one or several of the vertebrae may become displaced anteriorly, or a synovitis of the atlantoaxial joint may damage the transverse ligament of the atlas, resulting in forward displacement of the atlas on the axis, i.e., atlantoaxial subluxation. In either instance, serious and even life-threatening compression of the spinal cord may occur gradually or suddenly. Cautiously performed lateral radiographs in flexion and extension are useful in visualizing atlantoaxial dislocation or subluxation of the lower segments. Occipital headache and neck pain related to degenerative changes in the upper cervical facets is discussed with other cranial pains in “Third Occipital Nerve Headache” in Chap. 10.

Traumatic and Whiplash Injury

Injury to ligaments and muscles as a result of forcible extension and flexion of the neck can create a number of difficult clinical problems. The injury ranges from a minor sprain of muscles and ligaments to severe tearing of these structures, to avulsion of muscle and tendon from vertebral body, and even to vertebral and intervertebral disc damage. The latter lesions can be seen with MRI and, if severe, can result in root or spinal cord compression or, occasionally, in cartilaginous embolization leading to infarction of the spinal cord (see “Fibrocartilaginous Embolism” in Chap. 44). If there is preexisting cervical osteoarthritis, there may be considerable pain, and in extreme cases, cord compression.

However, the more ubiquitous and milder degrees of whiplash injury without the above described structural injuries are so often complicated by psychologic and compensation factors leading to prolonged disability that the syndrome has become a vexing issue without clear medical definition and it occupies a disproportionate amount of time on the part of physicians, compensation boards, and courts (see LaRocca for a review and especially the book by Malleon for an interesting discussion of the sociology and psychology of this subject). We have no doubt that authentic traumatic neck injuries exist, even at times from minor trauma, but we are in accord with these authors that the high frequency of putative whiplash injury is sustained by societal and legal structures.

Cervical Disc Herniation (See Table 11-1)

A common cause of neck, shoulder, and arm pain is disc herniation in the mid and lower cervical region; the process is comparable to disc herniation in the lumbar region but gives rise, of course, to a different set of symptoms (Table 11-1). The problem appears most often without a clear and immediate cause, but it may develop after trauma, which may be major or minor (from sudden hyperextension of the neck, falls, diving accidents, and forceful manipulations). The roots most commonly involved are the seventh (in 70 percent of cases) and the sixth (in 20 percent of cases); fifth- and eighth-root compression makes up the remaining 10 percent (Yoss et al).

When the protruded disc lies between the sixth and seventh vertebrae, there is involvement of the *seventh cervical root* as outlined in Table 11-1 and shown in Figure 11-6 A and B. The pain is then in the region of the

shoulder blade, or spine of the scapula, and posterolateral upper arm; it may project to the elbow and dorsal forearm, index and middle fingers, or all the fingers. Occasionally discomfort is felt in the pectoral or axillary region. Tenderness is most pronounced over the medial aspect of the shoulder blade opposite the third to fourth thoracic spinous processes and in the supraclavicular area and triceps region. Paresthesia and sensory loss are most evident in the lateral index and middle fingers. Weakness involves the extensors of the forearm and sometimes of the wrist; occasionally the handgrip is weak as well; the triceps may be weak and the triceps reflex is usually diminished or absent; the biceps and supinator reflexes are preserved.

With a laterally situated disc herniation between the fifth and sixth cervical vertebrae, the symptoms and signs are referred to the *sixth cervical root*. The full syndrome is characterized by pain at the trapezius ridge and tip

Figure 11-6. Cervical disc herniation as visualized with T2-weighted MRI. *A.* Parasagittal view of a large posterior disc extrusion at C6-C7. Smaller broad-based posterior disc bulges are seen at C4-C5 and C5-C6. *B.* Axial view of the large right posterolateral disc extrusion shown in (*A*) at C6-C7 (arrow) causing severe narrowing of the right neural foramen and compression of the exiting C7 nerve root. *C.* By way of contrast, an axial view of the broad-based posterior disc bulge at C4-C5 (arrows) causes only minimal narrowing of the spinal canal and no compression of the spinal cord.

of the shoulder, with radiation into the anterior-upper part of the arm, radial forearm, often the thumb, and sometimes the index finger as well. There may also be paresthesia and sensory impairment in the same regions; tenderness in the area above the spine of the scapula and in the supraclavicular and biceps regions; weakness in flexion of the forearm (biceps) and in contraction of the deltoid when sustaining arm abduction; and diminished or absent biceps and supinator reflexes (the triceps reflex is retained or sometimes has the appearance of being slightly exaggerated because of flaccidity of the biceps).

The *fifth cervical root* syndrome, produced by disc herniation between the fourth and fifth vertebral bodies, is characterized by pain in the shoulder and trapezius region and by supra- and infraspinatus weakness, manifest by an inability to abduct the arm and rotate it externally with the shoulder adducted (weakness of the supra- and infraspinatus muscles). There may be a slight degree of weakness of the biceps and a corresponding reduction in the reflex, but these are inconsistent findings. A small patch of diminished sensation commonly overlies the deltoid muscle.

Compression of the *eighth cervical root* at (C7-T1 disc) may mimic ulnar nerve palsy. The pain is along the medial side of the forearm and the sensory loss is in the distribution of the medial cutaneous nerve of the forearm and of the ulnar nerve in the hand. The weakness largely involves the intrinsic muscles supplied by the ulnar nerve (see "Ulnar Nerve" in Chap. 46). The reflexes may be unaffected but the triceps jerk is oftentimes reduced.

These cervical disc syndromes are usually incomplete in that only one or several of the typical findings are present. Particularly noteworthy is the occurrence, in laterally placed cervical disc rupture, of isolated weakness without pain, especially with discs at the fifth and sixth levels. Friis and coworkers have described the distribution of pain in 250 cases of herniated disc or spondylotic nerve root compression in the cervical region. Virtually every patient with pain, irrespective of the particular root(s) involved, *showed a limitation in the range of motion of the neck and aggravation of pain with movement (particularly hyperextension)*. Coughing, sneezing, and downward pressure on the head in the hyperextended position usually exacerbated the pain, and manual traction of the neck tended to relieve it.

Unlike herniated lumbar discs, cervical ones, if large and centrally situated, result in compression of the spinal cord. The centrally situated disc is often painless, and the cord syndrome may simulate multiple sclerosis or a degenerative neurologic disease. Bilateral hand numbness, paresthesia, or similar altered sensation is common. Failure to consider a protruded cervical disc in patients with obscure symptoms in the legs, including stiffness and falling, is a common error. A vague sensory change can often be detected on the thorax, the rostral margin of which is several dermatomes below the level of compression. The diagnosis and the level of disc protrusion can be confirmed by MRI or (Fig. 11-6) by CT myelography. Nerve conduction studies, F responses, and EMG are helpful in confirming the level of root compression and distinguishing pain of radicular origin from that originating in the

brachial plexus or in individual nerves of the arm (see "Brachial Neuritis" in Chap. 46).

Management of Herniated Cervical Disc

If pain alone is the problem, conservative measures should be instituted before turning to surgical removal of the disc. If there are signs of a rapidly or subacutely progressing myelopathy (i.e., leg and arm weakness, hyperreflexia in the legs, gait ataxia, sphincteric dysfunction) or intractable and persistent pain from radiculopathy, surgery is generally undertaken.

Treatment

In the case of cervical disc with radicular pain, a close-fitting foam collar is sometimes beneficial but many of our colleagues disagree on this point. The collar should be fitted so that minimal flexion and extension of the neck are allowed, but it must remain comfortable enough to encourage consistent use. The patient is advised to wear the collar at all times during the day, especially while riding in a car, unless this becomes completely impractical. Of even more uncertain value, and theoretically entailing a small risk, traction with a halter around the occiput and chin may be of some benefit in cervical disc syndromes. Analgesic medication may be required for many days.

In most instances the radicular pain subsides over a few weeks or less. Intractable cases may require surgery, especially if there is substantial weakness in the muscles corresponding to the affected root. Mild weakness alone is not recognized as an indication for surgery, and in those few cases where weakness alone has occurred, without pain, the same conservative measures outlined above should be implemented. However, there has never been a clear definition of the threshold of forearm, shoulder, or hand weakness that justifies surgery or might be irreversible if surgical decompression is not undertaken. Most often the surgeon tackles this problem through an anterior approach (transdiscally), which leaves the posterior elements intact and allows for retained stability of the spine.

Cervical Spondylosis (See also Chap. 44)

This is a chronic degenerative disease of the mid-and lower cervical spine that narrows the spinal canal and intervertebral foramina, causing compressive injury of the spinal cord and roots. The problem of central disc protrusion with overlying calcification, discussed above, often contributes as the main component of the narrowing of the canal. Hypertrophy of the facet joints and ligamentous buckling are added. Because the main effects of cervical spondylosis are on the cord, this process is discussed in detail in Chap. 44 but cervical spondylosis is also a common cause of neck and arm pain, as described earlier. If minor signs of spinal cord and root involvement are present, a collar to limit movement of the head and neck may halt the progression and lead to improvement. Decompressive laminectomy or anterior excision of single spondylotic spurs with or without fusion are reserved for instances of advancing neurologic symptoms or intractable

pain as discussed in Chap. 44. As with lumbar stenosis, success is not assured with surgery, but almost invariably, progression of symptoms is prevented.

Epidural Lipomatosis and Extramedullary Hematopoiesis

The first of these is a regularly encountered disorder that results from proliferation of fat in the spinal epidural space, most often dorsally in the thoracic region. It may cause a compressive myelopathy but is as often found incidentally on MRI. In current practice, corticosteroid administration is the most frequent cause. Similarly, the second process is from proliferation of bone marrow because of failure of hematopoiesis in the normal regions of the bone marrow.

These subjects are discussed further in Chap. 44.

Thoracic Outlet Syndromes

A number of anatomic anomalies occur in the lateral cervical region. These may, under certain circumstances, compress the brachial plexus, the subclavian artery, and the subclavian vein, causing muscle weakness and wasting, pain, and vascular abnormalities in the hand and arm. The condition is undoubtedly diagnosed more often than is justified, and the term has been applied ambiguously to a number of conditions, some of which are almost certainly nonexistent, comparable to the piri-formis syndrome in the buttock.

The most frequent of the abnormalities that cause neural compression and are encompassed by the term *thoracic outlet syndrome* are an anomalous incomplete cervical rib, with a sharp fascial band passing from its tip to the first rib; a taut fibrous band passing from an elongated and down-curving transverse process of C7 to the first rib; less often, a complete cervical rib, which articulates with the first rib; and anomalies of the position and insertion of the anterior and medial scalene muscles. Thus, the sites of potential neurovascular compression extend all the way from the intervertebral foramina and superior mediastinum to the axilla. Depending on the postulated abnormality and mechanism of symptom production, the terms *cervical rib*, *anterior scalene*, *costoclavicular*, and *neurovascular compression* have been applied. In addition, a *droopy shoulder syndrome* has been identified that purportedly stretches the brachial plexus and gives rise to similar symptoms; a majority of the patients have been young women with asthenic body habitus.

Variations in regional anatomy could explain these postulated mechanisms, but to this day there is not full agreement about the validity of anterior scalene and costoclavicular syndromes. An anomalous cervical rib, which arises from the seventh cervical vertebra and extends laterally between the anterior and medial scalene muscles and then under the brachial plexus and subclavian artery to attach to the first rib, obviously disturbs the anatomic relationships of these structures and may compress them (Fig. 11-7). However, as an estimated 1 percent of the population has cervical ribs, usually on both sides, and only about 10 percent of these persons

have neurologic or vascular symptoms (almost always one-sided), other factors must be operative.

The anterior and middle scalene muscles, which flex and rotate the neck, are both inserted into the first rib so that the subclavian artery and vein and the brachial plexus must pass between them. Hence abnormalities of insertion and hypertrophy of these muscles were once thought to be causes of the syndrome but sectioning them (scaleneotomy) has so rarely altered the symptoms that this mechanism is no longer given credence.

Three neurovascular syndromes are associated with a rudimentary and not fully ossified cervical rib (rarely with a complete cervical rib): subclavian venous or arterial compression and a brachial plexopathy. In all three forms, shoulder and arm pain is prominent. The discomfort is of the aching type and is felt in the posterior hemithorax, pectoral region, and upper arm. These syndromes sometimes coexist, but more often each occurs independently.

Compression or spontaneous thrombosis of the subclavian vein is a rare occurrence causing a dusky discoloration, venous distention, and edema of the arm. The vein may become thrombosed after prolonged exercise (Paget-Schrötter syndrome) or in cases of a clotting diathesis in cancer patients.

Compression of the subclavian artery, which results in ischemia of the limb, may be complicated by digital gangrene and retrograde embolization, also is a rare entity. A unilateral Raynaud phenomenon, brittle nails, and ulceration of the fingertips are important diagnostic findings. A supraclavicular bruit is suggestive but not in itself diagnostic of subclavian artery compression.

The conventional tests for vascular compression—obliteration of the pulse when the patient, seated and with the arm extended, takes and holds a full breath, tilts the head back, and turns it to the affected side (Adson test) or abducts and externally rotates the arm and braces the shoulders and turns the head to either side (Wright maneuver)—are not entirely reliable. Sometimes these maneuvers fail to obliterate the radial pulse in cases of proved compression; contrariwise, these tests may be positive in normal persons. Nevertheless, a positive test only on the symptomatic side (with reproduction of the patient's symptoms) is suggestive of the diagnosis of arterial compression and, by implication, some form of thoracic outlet syndrome. Plethysmographic recording of the radial pulse and ultrasound of the vessel add to the accuracy of these positional tests.

A primarily neurologic problem may characterize the thoracic outlet syndrome. There is slight wasting and weakness of the hypothenar, interosseous, adductor pollicis, and deep flexor muscles of the fourth and fifth fingers (i.e., the muscles innervated by the lower trunk of the brachial plexus and ulnar nerve). Weakness of the flexor muscles of the forearm may be present in advanced cases. Tendon reflexes are usually preserved. In addition, most patients complain of an intermittent aching of the arm, particularly of the ulnar side, and about half of them complain also of numbness and tingling along the ulnar border of the forearm and hand. A loss of superficial sensation in these areas is variable. It may be possible

Figure 11-7. Course of the brachial plexus and subclavian artery between the anterior scalene and middle scalene muscles as seen from coronal oblique (A) and sagittal oblique (B) perspectives. Dilatation of the subclavian artery just distal to the anterior scalene muscle is illustrated in (A). Immediately distal to the anterior and middle scalene muscles is another potential area of constriction, between the clavicle and the first rib. With extension of the neck and turning of the chin to the affected side (Adson maneuver), the tension on the anterior scalene muscle is increased and the subclavian artery compressed, resulting in a supraclavicular bruit and obliteration of the radial pulse.

to reproduce the sensory symptoms by firm pressure backwards on the scalenus muscle just above the clavicle, or more typically by downward and dorsal traction on the arm. Vascular features are often absent or minimal in patients with the neurologic form of the syndrome.

In patients with neurologic signs, nerve conduction studies usually disclose reduced amplitude of the ulnar sensory potentials. There may be decreased amplitude of the median motor evoked potentials as well, a mild but uniform slowing of the median motor conduction velocity, and a prolongation of the F-wave latency. Needle examination of affected hand muscles reveals large-amplitude motor units, suggesting collateral reinnervation. Somatosensory evoked potentials may be a useful adjunct to the conventional nerve conduction and EMG studies (Yiannikas and Walsh). Brachial artery MR angiography is usually reserved for patients with a suspected arterial occlusion, an aneurysm, or an obvious cervical rib. The place of venography in the diagnostic workup is uncertain, for a number of otherwise normal individuals can occlude the subclavian vein by fully abducting the arm.

In the authors' experience, unambiguous instances of thoracic outlet syndrome are not common. This has also been the experience of Wilbourn, whose review of this subject is recommended. One should be skeptical of the diagnosis unless the clinical and EMG features

enumerated above are present. Common mistakes are to confuse the thoracic outlet syndrome with carpal tunnel syndrome, ulnar neuropathy or entrapment at the elbow, or cervical radiculopathy caused by arthritis or disc disease. Brachial neuritis may have a similar presentation. Imaging studies and careful nerve conduction and EMG studies may be necessary to exclude all of these disorders.

Treatment

A conservative approach is advisable. If the main symptoms are pain and paresthesia, Leffert suggested the use of local heat, analgesics, muscle relaxants, and an assiduous program of special exercises to strengthen the shoulder muscles. A full range of neck motions is then practiced. On such a regimen, some patients experience a relief of symptoms after 2 to 3 weeks. Instruction by a physical therapist is invaluable.

Only if pain is severe and persistent and is clearly associated with the vascular or neurogenic features of the syndrome is surgery indicated. The usual approach is through the supraclavicular space, with cutting of fibrous bands and excision of the rudimentary rib. In cases of venous or minor arterial forms of the syndrome, some thoracic surgeons favor the excision of a segment of the first rib through the axilla. Pain is often relieved, but the sensorimotor defects improve only slightly. Sectioning of

the scalenus muscle is not endorsed because, as already noted, the role of muscle in causing thoracic outlet syndrome has been questioned.

Other Painful Conditions Originating in the Neck, Brachial Plexus, and Shoulder

The brachial plexus is an important source of shoulder and arm pain. The main disorders are brachial neuritis and metastatic infiltration and radiation damage to the plexus. Chapter 46 discusses these disorders in detail.

Metastases to the cervical region of the spine are less common than to other parts of the vertebral column. They are, however, frequently painful and may cause root compression. Posterior extension of the tumor from the vertebral bodies or compression fractures may lead to the rapid development of quadriplegia. Infiltration of the brachial plexus from tumor or sarcoid can produce similar syndromes.

The Pancoast tumor, usually a squamous cell carcinoma in the superior sulcus of the lung, may implicate the lower cervical and upper thoracic (T1 and T2) spinal nerves as they exit the spine. In these cases, a Horner syndrome, numbness of the inner side of the arm and hand, and weakness of all muscles of the hand and of the triceps muscle are combined with pain beneath the upper scapula and in the arm. The neurologic abnormalities may occur long before the tumor becomes visible radiographically.

Shoulder injuries (the common rotator cuff injury, or tear), subacromial or subdeltoid bursitis, periarthrosis or capsulitis (frozen shoulder), tendonitis, and arthritis may develop in patients who are otherwise well, but these conditions also occur as complications of hemiplegia. The pain tends to be severe and extends toward the neck and down the arm into the hand. The dorsum of the hand may tingle without other signs of nerve involvement. Immobility of an arm following myocardial infarction may be associated with pain in the shoulder and arm and with vasomotor changes and secondary arthropathy of the hand joints (shoulder-hand syndrome); after a time, osteoporosis and atrophy of cutaneous and subcutaneous structures occur (Sudeck atrophy or Sudeck-Leriche syndrome). Similar changes may occur in the foot and leg, or all articular structures on the side of a hemiplegia, or in association with the painful lesions described in the first part of this chapter. The neurologist should know that these complications can be prevented by proper exercises and relieved by cooling of the affected limb.

Vasomotor, sudomotor, and trophic changes in the skin, with atrophy of the soft tissues and decalcification of bone, may follow the prolonged immobilization and disuse of an arm (i.e., frozen shoulder syndrome) or leg for whatever reason.

Medial and lateral epicondylitis (tennis elbow) are readily diagnosed by demonstrating tenderness over the affected parts and an aggravation of pain on certain movements of the wrist. We have observed entrapment of the ulnar nerve in some cases of medial epicondylitis. Certain diabetic men seem to be prone to traumatizing their ulnar nerves at the elbow with various motions such as those of tennis.

The pain of the carpal tunnel syndrome often extends into the forearm and sometimes into the anterior biceps region and may be mistaken for disease of the shoulder or neck. Similarly, involvement of the ulnar, radial, or median nerves may be mistaken for brachial plexus or root lesions. EMG and nerve conduction studies resolves this. (this common disorder is discussed in Chap. 46).

Polymyalgia Rheumatica (See also Chaps. 10 and 34)

This syndrome is observed in middle-aged and elderly persons and is characterized by severe pain, aching, and stiffness in the proximal muscles of the limbs and a markedly elevated erythrocyte sedimentation rate and C-reactive protein level. The shoulders are most affected, but half of these patients have hip or neck pain as well. Constitutional symptoms (loss of weight, fever, and anemia) and articular swelling are less consistent manifestations. Many physicians have drawn attention to the high incidence of depression, but as is typical of chronic disease, it is difficult to know whether this is a cause or an effect. A few patients have pitting edema of the hands or feet, as illustrated in the review by Salvarini and colleagues; others have knee or wrist arthritis or carpal tunnel syndrome. Arthroscopy and MRI suggest that the pain originates in a synovitis or, sometimes more accurately, a bursitis, and in an inflammation of periarticular structures. The fundamental cause is not known.

Activity of the disease in a given patient correlates with elevation of the sedimentation rate, almost always above 40 mm/h and typically higher than 70 mm/h (and corresponding elevation of C-reactive protein); unlike the case in polymyositis, with which it is confused, creatine kinase levels are normal. In many patients, polymyalgia rheumatica is associated with the headache of giant cell (temporal, or cranial) arteritis as discussed in Chap. 10. The precise concordance of these two allied conditions is not known but there is not a high frequency of overlap. The arteritis may affect one or both optic nerves; blindness is the main risk of the disease, as discussed in detail in Chap. 13.

Treatment This disorder is self-limiting, lasting 6 months to 2 years, and responds dramatically to corticosteroid therapy, although this may have to be continued in low dosage for several months or a year or longer. We begin treatment with 20 mg of prednisone if there is no evidence of temporal arteritis (which requires higher doses). The absence of improvement in a day or two should bring the diagnosis into question. The degree of hip and shoulder pain is the best guide to the duration of steroid therapy and the rate at which the drug is withdrawn, usually in very small increments every 2 weeks. The sedimentation rate or C-reactive protein can be used as an additional guide, but neither alone is adequate to alter the medication schedule.

Reflex Sympathetic Dystrophy and Causalgia (See Chap. 8)

This painful response to injury of the shoulder, arm, or leg, is usually the result of an incomplete nerve injury. It consists of protracted pain, characteristically described

as “burning,” together with cyanosis or pallor, swelling, coldness, pain on passive motion, osteoporosis, and marked sensitivity of the affected part to tactile stimulation. The condition has been variously described under such terms as *Sudeck atrophy*, *posttraumatic osteoporosis* (in which case the bone scan may show increased local uptake of radioactive nuclide), and the related *shoulder-hand syndrome*. The current term is *complex regional pain syndrome*. When the pain syndrome occurs in isolation, it is referred to as *causalgia*. Pharmacologic or surgical sympathectomy appears to relieve the symptoms in some patients. In others with a hypersensitivity of both C-fiber receptors and postganglionic sympathetic fibers, it is not helpful. Chapter 8 discusses this subject further.

Neuroma Formation after Nerve Injury

Persistent and often incapacitating pain and dysesthesias may follow any type of injury that leads to partial or complete interruption of a nerve, with subsequent *neuroma formation* or *intra-neural scarring*—fracture, contusion of the limbs, compression from prolonged lying on the arm while intoxicated, severing of sensory nerves in the course of surgical operations or biopsy of nerve, or incomplete regeneration after nerve suture. It is stated that the regenerated nerves in these cases contain a preponderance of unmyelinated C fibers and a reduced number of A- δ fibers; this imbalance is presumably related to the genesis of painful dysesthesias. These cases are best managed by complete excision of the neuromas with end-to-end suture of healthy nerve, but not all cases lend themselves to this procedure.

Another special type of neuroma is the one that forms at the end of a nerve severed at amputation (stump neuroma). Pain from this source is occasionally abolished by relatively simple procedures such as injection of lidocaine, resection of the distal neuroma, proximal neurotomy, or resection of the regional sympathetic ganglia. More common in clinical practice is the mundane, but painful, Morton neuroma, usually found on the plantar nerve between the third and fourth metatarsal bones (third interspace). Pain on compression of the forefoot is the characteristic Mulder sign. The Morton neuroma is visualized by MRI but those due to partial nerve injury are more difficult to reveal by imaging. Gadolinium infusion may be required and even then, differentiation from surrounding scar is problematic.

Erythromelalgia

This rare disorder of the microvasculature produces a burning pain and bright red color skin change, usually in the toes and forefoot and sometimes in the hands, precipitated by changes in ambient temperature. Since its first description by Weir Mitchell in 1878, many articles have been written about it, and recently the cause of a primary familial form was traced to a mutation in a component of a voltage-gated sodium channel. Each patient has a temperature threshold above which symptoms appear and the feet become bright red, warm, and painful. The afflicted patient rarely wears stockings or regular shoes because these tend to bring out the symptoms. The pain is relieved by walking on a cold surface or soaking the

feet in cold water and by rest and elevation of the legs. The peripheral pulses are intact, and there are no motor, sensory, or reflex changes. The review by Layzer is recommended.

Most cases are idiopathic, some familial and inherited as a dominant trait. There are secondary forms of the disease, the most important one being that associated with essential thrombocythemia (up to 25 percent of patients may have erythromelalgia as the first symptom) but also with other myeloproliferative disorders such as polycythemia vera and with collagen vascular diseases, including thrombotic thrombocytopenic purpura (TTP), during the use of calcium channel blockers and certain dopaminergic agonists such as pergolide and bromocriptine, and with occlusive vascular diseases. Some instances arise as a result of a painful polyneuropathy that predominantly affects the small sensory fibers; more often in these latter conditions, the redness and warmth are constant and the result of damage to sympathetic nerve fibers; see Chap. 46. These symptomatic forms have led some experts to question whether erythromelalgia is a type of neuropathy or is a vasculopathy (Davis et al).

The familial form of erythromelalgia has been traced to a mutation in a voltage-gated sodium channel (NaV 1.7) that is selectively expressed in dorsal root ganglia nociceptive neurons. In addition to its inherent value in explaining the manifestations of this disease, the discovery of this channelopathy has evinced interest in novel ways to treat pain by manipulating sodium channels.

Treatment According to Abbott and to Mitts and others, aspirin is useful in the treatment of paroxysms of secondary erythromelalgia and of some primary cases as well; others had recommended methysergide, which has fallen out of use because of retroperitoneal and cardiac valvular fibrosis. Even small doses of aspirin provide relief within an hour, lasting for several days, a feature that is diagnostic. Sano and colleagues report that cyclosporine was of great benefit in a case of familial erythromelalgia that had not responded to other medications.

A similar condition, restricted in topography to the region of an acquired single nerve or skin injury, has been described by Ochoa under the term *ABC syndrome* (angry, backfiring C-nociceptors). Episodes of pain and cutaneous vasodilatation were induced by mechanical or thermal stimulation and relieved by cooling. There may be persistent hyperalgesia over the affected area. Lance has suggested that a similar mechanism is operative in the “red ear syndrome” as a result of irritation of the third cervical root.

Myofascial Pain Syndrome and Fibromyalgia

A confusing problem in the differential diagnosis of neck and limb pain is posed by the patient with pains that are clearly musculoskeletal in origin but are not attributable to a disease of the spine, articular structures, or nerves. The pain is localized to certain vague points in skeletal muscles, particularly the large muscles of the neck and shoulder girdle, arms, and thighs. We have been unable to corroborate the ill-defined tender nodules or cords (trigger points) that have been reported as an essential element of this illness. Excision of such nodules has

not revealed any sign of inflammation or other disease process. The currently fashionable terms *myofascial pain syndrome*, *fibromyalgia*, and *fibrositis* have been attached to the syndrome, depending on the particular interest or personal bias of the physician. Many of the patients are middle-aged women, who also have the equally vague and vexing chronic fatigue syndrome. Some relief is

afforded by local anesthetic injections, administration of local coolants, stretching of underlying muscles ("spray and stretch"), massage, etc., but the results in any given individual are unpredictable and the status of the disorder is not settled. Certain serotonin reuptake inhibitors, generally used to treat depression, are currently favored as treatment by many pain specialists and rheumatologists.

Disorders of the Special Senses

- CHAPTER 12 **Disorders of Smell and Taste**
- CHAPTER 13 **Disturbances of Vision**
- CHAPTER 14 **Disorders of Ocular Movement and Pupillary Function**
- CHAPTER 15 **Deafness, Dizziness, and Disorders of Equilibrium**

The four chapters in this section are concerned with the clinical aspects of the highly specialized functions of taste and smell, vision, hearing, and the sense of balance. These special senses and the cranial nerves that subserve them represent the most finely developed parts of the sensory nervous system. Dysfunctions of the eye and ear are, of course, the domain of the ophthalmologist and otorhinolaryngologist, but they also are of great interest to the neurologist. Some defects in the special sensory apparatus reflect the presence of systemic disease and others represent the initial or leading manifestation of neurologic disease. In keeping with the general scheme of this text, the disorders of the special senses and of ocular movement are discussed in a particular sequence: first, certain facts of anatomic and physiologic importance, followed by cardinal clinical manifestations of disease, and then the syndromes of which these manifestations are a part.

Disorders of Smell and Taste

The sensations of smell (olfaction) and taste (gustation) are suitably considered together. Physiologically, these modalities share the singular attribute of responding primarily to chemical stimuli; i.e., the end organs that mediate olfaction and gustation are chemoreceptors. Also, taste and smell are interdependent clinically, as the appreciation of the flavor of food and drink depends to a large extent on their aroma, and an abnormality of one of these senses is frequently misinterpreted as an abnormality of the other. In comparison to sight and hearing, taste and smell play a less critical role in the life of the individual. However, chemical stimuli in communication between humans are probably very important for some functions that have not been fully explored. Pheromones (*pherein*, “to carry”; *hormon*, “exciting”), that is, odorants exuded from the body as well as perfumes, play a part in sexual attraction; noxious body odors repel. In certain vertebrates the olfactory system is remarkably well developed, rivaling the sensitivity of the visual system, but even humans, in whom the sense of smell is relatively weak, have the capacity to discriminate between as many as 10,000 different odorants (Reed).

Disorders of taste and smell can be persistently unpleasant, but only rarely is the loss of either of these modalities a serious handicap. Nevertheless, as all foods and inhalants pass through the mouth and nose, these two senses serve to detect noxious odors (e.g., smoke) and to avoid tainted food and potential poisons. The loss of these senses could then have serious consequences. Also, because a loss of taste and smell may signify a number of intracranial, neurodegenerative, and systemic disorders, they assume clinical importance.

OLFACTORY SENSE

Anatomic and Physiologic Considerations

Nerve fibers subserving the sense of smell have their cells of origin in the mucous membrane of the upper and posterior parts of the nasal cavity (superior turbinates and nasal septum). The entire olfactory mucosa covers an area of about 2.5 cm² and contains three cell types: the olfactory or receptor cells, which number between 6 and 10 million in each nasal cavity; sustentacular or supporting cells,

which maintain the electrolyte (particularly K) levels in the extracellular milieu; and basal cells, which are stem cells and the source of both the olfactory and sustentacular cells during regeneration. The olfactory cells are actually bipolar neurons. Each of these cells has a peripheral process (the olfactory rod) from which project 10 to 30 fine hairs, or cilia. These hair-like processes, which lack motility, are the sites of olfactory receptors.

The central processes of these cells, or *olfactory fila*, are very fine (0.2 mm in diameter) unmyelinated fibers that converge to form small fascicles enwrapped by Schwann cells that pass through openings in the cribriform plate of the ethmoid bone into the olfactory bulb (Fig. 12-1). Collectively, the central processes of the olfactory receptor cells constitute the *first cranial (olfactory) nerve*. Notably, this is the only site in the body where neurons are in direct contact with the external environment. The epithelial surface is covered by a layer of mucus, which is secreted by tubuloalveolar cells (Bowman glands) and within which there are immunoglobulins A and M, lactoferrin, and lysoenzyme as well as odorant-binding proteins. These molecules are thought to prevent the intracranial entry of pathogens via the olfactory pathway (Kimmelman).

In the olfactory bulb, the receptor-cell axons synapse with granule cells and mitral cells (so-called because they are triangular, like a bishop’s miter), the dendrites of which form brush-like terminals or olfactory glomeruli (Fig. 12-1). Smaller “tufted” cells in the olfactory bulb also contribute dendrites to the glomerulus. Approximately 15,000 olfactory-cell axons converge on a single glomerulus. This high degree of convergence is thought to account for an integration of afferent information. The mitral and tufted cells are excitatory; the granule cells—along with centrifugal fibers from the olfactory nuclei, locus ceruleus, and piriform cortex—inhibit mitral cell activity. Presumably, interaction between these excitatory and inhibitory neurons provides the basis for the special physiologic aspects of olfaction.

The axons of the mitral and tufted cells form the olfactory tract, which courses along the olfactory groove of the cribriform plate to the cerebrum. Lying caudal to the olfactory bulbs are groups of cells that constitute the anterior olfactory nucleus (Fig. 12-1). Dendrites of these cells synapse with fibers of the olfactory tract, while their

Figure 12-1. Diagram illustrating the relationships between the olfactory receptors in the nasal mucosa and neurons in the olfactory bulb and tract. Cells of the anterior olfactory nucleus are found in scattered groups caudal to the olfactory bulb. Cells of the anterior olfactory nucleus make immediate connections with the olfactory tract. They project centrally via the medial olfactory stria and to contralateral olfactory structures via the anterior commissure. *Inset:* diagram of the olfactory structures on the inferior surface of the brain (see text for details).

axons project to the olfactory nucleus and bulb of the opposite side; these neurons are thought to function as a reinforcing mechanism for olfactory impulses.

Posteriorly, the olfactory tract divides into medial and lateral olfactory striae. The medial stria contains fibers from the anterior olfactory nucleus; these pass to the opposite side via the anterior commissure. Fibers in the lateral stria originate in the olfactory bulb, give off collaterals to the anterior perforated substance, and terminate in the medial and cortical nuclei of the amygdaloid complex and the prepiriform area (also referred to as the lateral olfactory gyrus). The latter represents the *primary olfactory cortex*, which in humans occupies a restricted area on the anterior end of the parahippocampal gyrus and uncus (area 34 of Brodmann; see Figs. 22-1 and 22-2). Thus olfactory impulses reach the cerebral cortex without a relay through the thalamus; in this respect also, olfaction is unique among sensory systems. From the prepiriform cortex, fibers project to the neighboring entorhinal cortex (area 28 of Brodmann) and the medial dorsal nucleus of the thalamus; the amygdaloid nuclei connect with the hypothalamus and septal

nuclei. The role of these latter structures in olfaction is not well understood, but presumably they subserve reflexes related to eating and sexual function. As with all sensory systems, feedback regulation occurs at every point in the afferent olfactory pathway.

In quiet breathing, little of the air entering the nostril reaches the olfactory mucosa; sniffing carries the air into the olfactory crypt, which contains the olfactory receptors. To be perceived as an odor, an inhaled substance must be volatile—i.e., spread in the air as very small particles—and soluble in water. Molecules provoking the same odor seem to be related by their shape than by their chemical quality. When a jet of scented vapor is directed to the sensory epithelium, as by sniffing, a slow negative potential shift called the *electroolfactogram* (EOG) can be recorded from an electrode placed on the mucosa. The conductance changes that underlie this receptor potential are induced by molecules of odorous material dissolved in the mucus overlying the receptor.

The transduction of odorant stimuli to electrical signals is mediated in part by a guanosine triphosphate (GTP)-dependent adenylyl cyclase (“G protein”). Like

other cyclic adenosine monophosphate (AMP) pathways, this one utilizes the same intracellular *second messenger*, which opens a voltage gated calcium channel in the receptor. There follow conformational changes in transmembrane receptor proteins and a series of intracellular biochemical events that generate axon potentials.

Intensity of olfactory sensation is determined by the frequency of firing of afferent neurons. The quality of the odor is thought to be provided by “cross-fiber” activation and integration, as described earlier, because the individual receptor cells are responsive to a wide variety of odorants and exhibit different types of responses to stimulants—excitatory, inhibitory, and on-off responses have been obtained. The olfactory potential can be eliminated by destroying the olfactory receptor surface or the olfactory filaments. The loss of EOG occurs 8 to 16 days after severance of the nerve; the receptor cells disappear, but the sustentacular (Sertoli) cells are not altered. As a result of division of the basal cells of the olfactory epithelium, the olfactory receptor cells are constantly dying and being replaced by new ones. In this respect, the chemoreceptors, both for smell and for taste, constitute one of the few examples of neuronal regeneration in humans.

The trigeminal system also participates in chemesthesis through undifferentiated receptors in the nasal mucosa. These receptors have little discriminatory ability but a great sensitivity to irritant stimuli. The trigeminal afferents also release neuropeptides that result in hypersecretion of mucus, local edema, and sneezing. Finally, stimulation of the olfactory pathway at cortical sites of the temporal lobe may also induce olfactory experiences.

The olfactory system adapts quickly to a sensory stimulus, and for sensation to be sustained, there must be repeated stimulation. The olfactory sense differs from other senses in yet another way. It is common experience that an aroma can restore long-forgotten memories of complex experiences. That olfactory and emotional stimuli are strongly linked is not surprising in view of their common roots in the limbic system. Yet, paradoxically, the ability to recall an odor is negligible in comparison with the ability to recall sounds and sights. As Vladimir Nabokov has remarked, “Memory can restore to life everything except smells.” It is also interesting that dreams do not embody olfactory experiences.

The remarkable evolutionary role of olfactory receptors can be appreciated by the fact that about 2 percent of the human genome exists to express unique odorant receptors (over 500 distinct genes). The wide diversity of these transmembrane proteins permits subtle differentiation of thousands of different odorant molecules, as delineated by Young and Trask and the genetic basis for which Buck and Axel were awarded a Nobel Prize.

This specificity for molecules is encoded neuroanatomically. Different odorant molecules activate specific olfactory receptors. Each olfactory neuron expresses only one allele of one receptor gene. Moreover, each olfactory glomerulus receives inputs from neurons expressing only one type of odorant receptor. In this way, each of the glomeruli is attuned to a distinct type of odorant stimulus. Presumably, this encoding is preserved in the olfactory cortex.

Something is to be learned from a second, distinct olfactory system in many animals (the vomeronasal olfactory system or organ of Jacobson), in which the repertoire of olfactory receptors is much more limited than in their main olfactory system. This functionally and anatomically distinct olfactory tissue is attuned to pheromones and thereby importantly influences menstrual, reproductive, ingestive, and defensive behavior (see review of Wysocki and Meredith). The vomeronasal receptors employ different signaling mechanisms than other olfactory receptors and project to the hypothalamus and amygdala via a distinct accessory olfactory bulb.

Clinical Manifestations of Olfactory Lesions

Disturbances of olfaction may be subdivided into four groups, as follows:

1. *Quantitative abnormalities*: loss or reduction of the sense of smell (anosmia, hyposmia) or, rarely, increased olfactory acuity (hyperosmia)
2. *Qualitative abnormalities*: distortions or illusions of smell (dysosmia or parosmia)
3. *Olfactory hallucinations and delusions* caused by temporal lobe disorders or psychiatric disease
4. *Higher-order loss* of olfactory discrimination (olfactory agnosia)

Anosmia, or Loss of the Sense of Smell (Table 12-1)

This is the most frequent clinical abnormality and, if unilateral, usually is not recognized by the patient. Unilateral anosmia can sometimes be demonstrated in the hysterical patient on the side of anesthesia, blindness, or deafness. Bilateral anosmia, on the other hand, is a common complaint, and the patient is usually convinced that the sense of taste has been lost as well (*ageusia*). This calls attention to the fact that taste depends largely on the volatile particles in foods and beverages, which reach the olfactory receptors through the nasopharynx, and that the perception of flavor is a combination of smell, taste, and tactile sensation. This can be proved by demonstrating that patients with anosmia but without a complaint of ageusia are able to distinguish the elementary taste sensations on the tongue (sweet, sour, bitter, and salty). The olfactory defect can be verified readily enough by presenting a series of nonirritating olfactory stimuli (vanilla, peanut butter, coffee, tobacco) and asking the patient to sniff once and identify them. If the odors can be detected and described, even if they cannot be named, it may be assumed that the olfactory nerves are relatively intact (humans can distinguish many more odors than they can identify by name). If they cannot be detected, there is an olfactory defect. Ammonia and similar pungent substances are unsuitable stimuli because they do not test the sense of smell but have a primary irritating effect on the mucosal-free nerve endings of the trigeminal nerves.

The value of testing smell in one nostril at a time has been questioned, for example by Welge-Luessen and colleagues, who studied olfactory groove meningiomas.

Table 12-1

MAIN CAUSES OF ANOSMIA

Nasal

Smoking

Chronic rhinitis (allergic, atrophic, cocaine, infectious—herpes, influenza)

Overuse of nasal vasoconstrictors

Olfactory epithelium

Head injury with tearing of olfactory filaments

Cranial surgery

Subarachnoid hemorrhage, meningitis

Toxic (organic solvents, certain antibiotics—aminoglycosides, tetracyclines, corticosteroids, methotrexate, opiates, L-dopa)

Metabolic (thiamine and B12 deficiency, adrenal and thyroid deficiency, cirrhosis, renal failure, menses)

Wegener granulomatosis

Compressive and infiltrative lesions (craniopharyngioma, meningioma, aneurysm, meningoencephalocele)

Central

Degenerative diseases (Parkinson, Alzheimer, Huntington)

Temporal lobe epilepsy

Malingering and hysteria

They found, contrary to expectations, that this test was not sensitive to the presence of a unilateral lesion, ostensibly because of mixing of air in the nasopharynx. Nonetheless, other experience suggests that rapidly sniffing through one nostril does briefly allow segregation of each side of the nasal cavities and can detect unilateral lesions.

A more elaborate scratch-and-sniff test has been developed and standardized by Doty and colleagues (University of Pennsylvania Smell Identification Test). In this test the patient attempts to identify 40 microencapsulated odorants, and olfactory performance is compared with that of age- and sex-matched normal individuals. Unique features of this test are a means for detecting malingering and amenability to self-administration. Air-dilution olfactory detection is an even more refined way of determining thresholds of sensation and of demonstrating normal olfactory perception in the absence of odor identification. The use of olfactory evoked potentials is being investigated in some electrophysiology laboratories, but their reliability is uncertain. These last two refined techniques are essentially research tools and are not used in neurologic practice.

The loss of smell usually falls into one of three categories: *nasal* (in which odorants do not reach the olfactory receptors), *olfactory neuroepithelial* (caused by destruction of receptors or their axon filaments), and *central* (olfactory pathway lesions).

Viewed from another perspective, in an analysis of 4,000 cases of anosmia from specialized clinics, Hendriks found that the three most common diagnoses were viral infection of the upper respiratory tracts (the largest group), nasal or paranasal sinus disease, and head injury.

Regarding the nasal diseases responsible for bilateral hyposmia or anosmia, the most frequent are those in which hypertrophy and hyperemia of the nasal mucosa prevent olfactory stimuli from reaching the receptor cells. Heavy smoking is probably the most frequent cause of

hyposmia in clinical practice. Chronic atrophic rhinitis; sinusitis of allergic, vasomotor, or infective types; nasal polyposis; and overuse of topical vasoconstrictors are other common causes. Biopsies of the olfactory mucosa in cases of allergic rhinitis have shown that the sensory epithelial cells are still present, but their cilia are deformed and shortened and are buried under other mucosal cells. Influenza, herpes simplex, and hepatitis virus infections may be followed by hyposmia or anosmia caused by destruction of receptor cells; if the basal cells are also destroyed, this may be permanent. These cells may also be affected as a result of atrophic rhinitis and local radiation therapy or by a rare type of tumor (*esthesioneuroblastoma*) that originates in the olfactory epithelium. There is also a group of uncommon diseases in which the primary receptor neurons are congenitally absent or hypoplastic and lack cilia. One of these is the Kallmann syndrome of congenital anosmia and hypogonadotropic hypogonadism. A similar disorder occurs in Turner syndrome and in albinos because of an ill-defined congenital structural defect.

Anosmia that follows head injury is most often a result of tearing of the delicate filaments of the receptor cells as they pass through the cribriform plate, especially if the injury is severe enough to cause fracture. The damage may be unilateral or bilateral. With closed head injury, complete anosmia is relatively infrequent (6 percent of Sumner's series of 584 cases), but lesser degrees are common in our experience. Some recovery of olfaction occurs in about one-third of cases over a period of several days to months. Beyond 6 to 12 months, recovery is negligible. Cranial surgery, subarachnoid hemorrhage, and chronic meningeal inflammation may have similar effects.

In some of the cases of traumatic anosmia, there is also a loss of taste (ageusia). Ferrier, who first described traumatic ageusia in 1876, noted that there was always anosmia as well—an observation subsequently corroborated by Sumner. Often, the ageusia also clears within a few weeks. A bilateral traumatic lesion near the frontal operculum and paralimbic region, where olfactory and gustatory receptive zones are in close proximity, would best explain this concurrence, but this has not been proven. As stated earlier, the interruption of olfactory filaments alone would explain a reduction in the ability to perceive the subtleties of specific flavors, but not ageusia.

Olfactory acuity varies throughout the menstrual cycle, possibly through the imputed vomeronasal system in humans, and may be disordered during pregnancy. Nutritional and metabolic diseases such as thiamine deficiency (Wernicke disease), vitamin A deficiency, adrenal and perhaps thyroid insufficiency, cirrhosis, and chronic renal failure may give rise to anosmia, all as a result of sensorineural dysfunction. A large number of toxic agents—the more common ones being organic solvents (benzene), metals including platinum-containing chemotherapies, dusts, cocaine, corticosteroids, methotrexate, aminoglycoside antibiotics, tetracyclines, opiates, and L-dopa—can damage the olfactory epithelium (Doty et al). Alcoholics with Korsakoff psychosis also have a defect in odor discrimination (Mair et al). In this disorder, anosmia is presumably caused by degeneration of neurons

in the higher-order olfactory systems involving the medial thalamic nuclei.

Anosmia has been found in some patients with temporal lobe epilepsy and particularly in such patients who had been subjected to anterior temporal lobectomy. In these conditions, Andy and coworkers have found impairment in discriminating the quality of odors and in matching odors with test objects seen or felt.

As with other sensory modalities, olfaction (and taste) is diminished with aging (presbyosmia). The receptor cell population is depleted, and if the loss is regional, neuroepithelium is slowly replaced with respiratory epithelium (which is normally present in the nasal cavity and serves to filter, humidify, and warm incoming air). Neurons of the olfactory bulb may also be reduced as part of the aging process.

Bilateral anosmia has been a manifestation of *malingering*, now that it has been recognized as a compensable disability. The fact that true anosmics will complain inordinately of a loss of taste (but show normal taste sensation) may help to separate them from malingerers. If it were to be perfected, testing of olfactory evoked potentials would be of use here.

The nasal epithelium or the olfactory nerves themselves may be affected in Wegener granulomatosis and by craniopharyngioma, respectively. A meningioma of the olfactory groove may implicate the olfactory bulb and tract and may extend posteriorly to involve the optic nerve, sometimes with optic atrophy; if combined with papilledema on the opposite side, these abnormalities are known as the Foster Kennedy syndrome (see Chap. 13). A large aneurysm of the anterior cerebral or anterior communicating artery may produce a similar constellation. With tumors confined to one side, the anosmia may be strictly unilateral, in which case it will not be reported by the patient but will be found on examination. The limitations of testing each side of the nose separately have been mentioned earlier. These defects in the sense of smell are attributable to lesions of either the receptor cells and their axons or the olfactory bulbs, and current test methods do not distinguish between lesions in these two localities. In some cases of increased intracranial pressure, olfactory sense has been impaired without evidence of lesions in the olfactory bulbs.

The term *specific anosmia* has been applied to an unusual olfactory phenomenon in which a person with normal olfactory acuity for most substances encounters a particular compound or class of compounds that is odorless to him, although obvious to others. In a sense, this is a condition of "smell blindness," analogous to color blindness. The basis of this disorder is unclear, although there is evidence that specific anosmia for musky and uriferous odors is inherited as an autosomal recessive trait (see Amoore).

Whether a true *hyposmia* exists is a matter of conjecture, but it is so frequently reported by migraineurs that the problem seems worthy of attention. Anxious, highly introspective individuals may complain of being unduly sensitive to odors, but there is no proof of an actual change in their threshold of perception of odors. This issue comes into play in institutions with large numbers of persons who claim to be "chemosensitive" to certain

odors and induce a ban on these substances. The validity of this claim is in doubt.

Olfaction in Neurodegenerative Disease Hyman and colleagues have emphasized the many earlier observations of an early neuronal degeneration in the olfactory region of the hippocampus in cases of Alzheimer disease, Lewy body, and Parkinson disease. Moreover, a large proportion of patients with other degenerative diseases of the brain have anosmia or hyposmia. A number of theories have been proposed to explain the initial loss of smell, the most relevant of which is based on the finding that the earliest neuropathologic changes of many neurodegenerative processes begin in olfactory structures and then appears serially in neighboring structures, only later reaching the parts of the brain that produces the characteristic neurologic features of these diseases. The implication from these findings, originating with Braak and Braak, has been that Lewy bodies in particular are caused by a pathogen that enters through the peripheral olfactory system and proceeds centrally through the medial temporal lobe. Prions have been suggested as a candidate agent because of their ability to alter protein folding and to transfer this property in a sequentially topographic manner. The studies relating to olfaction in Parkinson disease have been reviewed by Doty, Braak and colleagues, and Benarroch. It should be emphasized to patients, however, that the reverse is not the case; i.e., the majority of individuals with hyposmia do not have a generalized neurodegenerative disease.

Dysosmia or Parosmia

These terms refer to distortions of odor perception where an odor is present. Parosmia may occur with local nasopharyngeal conditions such as infection of the nasal sinuses and upper respiratory infections. In some instances, the abnormal tissue itself may be the source of unpleasant odors; in others, where partial injuries of the olfactory bulbs have occurred, parosmia is in the nature of an olfactory illusion. Parosmia may also be a troublesome symptom in persons with depressive and psychotic illnesses, who may report that every article of food has an extremely unpleasant odor (cacosmia). Sensations of disagreeable taste are often associated (cacogeusia). Nothing is known of the basis of this state; there is usually no loss of discriminative sensation.

The treatment of parosmia is difficult. The use of neuroleptic or antiepileptic drugs has given unpredictable results. Claims for the efficacy of zinc and vitamins have not been verified (and there is a risk that zinc administration may interfere with the absorption of copper). Some reports indicate that repeated anesthetization of the nasal mucosa reduces or abolishes the parosmic disturbance. In many cases, the disorder subsides spontaneously. Minor degrees of parosmia are not necessarily abnormal, for unpleasant odors have a way of lingering for several hours and of being reawakened by other olfactory stimuli, as every pathologist knows.

Olfactory Hallucinations

The report of an odor without stimulus, olfactory hallucination, is always of central origin. The patient perceives

an odor that no one else can detect (phantosmia). Most often this a manifestation of temporal lobe seizures (“uncinate fits”), in which circumstances the olfactory hallucinations are brief and accompanied or followed by an alteration of consciousness and other manifestations of epilepsy (see Chap. 16 on epilepsy).

If the patient is convinced of the presence of what is in fact a hallucination and also gives it personal origin, the symptom assumes the status of a delusion (a fixed false belief). The combination of olfactory hallucinations and delusions of this type signifies a psychiatric illness. Zilstorff wrote informatively on this subject. There is often a complaint of a large array of odors, most of them noxious and seemingly emanating from the patient (intrinsic hallucinations); in others, they are attributed to an external source (extrinsic hallucinations). Both types vary in intensity and are remarkable with respect to their persistence. They may be combined with gustatory hallucinations. According to Pryse-Phillips, who took note of the psychiatric illness in a series of 137 patients with olfactory hallucinations, most were associated with endogenous depression or schizophrenia. In schizophrenia, the olfactory stimulus is usually interpreted as arising externally, and as being induced by someone for the purpose of upsetting the patient. In depression, the perception is of the stimulus being intrinsic. The patient may go to great lengths to rid himself of the perceived odor, the usual ones being excessive washing and use of deodorants; the condition may lead to social withdrawal. There is reason to believe that the amygdaloid group of nuclei is the source of the hallucinations, as stereotactic lesions here have reportedly ameliorated both the olfactory hallucinations and the psychiatric disorder (see Chitanondh).

Olfactory hallucinations and delusions may occur in conjunction with Alzheimer dementia, but one should also consider the possibility of a late-life depression.

Loss of Olfactory Discrimination (Olfactory Agnosia)

Finally, one must consider a disorder in which the primary perceptual aspects of olfaction (detection of odors, adaptation to odors, and recognition of different intensities of the same odor) are intact, but the capacity to distinguish between odors and their recognition by quality is impaired or lost. In the writings on this subject, this deficit is usually referred to as a disorder of olfactory discrimination. In dealing with other sense modalities, however, the inability to identify and name a perceived sensation would be called an *agnosia*. To recognize this deficit requires special testing, such as matching to sample, the identification and naming of a variety of scents, and determining whether two odors are identical or different.

Such an alteration of olfactory function has been shown to characterize patients with the alcoholic form of Korsakoff psychosis; this impairment is not attributable to impaired olfactory acuity or to failure of learning and memory (Mair et al). As indicated above, the olfactory disorder in the alcoholic Korsakoff patient is most likely caused by lesions in the medial dorsal nucleus of the thalamus; several observations in animals indicate that

this nucleus and its connections with the orbitofrontal cortex give rise to deficits in odor discrimination (Mair et al; Slotnick and Kaneko). Eichenbaum and associates demonstrated a similar impairment of olfactory capacities in a patient who had undergone extensive bilateral medial temporal lobe resections. The operation was believed to have eliminated a substantial portion of the olfactory afferents to the frontal cortex and thalamus, although there was no anatomic verification of this. In patients with stereotactic or surgical amygdalotomies, Andy and coworkers noted a similar reduction in odor discrimination. Thus it appears that both portions of the higher olfactory pathways (medial temporal lobes, and medial dorsal nuclei) are necessary for the discrimination and identification of odors.

GUSTATORY SENSE

Anatomic and Physiologic Considerations

The sensory receptors for taste (taste buds) are distributed over the surface of the tongue and, in smaller numbers, over the soft palate, pharynx, larynx, and esophagus. Mainly they are located in the epithelium along the lateral surfaces of the circumvallate and foliate papillae and to a lesser extent on the surface of the fungiform papillae. The taste buds are round or oval structures, each composed of up to 200 vertically oriented receptor cells arranged like the staves of a barrel. The superficial portion of the bud is marked by a small opening, the taste pore or pit, which opens onto the mucosal surface. The tips of the sensory cells project through the pore as a number of filiform microvilli (“taste hairs”). Fine, unmyelinated sensory fibers penetrate the base of the taste bud and synapse directly with the sensory taste cells, which have no axons.

The taste receptors are activated by chemical substances in solution and transmit their activity along the sensory nerves to the brainstem. There are four primary and readily tested taste sensations that have been long known: salty, sweet, bitter, and sour; recently a fifth, *umami*, signifying a savory taste—the taste of glutamate, aspartate, and certain ribonucleotides—has been added. The full range of taste sensations is much broader, consisting of combinations of these elementary gustatory sensations. Older notions of a “tongue map,” which implied the existence of specific areas subserving one or another taste, are incorrect. Any one taste bud is capable of responding to a number of sapid substances, but it is always preferentially sensitive to one type of stimulus. In other words, the receptors are only relatively specific. The sensitivity of these receptors is remarkable: as little as 0.05 mg/dL of quinine sulfate will arouse a bitter taste when applied to the base of the tongue.

A G-protein transduction system (gustducin), similar to the one for olfaction, has been found to be operative in signaling taste sensations in the tongue receptors. A discussion of this system can be found in the commentary by Brand.

The receptor cells of the taste buds have a brief life cycle (about 10 days), being replaced constantly by mitotic division of adjacent basal epithelial cells. The number of taste buds, not large to begin with, is gradually reduced with age; also, changes occur in the taste cell membranes, with impaired function of ion channels and receptors (Mistretta). Gustatory (and olfactory) acuity diminishes with age (everything begins to taste and smell the same). According to Schiffman, taste thresholds for salt, sweeteners, and amino acids are 2 to 2.5 times higher in the elderly than in the young. The reduction in the acuity of taste and smell with aging may lead to a distortion of food habits (e.g., excessive use of salt and other condiments) and contribute to the anorexia and weight loss of elderly persons.

Richter has explored the biologic role of taste in normal nutrition. Animals made deficient in sodium, calcium, certain vitamins, proteins, etc., will automatically select the correct foods, on the basis of their taste, to compensate for their deficiency. Interesting genetic polymorphisms in the receptor for sweet substances in rats have been found to underlie differences in the proclivity to ingest sweet substances, and a similar system has been proposed in humans (Chaudhari and Kinnamon).

Neural Innervation of the Tongue

Sensory impulses for taste arise from several sites in the oropharynx and are transmitted to the medulla via several cranial nerves (V, VII, IX, and X). The main pathway arises on the *anterior two-thirds of the tongue*; these taste fibers first run in the lingual nerve (a major branch of the mandibular-trigeminal [V] cranial nerve). After coursing within the lingual nerve for a short distance, the taste fibers diverge to enter the chorda tympani (a branch of the seventh nerve); thence they pass through the pars intermedia and geniculate ganglion of the seventh nerve to the rostral part of the nucleus of the tractus solitarius in the posterolateral medulla, where all taste afferents converge (see below and Fig. 47-3).

From the *posterior one-third of the tongue*, soft palate, and palatal arches, the sensory taste fibers are conveyed via the glossopharyngeal (IX) nerve and ganglion nodosum to the nucleus of the tractus solitarius. Taste fibers from the extreme dorsal part of the tongue and the few that arise from taste buds on the pharynx and larynx run in the vagus nerve. The *gustatory nucleus* is situated in the rostral and lateral parts of the nucleus tractus solitarius, which receive the special afferent (taste) fibers from the facial and glossopharyngeal nerves. Probably both sides of the tongue are represented in this nucleus.

Fibers from the palatal taste buds pass through the pterygopalatine ganglion and greater superficial petrosal nerve, join the facial nerve at the level of the geniculate ganglion, and proceed to the nucleus of the solitary tract (see Fig. 47-3). Possibly, some taste fibers from the tongue may also reach the brainstem via the mandibular division of the trigeminal nerve. The presence of this alternative pathway probably accounts for reported instances of unilateral taste loss that have followed section of the root of the trigeminal nerve and instances in

which no loss of taste has occurred with section of the chorda tympani.

The second sensory neuron for taste has been difficult to track. Neurons from the gustatory segment of the nucleus solitarius project to adjacent nuclei (e.g., dorsal motor nucleus of the vagus, ambiguus, salivatorius superior and inferior, trigeminal, and facial nerves), which serve viscerovisceral and viscerosomatic reflex functions, but those concerned with the conscious recognition of taste are currently considered to form an ascending pathway to a pontine parabrachial nucleus. From the latter, two ascending pathways have been traced (in animals). One is the solitariothalamic lemniscus to the ventroposteromedial nucleus of the thalamus. A second passes to the ventral parts of the forebrain, to parts of the hypothalamus (which probably influences autonomic function), and to other basal forebrain limbic areas in or near the uncus of the temporal lobe. Other ascending fibers lie near the medial lemniscus and are both crossed and uncrossed. Experiments in animals indicate that taste impulses from the thalamus project to the tongue-face area of the postrolandic sensory cortex. This is probably the end station of gustatory projections in humans as well, insofar as gustatory hallucinations have been produced by electrical stimulation of the parietal and/or rolandic opercula (Hausser-Hauw and Bancaud). Penfield and Faulk evoked distinct taste sensations by stimulating the anterior insula.

Clinical Manifestations of Disorders of Taste

Testing of Taste Sensation

Unilateral gustatory impairment can be identified by withdrawing the tongue with a gauze sponge and using a moistened applicator to place a few crystals of salt, sugar, lemon (sour), and quinine (bitter) on discrete parts of the tongue; the tongue is then wiped clean and the subject is asked to report what he had sensed. One use of such testing is to corroborate the existence of Bell palsy by comparing taste sensation on each side of the anterior tongue (see Chap. 47). A stimulus that has been used as a surrogate for sour sensation is a low-voltage direct current, the electrodes of which can be accurately placed on the tongue surface. If the taste loss is bilateral, mouth-washes with a dilute solution of sucrose, sodium chloride, citric acid, and quinine may be used. After swishing, the test fluid is spit out and the mouth rinsed with water. The patient indicates whether he had tasted a substance and is asked to identify it. Special types of apparatus (electrogustometers) have been devised for the measurement of taste intensity and for determining the detection and recognition thresholds of taste and olfactory stimuli (Krarup; Henkin et al), but these are beyond the needs of the usual clinical examination.

Causes of Loss of Taste

Apart from the loss of taste sensation that accompanies normal aging, smoking is probably the most common cause of impairment of taste sensation. Extreme drying

of the tongue from any cause may lead to temporary loss or reduction of the sense of taste (*ageusia* or *hypogeusia*), as saliva is essential for normal taste function. Saliva acts as a solvent for chemical substances in food and for conveying them to taste receptors. Dryness of the mouth (*xerostomia*) from inadequate saliva, as occurs in Sjögren syndrome; hyperviscosity of saliva, as in cystic fibrosis; irradiation of head and neck; and *pandysautonomia* all interfere with taste. Also, in *familial dysautonomia* (Riley-Day syndrome), the number of circumvallate and fungiform papillae is reduced, accounting for a diminished ability to taste sweet and salty foods. If unilateral, *ageusia* is seldom the source of complaint. Taste is frequently lost over the anterior two-thirds of one side of the tongue in cases of *mundane Bell palsy*, as indicated above and in Chap. 47.

A permanent decrease in the acuity of taste and smell (*hypogeusia* and *hyposmia*), sometimes associated with perversions of these sensory functions (*dysgeusia* and *dysosmia*), may follow influenza-like illnesses. These abnormalities have been associated with pathologic changes in the taste buds as well as in the nasal mucous membranes. In a group of 143 patients who presented with *hypogeusia* and *hyposmia*, 87 were of this postinfluenzal type, as determined by Henkin and colleagues; the remainder developed their symptoms in association with *scleroderma*, *acute hepatitis*, *viral encephalitis*, *myxedema*, *adrenal insufficiency*, *malignancy*, *deficiency of vitamins B and A*, and the administration of a wide variety of drugs. Also, according to Schiffman, more than 250 drugs have been implicated in the alteration of taste sensation, making it necessary to consider virtually all drugs as a cause of taste loss. Lipid-lowering drugs, antihistamines, antimicrobials, antineoplastics, bronchodilators, antidepressants, and antiepileptics are the main offenders, but little is known about the mechanisms by which drugs induce these effects. More obvious is altered taste because of nasally and orally administered inhaled drugs, including the "triptans" for migraine and a variety of anti-allergy and antiasthmatic medications.

Distortions of taste and loss of taste are sources of complaint in patients with certain local malignant tumors. Oropharyngeal tumors may, of course, abolish taste by invading the *chorda tympani* or lingual nerves and basal skull. Malnutrition because of neoplasm or radiation therapy may also cause *ageusia*. Some patients with certain cancers remark on a reduced perception for bitter foods, and some who have been radiated for breast cancer or sublingual or oropharyngeal tumors find sour foods intolerable. The loss of taste from radiation of the oropharynx is usually recovered within a few weeks or months; the reduced turnover of taste buds caused by radiation therapy usually recovers.

An interesting syndrome of *idiopathic hypogeusia*—in which decreased taste acuity is associated with *dysgeusia*, *hyposmia*, and *dysosmia*—has been described by

Henkin, Schechter and colleagues. Food has an unpleasant taste and aroma, to the point of being revolting (*cacogeusia* and *cacosmia*); the persistence of these symptoms may lead to a loss of weight, anxiety, and depression.

Unilateral lesions of the *medulla oblongata* have not been reported to cause *ageusia*, perhaps because the nucleus of the *tractus solitarius* is usually outside the zone of infarction or because there is representation from both sides of the tongue in each nucleus. Unilateral thalamic and parietal lobe lesions, however, have both been associated with contralateral impairment of taste sensation in rare cases.

As indicated above, a gustatory aura occasionally marks the beginning of a seizure originating in the frontoparietal (suprasylvian) cortex or in the uncus region. Gustatory hallucinations are much less frequent than olfactory ones. Nevertheless, gustatory sensations were reported in 30 of 718 cases of intractable epilepsy (Hausser-Hauw and Bancaud). During surgery, these investigators produced an aura of disagreeable taste by electrical stimulation of the parietal and frontal opercula, and also by stimulation of the hippocampus and amygdala (uncinate seizures). In their view, the low-threshold seizure focus for taste in the temporal lobe is secondary to functional disorganization of the opercular gustatory cortex by the seizure. Gustatory hallucinations were more frequent with right-hemisphere lesions, and in half of the cases, the gustatory aura was followed by a convulsion.

Zinc supplements are contained in over-the-counter and complementary medical products aimed at improving smell and appetite and for the treatment of incipient colds. We have had no opportunity to confirm the oft-cited benefits of zinc on any of these conditions, and the supporting evidence is sparse, however, the continued administration of zinc in high doses has been associated with the development of copper deficiency and a myeloneuropathy (see Chap. 38).

Burning Mouth Syndrome Another poorly defined disorder is the *burning mouth syndrome*, which occurs mainly in postmenopausal women and is characterized by persistent, severe intraoral pain (particularly of the tongue). We have seen what we believe to be fragmentary forms of the syndrome in which pain and burning are isolated to the alveolar ridge or gingival mucosa. The oral mucosa appears normal and some patients may report a diminution of taste sensation. A small number of such patients prove to have diabetes, Sjögren syndrome, or vitamins B₂ or B₁₂ deficiency (causing glossitis), but in most no systemic illness or local abnormality can be found. Many such patients that we have encountered appeared to have a depressive illness, but they responded only inconsistently to administration of antidepressants. A few patients have this oral complaint as a component of a small fiber neuropathy or ganglionopathy (see Chap. 46). Clonazepam may be useful, and capsaicin has been tried with uncertain results. This disorder is also commented on in Chap. 10.

Disturbances of Vision

The importance of the visual system is attested by the magnitude of its representation in the central nervous system (CNS). A large part of the cerebrum is committed to vision, including the visual control of movement and the perception of printed words, and the form and color of objects. The optic nerve, which is a CNS structure, contains more than a million fibers (compared to 50,000 in the auditory nerve). The visual system also has special significance in that study of this system has greatly advanced our knowledge of both the organization of all sensory neuronal systems and the relation of perception to cognition. Indeed, we know more about vision than about any other sensory function. Furthermore, the eyes, because of their diverse composition of epithelial, vascular, neural, and pigmentary tissues, are virtually a medical microcosm, susceptible to many diseases, and its tissues are available for inspection through a transparent medium.

Impairment of visual function, expressed as defects in acuity and alterations of visual fields, obviously stands as the most important symptom of eye disease. A number of terms are commonly used to describe visual loss. *Amaurosis* is a general term that refers to partial or complete loss of sight. *Amblyopia* refers to any monocular deficit in vision that occurs in the presence of normal ocular structures. A major cause of amblyopia is the suppression by the brain of vision from one eye during early childhood caused by either strabismus, anisometropia (a significant difference in refractive error), or by media opacities. *Nyctalopia* is the term for poor twilight or night vision and is associated with extreme myopia, cataracts, vitamin A deficiency, retinitis pigmentosa, and, often, color blindness. There are also a number of positive visual symptoms (phosphenes, migrainous scintillations, visual illusions, and hallucinations), but they are generally less significant than symptoms of visual loss. Irritation, redness, photophobia, pain, diplopia and strabismus, changes in pupillary size, and drooping or closure of the eyelids are other major ocular symptoms and signs. Impairment of vision may be unilateral or bilateral, sudden or gradual, episodic or enduring.

The common causes of failing eyesight vary with age. In infancy, congenital defects, retinopathy of prematurity, severe myopia, hypoplasia of the optic nerve, optic pits, and coloboma are the main causes. In childhood and

adolescence, nearsightedness or myopia, and amblyopia as a result of strabismus are the usual causes (see Chap. 14), although a pigmentary retinopathy or a retinal, optic nerve, or suprasellar tumor may also begin at this age. In middle age, usually beginning in the fifth decade, a progressive loss of accommodation (presbyopia) is almost invariable (at this age, half or more of the amplitude of accommodative power is lost and must be replaced by plus lenses). Still later in life, cataracts, glaucoma, retinal vascular occlusion and detachments, macular degeneration, and tumor, unilateral or bilateral, are the most frequent causes of visual impairment.

As a rule, *episodic visual loss* in early adult life, often hemianopic, is the result of migraine. The other important cause of transient (weeks) monocular visual loss in this age period is optic neuritis, often a harbinger of multiple sclerosis. Amaurosis in the child or young adult may also be caused by systemic lupus erythematosus and the related antiphospholipid syndrome, or by migraine, or there may be no discernible cause. Later in life, transient monocular blindness, or *amaurosis fugax*, lasting minutes to hours is more common; it is caused by vascular disease, particularly stenosis of the ipsilateral carotid artery. Table 13-1 lists the main causes of episodic monocular visual loss. Of course, at any age, diseases of the retina and of other components of the ocular apparatus are important causes of *progressive visual loss*, and the problem may at first be transient.

APPROACH TO THE PROBLEM OF VISUAL LOSS

In the investigation of a disturbance of vision, one inquires as to what the patient means when he claims that he cannot see properly, for the disturbance in question may vary from near- or farsightedness to diplopia, partial syncope, dizziness, or a hemianopia. Fortunately, the patient's statement can be checked by the measurement of visual acuity, which is the single most important part of the ocular examination. Inspection of the refractive media and the optic fundi—especially the macular region—the testing of pupillary reflexes, color vision, and the plotting of visual fields complete this part of the

Table 13-1

CAUSES OF EPISODIC VISUAL LOSS

<i>Adolescence and young adulthood</i>

examination. Examination of the eye movements is also essential, particularly if amblyopia predicated on an early life strabismus is suspected, as discussed in Chap. 14.

In the measurement of distance visual acuity the *Snellen chart*, which contains letters (or numbers or pictures) arranged in rows of decreasing size, is used (Fig. 13-1A). Each eye is tested separately and, if glasses are required,

glasses for distance, not reading glasses, should be worn. The letter at the top of the chart subtends 5 min of an arc at a distance of 200 ft (or roughly 60 m). The patient follows rows of letters that can normally be read at lesser distances. Acuity is reported as a nonmathematical fraction that represents the patient's ability compared to that of a person with normal distance vision. Thus, if the patient can read only the top letter, which would be normally be visible at 200 feet, the acuity is expressed as 20/200, or if the distance is measured in meters rather than feet, as 6/60. If the patient's eyesight is normal, the visual acuity will equal 20/20, or 6/6, corresponding to the eighth line on most charts. Many persons, especially during youth, can read at 20 ft the line that can normally be read at 15 ft from the chart (20/15) and hence have better than "normal" vision.

For bedside testing, a "near card" or newsprint held 14 in from the eyes can be used, and the results expressed in a distance equivalent as if a distance chart had been used (Fig. 13-1B). Here, the Jaeger system is used (J1 is "normal" vision, corresponding to the line 20/25 on a Snellen chart, J5 to 20/50, J10 to 20/100, J16 to 20/200, and so on). In young children, acuity can be estimated by having them mimic the examiner's finger movements at varying distances or having them recognize and pick up objects of different sizes from varying distances. The Teller acuity cards test a child's preference (and hence

Figure 13-1. A. Conventional Snellen Chart and B. Jaeger Card for the estimation of visual acuity. The Snellen chart is placed 20 feet from the subject. The Jaeger card is used at 16 inches from the subject's eyes and approximates Snellen acuity if convergence and accommodation are normal.

ability) to view cards with increasingly fine stripes. In most jurisdictions, a corrected acuity of 20/40 or better in one eye is required to obtain and retain a driver's license.

If the visual acuity (with glasses) is less than 20/20, either the refractive error has not been properly corrected or there is some other reason for diminished acuity. The possibility of a nonrefractive error can usually be ruled out if the patient can read the 20/20 line (not the near card) through a pinhole in a cardboard held in front of the eye. The pinhole permits a narrow shaft of light to fall on the fovea (the area of greatest visual acuity) without distortion by the curvature of the lens; this eliminates the eye's optical system, thereby testing the macula alone, and should give an acuity of 20/20 if the structures of the ocular media (cornea, lens, aqueous and vitreous humors) are clear.

Light entering the eye is focused by the biconvex lens onto the outer layer of the retina. Consequently, the cornea, fluid of the anterior chamber, lens, vitreous, and retina itself must be transparent. The clarity of these media can be determined ophthalmoscopically, and a complete examination requires that the pupil be dilated to at least 6 mm in diameter. This is accomplished by instilling two drops of 2.5 percent phenylephrine and/or 0.5 to 1.0 percent tropicamide in each eye after the visual acuity has been measured, the pupillary response recorded, and the intraocular pressure estimated. In elderly persons, lower concentrations of these mydriatics should be used. The mydriatic action of phenylephrine lasts for 3 to 6 h. Rarely, an *attack of angle-closure glaucoma* (manifesting itself by diminished vision, ocular pain, nausea, and vomiting) may be precipitated by pharmacologic pupillary dilatation; this requires the administration of pilocarpine to the eye and the immediate attention of an ophthalmologist. It is advisable to have access to pilocarpine if the pupils are to be dilated.

By looking through a high-plus lens of the direct ophthalmoscope from a distance of 6 to 12 in, the examiner can visualize opacities in the refractive media; by adjusting the lenses from a high-plus to a zero or minus setting, it is possible to "depth-focus" from the cornea to the retina. Depending on the refractive error of the examiner, lenticular opacities are best seen within the range of +20 to +12. The retina comes into focus with +1 to -1 lenses. The illuminated pupil appears as a red circular structure (red reflex), the color being provided by blood in the capillaries of the choroid layer. If all the refractive media are clear, reduced vision that is uncorrectable by glasses is caused by a defect in the macula, the optic nerve, or parts of the brain with which they are connected. The main limit of direct ophthalmoscopy is its inability to visualize lesions in the retina that lie anterior to the equator of the globe; these are seen only by the indirect method.

NONNEUROLOGIC CAUSES OF REDUCED VISION

It is hardly possible within the confines of this chapter to describe all the causes of opacification of the refractive media. Those with the most important medical or neurologic

implications are briefly commented upon. Although changes in the refractive media do not involve neural tissue primarily, certain ones assume importance because they are associated with neurologic disease and provide clues to its presence.

In the *cornea*, the most common abnormality that reduces vision is scarring caused by trauma and infection. Ulceration and subsequent fibrosis may occur following recurrent herpes simplex, herpes zoster, and trachomatous infections of the cornea, or with certain mucocutaneous-ocular syndromes (Stevens-Johnson, Reiter). Hypercalcemia secondary to sarcoidosis, hyperparathyroidism, and vitamin D intoxication or milk-alkali syndrome may give rise to precipitates of calcium phosphate and carbonate beneath the corneal epithelium, primarily in a plane corresponding to the interpalpebral fissure—so-called band keratopathy. Other causes of corneal opacity include chronic uveitis, interstitial keratitis, corneal edema, lattice corneal dystrophy (amyloid deposition), and long-standing glaucoma. Polysaccharides are deposited in the corneas in some of the mucopolysaccharidoses (see Chap. 37), and copper is deposited in the Descemet membrane in hepatolenticular degeneration (Kayser-Fleischer ring). Crystal deposits may be observed in multiple myeloma and cryoglobulinemia. The corneas are also diffusely clouded in certain lysosomal storage diseases (see Chap. 37). Arcus senilis occurring at an early age (because of hyperlipidemia), sometimes combined with yellow lipid deposits in the eyelids and periorbital skin (xanthelasma), serves as a marker of atheromatous vascular disease.

In the *anterior chamber* of the eye, a common problem is impediment to the outflow of aqueous fluid, associated with excavation of the optic disc and visual loss, i.e., *glaucoma*. In more than 90 percent of cases (of the open-angle type), the cause of this syndrome is unknown and a genetic factor is suspected. The drainage channels in this type appear normal. In approximately 5 percent of cases, the angle between iris and the peripheral cornea is narrow and blocked when the pupil is dilated (angle-closure glaucoma). In the remaining cases, the condition is a result of some disease process that blocks outflow channels—inflammatory debris of uveitis, red blood cells from hemorrhage in the anterior chamber (hyphema), new formation of vessels and connective tissue on the surface of the iris (rubeosis iridis), a relatively infrequent complication of ocular ischemia secondary to diabetes mellitus, retinal vein occlusion, or carotid artery occlusion. The visual loss is gradual in open-angle glaucoma and the eye looks normal, unlike the red, painful eye of angle-closure glaucoma that was described above in reference to pharmacologic dilation of the pupil to facilitate funduscopy. However, some cases of open-angle glaucoma may progress to rapid loss of vision.

Intraocular pressures that are persistently above 20 mm Hg may damage the optic nerve over time. This may be manifest first as an arcuate defect in the upper or lower nasal field or as a paracentral field defect, which, if untreated, may proceed to blindness. The classic finding in glaucoma is the *Bjerrum field defect*, consisting of an arcuate scotoma extending from the blind spot and

sweeping around the macula to end in a horizontal line at the nasal equator. Other characteristic glaucomatous field patterns are winged extensions from the blind spot (Seidel scotoma) and a narrowing of the superior nasal quadrant that may progress to a horizontal edge, corresponding to the horizontal raphe of the retina (nasal step). The damage is at the optic nerve head, the optic disc appearing excavated and any pallor that is present extends only to the rim of the disc and not beyond, thus distinguishing it from other optic neuropathies. Elongation of the optic cup in the vertical axis is typical. It is now appreciated that elevated intraocular pressure is only a concurrent finding and a risk factor for glaucoma and that optic damage may be seen in patients with near normal pressure. This represents a major revision of the previous view that pressure was the elemental cause of damage in glaucoma.

In the *lens*, cataract formation is the most common and mundane abnormality. The cause of the common type in the elderly is unknown. The “sugar cataract” of diabetes mellitus is the result of sustained high levels of blood glucose, which is changed in the lens to sorbitol, the accumulation of which leads to a high osmotic gradient with swelling and disruption of the lens fibers. Galactosemia is a much rarer cause, but the mechanism of cataract formation is similar, i.e., the accumulation of dulcitol in the lens. In hypoparathyroidism, lowering of the concentration of calcium in the aqueous humor is in some way responsible for the opacification of newly forming superficial lens fibers. Prolonged high doses of corticosteroids, as well as radiation therapy, induce lenticular opacities in some patients. Down syndrome and oculocerebrorenal syndrome (see Chap. 38), spinocerebellar ataxia with oligophrenia (see Chap. 39), and certain dermatologic syndromes (atopic dermatitis, congenital ichthyosis, incontinentia pigmenti) are also accompanied by lenticular opacities. Myotonic dystrophy (see Chap. 48) and, rarely, Wilson disease (see Chap. 37) are associated with special types of cataract. Subluxation of the lens, the result of weakening of its zonular ligaments, occurs in syphilis, Marfan syndrome (upward displacement), and homocystinuria (downward displacement).

In the *vitreous humor*, hemorrhage may occur from rupture of a ciliary or retinal vessel. On ophthalmoscopic examination, the hemorrhage appears as a diffuse haziness of part or all of the vitreous or, if the blood is between the retina and the vitreous and displaces the latter rather than mixing with it, takes the form of a sharply defined clot. The common cause is rupture of newly formed vessels of proliferative retinopathy in patients with diabetes mellitus, but there are many others including orbital or cranial trauma, rupture of an intracranial aneurysm or arteriovenous malformation with high intracranial pressure, retinal vein occlusion, sickle cell disease, age-related macular degeneration (ARMD), and retinal tears, in which the hemorrhage breaks through the internal limiting membrane of the retina. The most common vitreous opacities are benign “floaters” caused by the condensation of vitreous collagen fibers, which appear as darting gray flecks or threads with changes in

the position of the eyes; they may be annoying or even alarming until the person stops looking for them.

A sudden burst of flashing lights associated with an increase in floaters may mark the onset of retinal detachment. Patients complaining of bright flashes and spots in vision should be examined with the indirect ophthalmoscope to rule out tears, holes, or detachments of the vitreous or retina. Another common occurrence with advancing age is shrinkage of the vitreous humor and retraction from the retina, causing persistent streaks of light, usually in the periphery of the visual field. These phosphenes, also known as *Moore lightning streaks*, had been thought to be quite benign, but they may at times, indicate incipient retinal or vitreous tears or detachment, and their first appearance requires prompt evaluation by an ophthalmologist. They are most prominent on movement of the globe, on closure of the eyelids, at the moment of accommodation, with saccadic eye movements, and with sudden exposure to dark. The vitreous may also be infiltrated by lymphoma originating in the brain; biopsy by planar vitrectomy may be used to establish the diagnosis in those rare instances where the lymphoma is restricted to the eye; its presence can be inferred when there is vitreous cellular infiltration and also a brain lymphoma.

The term *uveitis* refers to an infective or noninfective inflammatory disease that affects any of the uveal structures (iris, ciliary body, and choroid). According to Bienfang and colleagues, uveitis accounts for 10 percent of all cases of legal blindness in the United States. Infective causes of posterior uveitis (choroidal) are toxoplasmal and cytomegalic inclusion disease, occurring mainly in patients with AIDS and other forms of reduced immune function. Noninfective autoimmune types are also common in the adult. The inflammation may be in the anterior part of the eye or in the posterior part, behind the iris and extending to the retina and choroid. Anterior uveitis is sometimes linked to ankylosing spondylitis and the human leukocyte antigen (HLA) B-27 marker, sarcoidosis, and recurrent meningitis (Vogt-Koyanagi-Harada disease); the posterior forms are associated with sarcoidosis, Behçet disease, and lymphoma.

Retinal diseases, particularly ARMD and diabetic retinopathy, are a more common cause of blindness than are neurologic diseases, as discussed further on, under “Other Diseases of the Retina.”

NEUROLOGIC CAUSES OF REDUCED VISION

Certain anatomic and physiologic facts are required for an interpretation of the neurologic lesions that affect vision. Visual stimuli entering the eye traverse the inner layers of the retina to reach its outer (posterior) layer, which contains two classes of photoreceptor cells: the flask-shaped cones and the slender rods. The photoreceptors rest on a single layer of pigmented epithelial cells, which form the outermost surface of the retina. The rods and cones and pigmentary epithelium receive their

blood supply from the capillaries of the choroid and, to a smaller extent, from the retinal arterioles. The rod cells contain rhodopsin, a conjugated protein in which the chromophore group is a carotenoid akin to vitamin A. The rods function in the perception of visual stimuli in subdued light (twilight or scotopic vision), and the cones are responsible for color discrimination and the perception of stimuli in bright light (photopic vision). Most of the cones are concentrated in the macular region, particularly in its central part, the *fovea*, and are responsible for the highest level of visual acuity. Traquair described the rapid fall-off of acuity as the distance from the fovea increases as "an island of vision in a sea of blindness." Specialized pigments in the rods and cones absorb light energy and transform it into electrical signals, which are transmitted to the bipolar cells of the retina and then, in turn, to the superficially (anteriorly) placed neurons, or ganglion cells (Fig. 13-2). There are no ganglion cells in the fovea.

The axons of the retinal ganglion cells, as they stream across the inner surface of the retina, pursue an arcuate course. Being unmyelinated, they are not visible, although fluorescein retinography shows a trace of their outlines; an experienced examiner, using a bright light and deep green filter, can visualize them through direct ophthalmoscopy.

The axons of ganglion cells are collected in the optic discs and then pass uninterruptedly through the *optic nerves*, *optic chiasm*, and *optic tracts* to synapse in the lateral geniculate nuclei, the superior colliculi, the midbrain pretectum and the suprachiasmatic nucleus of the hypothalamus (Figs. 13-2 and 13-3). The fibers derived from macular cells form a discrete bundle that first occupies the temporal side of the disc and optic nerve and then assumes a more central position within the nerve (papillomacular bundle). These fibers are of smaller caliber than the peripheral optic nerve fibers and appear to be especially sensitive to toxic and metabolic injury. Damage to the papillomacular bundle produces the "cecocentral" scotoma (extending from fixation to the blind spot). It is important to keep in mind that the retinal ganglion cells and their axon extensions are, properly speaking, an exteriorized part of the brain and that their pathologic reactions are the same as in other parts of the CNS.

In the optic chiasm, the fibers derived from the nasal half of each retina decussate and continue in the optic tract with the uncrossed temporal fibers of the other eye (Figs. 13-3 and 13-4). Thus, interruption of the left optic tract causes a right hemianopic defect in each eye, i.e., a homonymous (left nasal and right temporal) field defect (Fig. 13-3D). In partial tract lesions, the visual defects in the

Figure 13-2. Diagram of the cellular elements of the retina. Light entering the eye anteriorly passes through the full thickness of the retina to reach the rods and cones (first system of retinal neurons). Impulses arising in these cells are transmitted by the bipolar cells (second system of retinal neurons) to the ganglion cell layer. The third system of visual neurons consists of the ganglion cells and their axons, which run uninterruptedly through the optic nerve, chiasm, and optic tracts, synapsing with cells in the lateral geniculate body. (Courtesy of Dr. E.M. Chester.)

Figure 13-4. The geniculocalcarine projection, showing the detour of lower fibers around the temporal horn. Note that a very small proportion of the pathway traverses the parietal lobe.

the bundle is merely an artifact of fixation in experimental material. We are uncertain if the explanation of this particular configuration of visual field abnormality has a better explanation than the existence of Wilbrand's knee and are reluctant to discard it.

The optic chiasm lies just above the pituitary gland and also forms part of the anterior wall of the third ventricle; hence the crossing fibers may be compressed from below by a pituitary tumor, a meningioma of the tuberculum sellae, or an aneurysm, and from above by a dilated third ventricle or craniopharyngioma. The resulting field defect is bitemporal ("bitemporal hemianopia"; Fig. 13-3C); if the lesion has an anterior extension to the junction with one optic nerve there is a loss of full-field vision in that eye and a partial loss in the other ("functional scotoma"). Optic tract lesions, in comparison with chiasmatic and optic nerve lesions, are relatively rare and cause a full contralateral hemianopia. In albinism, there is an abnormality of chiasmatic decussation, in which a majority of the fibers cross to the other side. How this relates to the global albinic defect in pigmented epithelium is not known.

Approximately 80 percent of the fibers of the optic tract terminate in the lateral geniculate body, a thalamic nucleus, and synapse with the six laminae of its neurons. Three of these laminae (1, 4, 6), which constitute the large dorsal nucleus, receive crossed (nasal) fibers from the contralateral eye, and three (2, 3, 5) receive uncrossed (temporal) fibers from the ipsilateral eye. Selective occlusion of either component of the dual blood supply to the lateral geniculate, consisting of the anterior and posterior choroidal arteries, is infrequent but when it does occur, produces a characteristic "multiple sectoral field defect"; a quadruple sectoranopia, meaning homonymous sectoral defects in the upper and lower quadrants of both eyes due to occlusion of the anterior choroidal artery, and two horizontal sectoranopias with occlusion of the posterior (lateral) choroidal artery. The geniculate cells project to the visual (striate) cortex of the occipital lobe, also called area 17 (Brodmann classification) or V1 (Figs. 13-4 and 13-5).

Other optic tract fibers terminate in the pretectum and innervate both Edinger-Westphal nuclei, which subserve pupillary constriction and accommodation (see Fig. 14-8). A small group of fibers terminate in the supra-chiasmatic nuclei in animals and presumably also in humans. These anatomic details explain several useful clinical signs. If there is a lesion in one optic nerve, a light stimulus to the affected eye will have no effect on the pupil of either eye, although the ipsilateral pupil will still constrict consensually, i.e., in response to a light stimulus

Figure 13-5. Diagrammatic depiction of the retinal projections, showing the disproportionately large representation of the macula in the lateral geniculate nucleus and visual (striate) cortex. (Redrawn by permission from Barr ML, Kiernan J: *The Human Nervous System*, 4th ed. Philadelphia, Lippincott, 1983.)

from the normal eye. This phenomenon is termed an *afferent pupillary defect*.

In their course through the temporal lobes, the fibers from the lower and upper quadrants of each retina diverge. The lower ones arch around the anterior pole of the temporal horn of the lateral ventricle before turning posteriorly; the upper ones follow a more direct path through the white matter of the uppermost part of the temporal lobe (Fig. 13-4), and probably of the adjacent anterior parietal lobe. Both groups of fibers merge posteriorly at the internal sagittal stratum. For these reasons, incomplete lesions of the geniculocalcarine pathways (optic radiations) cause visual field defects that are partial and often not fully congruent (Fig. 13-3E and F).

It is in Brodmann area 17, embedded in the medial lip of the occipital pole, that cortical processing of the retinogeniculate projections occurs. The receptive neurons are arranged in columns, some of which are activated by edges and forms and others by moving stimuli or by color. The neurons for each eye are grouped together and have concentric, center-surround receptive fields. The deep neurons of area 17 project to the secondary and tertiary visual areas of the occipitotemporal cortex of the same and opposite cerebral hemispheres and also to other multisensory parietal and temporal cortices. Several of these extrastriate connections are just now being identified. Separate visual systems are utilized in the perception of motion, color, stereopsis, contour, and depth perception. Conceptually, the flow of secondary visual processing can be divided into a ventral stream, which carries predominantly spatial information to the parietal lobe ("the where") and a dorsal stream, which carries shape and color information to the temporal lobe ("the what") as articulated by Levine and colleagues. The classic studies of Hubel and Wiesel have elucidated much of this visual cortical anatomy and physiology and their papers, for which they were awarded the Nobel Prize, should be consulted for a fuller appreciation of the organization of the visual cortex.

The *normal development* of the connections described above requires that the visual system be activated at each of several critical periods of development. The early deprivation of vision in one eye causes a failure of development of the geniculate and cortical receptive fields of that eye. Moreover, in this circumstance the cortical receptive fields of the seeing eye become abnormally large and usurps the monocular dominance columns of the blind eye (Hubel and Wiesel). In children with a congenital cataract, the eye will remain amblyopic if the opacity is removed after a critical period of development. A severe strabismus in early life, especially an esotropia, will have the same effect (*amblyopia ex anopsia*).

The *vascular supply* of the eye is through the *ophthalmic branch of the internal carotid artery* that supplies the retina, posterior (uveal) coats of the eye, and optic nerve head. This artery gives origin to the posterior ciliary arteries; the latter form a rich circumferential plexus of vessels (arterial circle of Zinn-Haller) located deep to the lamina cribrosa. The lamina cribrosa is a sieve-like scleral (dural) structure through which the axons of the central

and nasal part of the disc run. This arterial circle supplies the optic disc and adjacent part of the distal optic nerve, the choroid, and the ciliary body; it anastomoses with the pial arterial plexus that surrounds the optic nerve. The other major branch of the ophthalmic artery is the *central retinal artery*. It supplies the inner retinal layers and issues from the optic disc, where it divides into four branches, each of which supplies a quadrant of the retina; it is these vessels and their branches that are visible by ophthalmoscopy. A short distance from the disc, these vessels lose their internal elastic lamina and the media (muscularis) becomes thin; they are properly classed as arterioles. The inner layers of the retina, including the ganglion and bipolar cells, receive their blood supply from these arterioles and their capillaries, whereas the deeper photoreceptor elements and the fovea are nourished by the underlying choroidal vascular bed, by diffusion through the retinal pigmented cells and the semipermeable Bruch membrane upon which they rest. In up to a third of the population, a small cilioretinal artery may arise from either the choroidal circulation or from the circle of Zinn-Haller and supply the macula. In the case of a central retinal artery occlusion, the presence of this cilioretinal artery leads to the preservation of central acuity.

Abnormalities of the Retina

As indicated above, the thin (100- to 350- μ m) retinal sheet and the optic nerve head, into which all visual information flows, are exteriorized parts of the CNS and the only part of the nervous system that can be inspected directly. A common limitation in the funduscopic examination in cases of visual loss is failure to carefully inspect the macular zone (which is located 3 to 4 mm lateral to the optic disc and provides for 95 percent of visual acuity). There are variations in the appearance of the normal macula and optic disc, and these may prove difficult to distinguish from disease. A normal macula may be called abnormal because of a slight aberration of the retinal pigment epithelium, a few drusen, or a deep optic cup (see further on). With experience, the examiner can visualize the unmyelinated nerve-fiber layer of the retina by using bright-green (red-free) illumination. This is most often helpful in detecting demyelinating lesions of the optic nerve, which produce a loss of discrete bundles of the radially arranged and arching bundles of retinal fibers as they converge to the disc.

The absence of receptive elements in the optic disc accounts for the normal blind spot. The normal optic disc varies in color, being paler in infants and in blond individuals. The ganglion cell axons normally acquire their myelin sheaths after penetration of the lamina cribrosa, but they sometimes do so in their intraretinal course, as they approach the disc. These myelinated fibers adjacent to the disc appear as white patches with fine-feathered edges and are a normal variant, not to be confused with exudates.

In evaluating *the retinal vessels*, one must remember that these are arterioles and not arteries. Since the walls of retinal arterioles are transparent, what is observed with the ophthalmoscope is a column of blood within them.

The central light streak of normal arterioles is thought to represent the reflection of light as it strikes the interface of the column of blood and the concave vascular wall. In *arteriolosclerosis* (usually coexistent with hypertension), the lumina of the vessels are segmentally narrowed because of fibrous tissue replacement of the media and thickening of the basement membrane. Straightening of the arterioles and venous compression by arterioles are other signs of hypertension and arteriolosclerosis. In this circumstance the vein is compressed by the thickened arteriole within the adventitial envelope shared by both vessels at the site of crossing. Progressive arteriolar disease, to the point of occlusion of the lumen, results in a narrow, white ("silver-wire") vessel with no visible blood column. This change is associated most often with severe hypertension but may follow other types of occlusion of the central retinal artery or its branches (see descriptions and retinal illustrations further on). Sheathing of the venules, probably representing focal leakage of cells from the vessels, is reportedly observed in up to 25 percent of patients with the optic neuritis of multiple sclerosis, but we have only rarely been able to detect it. Arterial and venule sheathing are also seen in leukemia, sarcoid, Behçet disease, and other forms of vasculitis.

In *malignant, or accelerated, hypertension* there are, in addition to swelling of the optic nerve head and the retinal arteriolar changes noted above, a number of extravascular lesions: the so-called soft exudates or cotton-wool patches, sharply marginated and glistening "hard" exudates, and retinal hemorrhages. In many patients who show these retinal changes, analogous lesions are found in the brain (necrotizing arteriolitis and microinfarcts) and underlie hypertensive encephalopathy.

Microaneurysms of retinal vessels appear as small, discrete red dots and are located in largest number in the paracentral region. They are most often a sign of diabetes mellitus, sometimes appearing before the usual clinical manifestations of that disease. The use of the red-free (green) light on the ophthalmoscope helps to pick out microaneurysms from the background. Microscopically, the aneurysms take the form of small (20- to 90- μ m) saccular outpouchings from the walls of capillaries, venules, or arterioles. The vessels of origin of the aneurysms are invariably abnormal, being either acellular branches of occluded vessels or themselves occluded by fat or fibrin.

The ophthalmoscopic appearance of *retinal hemorrhage* is determined by the structure of the particular tissue in which it occurs. In the superficial layer of the retina, they are linear or flame-shaped ("splinter" hemorrhages) because of their confinement by the horizontally coursing nerve fibers in that layer. These hemorrhages usually overlie and obscure the retinal vessels. Round or oval ("dot-and-blot") hemorrhages lie behind the vessels, in the outer plexiform layer of the retina (synaptic layer between bipolar cells and nuclei of rods and cones—Fig. 13-2); in this layer, blood accumulates in the form of a cylinder between vertically oriented nerve fibers and appears round or oval when viewed end-on with the ophthalmoscope. Rupture of arterioles on the inner surface of the retina—as occurs with ruptured intracranial

saccular aneurysms, arteriovenous malformations, and other conditions causing sudden severe elevation of intracranial pressure—permits the accumulation of a sharply outlined lake of blood between the internal limiting membrane of the retina and the vitreous or hyaloid membrane (the condensed gel at the periphery of the vitreous body); this is the subhyaloid or preretinal hemorrhage, termed *Terson syndrome*. Either the small superficial or deep retinal hemorrhage may show a central or eccentric pale (Roth) spot, which is caused by an accumulation of white blood cells, fibrin, histiocytes, or amorphous material between the vessel and the hemorrhage. This lesion is said to be characteristic of bacterial endocarditis, but it is also seen in leukemia and occasionally in embolic retinopathy caused by carotid disease.

Cotton-wool patches, or soft exudates, like splinter hemorrhages, overlie and tend to obscure the retinal blood vessels. These patches, even large ones, rarely cause serious disturbances of vision unless they involve the macula. Soft exudates are in reality infarcts of the nerve-fiber layer, caused by occlusion of precapillary arterioles; they are composed of clusters of ovoid structures called *cytoid bodies*, representing the terminal swellings of interrupted axons. *Hard exudates* appear as punctate white or yellow bodies; they lie in the outer plexiform layer, behind the retinal vessels, like the punctate hemorrhages. If present in the macular region, they are arranged in lines radiating toward the fovea (*macular star*). Hard exudates consist of lipid and other serum precipitants as a result of abnormal vascular permeability of a type that is not completely understood. They are observed most often in cases of diabetes mellitus and chronic hypertension.

Drusen in the retina (colloid bodies) appear ophthalmoscopically as pale yellow spots and are difficult to distinguish from hard exudates except when they occur alone; as a rule, hard exudates are accompanied by other funduscopic abnormalities. Although retinal drusen may be a benign finding, in many cases they reflect an ARMD and their accumulation in the macula eventually leads to significant visual loss. The source of retinal drusen is uncertain, but they may result from chronic inflammation generated by degeneration of the retinal pigment epithelium. *Hyaline bodies* located on or near the optic disc, are also referred to as drusen but must be distinguished from those occurring peripherally. In contrast to peripheral retinal drusen, drusen of the optic discs are probably mineralized residues of dead axons and can be seen on CT in some cases. Their main significance for neurologists is that drusen that are buried under the disc ("buried drusen") are often associated with anomalous elevation of the disc that can be mistaken for papilledema (see further on) but they are for the most part, benign.

The periphery of the retina may harbor a hemangioblastoma, which may appear during adolescence, before the more characteristic cerebellar lesion. A large retinal artery may be seen leading to it and there may be a large draining vein. Occasionally, retinal examination discloses the presence of a vascular malformation that may be coextensive with a much larger malformation of the optic nerve and basilar portions of the brain.

Ischemic Lesions of the Retina

Transient monocular blindness Transient ischemic attacks of visual loss involving all or part of the field of vision of one eye are referred to as *amaurosis fugax* or *transient monocular blindness (TMB)*. They are common manifestations of atherosclerotic carotid stenosis but have other causes. An altitudinal horizontal border, or “shade”, is often, but not invariably, an aspect of the visual loss. The shade may rise or fall at the onset or cessation of the spell and occasionally remains throughout the episode. Fortuitous inspection of the retina during an attack may show segments of arteries that are filled with white material that migrate distally over many minutes. There can be stagnation of arterial and venous blood flow, which returns within seconds or minutes as vision is restored (Fisher). One interpretation of these observations is that an embolus had occurred to the central retinal artery and had broken up and moved distally. Fisher went on to discredit the theory of the time that transient monocular blindness was due to vasospasm of the retinal arteries.

One or dozens of attacks may precede infarction of a cerebral hemisphere, or as often, they may abate without adverse consequence. In one series of 80 patients followed by Marshall and Meadows for 4 years, in an era prior to modern treatment of atherosclerosis, 16 percent developed permanent unilateral blindness, a completed hemispherical stroke, or both. Chapter 34 discusses this subject further.

Occlusion of the internal carotid artery usually causes no disturbance of vision whatsoever, provided that there are adequate anastomotic branches from the external carotid artery or other sources to the ophthalmic artery. Occasionally, occlusion of the proximal internal carotid artery is marked by an episode of transient monocular blindness on the same side, just as a hemispherical transient ischemic attack may indicate recent acute carotid occlusion. Chronic carotid occlusion with inadequate collateralization is associated with an ischemic oculopathy, which may predominantly affect the anterior or posterior segment or both. In this case, insufficient circulation to the anterior segment of the globe is manifest by scleral vascular congestion, cloudiness of the cornea, anterior chamber flare, and low intraocular pressure, or sometimes high intraocular pressure if neovascularization of the iris (rubeosis iridis) occurs and compromises the outflow of aqueous humor. Ischemia of the posterior segment of the eye is manifest by circulatory changes in the optic nerve or by venous stasis. Other signs of carotid disease may be present, for example, a local bruit over the carotid bifurcation.

Central retinal artery occlusion Most often, ischemia of the retina can be traced to occlusion of the central retinal artery or its branches by thrombi or emboli—*central retinal artery occlusion* (abbreviated CRAO). Occlusion is attended by sudden painless blindness. The retina becomes opaque and has a gray-yellow appearance; the arterioles are narrowed, with segmentation of columns of blood and a cherry-red appearance of the fovea (Fig. 13-6). With occlusions of smaller branches of the

Figure 13-6. Appearance of the fundus in central retinal artery occlusion. In addition to the paucity of blood flow in retinal vessels, the retina has a creamy gray appearance, and there is a “cherry-red spot” at the fovea. (Courtesy of Dr. Shirley Wray.)

central retinal artery by emboli, one may be able to see the occluding material. Most frequently observed are Hollenhorst plaques—glistening, white-yellow atheromatous particles (Fig. 13-7) seen in 40 of 70 cases of retinal embolism in the series of Arruga and Sanders but are as often an asymptomatic manifestation of carotid or aortic atherosclerosis. The particles may alternatively have the appearance white calcium from calcified aortic or mitral valves or atheroma of the great vessels, and red or white fibrin-platelet emboli from a number of sources, mostly undefined, or perhaps from the heart or its valves. Emboli to retinal artery branches may be difficult to see without fluorescein retinography; furthermore, most of these emboli soon disappear. Central retinal artery occlusion also occurs as a consequence of giant cell arteritis; patients who are in their 50s or older should be screened for this condition.

Figure 13-7. Glistening “Hollenhorst plaque” occlusion of a superior retinal artery branch (arrow). These occlusions represent atheromatous particles or, less often, platelet-fibrin emboli. Some are asymptomatic and others are associated with segmental visual loss or are seen after central retinal artery occlusion. (Courtesy of Dr. Shirley Wray.)

It has become routine in some centers to treat acute central retinal artery occlusion in an urgent manner with a number of methods in the hope that the embolus or thrombus will be propelled into more distal vessels. These treatments are generally aimed at lowering intraocular pressure (acetazolamide, inhalation of carbon dioxide; paracentesis of the anterior chamber, ballottement), to dilate the vessels, and reestablish flow. We can only offer the impression that these procedures have often not been successful, but some case series have suggested that local thrombolysis with intraarterial agents may be useful. A multicenter controlled trial of thrombolysis (Eagle Study cited under Schumacher and colleagues) was halted early because of safety concerns so this is not likely to remain an option for treatment.

Retinal venous occlusion Because the central retinal artery and vein share a common adventitial sheath, atheromatous plaques in the artery are said to be associated with *thrombosis of the retinal vein*. This results in a spectacular display of retinal lesions that differs from the picture of central retinal artery occlusion. The veins are engorged and tortuous, and there are multiple diffuse “dot-and-blot” and streaky linear retinal hemorrhages (Fig. 13-8). Retinal vein thrombosis is observed most frequently with diabetes mellitus, hypertension, and leukemia; less frequently with sickle cell disease; and rarely with multiple myeloma, and Waldenstrom macroglobulinemia in relation to the hyperviscosity that these two diseases cause. Sometimes, no associated systemic disease can be identified, in which case the possibility of an orbital mass (e.g., optic nerve glioma) should always be considered. In retinal vein thrombosis, visual loss is variable and there may be recovery of useful vision. In cases where macular

Figure 13-8. Occlusion of the central retinal vein with suffusion of the veins, swelling of the disc, and florid retinal hemorrhages. (Courtesy of Dr. Shirley Wray.)

edema ensues, recovery may be enhanced by laser photocoagulation.

Other causes of transient monocular blindness In addition to the typical ischemic cause of this syndrome, transitory retinal ischemia is observed occasionally as a manifestation of migraine; it has also occurred in polycythemia, hyperglobulinemia, antiphospholipid syndrome, hyperviscosity of any type, and sickle cell anemia. In younger persons, transient monocular blindness is relatively uncommon and the cause is often not immediately apparent. Ischemia related to the antiphospholipid antibody or “retinal migraine” is presumed to be responsible for many cases. Rarely, vasospasm of the central retinal artery may be implicated as a cause of transient monocular blindness, in which case the episodes may cease with the introduction of a calcium channel blocker, as reported by Winterkorn and colleagues.

A common and critical cause of sudden monocular blindness, especially in elderly persons, is *anterior ischemic optic neuropathy (AION)*, essentially an infarction of the nerve head. It is caused by disease of posterior ciliary vessels that supply the optic nerve and is considered further on in the discussion of diseases of the optic nerve. The retinal vessels in this condition usually have a normal appearance, but the disc is swollen. The arteritic form of this process is discussed in more detail in Chap. 34, but most cases are related to occlusion of small vessels as occurs typically in diabetes.

In summary, *sudden, painless, monocular loss of vision* should raise the question of either retinal ischemia, caused by occlusive disease of the central retinal artery or vein, or of ischemic optic neuropathy from disease of the ciliary vessels. Detachment of the retina, and macular and vitreous hemorrhages are relatively obvious causes as noted below.

Other Diseases of the Retina

Aside from vascular lesions, tears and detachments of the retina may impair vision acutely. The most common form of detachment is an intraretinal one caused by separation of the pigment epithelium layer from the sensory retina with fluid accumulation through a tear or hole in the retina. In so-called traction detachment—observed in cases of premature birth or proliferative retinopathy secondary to diabetes or other vascular disease—contracting fibrous tissue pulls the retina from the choroid.

Serous retinopathy, a cause of monocular visual disturbance in young or middle-aged males, may be associated with the use of corticosteroids. The entire perimacular zone is elevated by edema fluid. The condition may arise acutely or slowly. Metamorphopsia (distortion of vision) in one eye is a common presentation, but acuity is not much impaired. The optic disc remains normal. The retinal change (leakage of vascular fluid into the subretinal space) causes a loss of visualization of the detail of the choroid and is demonstrated by fluorescein angiography or by optical coherence tomography (OCT). The condition tends to resolve over several months and is treated by laser to seal the sites of leakage.

Chorioretinitis, generally the result of an infectious process, may cause difficulty in diagnosis. In many

patients the initial diagnosis had been retrobulbar neuritis. One cannot depend upon the appearance of a macular star (see above) for diagnosis.

A large number of patients with HIV-AIDS develop retinal lesions of various types. Infarcts of the nerve-fiber layer (cotton-wool patches), hemorrhages, and perivascular sheathing are the usual findings. Toxoplasmosis is the most common infective lesion, followed in frequency by cytomegalovirus (CMV), but histoplasmosis, *Pneumocystis carinii*, herpes zoster, syphilis, and tuberculosis are well documented. CMV may cause a particularly severe necrotizing retinitis and permanent impairment of vision. Both the retina and choroid may be involved by these diseases, in which case the ophthalmoscopic picture is characteristic, showing the destruction of the "punched-out" lesions that exposes the whitish sclera, and deposits of black pigment. The choroid may also be the site of viral and noninfective inflammatory reactions, often in association with painful recurrent iridocyclitis and lacrimal inflammation.

Degenerations of the retina are important causes of chronic progressive visual loss. The retinal degenerations assume several forms and many are associated with progressive conditions of the brain or other organs. The most frequent in youth and middle age is *retinitis pigmentosa*, a hereditary disease of the outer photoreceptor layer and subjacent pigment epithelium. The retina is thin, and there are fine deposits of black pigment in the shape of bone corpuscles, more in the periphery; later the optic discs become pale. The disorder is marked by constriction of the visual fields with relative sparing of central vision ("gun-barrel" vision), metamorphopsia (distorted vision), delayed recovery from glare, and nyctalopia (reduced twilight vision). The causes of retinitis pigmentosa and related retinal degenerations are diverse, too numerous to list here. Furthermore, the condition has been linked to deficits in more than 75 different genes. In one form of isolated retinitis pigmentosa, which follows an autosomal dominant pattern of inheritance, the gene for rhodopsin (a combination of vitamin A and the rod-cell protein opsin) produces a defective opsin, resulting in a diminution of rhodopsin, diminished response to light, and eventual degeneration of the rod cells (Dryja et al). Retinitis pigmentosa is associated with the Laurence-Moon-Biedl syndrome, with certain mitochondrial diseases (Kearns-Sayre syndrome, Chap. 38), and with a number of degenerative and metabolic diseases (e.g., Refsum disease) of the nervous system. Another early life hereditary retinal degeneration, characterized by massive central retinal lesions, is the autosomal recessive Stargardt form of juvenile tapetoretinal degeneration. Like retinitis pigmentosa, Stargardt disease may be accompanied by progressive spastic paraparesis or ataxia. *Nonpigmentary retinal degeneration* is a familiar feature of a number of rare syndromes and diseases, such as neuronal ceroid lipofuscinosis, Bassen-Kornzweig disease, Batten-Mayou disease, and others (see Chap. 37).

Medications have emerged as a cause of retinal damage. Phenothiazine derivatives, less often used in practice than they had been, may conjugate with the melanin of the pigment layer, resulting in degeneration of the outer

layers of the retina and a characteristic "bull's-eye retinopathy" observed by fluorescein angiography. If these drugs are administered in high dosages for protracted periods, the patient should be tested for defects in visual fields and color vision. Among drugs used to treat neurologic disease, the antiepileptic drug *vigabatrin* is notable for causing retinal degeneration and a concentric restriction of the visual fields in almost half of exposed patients. Elevated levels of gamma-aminobutyric acid (GABA) in the retina are presumably the cause of toxicity. High-dose tamoxifen has caused toxicity in the retina, characterized by the deposition of refractile opacities and in more severe cases, by macular edema.

A cancer-associated retinopathy (CAR) has been described in patients with an oat-cell carcinoma of the lung as a paraneoplastic illness (see Chap. 31). The typical presentation is of positive visual phenomenon and rapid bilateral visual loss. Antibodies against the recoverin protein, which modulates rhodopsin kinase, have been demonstrated in the serum of affected patients (Grunwald et al; Kornguth et al; Jacobson et al). More recently, a melanoma-associated retinopathy (MAR) that affects only rods has been described. These paraneoplastic processes are further described in Chap. 31.

Certain lysosomal diseases of infancy and early childhood are characterized by an abnormal accumulation of undegraded proteins, polysaccharides, and lipids in cerebral neurons, as well as in the macula and other parts of the retina (hence the terms *storage diseases* and *cerebromacular degenerations*). Corneal clouding, cherry-red spot and graying of the retina, and later optic atrophy are the observed ocular abnormalities. Chapter 37 discusses these diseases.

In some of these retinal diseases, minimal changes in the pigment epithelium or other layers of the retina may not be readily detected by ophthalmoscopy. A test to expose such subtle retinal changes is to estimate the time required for recovery of visual acuity following light stimulation (macular photostress test). The test is conducted by shining a strong light through the pupil of an affected eye for 10 s and measuring the time necessary for the acuity to return to the pretest level (normally 50 s or less). With macular lesions, recovery time is prolonged, but with lesions of the optic nerve, it is not affected. This phenomenon may also be observed in the eye on the side of a carotid occlusion, in essence, an ischemic retinopathy. Retinal diseases reduce or abolish the electrical activity generated by the outer layers of the retina, and this can be measured by the electroretinogram (ERG). Fluorescein retinography and various new imaging tests are now essential for proper diagnosis of retinal disease. OCT uses reflected light to construct a high-resolution two-dimensional image of the retinal layers; it is able to demonstrate with remarkable resolution retinal edema, tears, macular holes, and the thinning of the retinal nerve-fiber layer that follows optic neuropathy.

Age-Related Macular Degeneration This is the most important cause of visual loss in the elderly. As ARMD begins to disturb vision, the straight lines on the Amsler grid are observed by the patient to be distorted. Examination discloses a central scotoma, and an

alteration of the retina around the macula. Central vision is at first distorted, then gradually diminishes, impairing reading, but these patients can still get about because of retained peripheral vision. The two most common types of macular degeneration are an atrophic “dry” type, which is a true pigmentary degeneration associated with retinal drusen, of unknown cause but with a genetic component, and an exudative “wet” type, which is the result of choroidal neovascularization that results in secondary macular damage. The wet form is amenable to laser treatment and to the injection into the orbit of ranibizumab or similar antiangiogenic monoclonal antibodies against vascular endothelial growth factor. Progression of the dry form may be slightly reduced by the use of antioxidants and zinc. The pathophysiology and treatment of ARMD have been reviewed by DeJong.

Diabetic Retinopathy Although not strictly speaking a problem taken up by neurologists, this is such an important cause of reduced vision and blindness that the basic facts should be known to all physicians. The earliest changes are of microaneurysms, and tiny intraretinal hemorrhages; these are present in almost all diabetics who have had type 1 disease for more than 20 years. Cotton-wool spots and small hemorrhages appear as the retina becomes ischemic. Subsequently, there is a more threatening proliferative retinopathy that consists of the formation of new blood vessels, and consequent leakage of proteins and blood. The proliferative feature occurs in half of type 1 diabetics, and 10 percent of those who have had type 2 disease for 15 to 20 years. The new vessels can grow into the vitreous, and hemorrhages from them may cause traction on the retina, which results in detachment. Visual loss may also be the result of macular edema. Reabsorption of

the edema leads to the deposition of lipid “hard exudates.” The maintenance of glucose control reduces the frequency and severity of retinopathy but does not prevent it. Locally elevated levels of vascular endothelial growth factor have been shown to be involved in the pathophysiology of diabetic retinal neovascularization, and recent studies show that improvement in neovascular leakage can be obtained, at least in the short term, with intravitreal injections of the antivascular endothelial growth factor (anti-VEGF) antibody, bevacizumab. The review of the subject by David and colleagues is recommended.

Papilledema and Raised Intracranial Pressure

Of the various abnormalities of the optic disc, *papilledema* or *optic disc swelling* has the greatest neurologic implication, for it signifies the presence of increased intracranial pressure. The term papilledema has come to mean disc swelling due to raised intracranial pressure although there are other causes of a similar fundusoscopic appearance. It must be made clear, however, that an ophthalmoscopic appearance identical to that of papilledema can be produced by infarction of the optic nerve head (the “papillopathy” of anterior ischemic optic neuropathy) and by inflammatory changes in the intraorbital portion of the optic nerve (“papillitis”, a form of optic neuritis). Certain clinical and fundusoscopic findings, listed in Table 13-2 and described below, assist in distinguishing between these processes, although all share the basic feature of conspicuous optic disc swelling.

In its mildest form, papilledema appears as slight elevation of the disc and blurring of the disc margins, especially of the superior and inferior aspects, and a mild fullness of the veins in the disc. Subtle disc elevation

Table 13-2

CAUSES OF OPTIC DISC SWELLING

OPHTHALMIC ABNORMALITY	UNDERLYING CAUSE	VISUAL LOSS	ASSOCIATED SYMPTOMS	PUPILS
Papilledema	Increased intracranial pressure	None or transient blurring; constriction of visual fields and enlargement of blind spot; findings almost always binocular	Headache; signs of intracranial mass	Normal unless succeeded by optic atrophy
Anterior ischemic optic neuropathy	Infarction of disc and intraorbital optic nerve due to atherosclerosis or temporal arteritis	Acute visual loss, monocular (usually); may be an altitudinal defect	Headache with temporal arteritis	Afferent pupillary defect
Optic neuritis ^a (“papillitis”)	Inflammatory changes in disc and intraorbital part of optic nerve—usually due to MS, sometimes to ADEM	Rapidly progressive visual loss; usually monocular	Tender globe, pain on ocular movement	Afferent pupillary defect
Hyaline bodies ^b (drusen)	Congenital, familial	Usually none but may be slowly progressive Enlargement of blind spot or arcuate inferior nasal defect	Usually none; rarely transient visual obscurations	Normal

MS, multiple sclerosis; ADEM, acute disseminated encephalomyelitis.

^aOptic neuritis affecting the retrobulbar portion of the nerve shows no fundusoscopic changes.

^bMay be mistaken for papilledema (pseudopapilledema).

Figure 13-9. Mild papilledema with hyperemia of the disc and slight blurring of the disc margins. (Courtesy of Dr. Shirley Wray.)

is also indicated by a loss of definition of the vessels overlying the disc as they approach the disc margin from the periphery; this appearance is produced by edema in the adjacent retina. Because many normal individuals, especially those with hypermetropia, have ill-defined disc margins, the early stage of papilledema may be difficult to detect (Fig. 13-9). Pulsations of the retinal veins, best seen where the veins turn to enter the disc, will have disappeared by the time intracranial pressure is raised, but this finding is not specific, as venous pulsations are not present in a proportion of normal individuals in the seated position. On the other hand, the presence of spontaneous venous pulsations is a reliable indicator of an intracranial pressure below 200 mm H₂O, and thus usually excludes papilledema (Levin). Fluorescein angiography, red-free fundus photos (which highlight the retinal nerve fibers), and newer imaging techniques alluded to above (ocular coherence tomography) are helpful in detecting early edema of the optic discs.

More severe degrees of papilledema appear as further elevation, or “mushrooming” of the entire disc and surrounding retina. There is subtle or overt edema and obscuration of vessels at the disc margins and, in some instances, peripapillary hemorrhages (Fig. 13-10). When advanced as a result of raised intracranial pressure, papilledema is almost always bilateral although it may be asymmetric. Purely unilateral edema of the optic disc is indicative of a perioptic meningioma or other tumor involving the optic nerve, but it can sometimes occur at an early stage of increased intracranial pressure. As the papilledema becomes chronic, elevation of the disc margin becomes less prominent and pallor of the optic nerve head, representing a dropout of nerve fibers (atrophy), becomes more evident (Fig. 13-11). Varying degrees of secondary optic atrophy remain in the wake of papilledema that has persisted for more than several days or weeks, leaving the disc pale, gliotic, and shrunken. Constriction in one quadrant of the nasal portion of the visual field is an early sign of the loss of nerve fibers from optic atrophy.

Acute papilledema, while it may enlarge the blind spot slightly, does not greatly affect visual acuity (except

Figure 13-10. Fully developed papilledema. The main characteristics are marked swelling and enlargement of the disc, vascular engorgement, obscuration of small vessels at the disc margin as a result of nerve-fiber edema, and white “cotton-wool spots” that represent superficial infarcts of the nerve-fiber layer. (Courtesy of Dr. Shirley Wray.)

transiently during spontaneous waves of increased intracranial pressure). Therefore, acute optic disc swelling in a patient with severely reduced vision cannot be attributed to papilledema; instead, intraorbital optic neuritis (papillitis) or infarction of the nerve head (ischemic optic neuropathy) must be present. Chronic or recurrent papilledema may result in optic atrophy and cause a reduction in visual acuity by that mechanism.

The examiner is also aided by the fact that *papilledema due to raised intracranial pressure is generally bilateral*, although, as mentioned earlier, the degree of disc swelling may not be symmetrical. In contrast, papillitis and infarction of the nerve head affect one eye, but there are exceptions to both of these statements. The pupillary reaction to light is muted only with infarction and optic neuritis, not with acute papilledema (once secondary optic atrophy supervenes, the loss of afferent light reaction is indeed observed). The occurrence of papilledema on one side

Figure 13-11. Chronic papilledema with beginning optic atrophy, in which the disc stands out like a champagne cork. The hemorrhages and exudates have been absorbed, leaving a glistening residue around the disc. (Courtesy of Dr. Shirley Wray.)

and optic atrophy on the other is referred to as the Foster Kennedy syndrome; it is typically caused by a frontal lobe tumor or an olfactory meningioma on the side of the atrophic disc. In its complete form, which is seen only rarely, there is also anosmia on the side of the optic atrophy. Another cause of the same fundoscopic appearance has been called the “pseudo-Foster Kennedy syndrome,” which occurs when papillitis in one eye occurs years after an optic neuropathy of the opposite one.

Although, as mentioned, the term papilledema is generally reserved for disc swelling from raised intracranial pressure, an identical appearance caused by infarction of the nerve head is characterized by extension of the swelling beyond the nerve head, as described below. The papilledema of increased pressure is associated with peripapillary hemorrhages whereas these are uncommon with infarction of the nerve. Often these distinctions cannot be made on the basis of the fundoscopic appearance alone, in which case the most reliable distinguishing feature is again the presence or absence of visual loss (Table 13-2). Papilledema caused by increased intracranial pressure cannot be distinguished from combined edema of the optic nerve and retina, which typifies malignant hypertension.

Chronic papilledema, as occurs in pseudotumor cerebri (see Chap. 31), presents a special problem in diagnosis, and represents a risk for permanent reduction in visual acuity from secondary optic atrophy. In addition to testing visual acuity at regular intervals, our colleagues advise serial evaluation of the visual fields as constriction of the nasal field, detectable by automated perimetry and tangent screen testing, is an early and ominous optic atrophy.

The essential element in the pathogenesis of papilledema is an increase in pressure in the sheaths surrounding the optic nerves, which communicate directly with the subarachnoid space of the brain. This was demonstrated convincingly by Hayreh (1964), who produced bilateral chronic papilledema in monkeys by inflating balloons in the subarachnoid space and then opening the sheath of one optic nerve; the papilledema promptly subsided on the operated side but not on the opposite side. The appearance of the swollen disc, however, has also been ascribed to a blockage of axoplasmic flow in the optic nerve fibers (Minckler et al; Tso and Hayreh). It was found that compression of the optic nerve by elevated cerebrospinal fluid (CSF) pressure resulted in swelling of axons behind the optic nerve head and leakage of their contents into the extracellular spaces of the disc. In our opinion, the block in axoplasmic flow alone could not account for the marked congestion of vessels and hemorrhages that accompany papilledema and a component of vascular congestion is likely.

The mechanism of papilledema that on rare occasions accompanies spinal tumors, particularly oligodendrogliomas, and the Guillain-Barré syndrome is not entirely clear. Usually the CSF protein is more than 1,000 mg/100 mL, but this cannot be the entire or only explanation, as instances occur in which the protein concentration is only slightly elevated (also the concentration of protein in the ventricular and cerebral subarachnoid spaces is considerably lower than in the lumbar sac, where it is usually sampled; see Chap. 30). In other diseases that at times

give rise to papilledema—e.g., chronic lung disease with hypercapnia, cancer with meningeal infiltration, or dural arteriovenous malformation—the mechanism is most often one of a generalized increase of intracranial pressure. Other causes of papilledema are cyanotic congenital heart disease, and other forms of polycythemia, hypocalcemia though an obscure mechanism, and POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes; see Chap. 46).

Diseases of the Optic Nerves

The optic nerves, which constitute the axonic projections of the retinal ganglion cells to the lateral geniculate bodies and superior colliculi can be inspected in the optic nerve head. Observable changes in the optic disc are therefore of particular importance. They may reflect the presence of raised intracranial pressure as already described; optic neuritis (“papillitis”); infarction of the optic nerve head; congenital defects of the optic nerves (optic pits and colobomas); hypoplasia and atrophy of the optic nerves; and glaucoma. Illustrations of these and other abnormalities of the disc and ocular fundus can be found in the atlas by E.M. Chester and in the text by Biousse and Newman. In general, optic neuropathies are distinguished from other causes of visual loss by a predominance of loss of color vision and by the presence of an afferent pupillary defect.

Table 13-3 lists the main causes of optic neuropathy, which are discussed in the following portions of this chapter.

Optic Neuritis (Papillitis; Retrobulbar Neuritis) (See Chap. 36)

This inflammatory process causes unilateral acute impairment of vision that may appear in one or both eyes, either simultaneously or successively. It develops in a number of clinical settings, but has a special relationship to multiple sclerosis. The most common situation is one in which an adolescent or young adult woman has a rapid diminution of vision in one eye as though a veil had covered the eye, sometimes progressing within hours or days to complete blindness.

The optic disc and retina may appear normal, in which case the condition is of the more common retrobulbar variety, but if the inflammation is near the nerve head, there is swelling of the disc, i.e., papillitis (Fig. 13-12). The disc margins are then seen to be elevated, blurred, and, rarely, surrounded by hemorrhages. As indicated above, papillitis is associated with marked impairment of vision and a central scotoma that encompasses the blind spot (cecocentral), thus distinguishing it from the acute papilledema of increased intracranial pressure. Pain on movement and tenderness on pressure of the globe, and a difference between the two eyes in the perception of brightness of light are other common, but not invariable findings (Table 13-2). The pupil on the affected side has a muted constriction response to direct light. In the following days and weeks, the patient may report an increase in blurring of vision with exertion or with exposure to heat (Uhthoff phenomenon). In papillitis, but not retrobulbar neuritis, examination may disclose haziness of the

Table 13-3

CAUSES OF UNILATERAL AND BILATERAL OPTIC NEUROPATHY

I. Demyelinative (optic neuritis)
Multiple sclerosis
Postinfectious and viral neuroretinitis
II. Ischemic
Arteriosclerotic (usually in-situ occlusion; occasionally carotid artery disease)
Granulomatous (giant cell) arteritis
Syphilitic arteritis
III. Parainfectious
Cavernous sinus thrombosis
Paranasal sinus infection
IV. Toxins and drugs
Methanol
Ethambutol
Chloroquine
Streptomycin
Chlorpropamide
Chloramphenicol
Tiagabine
Linezolid
Infliximab
Sildenafil
Ergot compounds
V. Deficiency states
Vitamin B ₁₂
Thiamine or possibly several B vitamins ("tobacco-alcohol" amblyopia)
Epidemic nutritional types (Cuban, Jamaican)
VI. Heredofamilial and developmental
Dominant juvenile optic atrophy
Leber optic atrophy
Developmental failure of disc or papillomacular bundle
Progressive hyaline body encroachment
VII. Compressive and infiltrative
Meningioma of sphenoid wing or olfactory groove
Metastasis to optic nerve or chiasm
Glioma of optic nerve (neurofibromatosis type I)
Optic atrophy following long-standing papilledema
Pituitary tumor and apoplexy
Thyroid ophthalmopathy
Sarcoidosis
Giant aneurysms
Lymphoma
Wegener granulomatosis
VIII. Radiation-induced optic neuropathy

vitreous that causes difficulty in visualizing the retina. Inflammatory sheathing of the retinal veins, as described by Rucker, is known to occur but has been uncommon in our patients. In extreme cases, edema may suffuse from the disc to cause a rippling in the adjacent retina. However, as just noted, most cases of optic neuritis are retrobulbar, and little is seen when examining the optic nerve head. In approximately 10 percent of cases, both eyes are involved, either simultaneously or in rapid succession.

Sometimes, no cause can be found for optic neuropathy, but a first bout of multiple sclerosis is always suspected, as discussed in Chap. 36. After several weeks to months, there is spontaneous recovery; vision returns to normal in more than two-thirds of cases. Recovery of

Figure 13-12. Acute optic neuritis in a patient with multiple sclerosis. The disc is swollen from an inflammatory process near the nerve head (papillitis), and the patient is virtually blind in the affected eye.

vision occurs spontaneously, or may be hastened by the intravenous administration of high doses of corticosteroids. In one frequently cited study, the oral administration of these drugs increased the frequency of a relapse of optic neuritis so that intravenous agents are used instead (see "Treatment of Optic Neuritis" in Chap. 36). Diminution of brightness, dyschromatopsia, or a scotoma may remain; rarely, the patient is left blind.

As time progresses, more than half of adults with optic neuritis will develop other symptoms and signs of multiple sclerosis, usually within 5 years, and probably even more so when they are observed for longer periods. Conversely, in approximately 15 percent of patients with multiple sclerosis, the history discloses that retrobulbar neuritis was the first symptom. A proportion of patients with acute optic neuritis are found at the time of an acute attack to have characteristic features of multiple sclerosis on MRI of the cerebrum and spine.

Postinfectious demyelinating disease is a possible cause in some cases that do not later show signs of multiple sclerosis. Less is known about children with retrobulbar neuropathy, in whom the disorder is more often bilateral and frequently related to a preceding viral infection ("neuroretinitis," see below). Their prognosis is better than that of adults. Formerly, optic neuritis was often attributed to paranasal sinus disease, but this condition rarely affects vision and with a few exceptions, the association is tenuous, as discussed further on. Optic neuritis is a main component of neuromyelitis optica (Devic disease; see Chap. 36); the prognosis for recovery is generally poorer than for optic neuritis in multiple sclerosis, but there are many exceptions.

Despite the return of visual acuity in the majority of patients with optic neuritis, a degree of optic atrophy almost always results. The disc then appears shrunken and pale, particularly in its temporal half (temporal pallor), and the pallor extends beyond the margins of the disc into the peripapillary retinal nerve fibers. The pattern-shift visual evoked potential becomes delayed; as a result, this test is a highly sensitive indicator of previous, even asymptomatic, episodes of optic neuritis.

The treatment of optic neuritis is taken up with multiple sclerosis in Chap. 36.

Leber hereditary optic neuropathy, a maternally inherited mitochondrial disorder, is an infrequent but important cause of blindness in children and younger adults because it may simulate the more common inflammatory optic neuropathies, even at times causing a relatively abrupt onset of visual loss followed by some degree of recovery (see “Hereditary Optic Atrophy of Leber” in Chap. 37). The visual field defect typically takes the form of a cecentral scotoma. Certain nutritional and toxic states may do the same, as well as sarcoidosis and the numerous other causes of optic neuropathy discussed further on.

Neuroretinitis is a rare post- or parainfectious process seen mostly in children and young adults, sometimes in association with exposure to the *Bartonella henselae* bacteria the cause of cat scratch fever. Papillitis is accompanied by macular edema and exudates situated radially in the Henle layer, producing a “macular star” appearance.

Ischemic Optic Neuropathy (Anterior, AION and Posterior, PION)

In persons older than 50 years of age, *ischemic infarction of the optic nerve head* is the most common cause of a persistent monocular loss of vision (Fig. 13-13). The onset is abrupt and painless, but on occasion the visual loss is progressive for several days. The field defect is often altitudinal and involves the area of central fixation, accounting for a severe loss of acuity. Swelling of the optic disc, extending for a short distance beyond the disc margin, and associated small, flame-shaped hemorrhages, is typical; less often, if the infarction is situated behind the optic nerve head, the disc appears entirely normal. The retina and retinal vessels are not affected, as they are in cases of embolic occlusion of the central retinal artery. AION may also complicate intraocular surgery. As the disc edema subsides, optic atrophy becomes evident. The second eye

Figure 13-13. Anterior ischemic optic neuropathy (AION) related to hypertension and diabetes. There is diffuse disc swelling from infarction that extends into the retina as a milky edema. The veins are engorged. “Cotton-wool” infarcts can be seen to the left of the disc and a “flame” hemorrhage extends from the right disc margin.

may be similarly affected at a later date, particularly in those patients with hypertension and diabetes mellitus. Usually, there are no premonitory symptoms or episodes of transient visual loss.

Despite these distinctive features, ischemic optic neuropathy can sometimes be difficult to differentiate from optic neuritis, as pointed out by Rizzo and Lessell. This proves particularly problematic when visual loss evolves over days, the disc is swollen, and pain accompanies the ischemic condition. However, the age of the patient and nature of the field defect (central in optic neuritis in contrast to sometimes altitudinal in ischemic neuropathy) further serve to clarify the situation. Furthermore, arteritic and non-arteritic forms of ischemic optic neuropathy are distinguished, the former being the result of temporal (giant cell) arteritis.

As to the pathogenesis of non-arteritic ischemic optic neuropathy, the usual (anterior) form has been attributed by Hayreh to ischemia in the posterior ciliary artery circulation and more specifically to occlusion of the branches of the peripapillary choroidal arterial system. A small cup-to-disc ratio is reportedly a risk factor. Infarction of the posterior portions of the optic nerve(s) is uncommon (posterior ischemic optic neuropathy, PION). Most cases of either type occur on a background of hypertensive vascular disease and diabetes, but not necessarily in relation to carotid artery atherosclerotic stenosis, which in our experience has accounted for only a few cases (see below).

A relationship has been observed between ischemic optic neuropathy and the use of nitric oxide inhibitors, such as sildenafil, for erectile dysfunction. The visual loss has occurred within 24 h of taking the drug and is usually unilateral. According to Pomeranz and colleagues, all affected patients have had risk factors for vascular disease such as hypertension, diabetes, or hyperlipidemia, but there have been exceptions, and these risk factors are likely to be present in older men who are also likely to use the drug. There may be complete recovery or persistent blindness. Massive blood loss or intraoperative hypotension, particularly in association with the use of cardiac surgery with a bypass pump, may also produce visual loss, and ischemic infarction of the retina and optic nerve.

A remarkable unilateral or bilateral optic neuropathy, which we have observed and which is also presumably ischemic in nature, occurs after prolonged laminectomy operations that are performed with the patient in the prone position. Obese individuals and those with small optic cups are seemingly at risk for this complication. Some recovery is possible after many weeks but most patients remain blind from infarction of the optic nerve heads. Blood loss of greater than 1 L, and surgery longer than 6 hours seem to be common to most cases. The reported cases have been summarized from a registry by Lee and coworkers.

Temporal, or giant cell, arteritis is another important cause of AION or PION (see also Chap. 10 on the related headache and Chap. 34 for a discussion of cerebrovascular disease in association with giant cell arteritis). Fleeting premonitory symptoms of visual loss (amaurosis fugax) may precede infarction of the nerve. Infarction caused by

cranial arteritis may affect both optic nerves in close succession and, less often, ocular motor function. Temporal arteritis less often presents with the picture of central retinal artery occlusion or posterior ischemic optic neuropathy (in which ischemic injury to the optic nerve is not accompanied by acute changes in the appearance of the disc).

The condition called "orbital pseudotumor", essentially an inflammatory condition of all the orbital contents, is discussed in Chap. 14 on oculomotor disorders but is mentioned here because optic neuropathy and visual loss can be a component of the syndrome.

Systemic lupus erythematosus, diabetes, sarcoidosis, neurosyphilis, and AIDS rarely give rise to optic neuropathies.

Optic Neuropathy Caused by Acute Cavernous and Paranasal Sinus Disease

A number of disease processes adjacent to the orbit and optic nerve can cause blindness, usually with signs of compression or infarction of the optic and oculomotor nerves. They are seen far less frequently than are ischemic optic neuropathy and optic neuritis. Septic cavernous sinus thrombosis (see "Cavernous Sinus Thrombosis" in Chap. 34), for example, may be accompanied by blindness of one eye or both eyes asymmetrically. In our experience with 4 such patients, the visual loss appeared days after the characteristic chemosis and oculomotor palsies of the venous sinus occlusion. The mechanism of visual loss, sometimes without swelling of the optic nerve head, is unclear but most likely relates to retrobulbar ischemia of the nerve.

Similarly, optic and oculomotor disorders may rarely complicate ethmoid or sphenoid sinus infections. Severe diabetes with mucormycosis or other invasive fungal or bacterial infection is the usual setting for these complications. Although the formerly held notion that uncomplicated sinus disease is a cause of optic neuropathy is no longer tenable, there are still a few instances in which such an association occurs but the nature of the visual loss remains unclear. Slavin and Glaser described a case of loss of vision from a sphenothmoidal sinusitis with cellulitis at the orbital apex. Visual symptoms in these exceptional circumstances can occur prior to overt signs of local inflammation. An otherwise benign sphenoidal mucocele may cause a compressive optic neuropathy, usually with accompanying ophthalmoparesis and slight proptosis.

Toxic and Nutritional Optic Neuropathies (Table 13-3)

Simultaneous impairment of vision in the two eyes, with central or centrocecal scotomas, is often caused not by a demyelinating process but also by toxic or nutritional processes. The latter condition is observed most often in the chronically alcoholic or malnourished patient. Impairment of visual acuity evolves over several days or a week or two, and examination discloses bilateral, roughly symmetrical central or centrocecal scotomas, the peripheral fields being intact. With appropriate treatment (nutritious diet and vitamins B) instituted soon after

the onset of amblyopia, complete recovery is possible. If treatment is delayed, patients are left with varying degrees of permanent defect in central vision and pallor of the temporal portions of the optic discs. This disorder has been referred to as "tobacco-alcohol amblyopia," the implication being that it is caused by the toxic effects of tobacco or alcohol or both. In fact, the problem is one of nutritional deficiency and is more properly designated as *deficiency amblyopia* or *nutritional optic neuropathy* (see Chap. 41). The same disorder may be seen under conditions of severe dietary deprivation (see Chap. 41) and in patients with vitamin B₁₂ deficiency.

A subacute optic neuropathy of possible toxic origin was described in Jamaican natives. It was characterized by bilaterally symmetrical central visual loss and had additional features of nerve deafness, ataxia, and spasticity in some cases. A similar condition is described periodically in other Caribbean countries, two decades ago in Cuba, where an optic neuropathy of epidemic proportions was associated with a sensory polyneuropathy. A nutritional etiology, possibly contributed to by tobacco use (putatively cigars in the Cuban epidemic), was the likely cause of these outbreaks (see Sadun et al and The Cuba Neuropathy Field Investigation Team report). A putative role of exposure to cyanide, either from smoking or consumption of cassava, has been a feature of some of these epidemics.

Impairment of vision because of *methyl alcohol intoxication* (methanol) is abrupt in onset and characterized by large symmetrical central scotomas as well as symptoms of acidosis. Treatment is directed mainly to correction of the acidosis and possibly, the administration of fomepizole. The same may occur with ethylene glycol ingestion. The subacute development of central field defects is attributable to other toxins and to the chronic administration of certain therapeutic agents, notably halogenated hydroxyquinolines (clioquinol), chloramphenicol, ethambutol, linezolid, isoniazid, streptomycin, chlorpropamide (Diabinese), infliximab, and various ergot preparations. The main drugs reported to have a toxic effect on the optic nerves are listed in Table 13-3 and have been catalogued more extensively by Grant.

Developmental Abnormalities of the Optic Nerve

Congenital cavitary defects because of defective closure of the optic fissure may be a cause of impaired vision because of failure of development of the papillomacular bundle. Usually the optic pit or a larger coloboma is unilateral and unassociated with developmental abnormalities of the brain (optic disc dysplasia and dysplastic coloboma). A hereditary form is known (Brown and Tasman). Vision may also be impaired as a result of a developmental anomaly in which the discs are of small diameter (hypoplasia of the optic disc, or micropapilla).

Other Optic Neuropathies

Optic nerve and chiasmal compression and infiltration by gliomas, meningiomas, craniopharyngiomas, and metastatic tumors may cause scotomas and optic atrophy (see Chap. 31). Pituitary tumors characteristically cause

bitemporal hemianopia, but very large adenomas, in particular if there is pituitary apoplexy (involutional bleeding into the pituitary), can cause blindness in one or both eyes (see “Pituitary Apoplexy” in Chap. 31). Infiltration of an optic nerve may occur in sarcoidosis (see Fig. 32-4, *bottom panel*), granulomatosis with polyangiitis (formerly Wegener granulomatosis), and with certain neoplasms, notably leukemia and lymphoma.

Of particular importance is the optic nerve glioma that occurs in 15 percent of patients with type I von Recklinghausen neurofibromatosis. Usually, it develops in children, often before the fourth year, causing a mass within the orbit and progressive loss of vision. If the eye is blind, the recommended therapy is surgical removal to prevent extension into the optic chiasm and hypothalamus. If vision is retained, radiation and chemotherapy are the recommended forms of treatment. Although most such gliomas are of low grade, a rare malignant form (glioblastoma) has been described in adults.

Thyroid ophthalmopathy with orbital edema, exophthalmos, and usually, swelling of extraocular muscles is an occasional cause of optic nerve compression.

Radiation-induced damage of the optic nerves and chiasm has been well documented. In a series of 219 patients at the M.D. Anderson Cancer Center who received radiotherapy for carcinomas of the nasal or paranasal region, retinopathy occurred in 7, optic neuropathy with blindness in 8, and chiasmatic damage with bilateral visual impairment in 1. These complications followed the use of more than 50 Gy (5,000 rad) of radiation (see Jiang et al). Radiation-induced optic neuropathy is typically delayed, occurring at an average of 18 months after radiation exposure, and is often accompanied by enhancement of the nerve on MRI. This is also addressed in Chap. 31.

In the case of pseudotumor cerebri, the visual loss may be unexpectedly abrupt, appearing in a day or less, and even sequentially in both eyes. This seems to happen most often in patients with constitutionally small optic nerves, no optic cup of the nerve head and, presumably, a small aperture of the lamina cribrosa. Such explosive visual loss in pseudotumor cerebri may respond to urgent optic nerve fenestration, but this approach is controversial, as discussed in “Pseudotumor Cerebri” in Chap. 30.

NEUROLOGY OF THE CENTRAL VISUAL PATHWAYS

From the retina there is a point-to-point projection to the lateral geniculate nucleus and from there, to the calcarine cortex of the occipital lobe. Thus the visual cortex receives a spatial pattern of stimulation that corresponds with the retinal image of the visual field. Visual impairments caused by lesions of the central pathways usually involve only a part of the fields, and a plotting of the fields provides fairly specific information as to the site of the lesion.

For purposes of description of the visual fields, each retina and macula are divided into a temporal and

nasal half by a vertical line passing through the fovea. A horizontal line represented roughly by the junction of the superior and inferior retinal vascular arcades also passes through the fovea and divides each half of the retina and macula into upper and lower quadrants. Visual field defects are always described from the patient’s view (nasal, temporal, superior, inferior) rather than of the retinal defect or the examiner’s perspective. The retinal image of an object in the visual field is inverted and reversed from right to left, like the image on the film of a camera. Thus the left visual field of each eye is represented in the opposite half of each retina, with the upper part of the field represented in the lower part of the retina (Fig. 13-3). Figure 13-5 illustrates the retinal projections to the geniculate nuclei and occipital cortex.

Testing for Abnormalities of the Visual Fields

Figure 13-3 illustrates the visual field defects caused by lesions of the retina, optic nerve and tract, lateral geniculate body, geniculocalcarine pathway, and striate cortex of the occipital lobe. In the alert, cooperative patient, the visual fields can be plotted fairly accurately at the bedside. With one of the patient’s eyes covered and the other fixed on the corresponding eye of the examiner (patient’s right with examiner’s left), a target—such as a moving finger, a cotton pledget, or a white disc mounted on a stick—is brought from the periphery toward the center of the visual field (confrontational testing). With the target at an equal distance between the eye of the examiner and that of the patient, the fields of the patient and examiner are then compared. Similarly, the patient’s blind spot can be aligned with the examiner’s, and its size determined by moving a small target outward from the blind spot until it is seen. Central and paracentral defects in the field can be outlined the same way. For reasons not known, red-green test objects are more sensitive than white ones in detecting defects of the visual pathways.

It should be emphasized that movement of the visual target provides the coarsest stimulus to the retina, so that a perception of its motion may be preserved while a stationary target of the same size may not be seen. In other words, moving targets are less useful than static ones in confrontational testing of visual fields. Finger counting and comparison of color intensity of a red object or the clarity of the examiner’s hand from quadrant to quadrant are simple confrontation tests that will disclose most field defects. Glaser recommends presenting the examiner’s hands simultaneously, one on each side of the vertical meridian; the hand in the hemianopic field appears blurred or darker than the other. Similarly, a scotoma may be defined by asking the patient to report changes in color or brightness of a red test object as it is moved toward or away from the point of fixation. Similarly, a central scotoma may be identified by having the patient fix with one eye on the examiner’s nose, on which the examiner places the index finger of one hand or a white-headed pin and has the patient compare it for brightness, clarity, and color with a finger or pin held in the periphery.

We continue to teach that these confrontation techniques are reasonably sensitive for routine clinical work if performed carefully, but we are chastened by the article from Pandit and colleagues, who found false-negative findings in 42 percent of patients tested with quadrant finger counting, using static automated perimetry as a standard. If any defect is found or suspected by confrontational testing, the fields should be charted and scotomas outlined on a tangent screen or perimeter. Accurate computer-assisted perimetry is now available in most ophthalmology clinics. Although the commonly used automated techniques encompass only the central visual field, this is adequate to detect most clinically important changes.

The method of testing by double simultaneous stimulation may elicit defects in the central processing of vision that are undetected by conventional perimetry. Movement of one finger in all parts of each temporal field may disclose no abnormality, but if movement is simultaneous in analogous parts of both temporal fields, the patient with a parietal lobe lesion, especially on the right, may perceive only the one in the normal right hemifield. In young children or uncooperative patients, the integrity of the fields may be roughly estimated by observing whether the patient is attracted to objects in the peripheral field or blinks in response to sudden threatening gestures in half of the visual field.

A type of abnormality disclosed by visual field examination is *concentric constriction*. This may be a result of severe papilledema, in which case it is usually accompanied by an enlargement of the blind spot. A progressive constriction of the visual fields, at first unilateral and later bilateral, associated with pallor of the optic discs (optic atrophy), should suggest a chronic meningeal process involving the optic nerves (syphilis, cryptococcosis, sarcoidosis, lymphoma). Long-standing, untreated glaucoma and retinitis pigmentosa are other causes of concentric constriction. Marked constriction of the visual fields of unvarying degree, regardless of the distance of the visual stimulus from the eye ("gun-barrel" or "tunnel" vision), however, is a sign of hysteria. With organic disease, the constricted visual field naturally enlarges as the distance between the patient and the test object increases.

A regional constriction of the field, especially in a nasal quadrant, usually signifies early optic atrophy, as mentioned earlier; it is the first sign that chronic papilledema is threatening the patient's vision.

Prechiasmal Lesions

Lesions of the macula, retina, or optic nerve cause a *scotoma* (an island of impaired vision surrounded by normal vision) rather than a defect that extends to the periphery of one visual field ("field cut"). Scotomas are named according to their position (central, cecocentral) or their shape (ring, arcuate). A small scotoma that is situated in the macular part of the visual field may seriously impair visual acuity.

Scotomas are the main features of optic neuropathy, the main causes of which were discussed earlier and are listed in Table 13-3. Demyelinating disease (optic neuritis),

Leber hereditary optic atrophy, toxins and nutritional deficiencies, and vascular disease (ischemic optic neuropathy or occlusion of a branch of the retinal artery) are the main ones. Orbital or retroorbital tumors and infectious or granulomatous processes (e.g., sarcoidosis, retinal toxoplasmosis in AIDS) are other common causes. In the elderly, there may be compression of the optic nerve by a dolichoectatic aneurysm of the carotid, ophthalmic, or basilar arteries.

As discussed earlier, certain toxic and malnutritional states are characterized by more or less symmetrical bilateral central scotomas (involving the fixation point), or cecocentral ones (involving both the fixation point and the blind spot). The cecocentral scotoma, which tends to have an arcuate border, represents a lesion that is predominantly in the distribution of the papillomacular bundle. However, the presence of this visual field abnormality does not establish whether the primary defect is in the cells of the origin of the bundle, i.e., the retinal ganglion cells, or in their fibers. Demyelinating disease is characterized by unilateral or asymmetrical bilateral scotomas. Vascular lesions that take the form of retinal hemorrhages or infarctions of the nerve-fiber layer (cotton-wool patches) give rise to unilateral scotomas; occlusion of the central retinal artery or its branches causes infarction of the retina and, as a rule, a loss of central vision, while occlusion of a branch of the retinal artery may cause an altitudinal defect. As pointed out earlier, AION causes sudden monocular blindness, or an altitudinal field defect. Since the optic nerve also contains the afferent fibers for the pupillary light reflex, extensive lesions of the nerve will cause an afferent pupillary defect, which was mentioned earlier and is considered further in Chap. 14.

Lesions of the Chiasm, Optic Tract, and Geniculocalcarine Pathway

Hemianopia (hemianopsia) means blindness in half of the visual field. *Bitemporal hemianopia* indicates a lesion of the decussating fibers of the optic chiasm and is caused most often by the suprasellar extension of a tumor of the pituitary gland (Fig. 13-3C). It may also be the result, at this same site, of a craniopharyngioma, a saccular aneurysm or dolichoectatic artery of the anterior circle of Willis, and a meningioma of the tuberculum sellae; less often, it may be a result of sarcoidosis, metastatic carcinoma, ectopic pinealoma or dysgerminoma, Hand-Schüller-Christian disease, or hydrocephalus with dilatation and downward herniation of the anterior part of the third ventricle (Corbett). In some instances a tumor pushing upward presses the medial parts of the optic nerves, just anterior to the chiasm, against the anterior cerebral arteries. Chiasmal syndromes from causes other than pituitary adenoma are usually associated with unilateral optic disc atrophy, a relative afferent pupillary defect and a greater defect in the inferior field.

Heteronymous field defects, i.e., scotomas or field defects that differ in the two eyes, are a sign of involvement of the optic chiasm or the adjoining optic nerves or tracts; they are caused by craniopharyngiomas, or other

suprasellar tumors and, rarely, by mucocoeles, angiomas, giant carotid aneurysms, and opticochiasmic arachnoiditis.

The visual field pattern created by a lesion in the optic nerve as it joins the chiasm typically includes a scotomatous defect on the affected side coupled with a contralateral superior quadrantanopia ("junctional field defect"). As noted previously, the latter is caused by interruption of nasal retinal fibers from the contralateral optic nerve. This was originally attributed to fibers projecting into the base of the affected optic nerve but there is now evidence against the existence of this structure as mentioned earlier, and discussed in the reference by Horton. Variations in the pattern of visual loss from chiasmal lesions are frequent, in part accounted for by the location of the chiasm in an individual patient—a postfixed chiasm making unilateral eye findings more common.

Homonymous hemianopia (a loss of vision in corresponding halves of the visual fields) signifies a lesion of the visual pathway behind the chiasm and, if complete, gives no more information than that. *Incomplete homonymous hemianopia* has more localizing value. As a rule, if the field defects in the two eyes are identical (congruous), the lesion is likely to be in the calcarine cortex and subcortical white matter of the occipital lobe; if they are *incongruous*, the visual fibers in the optic tract or in the parietal or temporal lobe are more likely to be implicated. Absolute congruity of field defects is actually infrequent, even with occipital lesions.

The lower fibers of the geniculocalcarine pathway (from the inferior retinas) swing in a wide arc over the temporal horn of the lateral ventricle and then proceed posteriorly to join the upper fibers of the pathway on their way to the calcarine cortex (Fig. 13-3). This arc of fibers is known variously as the Flechsig, Meyer, or Archambault loop, and a lesion that interrupts these fibers will produce a *superior homonymous quadrantanopia* (contralateral upper temporal and ipsilateral upper nasal quadrants; Fig. 13-3E), or in incomplete cases, a homonymous superior wedge defect respecting the vertical meridian. This clinical effect was first described by Harvey Cushing, so that his name also was in the past applied to the loop of temporal visual fibers. Parietal lobe lesions are said to affect the inferior quadrants of the visual fields more than the superior ones, but this is difficult to document; with a lesion of the right parietal lobe, the patient ignores the left half of space; with a left parietal lesion, the patient is often aphasic. As to the localizing value of *quadrantic defects*, the report of Jacobson is of interest; he found, in reviewing the imaging studies of 41 patients with inferior quadrantanopia and 30 with superior quadrantanopia, that in 76 percent of the former and 83 percent of the latter the lesions were confined to the occipital lobe.

If the entire optic tract or calcarine cortex on one side is destroyed, the homonymous hemianopia is complete. But often that part of the field subserved by the macula is spared, i.e., there is a 5- to 10-degree island of vision around the fixation point on the side of the hemianopia (sparing of fixation, or *macular sparing*). With infarction of the occipital lobe as a result of occlusion of the posterior cerebral artery, the macular region, represented in the

most posterior part of the striate cortex, may be spared by virtue of collateral circulation from branches of the middle cerebral artery. With other types of destructive lesions, this effect is not seen. Incomplete lesions of the optic tract and radiation also usually spare central (macular) vision. Nonvascular lesions of both occipital poles result in bilateral central scotomas; if all the calcarine cortex or all the subcortical geniculocalcarine fibers on both sides are completely destroyed, the bilateral hemianopias cause cerebral, or "*cortical*," blindness (see below and Chap. 22).

An *altitudinal defect* is one that is confined by a horizontal border and crosses the vertical meridian. *Homonymous altitudinal hemianopia* is usually caused by lesions of both occipital lobes below or above the calcarine sulcus, and rarely to a lesion of the optic chiasm or nerves. Just as with the contralateral representation of the visual fields in respect to the vertical meridian, the representation of the upper visual field is in the bank of neurons below the calcarine fissure and vice versa. The most common cause of this rare phenomenon is still occlusion of both posterior cerebral arteries. Herniation of the occipital lobe over the tentorial margin can produce a homonymous superior altitudinal defect by selectively compressing the inferior branches of the posterior cerebral arteries. A monocular altitudinal hemianopia, by contrast, is almost invariably an ischemic optic neuropathy that arises from occlusion of the posterior ciliary vessels.

In certain instances of homonymous hemianopia, the patient is capable of some visual perception in the hemianopic fields, a circumstance that permits the study of the vulnerability of different visual functions. Colored targets may be detected in the hemianopic fields, whereas achromatic ones cannot. But even in seemingly complete hemianopic defects, in which the patient admits to being blind, it has been shown that he may still react to visual stimuli when forced-choice techniques are used. Blythe and coworkers found that 20 percent of their patients with no ability to discriminate patterns in the hemianopic field nonetheless could still reach accurately and look at a moving light in the "blind" field. This type of residual visual function has been called "blindsight" by Weiskrantz and colleagues. These residual visual functions are generally attributed to the preserved function of retinocollicular or geniculoprestriate cortical connections, but in some cases, they may be a result of sparing of small islands of calcarine neurons. In yet other instances of complete homonymous hemianopia, the patient may be little disabled by visual field loss (Benton et al; Meienberg). This is because of preservation of vision in a small monocular part of the visual field known as the *temporal crescent*. The latter is a peripheral unpaired portion of the visual field, between 60 and 100 degrees from the fixation point, and is represented in the most anterior part of the visual striate cortex. In particular, the temporal crescent is sensitive to moving stimuli, allowing the patient to avoid collisions with people and objects. The tendency for patients with occipital lesions to have greater sensitivity for kinetic stimuli than for static ones was described by Riddoch in 1917.

Blindness in the Hysterical or Malingering Patient

Hysterical, or *psychogenic blindness*, is described in Chap. 51, along with other features of hysteria, but a few comments are in order here. Feigned or hysterical visual loss is usually detected by attending to the patient's activities when he thinks he is unobserved, and it can be confirmed by a number of simple tests. Complete feigned blindness is disproved by observing the normal ocular jerk movements in response to a rotating optokinetic drum or strip, or by noting that the patient's eyes follow their own image in a mirror that is moved in front of them. The hysterical nature of *total monocular blindness* is apparent from the presence of a normal direct pupillary response to light. An optokinetic response in the nonseeing eye (with the good eye covered) is an even more convincing test. The visual evoked potential from the allegedly blind eye is also normal. Hysterical monocular loss may also be revealed by the use of red-green glasses and an acuity chart with red and green letters, where each eye can only see letters with the color of its lens. The patient cannot tell which letters should be visible to them, and the intact acuity in the involved eye is soon exposed. *Hysterical homonymous hemianopia* is rare and is displayed mostly by practiced malingerers; all manner of field defects are common in this population (Keane). The uniformly constricted tubular field defect of hysteria has already been mentioned. Star- and spiral-shaped visual fields are also indicative of psychogenic visual loss.

Cerebral Forms of Blindness and Visual Agnosia (See also Chap. 22)

The ability to recognize visually presented objects and words depends on the integrity not only of the visual pathways and primary visual area of the cerebral cortex (area 17 of Brodmann) but also of those cortical areas that lie just anterior to area 17 (areas 18 and 19 of the occipital lobe and area 39—the angular gyrus of the dominant hemisphere). Blindness that is the result of destruction of both visual and adjacent regions of the occipital lobes is termed *cortical* or *cerebral blindness*. Another remarkable condition exists in which the patient denies or is oblivious to blindness despite overt manifestations of the defect (Anton syndrome).

In distinction to these forms of blindness, there is a less-common category of visual impairment in which the patient cannot understand the meaning of what he sees, i.e., *visual agnosia*. Primary visual perception is more or less intact, and the patient may accurately describe the shape, color, and size of objects and draw copies of them. Despite this, he cannot identify the objects unless he hears, smells, tastes, or palpates them. The failure of visual recognition of words alone is called *visual verbal agnosia*, or *alexia*. Visual-object agnosia rarely occurs as an isolated finding; as a rule, it is combined with visual verbal agnosia, homonymous hemianopia, or both. These abnormalities arise from lesions of the dominant occipital cortex and adjacent temporal and parietal cortex (angular gyrus) or from a lesion of the left calcarine cortex

combined with one that interrupts the fibers crossing from the right occipital lobe (see Fig. 22-6). In the latter case, fibers responsible for writing are spared, and the patient remains with a syndrome of alexia without agraphia.

Failure to understand the meaning of an entire picture even though some of its parts are recognized is referred to as *simultanagnosia*, and is found in bilateral lesions of the occipital–parietal junction. When combined with deficits in visual control of eye and hand movements (optic ataxia and ocular apraxia), the resulting condition is referred to as Balint syndrome. A failure to recognize familiar faces is called *prosopagnosia* and typically results from occipital–temporal lesions. These and other variants of visual agnosia (including visual neglect) and their pathologic bases are dealt with more fully in Chap. 22.

Other cerebral disturbances of vision include various types of distortion in which images seem to recede into the distance (*teleopsia*), appear too small (*micropsia*), or, less frequently, seem too large (*macropsia*). If such distortions are perceived with only one eye, a local retinal lesion should be suspected. If perceived with both eyes, they usually signify disease of the temporal lobes, in which case the visual disturbances tend to occur in attacks and are accompanied by other manifestations of temporal lobe seizures (see Chap. 16). *Palinopsia*, a persistence of repetitive afterimages, similar to the appearance of a celluloid movie strip, occurs with right parietooccipital lesions; it has been a consequence of seizures in the cases we have encountered, but instances associated with static disorders (tumor, infarction) have been described as well. Patients describe the images as “trailing” or “echoing.” With parietal lobe lesions, objects may appear to be askew or even turned upside down. More often, lesions of the vestibular nucleus or its immediate connections produce the illusion that objects are tilted or turned upside down (*tortopsia*), or that straight lines are curved. Presumably this is the result of a mismatch between the visual image and the otolithic, or vestibular input to the visual system.

Abnormalities of Color Vision

Normal color vision depends on the integrity of cone cells, which are most numerous in the macular region. When activated, they convey information to special columns of cells in the striate cortex. Three different cone pigments with optimal sensitivities to blue, green, and orange-yellow wavelengths are said to characterize these cells; presumably each cone possesses only one of these pigments. Transmission to higher centers for the perception of color is effected by neurons and axons that encode at least two pairs of complementary colors: red-green in one system and yellow-blue in the other. In the optic nerves and tracts, the fibers for color are of small caliber and seem to be preferentially sensitive to certain noxious agents and to pressure. The geniculostriate fibers for color are separate from fibers that convey information about form and brightness, but course alongside them; hence, there may be a homonymous color hemianopia (*hemiachromatopsia*). The visual fields for blue-yellow are smaller than those for white light, and the red and green fields are smaller than those for blue-yellow.

Diseases may affect color vision by abolishing it completely (*achromatopsia*) or partially by quantitatively reducing one or more of the three attributes of color—brightness, hue, and saturation. Or, only one of the complementary pairs of colors may be lost, usually red-green. The disorder may be congenital and hereditary or acquired. The most common form, and the one to which the term *color blindness* is usually applied, is a male sex-linked inability to see red and green while normal visual acuity is retained. The main problem arises in relation to traffic lights, but patients learn to use the position of the light as a guide. Several other genetic abnormalities of cone pigments and their phototransduction have been identified as causes of achromatopsia. The defect cannot be seen by inspecting the retina. A failure of the cones to develop or a degeneration of cones may cause a loss of color vision, but in these conditions visual acuity is often diminished, a central scotoma may be present, and, although the macula also appears to be normal ophthalmoscopically, fluorescein angiography shows the pigment epithelium to be defective. Whereas congenital color vision defects are usually protan (red) or deutan (green), leaving yellow-blue color vision intact, most acquired lesions affect all colors, at times disparately. Lesions of the optic nerves usually affect red-green more than blue-yellow; the opposite is true of retinal lesions. An exception is a rare, dominantly inherited, optic atrophy, in which the scotoma mapped by a large blue target is larger than that for red.

Damasio has drawn attention to a group of acquired deficits of color perception with preservation of form vision, the result of focal damage (usually infarction) of the visual association cortex, and subjacent white matter. Color vision may be lost in a quadrant, half of the visual field, or the entire field. The latter, or full-field achromatopsia, is the result of bilateral occipitotemporal lesions involving the fusiform and lingual gyri, a localization that accounts for its frequent association with visual agnosia (especially prosopagnosia), and some degree of visual field defect. A lesion restricted to the inferior part of the right occipitotemporal region, sparing both the optic radiations and striate cortex, causes the purest form of achromatopsia (left hemiachromatopsia). With a similar left-sided lesion, alexia may be associated with the right hemiachromatopsia.

Other Visual Disorders

In addition to the losses of perception of form, movement, and color, lesions of the visual system may also give rise to a variety of positive sensory visual experiences. The simplest of these are called phosphenes, i.e., flashes of light and colored spots in the absence of luminous stimuli. Mechanical pressure on the normal eyeball may induce them at the retinal level, as every child discovers. Or they may occur with disease of the visual system at many different sites. As mentioned earlier, elderly patients commonly complain of flashes of light in the peripheral field of one eye, most evident in the dark (*Moore lightning streaks*); these are related to vitreous tags that rest on the retinal equator, and may be quite benign,

or may be residual evidence of retinal detachment. Cancer associated retinopathy is frequently associated with photopsias prior to visual loss. Retinal toxicity from digitalis causes chromatopsia with a characteristic “yellowish vision” and may also cause photopsias. In patients with migraine, activation of nerve cells in the occipital lobe, gives rise to the bright zigzag lines of a fortification spectrum. Stimulation of the cortical terminations of the visual pathways accounts for the simple or unformed visual hallucinations in epilepsy. Formed or complex visual hallucinations (of people, animals, landscapes) are observed in a variety of conditions, notably in old age when vision fails (Charles Bonnet syndrome, discussed in “Visual Hallucinations” in Chap. 22), in the withdrawal state following chronic intoxication with alcohol and other sedative-hypnotic drugs (see Chaps. 42 and 43), in Alzheimer disease, and in infarcts of the occipitoparietal or occipitotemporal regions (release hallucinations) or the diencephalon (“peduncular hallucinosis”). These disorders are also discussed in Chap. 22.

Occasionally, patients in whom a hemianopia is evident only when tested by double simultaneous stimulation (a component of visual neglect) may displace an image to the non-affected half field (*visual allesthesia*), or a visual image may persist for minutes to hours or reappear episodically, after the exciting stimulus has been removed (*palinopsia* or *paliopsia* mentioned earlier); the latter disorder also occurs in defective but not blind homonymous fields of vision. *Polyopia*, the perception of multiple images when a single stimulus is presented, is said to be associated predominantly with right occipital lesions and can occur with either eye. Usually there is one primary and a number of secondary images, and their relationships may be constant or changing. Bender and Krieger, who described several such patients, attributed the polyopia to unstable fixation. When this is monocular, there is either a defect in the lens or, more often, hysteria. *Oscillopsia*, or illusory movement of the environment, is a perception caused by nystagmus and occurs mainly with lesions of the labyrinthine-vestibular apparatus; it is described with disorders of ocular movement. A rare idiopathic myokymia of one superior oblique muscle may produce a monocular oscillopsia (see “Fourth Nerve Palsy” in Chap. 14).

Chapter 22 further discusses the clinical effects and syndromes that result from occipital lobe lesions.

Amblyopia Because of Early Life Strabismus (Amblyopia Ex Anopsia)

As noted in the introductory part of this chapter, the generic term “amblyopia” has been adopted for a special circumstance in which a normal eye fails to acquire its potential visual acuity because images are not properly projected onto the fovea during a formative period of cerebral development. It is a disorder, as in the quip by van Noorden and Campos, “in which the patient sees nothing and the doctor sees nothing.” The period of risk is during the first 7 years but is greatest in the earlier part of this epoch, and the visual loss may still be rectifiable beyond the time.

The degradation of vision and disuse of the fovea may be the result of a number of processes, most often misaligned ocular axes (strabismus) and also including unequal refractive errors (anisometropia; discussed in Chap. 14). These conditions are the most common sources of visual disturbance in children. The uncorrected condition also accounts for an estimated 3 percent of monocular visual loss in adults. By convention, the diagnosis of amblyopia requires that a loss of 2 lines or more between eyes be observed on the Snellen chart.

The developmental deficiency in the occipital cortex that gives rise to amblyopia has been extensively studied in animals and humans; a discussion of the subject can

be found in numerous texts including the one by van Noorden and Campos. Neurologists should be aware that screening children for the disorder is highly valuable even if treatment is not always successful. The correction of refractive errors, cataract, and other correctible ocular problems are attended to first. Attempts are then made to force the utilization of the disadvantaged eye in preference to the normal one; patching and atropine drops are the typical methods to accomplish this. Other techniques of management and a summary of clinical trials of each can be found in the review by Holmes and Clarke. Chapter 14 discusses the problem of strabismus and the latent phorias that create confusion in the neurologic examination.

Disorders of Ocular Movement and Pupillary Function

Ocular movement and vision are virtually inseparable. A moving object evokes movement of the eyes and almost simultaneously arouses attention and initiates the perceptive process. To look searchingly, i.e., to peer, requires stable fixation of the visual image on the center of the two retinas. One might say that the ocular muscles are at the service of vision.

Abnormalities of ocular movement are of three basic types. One category can be traced to a lesion of the extraocular muscles themselves, the neuromuscular junction, or to the cranial nerves that supply them (*nuclear* or *infranuclear palsy*). The second type is a derangement in the highly specialized neural mechanisms that enable the eyes to move together (*supranuclear* and *internuclear palsies*). This distinction, in keeping with the general concept of upper and lower motor neuron paralysis, hardly portrays the complexity of the neural mechanisms governing ocular motility. Perhaps more common but not primarily neurologic is a third group of disorders, *strabismus*, in which there is a congenital imbalance of the yoked muscles of extraocular movement that may lead to a developmental reduction in monocular vision (amblyopia), as discussed at the end of the previous chapter. Knowledge of the anatomic basis of normal movement is essential to an understanding of abnormal movement.

SUPRANUCLEAR CONTROL OF EYE MOVEMENT

Anatomic and Physiologic Considerations

In no aspect of human anatomy and physiology is the sensory guidance of muscle activity more instructively revealed than in the neural control of coordinated ocular movement. Moreover, the entirely predictable and “hard-wired” nature of the central and peripheral oculomotor apparatus allows for a very precise localization of lesions within these pathways. To focus the eyes voluntarily, to stabilize objects for scrutiny when one is moving, to bring into sharp focus near and far objects—all require the perfect coordination of six sets of extraocular muscles and three sets of intrinsic muscles (ciliary muscles, sphincters, and dilators of the iris). The neural mechanisms that govern these functions reside mainly in the midbrain and

pons but are greatly influenced by centers in the medulla, cerebellum, basal ganglia, and the frontal, parietal, and occipital lobes of the brain. Most of the nuclear structures and pathways concerned with fixation and stable ocular movements are now known and much has been learned of their physiology both from clinical-pathologic correlations in humans and from experiments in monkeys.

Accurate binocular vision is actually achieved by the associated action of all the ocular muscles. The symmetrical and synchronous movement of the eyes is termed *conjugate movement* or *gaze* (*conjugate* meaning yoked or joined together). The simultaneous movement of the eyes in different directions, as in convergence, is termed *dysconjugate* or *disjunctive*. These two forms of normal ocular movements are also referred to as *versions* (*versional*) and *vergence*, respectively. *Vergence movements* have two components—fusional and accommodative. The fusional movements are *convergence* and *divergence*, which maintain binocular single vision and depth perception (stereopsis); they are necessary at all times to ensure that visual images fall on corresponding parts of the retinas. *Convergent movements* are brought into action when one looks at a near object. The eyes turn inward and at the same time the pupils constrict and the ciliary muscles relax to thicken the lens and allow near vision (the accommodative-near reflex, or triad). Divergence, albeit slight, is required for distant vision.

Rapid voluntary conjugate movements of the eyes to the opposite side are initiated in area 8 of the frontal lobe (see Fig. 22-1) and relayed to the pons. These quick movements are termed *saccadic* (peak velocity may exceed 700 degrees per second). Their purpose is to rapidly change ocular fixation and bring images of new objects of interest onto the foveae. Saccades are so rapid that there is no subjective awareness of movement during the change in eye position, essentially, a momentary blindness. Saccadic movements can be elicited by instructing an individual to look to the right or left (commanded saccades), or to move the eyes to a target (refixation saccades). These two movements are sometimes differently affected in neurologic disease. Saccades may also be elicited reflexively, as when a sudden sound or the appearance of an object in the peripheral field of vision attracts attention and triggers an automatic movement of the eyes in the direction of the stimulus. Saccadic latency,

the interval between the appearance of a target and the initiation of a saccade, is approximately 200 ms.

The neurophysiologic pattern of pontine neurons that produces a saccade has been characterized as “pulse-step” in type. This refers to the sudden increase in neuronal firing (the pulse) that is necessary to overcome the inertia and viscous drag of the eyes and move them into their new position; it is followed by a return to a new baseline firing level (the step), which maintains the eyes in their new position by tonic contraction of the extraocular muscles (*gaze holding*).

Saccades are distinguished from the slower and smoother *pursuit* or *following movements*, for which the major stimulus is a moving target. The function of pursuit movements is to stabilize the image of a moving object on the foveae, and thus to maintain a continuous clear image of the object as the object changes position (“smooth tracking”). Unlike saccades, pursuit movements to each side are generated in the *ipsilateral* parietooccipital cortex, with modulation by the ipsilateral cerebellum, especially the vestibulocerebellum (flocculus and nodulus). Another portion of the cerebellum, the posterior vermis, also influences saccadic movements (see further on).

When following a moving target, as the visual image slips off the foveae, the firing rate of the governing motor neurons increases in proportion to the speed of the target, so that eye velocity matches target velocity. If the eyes fall behind the target, supplementary catch-up saccades are required for refixation. The pursuit movement is then not smooth, but becomes jerky (“saccadic” pursuit). A lesion of one cerebral hemisphere may cause pursuit movements to that side to break up into saccades. Diseases of the basal ganglia are also a common cause of a disruption of normally smooth pursuit into a ratchet-like saccadic pursuit in all directions.

If a series of visual targets enters the visual field, as when one is watching trees from a moving car or the stripes on a rotating drum, involuntary repeated quick saccades refocus the eyes centrally; the resulting cycles of pursuit and refixation are termed *optokinetic nystagmus*. This phenomenon is used as a bedside test, the main value of which is in revealing a lesion of the ipsilateral posterior parietal lobe. It may also be found that a frontal lobe lesion eliminates the quick nystagmoid refixation phase away from the side of the lesion, thereby causing the eyes to continue to follow the target until it is out of view. This optokinetic phenomenon is described more fully further on, in the section on nystagmus.

Vestibular influences are of particular importance in stabilizing images on the retina during head and body movement. By means of the *vestibuloocular reflex* (VOR), a prompt short latency movement of the eyes is produced that is equal and opposite to movement of the head. During sustained rotation of the head, the VOR is supplemented by the optokinetic system, which enables one to maintain compensatory eye movements for a more prolonged period. If the VOR is lost, as occurs with disease of the vestibular apparatus or eighth nerve, the slightest movements of the head, especially those occurring during locomotion, cause a movement of

images across the retina large enough to impair vision. A unilateral loss of the VOR strongly implicates a disease of the vestibular apparatus on the side toward the rotation of the head. When objects are tracked using both eye and head movements, the VOR must be suppressed, otherwise the eyes would remain fixed in space; to accomplish this, the smooth pursuit signals cancel the unwanted vestibular ones (Leigh and Zee). It follows that the inability to suppress the VOR, while viewing a target as the patient is rotated, is indicative of a defect of supranuclear pursuit.

Horizontal Gaze

Saccades

As already mentioned, the signals for volitional horizontal gaze saccades originate in the eye field of the opposite frontal lobe (area 8 of Brodmann, see Fig. 22-1) and are modulated by the adjacent supplementary motor eye field and by the posterior visual cortical areas. Leichnetz traced the cortical-to-pontine pathways for saccadic horizontal gaze in the monkey. These fibers traverse the internal capsule and separate at the level of the rostral diencephalon into two bundles, the first being a primary ventral “capsular–peduncular” bundle, which descends through the most medial part of the cerebral peduncle. This more ventral pathway undergoes a partial decussation in the low midbrain, at the level of the trochlear nucleus, and terminates mainly in the vaguely defined paramedian pontine reticular formation (PPRF) of the opposite side, neurons of which, in turn, project to the adjacent sixth nerve nucleus (Fig. 14-1). A second, more dorsal “transthalamic” bundle is predominantly uncrossed and courses through the internal medullary lamina and paralamina parts of the thalamus to terminate diffusely in the pretectum, superior colliculus, and periaqueductal gray matter. An off-shoot of these fibers (the prefrontal oculomotor bundle) projects to the rostral part of the oculomotor nucleus and to the ipsilateral rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) and to the interstitial nucleus of Cajal (INC), which are involved in vertical eye movements, as discussed in the next section.

Pursuit

The pathways for smooth pursuit movements are less well defined. One probably originates in the posterior parietal cortex and the adjacent temporal, and anterior occipital cortex (area MT of the monkey) and descends to the ipsilateral dorsolateral pontine nuclei. Also contributing to smooth pursuit movements are projections from the frontal eye fields to the ipsilateral dorsolateral pontine nuclei. The latter, in turn, project to the flocculus and dorsal vermis of the cerebellum, which provide stability for the pursuit movements. However, for the purposes of clinical work, lesions of the posterior parietal cortex are the ones known to impair pursuit toward the damaged side. Part of the frontal eye fields have been shown experimentally to participate in pursuit eye movements, but the influence of this area on pursuit is far less than that of the parietal lobes and is insignificant clinically.

Figure 14-1. The supranuclear pathways subserving saccadic horizontal gaze to the left. The pathway originates in the right frontal cortex, descends in the internal capsule, decussates at the level of the rostral pons, and descends to synapse in the left pontine paramedian reticular formation (PPRF). Further connections with the ipsilateral sixth nerve nucleus and contralateral medial longitudinal fasciculus are also indicated. Cranial nerve nuclei III and IV are labeled on left; nucleus of VI and vestibular nuclei (VN) are labeled on right. The right MLF (green line) is labeled between the 3rd and 6th nerves on that side. LR, lateral rectus; MLF, medial longitudinal fasciculus; MR, medial rectus.

Brainstem (Internuclear) Pathways and Oculomotor Nuclei

Conventionally, the term *ocular motor nuclei* refers to the nuclei of the third, fourth, and sixth cranial nerves; the term *oculomotor nucleus* refers to the third nerve nucleus alone. Ultimately, all the pathways mediating saccadic and pursuit movements in the horizontal plane, as well as for vestibular and optokinetic movements, converge on the pontine tegmental center for horizontal gaze, the PPRF. Also required for horizontal versional movements are the nuclei prepositus hypoglossi and their commissure, the abducens and medial vestibular nuclei, and pathways in the pontine and tegmentum of the brainstem that interconnect the oculomotor nuclei (Fig. 14-1).

The PPRF and the prepositus and medial vestibular nuclei are conceptualized as a “neural integrator” and relay station for horizontal saccade pathways. It is further considered that the PPRF projects to the sixth nerve nucleus to command horizontal eye movement. However, it is understood from animal experiments that

supranuclear neural signals that encode smooth pursuit, and vestibular and optokinetic movements bypass the PPRF and project independently to the abducens nuclei (Hanson et al).

The fiber bundle connecting the third and sixth nerve nuclei, and connecting both these nuclei with the vestibular nuclei lies in the medial tegmentum of the brainstem; this pathway is the *medial longitudinal fasciculus* (MLF). The fibers of the MLF emanating from the sixth nerve nucleus cross in the pons and ascend to the contralateral medial rectus subnucleus of the third nerve. In this way, the abduction of one eye is yoked to adduction of the opposite one to produce conjugate horizontal gaze as described just below.

The abducens nucleus contains two groups of neurons, each with distinctive morphologic and physiologic properties: (1) the intranuclear abducens motor neurons, which innervate the ipsilateral lateral rectus muscle, and (2) abducens internuclear neurons, which project via the contralateral MLF to the medial rectus neurons of the opposite oculomotor nucleus. Conjugate lateral gaze is

accomplished by the simultaneous activation of the ipsilateral lateral rectus, and the contralateral medial rectus, again, the latter through fibers that run in the medial portion of the MLF. Interruption of the MLF results in a discrete impairment or loss of adduction of the eye ipsilateral to the lesion, a sign referred to as *internuclear ophthalmoplegia*, the details of which are discussed further on (Fig. 14-1).

Two other ascending pathways between the pontine centers and the mesencephalic reticular formation have been traced: one traverses the central tegmental tract and terminates in the pretectum, in the nucleus of the posterior commissure; the other is a bundle separate from the MLF that passes around the nuclei of Cajal and Darkschewitsch to the riMLF. These nuclei are involved more in vertical gaze and are described below. In addition, each vestibular nucleus projects onto the abducens nucleus, and the MLF of the opposite side. This pathway is considered to generate the slow phase of the VOR.

Although direct projections from the frontal eye fields that bypass the PPRF and innervate the oculomotor nuclei, as described above, undoubtedly exist, indirect projections are more important in the voluntary control of conjugate eye movements. According to Leigh and Zee, a more accurate view of these various voluntary influences is one of a hierarchy of cell stations and parallel pathways that do not project directly to oculomotor nuclei but to adjacent *premotor* or *burst neurons*, which discharge at high frequencies immediately preceding a saccade. The premotor or burst neurons for horizontal saccades lie within the PPRF and those for vertical saccades in the riMLF (see below). Yet a third class of neurons (omnipause cells), lying in the midline of the pons, is involved in the inhibition of unwanted saccadic discharges. Nonetheless, in clinical work, the circuit that comprises in sequence (1) frontal lobe eye fields, (2) contralateral pontine PPRF, (3) abducens nucleus, (4) MLF, and (5) opposite oculomotor nucleus makes understandable a number of highly characteristic defects of horizontal ocular motion, as detailed in the remainder of the chapter.

Vertical Gaze

In contrast to horizontal gaze, which is generated by unilateral aggregates of cerebral and pontine neurons, vertical eye movements, with few exceptions, are under bilateral control of the cerebral cortex and upper brainstem. The groups of nerve cells and fibers that govern upward and downward gaze, as well as torsional saccades, are situated in the pretectal areas of the midbrain and involve three integrated structures—the riMLF, the INC, and the nucleus and fibers of the posterior commissure (Fig. 14-2).

The *riMLF* lies at the junction of the midbrain and thalamus, at the rostral end of the medial longitudinal fasciculus, just dorsomedial to the rostral pole of the red nucleus. It functions as the “premotor” nucleus with “burst cells” for the production of fast (saccadic) vertical versional and torsional movements. Input to the riMLF arises both from the PPRF and the vestibular nuclei. Each riMLF projects mainly ipsilaterally to the oculomotor and

Figure 14-2. Pathways for the control of vertical eye movements. The main structures are the interstitial nucleus of Cajal (INC), the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), and the subnuclei of the third nerve, all located in the dorsal midbrain. Voluntary vertical movements are initiated by the simultaneous activity of both frontal cortical eye fields. The riMLF serves as the generator of vertical saccades and the INC acts tonically to hold eccentric vertical gaze. The INC and riMLF connect with their contralateral nuclei via the posterior commissure, where fibers are subject to damage. Projections for upgaze cross through the commissure before descending to innervate the third nerve nucleus, while those for downgaze may travel directly to the third nerve, thus accounting for the frequency of selective upgaze palsies (see text). The MLF carries signals from the vestibular nuclei, mainly ipsilaterally, to stabilize the eyes in the vertical plane (VOR) and maintain tonic vertical position.

trochlear nuclei, but each riMLF is also connected to its counterpart by fibers that traverse the posterior commissure. Bilateral lesions of the riMLF or of their interconnections in the posterior commissure are more common than unilateral ones, and cause a loss either of downward saccades or of all vertical saccades.

The *INC* is a small collection of cells that lies just caudal to the riMLF on each side. Each nucleus projects to the motor neurons of the opposite elevator muscles (superior rectus and inferior oblique) by fibers that cross through the posterior commissure, and it projects ipsilaterally and directly to the depressor muscles (inferior rectus and superior oblique). The functional role of the INC appears to be in holding eccentric vertical gaze, especially after a saccade; it is also integral to the vestibuloocular reflex. Lesions of the INC produce a vertical gaze-evoked and torsional nystagmus, and an ocular tilt reaction and probably slow all conjugate eye movements, mainly vertical ones.

Lesions of the *posterior commissure* are common; they interrupt signals crossing to and from the INC and the riMLF. A lesion here characteristically produces a paralysis of upward gaze and of convergence, often associated with mild mydriasis, accommodative loss, convergence nystagmus, lid retraction (Collier “tucked lid” sign), and, less commonly, ptosis. This constellation is the *Parinaud syndrome*, also referred to as the pretecal, dorsal midbrain, or sylvian aqueduct syndrome (see “Vertical Gaze Palsy” further on). In some instances, only a restricted combination of these signs is seen. The same syndrome may be produced by unilateral lesions of the posterior commissure, presumably by interrupting bidirectional connections from the riMLF and INC. With acute lesions of the commissure, there is a tonic downward deviation of the eyes and lid retraction (“setting-sun sign”).

The MLF is the main conduit of signals that control vertical gaze from the vestibular nuclei in the medulla to the midbrain centers. For this reason, with internuclear ophthalmoplegia, along with the characteristic adductor paresis on the affected side, vertical pursuit and the VOR are impaired. This is most evident when there are bilateral internuclear ophthalmoplegias. Vertical deviation of the ipsilateral eye (*skew*) may be seen in cases of unilateral internuclear ophthalmoplegia, as discussed further on.

Vestibulocerebellar Influences on Eye Movements

There are important vestibulocerebellar influences on both smooth pursuit and saccadic movements (see also Chap. 5). The flocculus and posterior vermis of the cerebellum receive abundant sensory projections from proprioceptors of the cervical musculature (responsive to head velocity), the retinas (sensitive to target velocity), proprioceptors of eye muscles (eye position and eye velocity), auditory and tactile receptors, and the superior colliculi and PPRF. Cerebellar efferents concerned with ocular movement project onto the vestibular nuclei, and the latter, in turn, influence gaze mechanisms through several projection systems: one, for horizontal movements, consists of direct projections from the vestibular nuclei to the contralateral sixth nerve nucleus; another, for vertical movements, projects via the contralateral MLF to third and fourth nerve nuclei (Figs. 14-1 and 14-2).

Lesions of the flocculus and posterior vermis are consistently associated with deficits in smooth pursuit movements and an inability to suppress the vestibuloocular reflex by fixation (Baloh et al). Floccular lesions are also an important cause of downbeat nystagmus. As indicated in Chap. 5, patients with cerebellar (floccular) lesions are unable to hold eccentric positions of gaze and must make repeated saccades to look at a target that is away from the neutral position (*gaze-paretic nystagmus*, a term also applied to nystagmus arising from a lesion in the PPRF). This phenomenon is explained by the fact that with acute, one-sided lesions of the vestibulocerebellum, the inhibitory discharges of the Purkinje cells onto the ipsilateral medial vestibular nucleus are removed, and the eyes deviate away from the lesion. When gaze to the side of

the lesion is attempted, the eyes drift back to the midline, and fixation can be corrected only by a saccadic jerk. The head and neck may also turn away from the lesion (the occiput toward the lesion and the face away). In addition, the vestibuloocular reflexes, which coordinate eye movements with head movements, are improperly adjusted (Thach and Montgomery). The interested reader can find further details concerning cerebellar influences on ocular movements in the monograph by Leigh and Zee and the review by Lewis and Zee.

Testing of Conjugate Gaze

It is apparent from the foregoing remarks that there is considerable clinical information to be obtained from an analysis of ocular movements. To fully examine the eye movements, the patient should be asked to look quickly to each side as well as up and down (saccades) and to follow a moving target (pursuit of a light, the examiner’s finger, or an optokinetic drum). A patient with stupor and coma can be examined by passively turning the head or by irrigating the external auditory canals; these are vestibular stimuli to reflex eye movement as discussed in Chap. 17.

Most individuals make accurate saccades to a target. Alterations of saccadic movements, particularly overshooting of the eyes (*hypermetria*), are characteristic of a cerebellar lesion. *Slowness of saccadic movements* is mainly the result of disease of the basal ganglia such as Huntington and Wilson diseases, ataxia-telangiectasia, progressive supranuclear palsy, olivopontocerebellar degeneration, and certain lipid storage diseases. Lesions involving the PPRF may also be accompanied by slow saccadic movements to the affected side. Hypometric, slow saccades occurring only in the adducting eye indicate an incomplete internuclear ophthalmoparesis caused by a lesion of the ipsilateral MLF. When the earliest sign of a progressive eye movement disorder is slow saccades in the vertical plane, the likely diagnosis is progressive supranuclear palsy, but the same sign may occur in Parkinson disease and several less common processes that affect the basal ganglia, as discussed further on under “Vertical Gaze Palsy.” Slow up-and-down saccades are also found in Niemann-Pick disease type C.

Yet another saccadic disorder takes the form of an *inability to initiate voluntary movements*, either vertically or horizontally. This abnormality may be congenital in nature, as in the ocular “apraxia” of childhood (Cogan syndrome, see below) and in ataxia-telangiectasia; an acquired difficulty in the initiation of saccadic movements may be seen in patients with Huntington disease or with a lesion of the contralateral frontal lobe or ipsilateral pontine tegmentum. The most common explanation for the inability to move the eyes is hysteria, a circumstance that can be exposed by noting the patient will follow his own eyes in a mirror.

In addition to abnormalities of the saccades themselves, saccadic latency or reaction time (the interval between the impulse to move and movement) is prolonged in Huntington chorea and Parkinson disease. Saccadic latency is also increased in corticobasal ganglionic degeneration

(see Chap. 39), in which case it seems to correspond to the degree of motor apraxia. The obligate need to initiate eye movements with a blink is often a subtle sign of disordered supranuclear control of conjugate movements that is evident in these same diseases and in other processes including frontal lobe lesions.

Fragmentation of smooth pursuit movement, a frequent neuroophthalmic finding, is a jerky irregularity of tracking that has been called “saccadic pursuit”. Two broad categories of disorders give rise to this phenomenon; a vestibulocerebellar and an extrapyramidal type. The former is commonly the result of sedative drug intoxication—with barbiturates, diazepam, and others as well as from a lesion of the vestibulocerebellar apparatus. In both, there is gaze directed nystagmus that seemingly interrupts pursuit movements as well. It is possible that sedatives cause this disturbance by affecting this same system.

A similar-appearing phenomenon, but one that does not manifest nystagmus, nicely called “*cogwheel eye movements*”, is seen in certain extrapyramidal diseases such as Parkinson disease, Huntington disease, and progressive supranuclear palsy. In these diseases there is a ratchet-like impairment of smooth pursuit movements in association with slow, hypometric saccades (“saccadic pursuit”). Indeed, according to Vidailhet and colleagues, smooth pursuit movements are impaired in all types of basal ganglionic degenerations.

Asymmetrical impairment of smooth pursuit movements is indicative of a parietal or a frontal lobe lesion. Pursuit is impaired *toward the side of a parietal lesion and away from a frontal lesion*, as described earlier. This is not a common clinical phenomenon unless elicited by optokinetic testing as explained further on.

Vestibuloocular Reflex (VOR) Testing

This refers to involuntary conjugate eye movements that are contraversive to head turning and is manifest in unresponsive patients. Stimulation of the labyrinths by caloric or electrical activation elicits an identical phenomenon and can be performed in awake patients as well, as described in Chap. 17 on Coma.

Optic Fixation Reflex

The ability to *suppress* the VOR by visual fixation can provide considerable information and may be tested in various ways depending on the clinical need. One such test in the cooperative patient is performed by requesting that the patient fixate on a distant target and rapidly turning the head to one side by 5 to 10 degrees and (see “Tests of Labyrinthine Function” in Chap. 15). Slippage of fixation (impaired vestibuloocular reflex) is appreciated by observing a small corrective saccade in the direction opposite head turning. An alternative is to rotate the patient in a chair while he fixates on the thumb of his outstretched hand. There should be no loss of fixation at moderate rotational speeds; nystagmus during this maneuver is an abnormal sign. Zee has described yet another means of testing the VOR in which the examiner observes the optic nerve head while the patient rotates the head back and forth at a rate of one to two cycles per second. If the VOR is impaired, the optic nerve head

appears to oscillate. Normally, movement of the head at this rate does not cause blurring of vision because of the rapidity with which the VOR accomplishes compensatory eye movements. As a result of inability to suppress the VOR, the patient experiences a feeling of instability.

Testing the Near Response (Accommodative Triad)

Combined convergence and accommodative movements are tested by asking the patient to look at his thumbnail, the examiner’s finger, or object as it is brought toward the eyes. However, these fusional movements are frequently impaired in the elderly and in confused or inattentive patients and should not be interpreted as the result of disease in the ocular motor pathways. Otherwise, the absence or impairment of these movements should suggest a lesion in the rostral midbrain as a component of the Parinaud syndrome. *Convergence spasms* and *retraction nystagmus* may accompany paralysis of vertical gaze from a dorsal midbrain lesion. But when such convergent spasms occur alone, they are characteristic of hysteria, in which full horizontal movement can usually be obtained if each eye is tested separately. Also, cycloplegic eye drops will abolish accommodation and pupillary miosis.

Impairment of Conjugate Gaze

Horizontal Gaze Palsy

Strictly speaking, gaze palsy refers to a complete loss of both saccadic and pursuit movements to one side. Gaze paresis would then refer to an incomplete loss of the same capacity. Operationally, a distinction is made between supranuclear disorders of gaze that can be overcome by intense stimuli, and certain nuclear lesions that cause an insurmountable loss of gaze to one side that cannot be overcome except by physically moving the globes (forced ductions).

As a rule, the horizontal gaze palsies of cerebral and pontine origin are readily distinguished by the side of an accompanying hemiparesis. When there is a tonic deviation of the eyes ipsilateral to a cerebral lesion, this relationship is expressed as “*the eyes look toward the lesion and away from the hemiparesis.*” The opposite pertains to brainstem gaze palsies, that is, gaze is impaired toward the side opposite the lesion, and if there is gaze deviation, the eyes are turned toward a hemiparesis. Palsies of pontine origin need not have an accompanying hemiparesis but are associated with other signs of pontine disease, particularly peripheral facial palsies and internuclear ophthalmoplegia on the same side as the paralysis of gaze. Pontine gaze palsies tend to be longer lasting than those of cerebral origin. Also, in the case of a cerebral lesion (but not a pontine lesion), the eyes turn to the paralyzed side if they are fixated on the target, and the head is rotated passively to the opposite side (i.e., by utilizing the VOR).

Cerebral Origin An acute lesion of one frontal lobe, such as an infarct, usually causes impersistence or paresis of contralateral gaze (more so than an actual palsy of gaze), and the eyes may for a limited time turn involuntarily toward the side of the cerebral lesion. In most cases of acute frontal lobe damage, the gaze palsy is incomplete

and temporary, lasting for a week or less. Almost invariably, it is accompanied by hemiparesis. Forced closure of the eyelids may cause the eyes to move paradoxically to the side of the hemiparesis rather than upward (the latter being the Bell phenomenon), as would be expected. Similarly, during sleep, the eyes may also deviate conjugately away from the side of the lesion toward the side of the hemiplegia. As indicated above, pursuit movements away from the side of the lesion tend to be fragmented or lost. Posterior parietal lesions reduce pursuit movements but do not cause gaze palsy.

With bilateral frontal lesions, the patient may be unable to turn his eyes voluntarily in any direction but retains fixation and following movements. Occasionally, a deep cerebral lesion, particularly a thalamic hemorrhage extending into the midbrain, will cause the eyes to deviate conjugately to the side opposite the lesion (“wrong-way” gaze); the basis for this anomalous phenomenon is not established, but interference with descending oculomotor tracts in the midbrain has been postulated by Tijssen. It should be emphasized that cerebral gaze paralysis is not attended by strabismus or diplopia, i.e., the eyes always move conjugately. The usual causes of gaze paresis are vascular occlusion with infarction, hemorrhage, and abscess or tumor of the frontal lobe.

A seizure originating in the frontal lobe may also drive the eyes to the opposite side. When the eyes are driven contralaterally from the cerebral focus they may not return to the midline, giving the impression of gaze palsy. Also, in the postictal period, the eyes may reside in the opposite direction, ipsilaterally to the seizure focus.

Brainstem Origin The most common source of a nuclear-infranuclear gaze palsy is a lesion in the pontine horizontal gaze complex (PPRF; also involving the abducens nucleus), which causes ipsilateral gaze palsy and deviation of the eyes to the opposite side (Table 14-1). A unilateral lesion in the rostral midbrain tegmentum, by interrupting the cerebral pathways for horizontal conjugate gaze before their decussation, will also cause a paresis of gaze to the opposite side. Vestibulocerebellar lesions can cause yet another disorder of conjugate gaze that simulates a gaze palsy in which the eyes are forced,

or driven to one side in a manner termed “pulsion” that prevents voluntary movement to the other side.

Vertical Gaze Palsy

Midbrain lesions affecting the pretectum and the region of the posterior commissure interfere with conjugate movements in the vertical plane. Paralysis of vertical gaze is a prominent feature of the *Parinaud* or *dorsal midbrain syndrome* described earlier. Upward gaze in general is affected far more frequently than downward gaze because, as already explained, some of the fibers subserving upgaze cross rostrally and posteriorly between the riMLF and INC and are subject to interruption before descending to the oculomotor nuclei, whereas the pathways for downgaze apparently project directly downward to oculomotor nuclei from the two controlling centers.

The range of upward gaze is frequently restricted by extraneous factors, such as drowsiness, increased intracranial pressure, and particularly, aging. In a patient who cannot elevate the eyes voluntarily, the presence of reflex upward deviation of the eyes in response to flexion of the head (“doll’s-head maneuver”) or to voluntary forceful closure of the eyelids (*Bell phenomenon*) indicates that the nuclear and infranuclear mechanisms for upward gaze are intact and that the defect is supranuclear. However, useful this rule may be, in some instances of disease of the peripheral neuromuscular apparatus—such as Guillain-Barré syndrome and myasthenia gravis—in which voluntary upgaze may be limited, the strong stimulus of eye closure may cause upward deviation, whereas voluntary attempts at upgaze are unsuccessful, thereby spuriously suggesting a lesion of the upper brainstem. In addition, approximately 15 percent of normal adults do not show a Bell phenomenon; in others, deviation of the eyes is paradoxically downward.

In patients who during life had shown an isolated palsy of downward gaze, autopsy has disclosed bilateral lesions of the rostral midbrain tegmentum (just medial and dorsal to the red nuclei). An unusual case, described by Bogousslavsky and colleagues, suggests that a paralysis of vertical gaze may follow a strictly unilateral infarction that comprises the posterior commissure, riMLF, and INC. Hommel and Bogousslavsky have summarized the location of strokes that cause monocular and binocular vertical gaze palsies.

Several *degenerative* and related processes exhibit selective or prominent upgaze or vertical gaze palsies, as mentioned earlier (Table 14-1). In progressive supranuclear palsy, a highly characteristic feature is a selective paralysis of vertical gaze, with the more specific feature being downward paralysis beginning with impairment of saccades and later, restriction of all vertical movements. Parkinson and Lewy-body diseases (see Chap. 39), corticobasal ganglionic degeneration (see Chap. 39), and Whipple disease of the brain (see Chap. 40) may also produce vertical gaze palsies as these diseases progress.

Other Supranuclear Disorders of Gaze

The *ocular tilt reaction*, in which skew deviation (unilateral vertical separation of the eyes, discussed further on)

Table 14-1

DISEASES EXHIBITING UPGAZE OR VERTICAL GAZE PALSY

Midbrain infarction and hemorrhage
Tumor in the region of the dorsal midbrain (e.g., pinealoma)
Advanced hydrocephalus with enlargement of third ventricle
Progressive supranuclear palsy
Parkinson disease
Lewy body disease
Cortical basal ganglionic degeneration
Whipple disease
Metabolic diseases of childhood (Niemann-Pick type C, Gaucher, Tay-Sachs)
Any cause of bilateral internuclear ophthalmoplegia (e.g., multiple sclerosis)

is combined with ocular torsion and head tilt, is attributed to an imbalance of otolithic-ocular and otolithic-colic reflexes. In lesions involving the vestibular nuclei, as occurs in lateral medullary infarction, the eye is lower on the side of the lesion. With lesions of the MLF or INC, which can also cause skew and an ocular tilt reaction, the eye is higher on the side of the lesion.

Another unusual disturbance of gaze is the *oculogyric crisis*, or *spasm*, which consists of a tonic spasm of conjugate deviation of the eyes, usually upward and less frequently, laterally or downward. Recurrent attacks, sometimes associated with spasms of the neck, mouth, and tongue muscles and lasting from a few seconds to an hour or two, were pathognomonic of postencephalitic parkinsonism in the past. Now this phenomenon is observed as an acute reaction in patients being given phenothiazine and related neuroleptic drugs and in Niemann-Pick disease. The pathogenesis of these ocular spasms is not known. In the drug-induced form, upward deviation of the eyes is often associated with a report by the patient of peculiar obsessional thoughts; the entire syndrome can be terminated by the administration of an anticholinergic medication such as benztropine.

Congenital oculomotor "apraxia" (Cogan syndrome) is a congenital disorder characterized by unusual eye and head movements that are obligately tied together during attempts to change the position of the eyes. The patient is unable to make normal voluntary horizontal saccades when the head is stationary. If the head is free to move and the patient is asked to look at an object to either side, the head is thrust to one side and the eyes turn in the opposite direction; the head overshoots the target, and the eyes, as they return to the central position, fixate on the target. Both voluntary saccades and the quick phase of vestibular nystagmus are defective. The pathologic anatomy is not understood but the condition abates over time. This same phenomenon is also seen in ataxia-telangiectasia (Louis-Bar disease, Chap. 37) and with agenesis of the corpus callosum, in which both horizontal and vertical saccades may be affected.

NUCLEAR AND INFRANUCLEAR DISORDERS OF EYE MOVEMENT

Anatomic Considerations

The third (oculomotor), fourth (trochlear), and sixth (abducens) cranial nerves innervate the extrinsic muscles of the eye. Because their actions are closely integrated and many diseases involve all of them at once, they are suitably considered together.

The *oculomotor (third-nerve) nuclei* consist of several paired groups of motor nerve cells adjacent to the midline, and ventral to the aqueduct of Sylvius at the level of the superior colliculi. A centrally located group of cells that innervate the pupillary sphincters and ciliary bodies (muscles of accommodation) is situated dorsally in the Edinger-Westphal nucleus that subserves pupillary reactions to light and the near vision response; this is the parasympathetic portion of the oculomotor

nucleus. Ventral to this nuclear group are cells that mediate the actions of the levator of the eyelid, superior and inferior recti, inferior oblique, and medial rectus, in this dorsal-ventral order. This functional arrangement has been determined in cats and monkeys by extirpating individual extrinsic ocular muscles and observing the retrograde cellular changes (Warwick). Subsequent studies using radioactive tracer techniques have shown that medial rectus neurons occupy three disparate locations within the oculomotor nucleus rather than being confined to its ventral tip (Büttner-Ennever and Akert). These experiments also indicated that the medial and inferior recti, and the inferior oblique are innervated strictly ipsilaterally from the oculomotor nuclei, whereas the superior rectus receives only crossed fibers, and the levator palpebrae superioris (lid elevators) has bilateral innervations. Whether this precise arrangement is reproduced in humans is not known. Vergence movements are under the control of medial rectus neurons and not, as was once supposed, by an unpaired medial group of cells (nucleus of Perlia).

The fibers of the third-nerve nucleus course ventrally in the midbrain, crossing the medial longitudinal fasciculus, red nucleus, substantia nigra, and medial part of the cerebral peduncle successively. Lesions involving these structures therefore interrupt oculomotor fibers in their intramedullary (fascicular) course and give rise to several crossed syndromes of hemiplegia and ocular palsy. With regard to the oculomotor subnuclei, schematic arrangements of their projections have been derived from various sources, mainly experimental but some clinical, and are shown in the figure from Ksiazek and colleagues (Fig. 14-3). The emerging fibers can be considered as situated in medial, lateral and rostro-caudal groups, with

Figure 14-3. Topographic arrangement of oculomotor fascicular fibers in the mesencephalon. P, pupil; SR, superior rectus; IR, inferior rectus; MR, medial rectus; IO, inferior oblique; LP, levator palpebrae; CCN, central caudal nucleus. (From Ksiazek SM, Slamovits TL, Rosen CE, et al: Fascicular arrangement in partial oculomotor paresis. *Am J Ophthalmol* 118: 97, 1994.)

the pupillary fibers occupying the rostro-medial aspect. This location of axons destined for the pupil continues through the third nerve. This information becomes useful in recognizing that combined pupillary and inferior and medial rectus palsies on one side may be the result of a fascicular lesion of the oculomotor nerve.

The *sixth nerve (abducens)* arises at the level of the lower pons from a paired group of cells in the floor of the fourth ventricle, adjacent to the midline. The intrapontine portion of the facial nerve loops around the sixth-nerve nucleus before it turns anterolaterally to make its exit; a lesion in this locality therefore causes a homolateral paralysis of the lateral rectus and facial muscles. It is important to note that the efferent fibers of the oculomotor and abducens nuclei have a considerable intramedullary extent, i.e., their fascicular portions (Fig. 14-4A and B).

The cells of origin of the *trochlear nerves* are just caudal to those of the oculomotor nerves in the lower midbrain. Unlike the third and sixth nerves, the fourth nerve emerges from the dorsal surface of the lower midbrain and then courses posteriorly (dorsally) and decussates a short distance from its origin, just caudal to the inferior colliculi.

Figure 14-4. A. Midbrain in horizontal section, indicating the effects of lesions at different points along the intramedullary course of the third-nerve fibers. A lesion at the level of oculomotor nucleus results in homolateral third-nerve paralysis and homolateral anesthesia of the cornea. A lesion at the level of red nucleus results in homolateral third-nerve paralysis and contralateral ataxic tremor (Benedikt and Claude syndromes). A lesion near the point of exit of third-nerve fibers results in homolateral third-nerve paralysis and crossed corticospinal tract signs (Weber syndrome; see Table 47-2). B. Brainstem at the level of the sixth-nerve nuclei, indicating effects of lesions at different loci. A lesion at the level of the nucleus results in homolateral sixth- and seventh-nerve paralyzes with varying degrees of nystagmus and weakness of conjugate gaze to the homolateral side. A lesion at the level of corticospinal tract results in homolateral sixth-nerve paralysis and crossed hemiplegia (Millard-Gubler syndrome).

The nerves proceed circumferentially and ventrally around the midbrain toward the entry of the nerve into the posterior cavernous sinus. Each nucleus therefore innervates the *contralateral* superior oblique muscle. The long extraaxial course and the position of the nerves adjacent to the brainstem is a putative explanation for the common complication of fourth-nerve palsy in head injury (see Chap. 35). The superior oblique muscle forms a tendon that passes through a pulley structure (the trochlea) and attaches to the upper aspect of the globe. When the eye is adducted, the muscle exerts an upward pull, but being attached to the globe behind the axis of rotation, it causes depression and intorsion of the eye; in abduction, it thereby pulls the ocular meridian toward the nose, thereby causing intorsion (i.e., clockwise in the right eye and counterclockwise in the left from the examiner's perspective).

The oculomotor nerve, soon after it emerges from the brainstem, passes between the superior cerebellar and posterior cerebral arteries. The nerve (and sometimes the posterior cerebral artery) may be compressed at this point by herniation of the uncus gyrus of the temporal lobe through the tentorial opening (see Chap. 17). The sixth nerve, after leaving the brainstem, sweeps upward along the clivus and then runs alongside the third and fourth cranial nerves; together they course anteriorly, pierce the dura just lateral to the posterior clinoid process, and run in the lateral wall of the cavernous sinus, where they are closely applied to the internal carotid artery and first and second divisions of the fifth nerve (Fig. 14-5 and "Cavernous Sinus Thrombosis" in Chap. 34).

When infraclinoid retrocavernous compressive lesions, such as aneurysms and tumors, affect the oculomotor nerve, they tend to also involve all three divisions of the trigeminal nerve. In the posterior portion of the cavernous sinus, the first and second trigeminal divisions are involved along with the oculomotor nerves; in the anterior portion, only the ophthalmic division of the trigeminal nerve is affected.

Just posterior and superior to the cavernous sinus, the oculomotor nerve crosses the terminal portion of the internal carotid artery at its junction with the posterior communicating artery. An aneurysm at this site frequently damages the third nerve; this serves to localize the site of compression or bleeding.

Together with the first division of the fifth nerve, the third, fourth, and sixth nerves enter the orbit through the superior orbital fissure. The oculomotor nerve, as it enters the orbit, divides into superior and inferior branches, although a functional separation of nerve bundles occurs well before this anatomic bifurcation. The superior branch supplies the superior rectus and the voluntary (striated) part of the levator palpebrae (the involuntary part is under the control of sympathetic fibers of Müller); the inferior branch supplies the pupillary and ciliary muscles and all the other extrinsic ocular muscles except, of course, two—the superior oblique and the lateral rectus which are innervated by the trochlear and abducens nerves, respectively. *Superior branch lesions* of the oculomotor nerve caused by an aneurysm or more commonly by diabetes, result in ptosis and uniocular upgaze paresis.

Figure 14-5. (See also Fig. 34-29.) The cavernous sinus and its relation to the cranial nerves. *A.* Base of the skull; the cavernous sinus has been removed on the right. *B.* The cavernous sinus and its contents viewed in the coronal plane.

Diplopia and Strabismus

Under normal conditions, all the extraocular muscles participate in every movement of the eyes; for proper movement, the contraction of any muscle requires relaxation of its antagonist. Clinically, however, an eye movement can be thought of in terms of the one muscle that is predominantly responsible for an agonist movement in that direction, e.g., outward movement of the eye requires the action of the lateral rectus; inward movement, action of the medial rectus. The action of the superior and inferior recti and the oblique muscles varies according to the position of the eye. When the eye is turned outward, the elevator is the superior rectus and the depressor is the inferior rectus. When the eye is turned inward, the elevator and depressor are the inferior and superior oblique muscles, respectively. The actions of the ocular muscles in different positions of gaze are illustrated in Fig. 14-6 and Table 14-2.

The term *binocular diplopia* refers to the symptom of double vision caused by a misalignment of the visual axes of the two eyes. With very few exceptions, in order to experience diplopia there must be some vision in both eyes. Put another way, covering one eye usually obliterates double vision. If the visual axes are separated by a significant amount, the individual may suppress the image from one eye and not experience diplopia. There is a form of *monocular diplopia* that is due to lenticular or retinal disease and is also a manifestation of hysteria.

Strabismus, strictly speaking, refers to a muscle imbalance that results in misalignment of the visual axes, but the term is used most often by neurologists to describe a congenital variety of misalignment. Strabismus may be caused by weakness of an individual eye muscle (*paralytic strabismus*) or by an imbalance of muscular tone, presumably because of a faulty “central” mechanism that normally maintains a proper angle between the two visual axes (*nonparalytic or pediatric strabismus*, see below).

Figure 14-6. Muscles chiefly responsible for vertical movements of the eyes in different positions of gaze. (Adapted by permission from Cogan DG: *Neurology of the Ocular Muscles*, 2nd ed. Springfield, IL, Charles C Thomas, 1956.)

Table 14-2

ACTIONS OF THE EXTRAOCULAR MUSCLES

MUSCLE	PRIMARY ACTION	SECONDARY ACTION	OCULOMOTOR NERVE
Medial rectus	Adduction	—	III
Lateral rectus	Abduction	—	VI
Superior rectus	Elevation	Intorsion	III
Inferior rectus	Depression	Extorsion	III
Superior oblique	Intorsion	Depression	IV
Inferior oblique	Extorsion	Elevation	III

(See also Fig. 14-5.)

Almost everyone has a slight tendency to strabismus, i.e., to misalign the visual axes when a target is viewed preferentially with one eye. This tendency is referred to as a *phoria* and is normally overcome by the fusion mechanisms. A misalignment that is manifest during binocular viewing of a target and cannot be overcome, even when the patient is forced to fixate with the deviant eye, is called a *tropia*. The ocular misalignment is then apparent by viewing the position of the patient's eyes while they fixate on a distant target. When tested monocularly, the range of movement in the affected eye are normal, or nearly so. The prefixes *eso-* and *exo-* indicate that the phoria or tropia is directed inward or outward, respectively, and the prefixes *hyper-* and *hypo-*, that the deviation is upward or downward. Paralytic strabismus is primarily a neurologic problem; nonparalytic strabismus (referred to as *comitant strabismus* if the angle between the visual axes is the same in all fields of gaze) is an ocular muscle problem that is managed by ophthalmologists, although it is associated with a number of congenital cerebral diseases and forms of developmental delay.

Pediatric Nonparalytic Strabismus

It is in this sense that the unqualified term *strabismus* is often used. The normal slight exotropia of neonates corrects by about 3 months of age. Large malalignments (greater than 15 degrees) are considered abnormal, even at birth. Most children with developmental esotropic strabismus present between ages 2 and 3 years, whereas those with exotropia show the condition in a broader range of preschool years. Esodeviations are initially intermittent and then become persistent; exodeviations are commonly intermittent. In both cases, eye movements are full and the child initially alternates fixation.

Esotropia is typically an acquired problem as a result of congenital farsightedness and the overengagement of the near response in order to see clearly, thereby driving the eyes to cross. Treatment with glasses within 6 months of the onset of the strabismus restores vision and usually leads to realignment of the axes. Large degrees of esotropia that are not the result of hypermetropia (farsightedness) are best treated by surgical realignment.

In contrast, persistent exotropic strabismus in a child is usually associated with a developmental delay, often as a component of a recognizable mental retardation syndrome, as detailed in Chap. 38, or with ocular pathology. It does, however, occur in neurologically normal children. If mild, intermittent exotropia is initially treated by one of a number of nonsurgical means such as patching and visual exercises to stimulate convergence; surgical correction is reserved for unresponsive cases. Donohue has written an informative review of the subject.

Once binocular fusion is established, usually by 6 months of age, any type of ocular muscle imbalance will cause diplopia, as images then fall on disparate or noncorresponding parts of the two functionally active retinas. After a time, however, the child eliminates the diplopia by suppressing the image from one eye. After another variable period, the suppression becomes permanent, and the individual retains diminished visual acuity

in that eye, the result of prolonged disuse (*amblyopia ex anopsia*), as described in the last portion of Chap. 13.

Nonparalytic strabismus may create misleading ocular findings in the neurologic examination. Sometimes a slight phoric misalignment of the eyes is first noticed after a head injury or a febrile infection, or it may be exposed by any other neurologic disorder or drug intoxication that impairs fusional mechanisms (vergence). In a cooperative patient, nonparalytic strabismus may be demonstrated by showing that each eye moves fully when the other eye is covered. Tropias and phorias can also readily be detected by means of the simple "cover" and "cover-uncover" tests. When fusion is disrupted by covering one eye, the occluded eye will deviate; uncovering that eye results in a quick corrective movement designed to reestablish the fusion mechanism.

Clinical Effects of Lesions of the Third, Fourth, and Sixth Ocular Nerves

Third (Oculomotor) Nerve

A complete *third nerve lesion* causes ptosis, or drooping of the upper eyelid (as the levator palpebrae is supplied mainly by this nerve), and an inability to rotate the eye upward, downward, or inward. This corresponds to the weaknesses of the medial, superior, and inferior recti and the inferior oblique muscles. The remaining actions of the fourth and sixth nerves give rise to a position of the eye described by the mnemonic "down and out." The patient experiences diplopia in which the image from the affected eye is projected upward and medially. In addition, one finds a dilated, light-nonreactive pupil (iridoplegia), and paralysis of accommodation (cycloplegia) because of interruption of the parasympathetic fibers in the third nerve. However, the extrinsic and intrinsic (papillary) eye muscles may be affected separately in certain diseases. For example, infarction of the central portion of the oculomotor nerve, as occurs in diabetic ophthalmoplegia, typically spares the pupil, as the parasympathetic preganglionic pupilloconstrictor fibers lie near the surface. Conversely, compressive lesions of the nerve usually dilate the pupil as an early manifestation. After injury, regeneration of the third-nerve fibers may be aberrant, in which case some of the fibers that originally moved the eye in a particular direction now reach another muscle or the iris; in the latter instance the pupil, which is unreactive to light, may constrict when the eye is turned up and in.

Fourth (Trochlear) Nerve

A lesion of the *fourth nerve*, which innervates the superior oblique muscle, is the most common cause of isolated symptomatic vertical diplopia. Although oculomotor palsy was a more common cause of vertical diplopia in Keane's 1975 series, as stated earlier, in instances where this is the sole complaint, trochlear palsy (and brainstem lesions) have predominated in our material. Paralysis of the superior oblique muscle results in weakness of downward movement of the affected eye, most marked when the eye is turned inward (Fig. 14-7E), so that the patient complains of special difficulty in reading or going down stairs. The affected eye tends to deviate slightly upward when the patient

Figure 14-7. Diplopia fields with individual muscle paralysis. *The red glass is in front of the right eye, and the fields are projected as the patient sees the images (see text).* A. Paralysis of right lateral rectus. Characteristic: right eye does not move to the right. Field: horizontal homonymous diplopia increasing on looking to the right. B. Paralysis of right medial rectus. Characteristic: right eye does not move to the left. Field: horizontal crossed diplopia increasing on looking to the left. C. Paralysis of right inferior rectus. Characteristic: right eye does not move downward when eyes are turned to the right. Field: vertical diplopia (image of right eye lower-most) increasing on looking to the right and down. D. Paralysis of right superior rectus. Characteristic: right eye does not move upward when eyes are turned to the right. Field: vertical diplopia (image of right eye uppermost) increasing on looking to the right and up. E. Paralysis of right superior oblique. Characteristic: right eye does not move downward when eyes are turned to the left. Field: vertical diplopia (image of right eye lower-most) increasing on looking to left and down. F. Paralysis of right inferior oblique. Characteristic: right eye does not move upward when eyes are turned to the left. Field: vertical diplopia (image of right eye uppermost) increasing on looking to left and up. (Adapted by permission from Cogan DG: *Neurology of the Ocular Muscles*, 2nd ed. Springfield, IL, Charles C Thomas, 1956.)

looks straight ahead. This defect may be overlooked in the presence of a third-nerve palsy if the examiner fails to note the absence of an expected intorsion as the patient tries to move the paretic eye downward. Head tilting to the opposite shoulder (Bielschowsky sign) is especially characteristic of fourth-nerve lesions; this maneuver causes a compensatory intorsion of the unaffected eye and ameliorates the double vision. Lesions affecting the trochlear nucleus (rather than the nerve itself) will cause paresis of the contralateral superior oblique muscle; here, the patient will tilt their head toward the side of the lesion to ameliorate the diplopia.

Bilateral trochlear palsies, as may occur after head trauma, give a characteristic alternating hyperdeviation depending on the direction of gaze (unilateral traumatic trochlear paresis is still the more common finding with head injury). A useful review of the approach to vertical diplopia is given by Palla and Straumann.

Sixth (Abducens) Nerve

Lesions of the *sixth nerve* result in a paralysis of the abducens muscle and a resultant weakness of lateral or outward movement leading to a crossing of the visual axes. The affected eye *deviates medially*, i.e., in the direction of the opposing muscle. Diplopia is experienced as horizontal separation that is greatest at a distance from the patient and the image of the affected eye is projected outward. Fig 14-7A). With incomplete sixth-nerve palsies, turning the head toward the side of the paretic muscle overcomes the diplopia.

Many causes of oculomotor palsies and of *combined palsies*, which are discussed in a later section, are listed in Table 14-3 and are illustrated in Fig. 14-7 and below.

The Analysis of Diplopia

Almost all instances of diplopia (i.e., seeing a single object as double) are the result of an acquired paralysis or paresis of one or more extraocular muscles. The signs of the oculomotor palsies, as described above, are manifest in various degrees of completeness. With complete palsies, the affected muscle can often be surmised from the resting dysconjugate positions of the globes. With incomplete paresis, noting the relative positions of the corneal light reflections and having the patient perform common versional movements will usually disclose the faulty muscle(s) *as the eyes are turned into the field of action of the paretic muscle*. The muscle weakness may be so slight, however, that no strabismus or defect in ocular movement is obvious, yet the patient experiences diplopia. It is then necessary to use the patient's report of the relative positions of the images of the two eyes. Certain precautions should be taken in testing: one is cognizance of the above-mentioned absence of diplopia when the visual axes are widely separated and, the object or light used for testing should not be obscured by the patient's nose.

Two rules are applied sequentially to identify the affected ocular muscle in the analysis of diplopia:

1. The *direction in which the images are maximally separated indicates the action of the pair of muscles at fault.*

Table 14-3

MAIN CAUSES OF INDIVIDUAL AND COMBINED OCULOMOTOR PALSIES

Lesions of the third (oculomotor) nerve	<i>Cavernous sinus and superior orbital fissure</i>
<i>Nuclear and intramedullary (fascicular)</i>	Tumor
Infarction (midbrain stroke)	Tolosa-Hunt syndrome
Demyelination	Internal carotid aneurysm
Tumor	Herpes zoster
Trauma	Diabetic infarction
Wernicke disease	<i>Orbit</i>
<i>Radicular (subarachnoid space and tentorial edge)</i>	Trauma
Aneurysm (posterior communicating or basilar)	Tumor and granuloma
Meningitis (infectious, neoplastic, granulomatous)	Lesions of the sixth (abducens) nerve
Diabetic infarction	<i>Nuclear (characterized by gaze palsy) and intramedullary (fascicular)</i>
Tumor	Möbius syndrome
Raised intracranial pressure (shift and herniation of medial temporal lobe, hydrocephalus, pseudotumor cerebri)	Wernicke syndrome
<i>Cavernous sinus and superior orbital fissure</i>	Infarction (pontine stroke)
Diabetic infarction of nerve	Demyelination
Aneurysm of internal carotid artery	Tumor
Carotid-cavernous fistula	Lupus
Cavernous thrombosis (septic and bland)	<i>Radicular (subarachnoid)</i>
Tumor (pituitary, meningioma, nasopharyngeal carcinoma, metastasis)	Aneurysm
Pituitary apoplexy	Trauma
Sphenoid sinusitis and mucocele	Meningitis
Herpes zoster	Tumor (clivus, fifth- and eighth-nerve schwannoma, meningioma)
Tolosa-Hunt syndrome	<i>Petrous</i>
<i>Orbit</i>	Infection of mastoid and petrous bone
Trauma	Thrombosis of inferior petrosal vein
Fungal infection (mucormycosis, etc.)	Trauma
Tumor and granuloma	<i>Cavernous sinus and superior orbital fissure</i>
Orbital pseudotumor	Carotid aneurysm
<i>Uncertain localization</i>	Cavernous sinus thrombosis
Migraine	Tumor (pituitary, nasopharyngeal, meningioma)
Postinfectious cranial mono- and polyneuropathy	Tolosa-Hunt syndrome
Lesions of the fourth (trochlear) nerve	Diabetic or arteritic infarction
<i>Nuclear and intramedullary (fascicular)</i>	Herpes zoster
Midbrain hemorrhage and infarction	<i>Orbit</i>
Tumor	Tumor and granulomas
Arteriovenous malformation	<i>Uncertain localization</i>
Demyelination	Migraine
<i>Radicular (subarachnoid space)</i>	Viral and postviral
Traumatic	Transient in newborns
Tumor (pineal, meningioma, metastasis, etc.)	
Hydrocephalus	
Pseudotumor cerebri and other causes of increased intracranial pressure	
Meningitis (infectious, neoplastic, granulomatous)	

Source: Adapted by permission from Leigh and Zee.

For example, if the greatest horizontal separation is in looking to the right, either the right abductor (lateral rectus) or the left adductor (medial rectus) muscle is weak; if maximal when gazing to the left, the left lateral rectus and right medial rectus are implicated (Fig. 14-6A and B). As a corollary, if the separation is mainly horizontal, the paresis will be found in one of the horizontally acting recti (a small vertical disparity should be disregarded); if the separation is mainly vertical, the paresis will be found in the remaining vertically acting muscles, and a small horizontal deviation should be disregarded.

2. The second step in analysis identifies which of the two implicated muscles is responsible for the diplopia. The image projected farther from the center is attributable to the eye with the parietic muscle.

The simplest maneuver for the analysis of diplopia consists of asking the patient to follow an object or light into the six cardinal positions of gaze. When the position of maximal separation of images is identified, one eye is covered and the patient is asked to identify which image disappears. The *red-glass* test is an enhancement of this technique. A red glass is placed in front of the patient's right eye (the choice of the right eye is arbitrary, but if the test is always done in the same way, interpretation is simplified). The patient is then asked to look at a flash-light (held at a distance of 1 m), to turn the eyes sequentially to the six cardinal points in the visual fields, and to indicate the positions of the red and white images and the relative distances between them. The positions of the two images are plotted as the patient indicates them to the examiner (i.e., from the patient's perspective;

Fig. 14-7). This allows the identification of both the field of maximal separation and the eye responsible for the eccentric image. If the white image on right lateral gaze is to the right of the red (i.e., the image from the left eye is projected outward), then the left medial rectus muscle is weak.

If the maximum vertical separation of images occurs on looking downward and to the *left* and the white image is projected farther down than the red, the paretic muscle is the left inferior rectus; if the red image (from the right eye) is lower than the white, the paretic muscle is the right superior oblique. As already mentioned, correction of vertical diplopia by a tilting of the head implicates the superior oblique muscle of the opposite side (or the ipsilateral trochlear nucleus). Separation of images on looking up and to the right or left will similarly distinguish paresis of the inferior oblique and superior rectus muscles. Most patients are attentive enough to open and close each eye and determine the source of the image thrown most outward in the field of maximal separation.

In the widely reproduced diagram analyzing diplopia from Cogan's 1956 book, we have noted the curiosity that the fields are shown from the perspective of the examiner rather than of the patient, as is the convention (and as incorrectly stated in the original legend). We have taken the liberty of repairing this reversal and showing the fields from the patient's perspective in Fig. 14-7.

There are several alternative methods for studying the relative positions of the images of the two eyes. One, a refinement of the red-glass test, is the *Maddox rod*, in which the occluder consists of a transparent red lens with series of parallel cylindrical bars that transform a point source of light into a red line perpendicular to the cylinder axes. The position of the red line is easily compared by the patient with the position of a white point source of light seen with the other eye. Another technique, the *alternate cover test*, requires less cooperation than the red-glass test and is, therefore, a passive maneuver that is more useful in the examination of children and inattentive patients. It does, however, require sufficient visual function to permit central fixation with each eye. The test consists of rapidly alternating an occluder or the examiner's hand from one eye to another and observing the deviations from and return to the point of fixation, as described earlier in the chapter in the discussion of tropias and phorias. Measuring the prismatic correction in each field of gaze with a prism bar allows the quantification of deviation and provides a method to follow diplopia over time.

The more sophisticated Lancaster test uses red/green glasses and a red and green bar of laser light projected on a screen to accomplish essentially the same result but has the advantage of reflecting the actual position and torsion of each eye. Detailed descriptions of the Maddox rod and alternate cover tests, which are the ones favored by neuroophthalmologists, can be found in the monographs of Leigh and Zee and of Glaser. In all these tests the examiner is aided by committing to memory the cardinal actions of the ocular muscles shown in Fig. 14-6 and Table 14-2.

Other Forms of Diplopia

The red-glass and other similar tests are most useful when a single muscle is responsible for the diplopia. If testing suggests that more than one muscle is involved, myasthenia gravis and thyroid ophthalmopathy are likely causes as they affect several muscles of ocular motility. Palsy of the oculomotor nerve causes a similar circumstance.

Monocular diplopia occurs most commonly in relation to diseases of the cornea and lens rather than the retina; usually the images are overlapping or superimposed rather than discrete. In most cases, monocular diplopia can be traced to a lenticular distortion or displacement but in some, no abnormality can be found and it is usually attributable to hysteria. Monocular diplopia has been reported in association with cerebral disease (Safran et al), but this must be a rare occurrence. Occasionally, patients with homonymous scotomas caused by a lesion of the occipital lobe will see multiple images (polyopia) in the defective field of vision, particularly when the target is moving.

Rarely, the acute onset of *convergence paralysis* gives rise to diplopia and blurred vision at all near points; most cases are a result of head injury, some to encephalitis or multiple sclerosis. Many instances of convergence paralysis do not have a demonstrable neurologic basis; they are caused by hysteria or remain unexplained. The ill-defined entity of *divergence paralysis* causes diplopia at a distance because of crossing of the visual axes; in such patients images fuse only at a near position. This disorder, the basis of which is unknown and for which there is no common lesion, is difficult to distinguish from mild bilateral sixth-nerve palsies and from convergence spasm, which is common in malingers and hysterics. A special type of divergence paralysis is seen regularly with strokes in the rostral midbrain; these display an asymmetrical incompleteness of ocular abduction on both sides (*pseudosixth palsy*). Based on scant clinical data, a center for active divergence has been postulated to reside in the rostral midbrain tegmentum.

Causes of Individual Third-, Fourth-, and Sixth-Nerve Palsies (Table 14-3)

Ocular palsies may have a central cause—i.e., a lesion of the nucleus or the intramedullary (fascicular) portion of the cranial nerve—but more often they are peripheral. Weakness of ocular muscles because of a lesion in the brainstem is usually accompanied by involvement of other cranial nerves and by signs referable to the “crossed” brainstem syndromes of a cranial nerve palsy on one side and a hemiparesis on the opposite side (see Table 34-3 and Chap. 47). Peripheral lesions, which may or may not be solitary, have a great variety of causes.

In the series reported by Rucker (1958, 1966), who analyzed 2,000 cases of paralysis of the oculomotor nerves, the most common sources of individual ocular motor palsies were tumors at the base of the brain or skull (primary, metastatic, meningeal carcinomatosis), head trauma, ischemic infarction of a nerve (generally associated with diabetes), and aneurysms of the circle of Willis, in that order. The sixth nerve was affected in about half of

the cases; third-nerve palsies were about half as common; and the fourth nerve was involved in less than 10 percent of cases. In 1,000 unselected cases reported subsequently by Rush and Younge, trauma was a more frequent cause than neoplasm and the frequency of aneurysm-related cases was fewer than in the aforementioned series; otherwise the findings were similar. Less-common causes of paralysis of the oculomotor nerves, but nonetheless seen by most practitioners, include variants of Guillain-Barré syndrome, herpes zoster, giant cell arteritis, ophthalmoplegic migraine, carcinomatous or lymphomatous meningitis, and the granulomatous disease sarcoidosis and Tolosa-Hunt syndrome, as well as fungal, tuberculous, syphilitic, and other forms of mainly chronic meningitis. *Myasthenia gravis*, discussed in Chap. 49, must always be considered in cases of ocular muscle palsy, particularly if several muscles are involved and if fluctuating ptosis is a prominent feature. Thyroid ophthalmopathy, discussed further on, presents in a similar fashion but without ptosis and is less common than myasthenia. Actually, in the above mentioned series, no cause could be assigned in 20 to 30 percent, although more cases are now being resolved with MRI.

Sixth-Nerve Palsy

Infarction of the sixth nerve is a common cause of sixth-nerve palsy in diabetics, in which case there is usually pain near the lateral canthus of the eye at the onset. An idiopathic form that occurs in the absence of diabetes—possibly atherosclerotic—is also well known. Isolated sixth nerve palsy with global headache, and more specifically when the sign is bilateral, sometimes proves to be caused by raised intracranial pressure from an intracranial neoplasm. In children, the most common tumor involving the sixth nerve is a pontine glioma; in adults, it is tumor arising from the nasopharynx. As the abducens nerve passes near the apex of the petrous bone it is in close relation to the trigeminal nerve. Both may be implicated by inflammatory or infectious lesions of the petrous (apex petrositis), manifest by facial pain and diplopia (Gradenigo syndrome). Among the causes of this syndrome is osteomyelitis of the petrous bone. Fractures at the base of the skull and petroclival tumors may have a similar effect, and sometimes head injury alone is the only assignable cause. Even in the absence of a fracture, fourth-nerve palsy is a more common complication of closed cranial injury (as noted below).

As mentioned, unilateral or bilateral abducens weakness may be a nonspecific sign of increased intracranial pressure from any source—including brain tumor, meningitis, and pseudotumor cerebri; rarely, it may appear after lumbar puncture, epidural injections, or insertion of a ventricular shunt. The type of bilateral weakness of ocular abduction that arises with infarction of the rostral mid-brain (pseudosixth) was described above. Occasionally, the nerve is compressed by a congenitally persistent trigeminal artery. A congenital form of bilateral abducens palsy is associated with bilateral facial paralysis (Mobius syndrome) as discussed in Chap. 38. Patients with the Duane retraction syndrome (absent sixth nerve) usually do not have diplopia and are aware of the

retraction problem but an examiner may note a defect in unilateral abduction (this entity is discussed further on).

Fourth-Nerve Palsy

The fourth nerve is particularly vulnerable to head trauma (this was the cause in 43 percent of 323 cases of trochlear nerve lesions collected by Wray from the literature). The reason for this vulnerability has been speculated to be the long, crossed course of the nerves. A fair number of cases remain idiopathic even after careful investigation. The fourth and sixth nerves are practically never involved by aneurysm. This reflects the relative infrequency of carotid artery aneurysms in the infraclinoid portion of the cavernous sinus, where they could impinge on the sixth nerve. (In contrast, supraclinoid aneurysms commonly involve the third nerve.) Herpes zoster ophthalmicus may affect any of the oculomotor nerves but particularly the trochlear, which shares a common sheath with the ophthalmic division of the trigeminal nerve. Diabetic infarction of the fourth nerve occurs, but far less frequently than infarction of the third or sixth nerves. Trochlear-nerve palsy may also be a false localizing sign in cases of increased intracranial pressure, but again, not nearly as often as abducens palsy. Entrapment of the superior oblique tendon is a rare cause (Brown syndrome) in which, in addition to diplopia, there is focal pain at the superomedial corner of the orbit; hence it may be mistaken for the Tolosa-Hunt syndrome, discussed further on. Trochlear-nerve palsies have been described in patients with lupus erythematosus and with Sjögren syndrome, but their basic pathology is not known. Some cases of fourth-nerve palsy are idiopathic and most of these resolve.

Superior oblique myokymia is an unusual but easily identifiable movement disorder, characterized by recurrent episodes of vertical diplopia, monocular blurring of vision, and a tremulous sensation in the affected eye; in this way it simulates a palsy. The globe is observed to make small arrhythmic torsional movements, especially when viewed with an ophthalmoscope. The problem is usually benign and responds to carbamazepine but rare instances presage pontine glioma or demyelinating disease. Compression of the fourth nerve by a small looped branch of the basilar artery has been suggested as the cause of the idiopathic variety, analogous to several other better documented vascular compression syndromes affecting cranial nerves. This notion is supported by findings on MRI reported by Yousry and colleagues.

Third-Nerve Palsy

The third nerve is commonly compressed by aneurysm, tumor, or temporal lobe herniation. In a series of 206 cases of third-nerve palsy collected by Wray and Taylor, neoplastic diseases accounted for 25 percent and aneurysms for 18 percent. Of the neoplasms, 25 percent were parasellar meningiomas and 4 percent were pituitary adenomas. The palsy is usually chronic, progressive, and painless. As emphasized earlier, enlargement of the pupil is a sign of extramedullary third nerve compression because of the peripheral location in the nerve of the pupilloconstrictor fibers. By contrast, infarction of the nerve in diabetics usually spares the pupil, as the damage is situated in the central portion of the nerve. The oculomotor palsy

that complicates diabetes (the cause in 11 percent in the Wray and Taylor series) develops over a few hours and is accompanied by pain, usually severe, in the forehead and around the eye. The prognosis for recovery (as in other nonprogressive lesions of the oculomotor nerves) is usually good because of the potential of the nerve to regenerate. Infarction of the third nerve occurs in nondiabetics as well.

In chronic compressive lesions of the third nerve (distal carotid, basilar, or, most commonly, posterior communicating artery aneurysm; pituitary tumor, meningioma, cholesteatoma) the pupil is almost always affected by way of dilatation or reduced light response. However, the chronicity of the lesion may permit aberrant nerve regeneration. This is manifest by pupillary constriction on adduction of the eye or by retraction of the upper lid on downward gaze or adduction.

Rarely, children or young adults have one or more attacks of ocular palsy in conjunction with an otherwise typical migraine (ophthalmoplegic migraine). The muscles (both extrinsic and intrinsic) innervated by the oculomotor or less commonly, by the abducens nerve, are affected. Possibly, spasm of the vessels supplying these nerves or compression by edematous arteries causes a transitory ischemic paralysis but these are speculations. Arteriograms done after the onset of the palsy usually disclose no abnormality. The oculomotor palsy of migraine tends to recover; after repeated attacks, however, there may be permanent partial paresis.

Painful Ophthalmoplegia, Tolosa-Hunt Syndrome, Cavernous Sinus Syndrome, and Orbital Pseudotumor (Table 14-4)

Some of the diseases discussed above are associated with a degree of pain, often over the site of an affected nerve

Figure 14-8. MRI of orbital pseudotumor showing swelling of the extraocular muscles and adjacent orbital contents. A “streaming” appearance of the fat as shown in the right orbit is characteristic. This patient was responsive to corticosteroids.

or muscle or in the immediately surrounding area. But the development over days or longer of a *painful unilateral ophthalmoplegia* constitutes a special syndrome that is usually traceable to an aneurysm, tumor, or inflammatory and granulomatous process in the anterior portion of the cavernous sinus or the adjacent superior orbital fissure. The idiopathic granulomatous painful condition has been termed *Tolosa-Hunt syndrome*; a similar but more extensive process is known as *orbital pseudotumor*. Although there is little pathologic material on which to base an understanding of these two diseases, they appear to be related orbital inflammations.

Orbital pseudotumor causes an inflammatory enlargement of the extraocular muscles, which often also encompasses the globe and other orbital contents accompanied by injection of the conjunctiva and lid and slight proptosis (Fig. 14-8). The Tolosa-Hunt syndrome lacks these features but is occasionally associated with additional signs of cavernous sinus disease, particularly sensory loss in the peri-orbital branches of the trigeminal nerve. In pseudotumor of the orbit, a single muscle or several may be involved and there is a tendency to relapse and later to involve the opposite globe. Visual loss from compression of the optic nerve is a rare complication of either condition. Associations with connective tissue disease have been reported in orbital pseudotumor but most cases in our experience have occurred in isolation. Ultrasonography examination or CT scans of the orbit show enlargement of the orbital contents in pseudotumor, mainly the muscles, similar to the findings in thyroid ophthalmopathy (which is not, however, painful unless there is secondary corneal ulceration).

The inflammatory changes of Tolosa-Hunt syndrome are limited to the superior orbital fissure and can sometimes be detected by MRI; coronal views taken after gadolinium infusion show the lesion to best advantage. However, sarcoidosis, lymphomatous infiltration, and a small meningioma may produce similar radiographic findings and granulomatous (temporal) arteritis rarely causes ophthalmoplegia. The sedimentation rate in our

Table 14-4

CAUSES OF PAINFUL OPHTHALMOPLÉGIA

Vascular

- Intracavernous carotid artery aneurysm
- Posterior communicating or posterior cerebral artery aneurysm
- Cavernous sinus thrombosis (septic and aseptic)
- Carotid-cavernous fistula
- Diabetic oculomotor mononeuropathy
- Temporal arteritis
- Ophthalmoplegic migraine

Neoplastic

- Pituitary adenoma
- Pituitary apoplexy
- Pericavernous meningioma
- Metastatic nodules to dura of cavernous sinus
- Giant-cell tumor of orbital bone
- Nasopharyngeal tumor invading cavernous sinus or orbit

Inflammatory and infectious

- Tolosa-Hunt syndrome
- Orbital pseudotumor
- Sinusitis
- Mucocele
- Herpes zoster
- Mucormycosis
- Sarcoidosis

patients with orbital pseudotumor or Tolosa-Hunt syndrome has varied but it has been moderately elevated in reported cases, sometimes accompanied by a leukocytosis at the onset of symptoms. Sarcoidosis also can infiltrate the posterior orbit or cavernous sinus and cause a single or multiple unilateral nerve ophthalmoparesis as discussed in Chaps. 13 and 47.

Treatment

Both the Tolosa-Hunt syndrome and orbital pseudotumor are treated with corticosteroids. A marked response with reduction in pain and improved ophthalmoplegia in 1 or 2 days is confirmatory of the diagnosis; however, as pointed out in the review by Kline and Hoyt, tumors of the parasellar region that cause ophthalmoplegia may also respond, albeit not to the same extent. In both diseases, we have generally given prednisone 60 mg and tapered the medication slowly; although there are no data to guide the proper treatment, corticosteroids should be continued for several weeks or longer. The absence of a response to steroids should cause reconsideration of the diagnosis of Tolosa-Hunt syndrome.

Cavernous sinus syndrome In the *cavernous sinus syndrome*, involvement of the oculomotor nerve on one or both sides is accompanied by periorbital pain and chemosis (Fig. 14-5B). In a series of 151 such cases reported by Keane, the third nerve (typically with pupillary abnormalities) and sixth nerve were affected in almost all and the fourth nerve in one-third; complete ophthalmoplegia, usually unilateral, was present in 28 percent. Sensory loss in the distribution of the ophthalmic division of the trigeminal nerve was often added, a finding that is helpful in the differentiation of cavernous sinus disease from other causes of orbital edema and ocular muscle weakness.

Trauma and neoplastic invasion are the most frequent causes of the cavernous sinus syndrome. Thrombophlebitis, intracavernous carotid aneurysm or fistula, fungal infection, meningioma, and pituitary tumor or hemorrhage account for a smaller proportion (see “Septic Cavernous Sinus Thrombophlebitis” and “Cavernous Sinus Thrombosis” in Chaps. 10 and 34). A dural arteriovenous fistula is another rare cause. Chapter 34 discusses this process more fully with other disorders of the cerebral venous sinuses; the optic neuropathy that sometimes accompanies the syndrome is noted in Chap. 13.

The other important considerations in older patients with painful ophthalmoplegia are *temporal arteritis* as mentioned above (see Chap. 10) and *thyroid ophthalmopathy* (although pain tends not to be prominent in the latter), which are discussed further on.

Acute Ophthalmoplegia (Table 14-5)

When a total or nearly complete loss of eye movements of both eyes evolves within a day or days, it raises a limited number of diagnostic possibilities. Keane, who analyzed 60 such cases, found the responsible lesion to lie within the brainstem in 18 (usually infarction and less often Wernicke disease), in the cranial nerves in 26 (Guillain-Barré syndrome or tuberculous meningitis), within the cavernous sinus in 8 (tumors or infection), and at the myoneural junction in 8 (myasthenia gravis and botulism). Our experience

Table 14-5

CAUSES OF COMPLETE OPHTHALMOPLÉGIA (ACUTE SYNDROMES ARE NOTED BY AN ASTERISK)

<i>Brainstem lesions</i>
Wernicke disease*
Pontine infarction*
Infiltrating glioma
Acute disseminated encephalomyelitis and multiple sclerosis
<i>Cranial nerve lesions</i>
Guillain-Barré syndrome*
Neoplastic meningitis
Granulomatous meningitis (tuberculous, sarcoid)
Cavernous sinus thrombosis
Tolosa-Hunt syndrome
Orbital pseudotumor*
<i>Neuromuscular junction syndromes</i>
Myasthenia gravis*
Thyroid ophthalmopathy
Lambert-Eaton syndrome
Botulism*
Congenital myasthenic syndromes (“slow-channel” disease)
<i>Muscle disease</i>
Progressive external ophthalmoplegia (mitochondrial and dystrophic types)
Oculopharyngeal dystrophy
Congenital polymyopathies (myotubular, nemaline rod, central core)

has tended toward the Guillain-Barré syndrome, as did Keane’s later series (2007), and, somewhat less frequently in our material, myasthenia. The ophthalmoplegic form of Guillain-Barré syndrome is almost always associated with circulating antibodies to GQ1b ganglioside (see Chap. 46). There may be an accompanying paralysis of the dilator and constrictor of the pupil (“internal ophthalmoplegia”) that is not seen in myasthenia.

Unilateral complete ophthalmoplegia has an even more limited list of causes, largely related to local disease in the orbit and cavernous sinus, mainly infectious, neoplastic, or thrombotic and most of which have already been mentioned.

Chronic and Progressive Bilateral Ophthalmoplegia

This is most often caused by an ocular myopathy (the mitochondrial disorder known as progressive external ophthalmoplegia), a restricted muscular dystrophy, thyroid ophthalmopathy (see below and Chap. 48), and, sometimes, myasthenia gravis or Lambert-Eaton syndrome. We have encountered instances of the Lambert-Eaton myasthenic syndrome that caused an almost complete ophthalmoplegia (but not as an initial sign, as it may be in myasthenia) and a patient with paraneoplastic brainstem encephalitis similar to the case reported by Crino and colleagues, but both of these are certainly rare as causes of complete loss of eye movements. Among the group of congenital myopathies, most of which are named for the morphologic characteristic of the affected limb musculature. A few of these—such as the central core, myotubular, and nemaline types, as well as the slow channel congenital myasthenic syndrome—may cause

a generalized ophthalmoparesis (see Chap. 48). Among the chronic conditions, progressive supranuclear palsy may ultimately produce complete ophthalmoplegia, after first affecting vertical gaze. Thyroid ophthalmopathy as a cause of chronic ophthalmoparesis is discussed below.

The *Duane retraction syndrome* (so-called because of the retraction of the globe and narrowing of the palpebral fissure that is elicited by attempted adduction) occurs when the lateral rectus branches are aberrantly innervated by the third nerve. Cocontraction of the medial and lateral recti results in retraction of the globe in all directions of ocular movement.

Mechanical-Restrictive Ophthalmoparesis Including Thyroid Ophthalmopathy

Several causes of a *pseudoparalysis of ocular muscles* that are due to mechanical restriction of the ocular muscles are distinguished from the neuromuscular and brainstem diseases discussed above. Processes that infiltrate the orbit, such as lymphoma, carcinoma and granulomatosis may limit the range of motion of individual or all the ocular muscles. In *thyroid disease*, a swollen and tight inferior or superior rectus muscle may limit upward and downward gaze; less frequently, involvement of the medial rectus limits abduction. The frequency of involvement of the ocular muscles is given by Wiersinga and colleagues as inferior rectus 60 percent; medial rectus 50 percent; and superior rectus 40 percent. In most instances of thyroid ophthalmopathy, diagnosis is clear as there is an associated proptosis, but in the absence of the latter sign, and particularly if the ocular muscles are affected on one side predominantly, there may be difficulty. The extraocular muscle enlargement can be demonstrated by CT scans and ultrasonography. This disorder is discussed further in Chap. 48. In a significant number of cases, 10 percent according to Bahn and Heufelder, there are no signs of hyperthyroidism. However, most of these patients have laboratory evidence of thyroid autoimmune disease.

The mechanical restriction of motion is confirmed by *forced duction tests* in which the eye is physically pulled or pushed over by the examiner. In the past, the insertions of the extraocular muscles were anesthetized and grasped by toothed forceps and attempts to move the globe are palpably restricted; more often, a cotton swab applied to the sclera is used to manipulate the globe.

Mixed Gaze and Ocular Muscle Paralysis

We have already considered two types of neural paralysis of the extraocular muscles: paralysis of conjugate movements (gaze) and paralysis of individual ocular muscles. Here we discuss a third, more complex one—namely, mixed gaze and ocular muscle paralysis. The mixed type is always a sign of an intrapontine or mesencephalic lesion that may be caused by a wide variety of pathologic changes.

Internuclear Ophthalmoplegia and Other Pontine Gaze Palsies

These abnormalities have been mentioned previously because they are components of numerous tegmental brainstem syndromes affecting both horizontal and

vertical gaze. A lesion of the lower pons in or near the sixth-nerve nucleus causes an ipsilateral paralysis of the lateral rectus muscle and a failure of adduction of the opposite eye, which is manifest simply as a gaze palsy to the side of the lesion. As already indicated, a presumed pontine center accomplishes horizontal conjugate gaze by simultaneously innervating the ipsilateral lateral rectus (via the abducens neurons) and the contralateral medial rectus via fibers that originate in the internuclear neurons of the abducens nucleus and cross at the level of the nucleus to traverse the MLF of the opposite side (Fig. 14-1).

With a complete lesion of the left MLF, the left ipsilateral eye fails to adduct when the patient looks to the right; this condition is referred to as *internuclear ophthalmoplegia* (INO; reciprocally, with a lesion of the right MLF, the right eye fails to adduct when the patient looks to the left—namely, *right internuclear ophthalmoplegia*). Quite often, rather than a complete paralysis of adduction, there are only slowed adducting saccades in the affected eye while its opposite quickly arrives at its fully abducted position. This can be brought out by having the patient make large side-to-side refixation movements between two targets or by observing the slowed corrective saccades induced by optokinetic stimulation. Typically, the affected eye at rest does not lie in an abducted position, but there are exceptions and in most cases the absence of exotropia most dependably differentiates INO from a partial third-nerve palsy with weakness of the medial rectus muscle. The exception is the WEBINO syndrome noted below. The two medial longitudinal fasciculi lie close together, each being situated adjacent to the midline, so that they are frequently affected together, yielding a bilateral internuclear ophthalmoplegia; this condition should be suspected when the predominant ocular finding is bilateral paresis of adduction.

A second component of INO is a nystagmus that is limited to, or most prominent in, the opposite (abducting) eye. The intensity of nystagmus varies greatly from case to case. Several explanations have been offered to account for this dissociated nystagmus, all of them speculative. The favored one invokes the Hering law in which activated pairs of yoked muscles receive equal and simultaneous innervation; because of an adaptive increase in innervation of the weak adductor there is a commensurate increase in innervation to the strong abductor (manifest as nystagmus). Whatever the afferent stimulus for this over-drive, it is probably proprioceptive (i.e., not visual), because occlusion of the affected eye does not suppress the nystagmus. The MLF also contains axons that originate in the vestibular nuclei and govern vertical eye position, for which reason an INO may also cause a skew (vertical deviation of one eye) or monocular vertical nystagmus with impairment of vertical fixation and pursuit (bilaterally with bilateral INO).

Lesions involving the MLF in the high midbrain cause a loss of convergence and an exotropia because of proximity to the medial rectus subnucleus. When the lesion is bilateral, both eyes are slightly abducted, giving rise to a “wall-eyed INO”, or WEBINO. Abducting nystagmus tends to be slight in this mesencephalic type. More commonly, the MLF is involved by a lesion in the

pons and convergence is spared and the globes are orthotropic, but there is sometimes an additional slight degree of horizontal gaze or sixth-nerve palsy as a result of disturbance of adjacent horizontal gaze centers. There may be yet another rare syndrome that has gone by the term "posterior INO of Lutz" (INO of abduction, in which the MLF is not involved); the lesion is proposed to be between the PPRF and the sixth nerve nucleus and the abduction paresis can be overcome by vestibular stimulation. The terms "anterior" and "posterior" INO have also been applied to these topographic syndromes but their meaning has been taken differently by various authors thus making them less useful.

The main cause of *unilateral INO* is a small paramedian pontine infarction. Other common lesions are lateral medullary infarction (where skew deviation is often a component), a demyelinating plaque of multiple sclerosis (more common as a cause of bilateral INO, as noted below), lupus erythematosus, and infiltrative tumors of the brainstem and fourth ventricular region. Occasionally, an INO is an unexplained finding after mild head injury or with subdural hematoma or hydrocephalus. Some of the more unusual causes are given in the experience of Keane (2005). Infarction and multiple sclerosis remained the most common in his series but trauma, transtentorial herniation, tumor, infection and hemorrhage were alternatives, the point being that a quarter were from unconventional processes. In addition, adductor weakness from myasthenia gravis can simulate an INO, even to the point of showing nystagmus in the abducting eye.

Bilateral INO is most often the result of a demyelinating lesion (multiple sclerosis) in the posterior part of the midpontine tegmentum. Pontine myelinolysis, pontine infarction from basilar artery occlusion, Wernicke disease, or infiltrating tumors are other causes. Brainstem damage following compression by a large cerebral mass has on occasion produced the syndrome.

An ipsilateral gaze palsy is the simplest oculomotor disturbance that results from a lesion in the paramedian tegmentum. More complex is the *one-and-a-half syndrome* that involves the pontine center for gaze plus the adjacent ipsilateral MLF on one side that combines an INO and a horizontal gaze palsy on the same side. It is usually of vascular or, less often, demyelinating cause. The gaze palsy is, of course, on the side of the lesion and the eyes are deviated contrawise. As a result, one eye lies fixed in the midline for all horizontal movements; the other eye makes only abducting movements and may be engaged in horizontal nystagmus in the direction of abduction (see Fisher; also Wall and Wray). Unlike the situation of an INO alone, the mobile eye rests abducted because of the gaze palsy, a sign that has been termed "paralytic pontine exotropia." In some cases the patient is able to adduct the eye ("non-paralytic exotropia," a condition which has other causes).

An incomplete version of the bilateral INO displays only bilateral nystagmus on gaze in one direction (due to paresis of gaze) and nystagmus only in the abducting eye with gaze directed to the other side (due to the lesion in the MLF on the same side). This has been summarized the mnemonic of nystagmus in both eyes looking toward the pontine lesion and in one eye looking away from the lesion.

Caplan has summarized the features of mixed oculomotor defects that occur with thrombotic occlusion of the upper part of the basilar artery ("top of the basilar" syndromes). These include upgaze or complete vertical gaze palsy and so-called pseudoabducens palsy, mentioned earlier. The latter is characterized by bilateral incomplete esotropia that simulates bilateral sixth nerve paresis (pseudoabducens palsy) but appears to be a type of sustained convergence or a paresis of divergence; it can be overcome by vestibular stimulation.

Skew Deviation *Skew deviation* is a disorder in which there is vertical deviation of one eye above the other that is caused by an imbalance of the vestibular inputs to the oculomotor system. The patient may complain of similar degrees of diplopia in all fields of gaze (comitant), or diplopia may vary with different directions of gaze. In either case, the patient complains of vertical diplopia. A non-comitant vertical deviation of the eyes, most pronounced when the affected eye is adducted and turned down, is characteristic of fourth-nerve palsy, described further on. Skew deviation does not have precise localizing value and is associated with a variety of lesions of the cerebellum and the brainstem, particularly those involving the MLF. With skew deviation due to cerebellar disease, the eye on the side of the lesion usually rests lower (in a ratio of 2:1 in Keane's series), but sometimes it is higher than the other eye. The corresponding image, of course, rests higher in the first instance and lower with the latter, which is most often a component of an INO.

The hypertropic eye has been known to alternate with the direction of gaze ("alternating skew") and has also been seen with the condition known as *periodic alternating nystagmus*. A cerebellar or other posterior fossa lesion is the usual cause. A mechanism for this sign has been proposed based on otolithic influences on cerebellar centers. Ford and coworkers have described a rare form of skew deviation caused by a monocular palsy of elevation stemming from a lesion immediately rostral to the ipsilateral oculomotor nucleus; a lesion of upgaze efferents from the ipsilateral riMLF was postulated but an abnormality of the vertical gaze holding mechanism related to the function of the INC is an alternative explanation.

Among the most unusual of the complex ocular disturbances is a subjective tilting of the entire visual field that may produce any angle of divergence but most often creates an illusion of environmental tilting of 45 to 90 degrees (*tortopia*) or of 180-degree vision (*upside-down vision*). Objects normally on the floor, such as chairs and tables, are perceived to be on the wall or ceiling. Although this symptom may arise as a result of a lesion of the parietal lobe or in the otolithic (utricle) apparatus, it has most often been associated in our experience with an internuclear ophthalmoplegia and slight skew deviation. Presumably the vestibular-otolithic nucleus or its connections in the MLF that maintain the vertical position of the ipsilateral eye are impaired. Lateral medullary infarction has been a common cause; other cases may be migrainous (Ropper, 1983). Ocular lateropulsion, in which the eyes are driven to one side and the patient feels pushed or pulled in the same direction, is another

component in some cases of lateral medullary infarction as discussed in Chap. 34.

Nystagmus

Nystagmus refers to involuntary rhythmic movements of the eyes and is of two general types. In the more common *jerk nystagmus*, the movements alternate between a slow component and a fast corrective component, or *jerk*, in the opposite direction. In *pendular nystagmus*, the oscillations are roughly equal in rate in both directions, although on lateral gaze the pendular type may be converted to the *jerk* type with the fast component to the side of gaze. Nystagmus reflects an imbalance in one or more of the systems that maintain stability of gaze. The causes may therefore be viewed as originating in (1) structures that maintain steadiness of gaze in the primary position; (2) the system for holding eccentric gaze—the so-called neural integrator; or (3) the VOR system, which maintains foveal fixation of images as the head moves. For the purposes of clinical work, however, certain types of nystagmus are identified as corresponding to lesions in specific structures within each of these systems, and it is this approach that we take in the following pages. One classification considers nystagmus as the result of a disturbance in the vestibular apparatus or its brainstem nuclei, the cerebellum, or a number of specific regions of the brainstem such as the MLF.

In testing for nystagmus, the eyes should be examined first in the central position and then during upward, downward, and lateral movements. *Jerk nystagmus* is the more common type. It may be horizontal or vertical and is elicited particularly on ocular movement in these planes, or it may be rotatory and, rarely, retractory or vergent. By custom the direction of the nystagmus is designated according to the direction of the fast component (referred to as “beating” to that side). There are several varieties of *jerk nystagmus*. Some occur spontaneously; others are readily induced in normal persons by drugs or by labyrinthine or visual stimulation.

Drug intoxication is certainly the most frequent cause of nystagmus. Alcohol, barbiturates, other sedative-hypnotic drugs, phenytoin, and other antiepileptic drugs are the common ones. This form of nystagmus is most prominent on deviation of the eyes in the horizontal plane, but occasionally it also may appear in the vertical plane. For no known reason, it may occasionally be asymmetrical in the two eyes.

Oscillopsia is the symptom of illusory movement of the environment in which stationary objects seem to move back and forth, up and down, or from side to side. It may be caused by ocular flutter (a cerebellar sign as discussed later) or coarse nystagmus of any type. With lesions of the labyrinths (as in aminoglycoside toxicity), the symptom of *oscillopsia* is only provoked by motion—e.g., walking or riding in an automobile—and indicates an impaired ability of the vestibular system to stabilize ocular fixation during body movement (i.e., impaired VOR function). In these circumstances, cursory examination of the eyes may disclose no abnormalities; however, if the patient’s head is rotated slowly from side to side or

moved rapidly in one direction while attempting to fixate a target, impairment of smooth eye movements and their replacement by saccadic or nystagmoid movements is evoked (see Chap. 15 for further discussion of these tests). If episodic and involving only one eye, *oscillopsia* is usually caused by myokymia of an ocular muscle (usually the superior oblique).

Nystagmus of Labyrinthine Origin (See also Chap. 15)

This is predominantly a horizontal or vertical unidirectional *jerk nystagmus*, often with a slight torsional component, that is evident when the eyes are close to the central position and changes minimally with the direction of gaze. It is more prominent when visual fixation is eliminated (conversely, it is suppressed by fixation). The observation of suppression with visual fixation is facilitated by the use of Frenzel lenses, but most instances are evident without elaborate apparatus. Vestibular nystagmus of peripheral (labyrinthine) origin beats in most cases away from the side of the lesion and increases as the eyes are turned in the direction of the quick phase (the Alexander law). In contrast, as noted below, nystagmus of brainstem and cerebellar origin is most apparent when the patient fixates upon and follows a moving target and the direction of nystagmus changes with the direction of gaze. Labyrinthine-vestibular nystagmus is horizontal, vertical, or oblique, and that of purely labyrinthine origin characteristically has an additional torsional component. Tinnitus and hearing loss are often associated with disease of the peripheral labyrinthine mechanism; also, vertigo, nausea, vomiting, and staggering may accompany disease of any part of the labyrinthine-vestibular apparatus or its central connections. These points are elaborated in Chap. 15. As a characteristic example, the intense nystagmus of benign positional vertigo (described fully in Chap. 15) is evoked by moving from the sitting to the supine position, with the head turned to one side. In this condition, nystagmus of vertical-torsional type and vertigo develop a few seconds after changing head position and persist for another 10 to 15 s. When the patient sits up, the nystagmus changes to beat in the opposite direction.

In many normal individuals, a few irregular jerks are observed when the eyes are moved far to one side (“nystagmoid” jerks), but the movements cease once lateral fixation is attained. A fine rhythmic nystagmus may also occur normally in extreme lateral gaze, beyond the range of binocular vision; but it is bilateral and disappears as the eyes move a few degrees toward the midline. These latter movements are probably analogous to the tremulousness of skeletal muscles when maximally contracted.

Nystagmus Caused by Brainstem and Cerebellar Disease

Brainstem lesions often cause a coarse, unidirectional, *gaze-dependent nystagmus*, which may be horizontal or vertical, meaning that the nystagmus is exaggerated when the eyes sustain an eccentric position of gaze; vertical nystagmus, for example, is brought out usually on upward gaze, less often downward. Unlike the vestibular nystagmus discussed above, the central type usually also

changes direction depending on the direction of gaze. The presence of bidirectional vertical nystagmus usually indicates disease in the pontomedullary or mesencephalic tegmentum. Vertigo is less common or less intense than with labyrinthine nystagmus, but signs of disease of other nuclear structures and tracts in the brainstem are frequent.

Spontaneous *upbeat nystagmus* is observed frequently in patients with demyelinating or vascular disease, tumors, or Wernicke disease. There is still uncertainty about the anatomic basis of coarse upbeat nystagmus. According to some authors, it has been associated with lesions of the anterior cerebellar vermis or another cerebellar site. Kato and associates cite cases with a lesion at the pontomedullary junction involving the nucleus prepositus hypoglossi, which receives vestibular connections and projects to all brainstem and cerebellar regions concerned with oculomotor functions. Bilateral internuclear ophthalmoplegia is also a cause.

Downbeat nystagmus, which is always of central origin, is characteristic of lesions in the medullary–cervical region such as syringobulbia, Chiari malformation, basilar invagination, and demyelinating plaques. It has also been seen with Wernicke disease and may be an initial sign of either paraneoplastic brainstem encephalitis or cerebellar degeneration with opsoclonus. Downbeat nystagmus, usually in association with oscillopsia, has also been observed in patients with lithium intoxication or with profound magnesium depletion (Saul and Selhorst). Halmagyi and coworkers, who studied 62 patients with downbeat nystagmus, found that half were associated with the Chiari malformation and various forms of cerebellar degeneration; in most of the remainder, the cause could not be determined. Cases associated with antibodies against glutamic acid decarboxylase (GAD), a substance that has a documented relationship to the stiff man syndrome have been reported by Antonini and colleagues and by other groups. Whether this antibody explains the idiopathic cases of downbeat nystagmus is not known.

Nystagmus of several types—including gaze-evoked nystagmus, downbeat nystagmus, and “rebound nystagmus” (gaze-evoked nystagmus that changes direction with refixation to the primary position)—occurs with cerebellar disease, particularly with lesions of the vestibulocerebellum or with brainstem lesions that involve the nucleus prepositus hypoglossi and the medial vestibular nucleus. Characteristic of cerebellar disease are several closely related disorders of saccadic movement that appear as nystagmus (opsoclonus, flutter, dysmetria) described below. Tumors situated in the cerebellopontine angle may cause a coarse bilateral horizontal nystagmus that is higher amplitude to the side of the lesion.

Nystagmus that occurs only in the abducting eye is referred to as *dissociated nystagmus* and is a common sign of internuclear ophthalmoplegia, as discussed earlier.

Infantile (Congenital, Pendular) Nystagmus

This is found in a variety of conditions in which central vision is lost early in life, such as albinism and various other diseases of the retina and refractive media.

Occasionally it is observed as a congenital abnormality, even without poor vision. The defect is postulated to be an instability of smooth pursuit or gaze-holding mechanisms. The nystagmus is always binocular and in one plane; i.e., it will remain horizontal even during vertical movement. It is mainly pendular (sinusoidal) except in extremes of gaze, when it comes to resemble jerk nystagmus. Head oscillation may accompany the nystagmus and is probably compensatory. With eye movement recordings it displays a feature unique among nystagmus, an exponentially increasing velocity of the slow phase.

Indications as to the congenital nature of nystagmus are that it remains horizontal in all directions of gaze; it is suppressed during convergence and may be associated with odd head positions or with head oscillations and with strabismus. Also characteristic is a paradoxical response to optokinetic testing (see below), in which the quick phase is in the same direction as the drum rotation.

The related condition of *latent nystagmus* is the result of a lack of normal development of stereoscopic vision and may be detected by noting that the nystagmus changes direction when the eyes are alternately covered. In a few individuals who later in life lose vision in one eye, the latent nystagmus becomes a *manifest latent nystagmus*.

In addition, severe visual loss or blindness of acquired type that eliminates the ability to accurately direct gaze, even in adulthood, produces nystagmus of pendular or jerk variety. Both horizontal and vertical components are evident and the characteristic feature is a fluctuation over several seconds of observation in the dominant direction of beating. We have seen this sign a number of times in patients who became blind from severe optic neuritis few years back. The formerly common syndrome of “miner’s nystagmus” is an associated condition that occurs in patients who have worked for many years in comparative darkness. The oscillations of the eyes are usually very rapid, increase on upward gaze, and may be associated with compensatory oscillations of the head.

Spasmus nutans, a specific type of pendular nystagmus of infancy, is accompanied by head nodding, and occasionally by wry positions of the neck. Most cases begin between the fourth and twelfth months of life, never after the third year. The nystagmus may be horizontal, vertical, or rotatory; it is usually more pronounced in one eye than the other (or limited to one eye) and can be intensified by immobilizing or straightening the head. Most infants recover within a few months or years. Most cases are idiopathic, but symptoms like those of spasmus nutans betray the presence of a perichiasmatic or third ventricular tumor (see also seesaw nystagmus below in “Other Types of Nystagmus”); rare cases accompany childhood retinal diseases. Although there is no direct connection to this syndrome, the rare condition of bobble-head doll syndrome, consisting of rhythmic head movements caused by lesions in or adjacent to the third ventricle as described in Chap 30.

Acquired forms of pendular nystagmus may occur with adult leukodystrophies (see Chap. 37), multiple sclerosis (see Chap. 36), toluene intoxication, and in the oculomasticatory myorhythmia of Whipple disease, in which the nystagmus is conjoined to rhythmic jaw movements (see Chap. 32).

Other Types of Nystagmus

Convergence nystagmus has already been alluded to in several contexts—it refers to a rhythmic oscillation in which a slow abduction of both eyes is followed by a quick movement of adduction, usually accompanied by quick rhythmic retraction movements of the eyes (*nystagmus retractorius*, *retraction nystagmus*) and by one or more features of the Parinaud–dorsal midbrain syndrome discussed earlier in the chapter. There may also be rhythmic movements of the eyelids or a maintained spasm of convergence, best brought out on attempted elevation of the eyes on command or downward rotation of an OKN drum (see below for discussion of optokinetic nystagmus, OKN). These unusual phenomena all point to a lesion of the upper midbrain tegmentum and are usually manifestations of vascular disease, traumatic damage, or tumor, notably pinealoma that compresses this region.

Seesaw nystagmus is a torsional-vertical oscillation in which the intorting eye moves up and the opposite (extorting) eye moves down, then both move in the reverse direction. It is occasionally observed in conjunction with chiasmatic bitemporal hemianopia caused by sellar or parasellar masses and after pituitary surgery. Spasmus nutans has some similarities, as mentioned above, and alternating skew may be a related phenomenon.

Periodic alternating nystagmus is a remarkable horizontal jerking that periodically (every 90 seconds or so) changes direction, interposed with a brief neutral period during which the eyes show no nystagmus, or jerk downward. Alternating nystagmus is seen with lesions in the lower brainstem but has also been reported with Creutzfeldt-Jakob disease, hepatic encephalopathy, lesions of the cerebellar nodulus, carcinomatous meningitis, anti-GAD antibodies, and varied other processes. A congenital form is associated with albinism. It differs from *ping-pong gaze*, which is a saccadic variant with a more rapid alternating of gaze from side to side and usually the result of bilateral cerebral strokes.

So-called *palatal nystagmus*, which is really a tremor, is caused by a lesion of the central tegmental tract and may be accompanied by a convergence–retraction nystagmus that has the same beat as the palatal and pharyngeal muscles, as discussed in Chap. 4.

Optokinetic Nystagmus

When one is watching a moving object (e.g., the passing landscape from a train window, a rotating drum with vertical stripes, or a strip of cloth with similar stripes), a rhythmic jerk nystagmus, *optokinetic nystagmus* (OKN), normally appears. This phenomenon is explained by a slow component of nystagmus that represents an involuntary pursuit movement to the limit of comfortable conjugate gaze followed by a quick saccadic movement in the opposite direction in order to fixate the next new target that is entering the visual field. With unilateral lesions of the parietal region, the slow pursuit phase of the OKN may be lost or diminished when the stimulus—e.g., the striped OKN drum—is moving *toward the side of the lesion*, whereas rotation of the drum to the opposite side elicits a normal response. (A prominent neurologist of our

acquaintance in past days correctly made the diagnosis of parietal lobe abscess on the basis of fever and absent pursuit to the side of the lesion.) It is remarkable that patients with hemianopia caused by an occipital lobe lesion show a normal optokinetic response. The loss of the pursuit phase with a parietal lesion is presumably because of interruption of efferent pathways from the parietal cortex to the brainstem centers for conjugate gaze. On the other hand, frontal lobe lesions allow the eyes to tonically follow in the direction of the target but with little or no fast-phase correction in the direction opposite the lesion. In recent years, however, it has been suggested from primate experiments that there is a subcortical relay station for OKN in the geniculate nucleus of the optic tract contralateral to the slow phase of nystagmus.

An important additional fact about OKN is that the ability to evoke it in all directions proves that the patient is not blind. Each eye can be tested separately to exclude monocular blindness. Thus the test is of particular value in the examination of hysterical patients and malingerers who claim that they cannot see, and of neonates and infants (a nascent OKN is established within hours after birth and becomes more easily elicitable over the first few months of life).

Caloric-induced nystagmus *Labyrinthine stimulation*—e.g., irrigation of the external auditory canal with warm or cold water, or “caloric testing”—produces a marked nystagmus. Cold water induces a slow tonic deviation of the eyes toward the irrigated ear and a compensatory nystagmus in the opposite direction; warm water does the reverse. Thus the acronym taught to generations of medical students: COWS, or “cold opposite, warm same,” to refer to the direction of the fast phase of the induced nystagmus. The slow tonic component reflects impulses originating in the semicircular canals, and the fast component is a corrective movement. Chapter 15 discusses the production of nystagmus by labyrinthine stimulation and other features of vestibular nystagmus.

Other Spontaneous Ocular Movements

Roving conjugate eye movements are characteristic of light coma. Slow horizontal ocular deviations that shift every few seconds from side to side (*ping-pong gaze*) is a form of roving eye movement that occurs with bihemispheric infarctions or sometimes with posterior fossa lesions. Fisher has noted a similar slower, side-to-side pendular oscillation of the eyes (“windshield-wiper eyes”). This phenomenon has been associated with bilateral hemispheric lesions that have presumably released a brainstem pacemaker.

Ocular bobbing is a term coined by Fisher to describe a distinctive spontaneous fast downward jerk of the eyes followed by a slow upward drift to the midposition. It is observed in comatose patients in whom horizontal eye movements have been obliterated by large destructive lesions of the pons, less often of the cerebellum. The movements may be disconjugate in the vertical plane, especially if there is an associated third-nerve palsy on one side.

Other spontaneous vertical eye movements have been given a variety of confusing names: *atypical bobbing*, *inverse bobbing*, *reverse bobbing*, and *ocular dipping*. For the most part, they are observed in coma of metabolic or anoxic origin and in the context of preserved horizontal eye movements (in distinction to ocular bobbing). *Ocular dipping* is the term we have used to describe an arrhythmic slow conjugate downward movement followed in several seconds by a more rapid upward movement; it occurs spontaneously but may at times be elicited by moving the limbs or neck. Anoxic encephalopathy has been the most common cause, but a few cases have followed drug overdose (Ropper, 1981).

Oculogyric crisis, formerly associated with postencephalitic parkinsonism, is now most often caused by phenothiazine drugs, as discussed earlier.

Saccadic Intrusions (Opsoclonus and Ocular Dysmetria)

This group of phasic or repetitive eye movements is distinguished from nystagmus in that the first movement is a fast saccade, in contrast to jerk nystagmus, where by definition the movement starts with a slow phase. *Opsoclonus* is the term applied to rapid, conjugate oscillations of the eyes in horizontal, rotatory, and vertical directions, made worse by voluntary movement or the need to fixate the eyes. These movements are continuous and chaotic, without an intersaccadic pause (hence the colorful term *saccadomania*), and are almost unique among disorders of ocular movement in that they persist in sleep. As indicated in Chap. 6, they are sometimes part of a widespread myoclonus associated with parainfectious disease, occasionally with AIDS, poststreptococcal infection, West Nile virus encephalitis, and rickettsial infections, but most characteristically as a paraneoplastic manifestation with severe ataxia ("Paraneoplastic Cerebellar Degeneration" discussed in Chap. 31). Opsoclonus may also be observed in patients who are intoxicated with antidepressants, anticonvulsants, organophosphates, cocaine, lithium, thallium, and haloperidol; in the nonketotic hyperosmolar state; and in cerebral Whipple disease, where the eye movements are coupled with rhythmic jaw movements (oculomasticatory myorhythmia). A childhood form, associated with limb ataxia and myoclonus that is responsive to adrenocorticotrophic hormone (ACTH), may persist for years without explanation, as in the "dancing eyes" of children (Kinsbourne syndrome). However, a distant (paraneoplastic) effect of neuroblastoma remains the main consideration in children with this ocular disorder. There is also a self-limited benign form in neonates. Similar movements have been produced in monkeys by creating bilateral lesions in the pretectum.

Ocular dysmetria, the analogue of limb dysmetria, consists of an overshoot or undershoot of the eyes on attempted fixation followed by several cycles of oscillation of diminishing amplitude until fixation is attained. The dysmetria may occur on eccentric fixation or on refixation to the primary position of gaze. It probably reflects dysfunction of the anterosuperior vermis and underlying deep cerebellar nuclei.

Ocular flutter refers to occasional bursts of very rapid horizontal oscillations around the point of fixation; this abnormality is also associated with cerebellar disease. Flutter at the end of a saccade, called *flutter dysmetria* ("fish-tail nystagmus") has the appearance of dysmetria, but careful analysis indicates that it is probably a different phenomenon. Whereas the inaccurate saccades of ataxia are separated by normal brief pause (intersaccadic interval), flutter dysmetria consists of consecutive saccades without an intersaccadic interval (Zee and Robinson). Nonetheless, all those movements have the same implication of cerebellar cortical disease.

Opsoclonus, ocular dysmetria, and flutter-like oscillations may occur together, or a patient may show only one or two of these ocular tremors, either simultaneously or in sequence. One hypothesis relates opsoclonus and ocular flutter to a disorder of the saccadic "pause neurons" (see above), but their exact anatomic basis has not been elucidated. Some normal individuals can voluntarily induce flutter.

An eye movement difficult to classify is ocular neuromyotonia that is found after radiation that includes the field of the ocular motor nerves (and less characteristically from vascular or tumor compression). There is intermittent contraction of one or more ocular muscles that may cause paroxysmal diplopia. The similar syndrome of superior oblique myokymia was discussed in an earlier section of the chapter.

Disorders of the Eyelids and Blinking

A consideration of oculomotor disorders would be incomplete without reference to the eyelids and blinking. In the normal individual, the eyelids on both sides are at the same level with respect to the limbus of the cornea and there is a variable prominence of the eyes, depending on the width of the palpebral fissure. The function of the lids is to protect the delicate corneal surfaces against injury and the retinae against glare; this is done by blinking and lacrimation. Eyelid movement is normally coordinated with ocular movement—the upper lids elevate when looking up and descend when looking down. Turning the eyes quickly to the side is sometimes attended by a single blink, which is necessarily brief so as not to interfere with vision. When the blink duration is prolonged, it is indicative of an abnormally intense effort required to initiate the saccade; usually this is because of frontal lobe or basal ganglionic disease.

Closure and opening of the eyelids is accomplished through the reciprocal action of the levator palpebrae and orbicularis oculi muscles. Relaxation of the levator and contraction of the orbicularis effect closure; the reverse action of these muscles effects opening of the closed eyelids. Opening of the lids is aided by the tonic innervation of the superior tarsal (Müller) muscle, which is innervated by sympathetic fibers. The levator is innervated by the oculomotor nerve, and the orbicularis by the facial nerve. The trigeminal nerves provide sensation to the eyelids and are also the afferent limbs of corneal and palpebral reflexes. Central mechanisms for the control of blinking, in addition to the reflexive brainstem

connections between the third-, fifth-, and seventh-nerve nuclei, include slower and polysynaptic circuits of the cerebrum, basal ganglia, and hypothalamus. Voluntary lid closure is initiated through frontobasal ganglionic connections.

The eyelids are kept open by the tonic contraction of the levator muscles, which overcomes the elastic properties of the periorbital muscles. The eyelids close during sleep and certain altered states of consciousness as a result of relaxation of the levator muscles. Facial paralysis causes the closure to be incomplete.

Blinking occurs irregularly at a rate of 12 to 20 times a minute, the frequency varying with the state of concentration and with emotion. The natural stimuli for the blink reflex (blinking is always bilateral) are corneal contact (corneal reflex), a tap on the brow or around the eye, visual threat, an unexpected loud sound, and, as indicated above, turning of the eyes to one side. There is normally a rapid adaptation of blink to visual and auditory stimuli but not to corneal stimulation.

Electromyography of the orbicularis oculi reveals two components of the blink response, an early and late one, features that are readily corroborated by clinical observation. The early response consists of only a slight movement of the upper lids; the immediately following response is more forceful and approximates the upper and lower lids. Whereas the early part of the blink reflex is beyond volitional control, the second part can be inhibited voluntarily.

Blepharospasm, an excessive and forceful closure of the lids, is a common disorder that is seen in isolation or as part of a number of dyskinesias and drug-induced movement disorders. Extremes of this condition may result in functional blindness. Increased blink frequency is a subtle part of the same condition but also occurs with corneal irritation. The opposite sign, reduced frequency of blinking (<10/min), is characteristic of progressive supranuclear palsy and Parkinson disease. In these cases, adaptation to repeated supraorbital tapping at a rate of about 1/s is impaired; therefore the patient continues to blink with each tap on the forehead or glabella, referred to as the glabellar, or *Myerson sign*.

A lesion of the oculomotor nerve, by paralyzing the levator muscle, causes *ptosis*, i.e., drooping of the upper eyelid. A lesion of the facial nerve, as in Bell palsy, results in an inability to close the eyelids because of weakness of orbicularis oculi, retraction of the upper lid (as a result of the unopposed action of the levator), and loss of the blink reflex on the affected side. In some instances of Bell palsy, even after nearly full recovery of facial movements, blink frequency and amplitude may be reduced on the previously paralyzed side. A trigeminal nerve lesion on one side, by reducing corneal sensation, interferes with the blink reflex on both sides, whereas Bell palsy does not abolish the contralateral blink. Aberrant regeneration of the third nerve after an injury may result in a condition wherein the upper lid retracts on lateral or downward gaze (pseudo-von Graefe sign). Aberrant regeneration of the facial nerve after Bell palsy has an opposite effect—closure of the lid with jaw movements or speaking (one of the Marcus Gunn phenomena, the other being an afferent

pupillary defect to light). There is also a congenital and sometimes hereditary anomaly in which a ptotic eyelid retracts momentarily when the mouth is opened or the jaw is moved to one side. In other cases, inhibition of the levator muscle and ptosis occurs with opening of the mouth (“inverse Marcus Gunn phenomenon,” or Marin Amat syndrome).

A useful clinical rule is that a combined paralysis of the levator, and orbicularis oculi muscles (i.e., the muscles that open and close the lids) indicates a myopathic disease such as myasthenia gravis or myotonic dystrophy. This is because the third and seventh cranial nerves are rarely affected together in peripheral nerve or brainstem disease. An infrequent but overlooked cause of unilateral static ptosis is a dehiscence of the tarsal muscle attachment; it can be identified by the loss of the upper lid fold just below the brow.

Bilateral ptosis is a characteristic feature of certain muscular dystrophies and of myasthenia gravis; congenital ptosis and progressive sagging of the upper lids in the elderly are other common forms as well botulism whether naturally acquired or after botulinum toxin treatments. An effective way of demonstrating that mild ostensibly unilateral ptosis is in fact bilateral is to lift the ptotic side and observe that the opposite lid promptly droops. This reflects the enhanced effort required to maintain patency of the lids. Unilateral ptosis is a notable feature of third-nerve lesions (see above) and of sympathetic paralysis, namely, the Horner syndrome. It may be accompanied by an overaction (compensation) of the frontalis and the contralateral levator palpebrae muscles. In patients with myasthenia, Cogan has described a “lid twitch” phenomenon, in which there is a transient retraction of the upper lid when the patient moves visual fixation from the down position to straight ahead. Brief fluttering of the lid margins upon moving the eyes vertically is also characteristic of myasthenia.

The opposite of ptosis, i.e., *retraction of the upper lids*, with a staring expression (Collier sign) is observed with orbital tumors and in thyroid disease, the latter also being the most common cause of unilateral and bilateral proptosis. A staring appearance alone is observed in Parkinson disease, progressive supranuclear palsy, and hydrocephalus in young children, in which there may be downturning of the eyes (“sunset sign”), and paralysis of upward gaze. Retraction of the eyelids may also be part of a dorsal midbrain syndrome and is accompanied by a light-near pupillary dissociation; it is not accompanied by a lid lag (von Graefe sign) on downward gaze, in distinction to what is observed in thyroid ophthalmopathy. Slight lid retraction has been observed in a few patients with hepatic cirrhosis, Cushing disease, chronic steroid myopathy, and hyperkalemic periodic paralysis. Lid retraction can be a reaction to ptosis on the other side; this is clarified by lifting the ptotic lid manually, and observing the disappearance of contralateral retraction as mentioned above.

Myotonic dystrophy features ptosis as a component of the myopathic facies. In myotonia congenita, forceful closure of the eyelids may induce a strong aftercontraction. In certain extrapyramidal diseases, particularly

progressive supranuclear palsy, and Parkinson disease, even gentle lid closure may elicit blepharoclonus and blepharospasm on attempted opening of the lids; or there may be a delay in the opening of the tightly closed eyelids. Acute right parietal or bifrontal lesions often produce a peculiar disinclination to open the eyelids, even to the point of offering active resistance to forced opening. The closed lids give the false impression of diminished alertness and has incorrectly been called an apraxia of lid opening.

THE PUPILS

The testing of pupillary size and reactivity, which can be accomplished by the use of a flashlight and simple gauge (we favor the circular laminated card—the *Iowa pupil gauge*), yields important, often vital clinical information. Essential, of course, is the proper interpretation of pupillary reactions, and this requires some knowledge of their underlying neural mechanisms.

The diameter of the pupil is determined by the balance of innervation between the constricting sphincter and radially arranged dilator muscles of the iris, the sphincter muscle playing the major role in the light response. The *pupilloconstrictor* (*parasympathetic*) fibers arise in the Edinger-Westphal nucleus in the high mid-brain, join the third cranial (oculomotor) nerve, and synapse in the ciliary ganglion, which lies in the posterior part of the orbit. The postganglionic fibers then enter the globe via the short ciliary nerves; approximately 3 percent of the fibers innervate the sphincter pupillae and 97 percent the ciliary body, which is primarily responsible for accommodative constriction of the pupil. The sphincter of the pupil comprises 50 motor units, according to Corbett and Thompson.

The *pupillodilator* (*sympathetic*) fibers arise in the posterolateral part of the hypothalamus and descend, uncrossed, in the lateral tegmentum of the midbrain, pons, medulla, and cervical spinal cord to the eighth cervical, and first and second thoracic segments, where they synapse with lateral horn neurons. The latter give rise to preganglionic fibers, most of which leave the cord by the second ventral thoracic root and proceed through the stellate ganglion to synapse in the superior cervical ganglion. The postganglionic fibers course along the internal carotid artery and traverse the cavernous sinus, where they join the first division of the trigeminal nerve, finally reaching the eye as the long ciliary nerve that innervates the dilator muscle of the iris. Some of the postganglionic sympathetic fibers also innervate the sweat glands and arterioles of the face, and Müller's muscle in the eyelid.

The Pupillary Light Reflex

The most common stimulus for pupillary constriction is exposure of the retina to light. Reflex pupillary constriction is also part of the act of convergence and accommodation for near objects (near synkinesis).

The pathway for the pupillary light reflex consists of three parts (Fig. 14-9). There is an *afferent limb*, fibers of

Figure 14-9. Diagram of the pathways subserving the pupillary light reflex. (Redrawn with permission from Bradford CA [ed]: *Basic Ophthalmology*, 7th Edition. San Francisco, American Academy of Ophthalmology, 1975.)

which originate in the retinal receptor cells, pass through the bipolar cells, and synapse with the retinal ganglion cells; axons of these cells run in the optic nerve and in the ipsilateral tract. The light reflex fibers leave the optic tract just rostral to the lateral geniculate body and enter the high mid-brain, where they synapse in the pretectal nucleus. The *special intercalated neurons*, which pass ventrally to the ipsilateral Edinger-Westphal nucleus and, via fibers that cross in the posterior commissure, go on to the contralateral Edinger-Westphal nucleus (labeled “pretecto-oculomotor” tract in Fig. 14-9). The effector arm of the reflex consists of an *efferent two-neuron pathway* from the Edinger-Westphal nucleus that synapses in the ciliary ganglion, from which the short ciliary nerves innervate the sphincter to cause pupillary constriction.

Alterations of the Pupils

The pupils tend to be large in children and small in the aged, sometimes markedly miotic but still reactive (senile miosis). An asymmetry of the pupils of 0.3 to 0.5 mm is found in 20 percent or more of normal individuals. A lesion that destroys only a small number of nerve cells in the Edinger-Westphal nucleus or ciliary ganglion will cause paralysis of a sector or sectors of the iris and deform the pupil to a pear or elliptical shape.

Normally the pupil constricts under a bright light (direct reflex), and the other unexposed pupil also constricts (consensual reflex). With complete or nearly complete interruption of the optic nerve, the pupil will fail to react to direct light stimulation; however, the pupil of the blind eye will still show a consensual reflex, i.e., it will constrict with illumination of the healthy eye.

Contrariwise, lack of direct and consensual light reflex with retention of the consensual reflex in the opposite eye places the lesion in the efferent limb of the reflex arc, i.e., in the homolateral oculomotor nerve or its nucleus. A lesion of the afferent limb of the light reflex pathway will not affect the near responses of the pupil, and lesions of the visual pathway caudal to the point where the light reflex fibers leave the optic tract will not alter the pupillary light reflex (Fig. 14-9).

Following initial constriction, the pupil may normally dilate slightly in spite of a light shining steadily in one or both eyes. Slowness of response along with failure to sustain pupillary constriction, or "pupillary escape," is sometimes referred to as the *Marcus Gunn pupillary sign*; a mild degree of it may be observed in normal persons, but it is far more prominent in cases of damage to the retina or optic nerve. The unilateral inadequacy of pupillary response may be used to expose mild degrees of retrobulbar optic neuropathy. This relative "afferent pupillary defect" is tested always in a dimly lighted room with the patient fixating on a distant target. If a light is shifted quickly from the normal to the impaired eye, the direct light stimulus is no longer sufficient to maintain the previously evoked consensual pupillary constriction and both pupils dilate. A variant of this maneuver is the "swinging-flashlight test," in which each pupil is alternately exposed to light at 3-s intervals and the pupil on the side of an optic neuropathy displays a paradoxical dilatation just as the light is brought to it.

Hippus, a rapid fluctuation in pupillary size, is common in metabolic encephalopathy but otherwise has no particular significance and is occasionally seen in normal persons. To distinguish hippus from the Marcus Gunn afferent pupillary defect one carefully observes the first movement of the pupil as the light is repeatedly moved to the affected eye; in hippus, half of the initial responses will be dilation and half, constriction, whereas in a deaf-ferented pupil all the initial movements are dilation.

Horner Syndrome

Interruption of the sympathetic fibers results in miosis and ptosis (because of paralysis of the pupillary dilator muscle and of Müller muscle, respectively). The lesion may be central, between the hypothalamus and the points of exit of sympathetic fibers from the spinal cord (C8 to T3, mainly T2), or peripheral, in the cervical sympathetic chain, superior cervical ganglion, or along the carotid artery. A congenital form caused by perinatal injury, usually of the sympathetic chain in the neck is seen regularly in our clinics (Fig. 14-10). A hereditary form of the Horner syndrome (autosomal dominant) is also known, usually but not always associated with a congenital absence of pigment in the affected iris (heterochromia iridis) (Hageman et al).

To the ophthalmic findings may be added loss of sweating on the same side of the face and redness of the conjunctiva. The entire complex is called the *Horner syndrome*, *Bernard-Horner syndrome*, or *oculosympathetic palsy*. The pupillary change may be subtle and may require covering the eyes or dimming the room lights to observe the lack of expected mydriasis on one side.

Figure 14-10. Congenital Horner syndrome on the patient's left. In addition to the miosis and ptosis, the patient's left iris is gray in color and the right, brown.

Most cases are caused by peripheral interruption of the sympathetic chain but the same effect may be produced by ipsilateral lesions of the sympathetic tract in the medulla or cervical cord. The pattern of sweating may be helpful in localizing the lesion in the following manner: With lesions at the level of the common carotid artery, loss of sweating involves the entire side of the face. With lesions distal to the carotid bifurcation, loss of sweating is not found or is confined to the medial aspect of the forehead and side of the nose (Morris et al). Retraction of the eyeball (enophthalmos), considered a component of the syndrome, is probably an illusion created by narrowing of the palpebral fissure.

Bilateral Horner syndrome is a rare occurrence; usually it is found in autonomic neuropathies and in high cervical cord transection. Although difficult to appreciate, bilateral miosis may be detected (using pupillometry or direct observation) by noting a lag in the redilation of the initially small pupils when light is withdrawn (Smith and Smith, 1999).

Stimulation or irritation of the sympathetic fibers, a rare phenomenon, has the opposite effect, i.e., lid retraction, dilatation of the pupil, and apparent proptosis. Use is made of this phenomenon in the testing of the *ciliospinal pupillary reflex*, which is evoked by pinching the neck (afferent, C2, C3) and effecting pupillary enlargement through cervical efferent sympathetic fibers.

Extreme bilateral constriction of the pupils (miosis) is commonly observed with pontine lesions, presumably because of interruption of the pupillodilator fibers but the mechanism is not entirely clear. Narcotic ingestion is the most common cause of bilateral miosis in clinical practice except in the elderly, who often acquire small pupils, particularly if medication drops for glaucoma are being used.

Interruption of the parasympathetic fibers causes an abnormal dilatation of the pupils (mydriasis), often with loss of pupillary light reflex; in cases of coma, this is the

result of a midbrain lesion (the “blown” or Hutchinson pupil, described in Chap. 17 in the context of cerebral masses causing coma) and with direct compression of the oculomotor nerve, as by aneurysm of the circle of Willis, tumor, or temporal lobe herniation. Other signs of oculomotor palsy are usually conjoined.

As an ancillary test to determine the cause of changes in the size of the pupils, the functional integrity of the sympathetic and parasympathetic nerve endings in the iris may be determined by the use of certain drugs detailed in the next section. Atropinics dilate the pupils by paralyzing the parasympathetic nerve endings; physostigmine and pilocarpine constrict the pupils, the former by inhibiting cholinesterase activity at the neuromuscular junction and the latter by direct stimulation of the sphincter muscle of the iris. Epinephrine and phenylephrine dilate the pupils by direct stimulation of the dilator muscle. Cocaine dilates the pupils by preventing the reabsorption of norepinephrine into the nerve endings. Morphine and other narcotics act centrally to constrict the pupils. More recently, the alpha-agonist drug, apraclonidine, has been shown to reliably reverse the anisocoria of Horner syndrome and has become the preferred drug for testing. One drop (0.5 percent solution) is placed in each eye, the eyes are kept closed for 1 min and the drops are repeated 5 min later. Enlargement of the miosis with the affected pupil becoming larger than the unaffected one 30 to 45 min after instillation is definite evidence of a Horner syndrome. Ptosis is also reduced, sometimes to a remarkable extent. It was originally developed as a treatment for glaucoma (Koc et al).

In *diabetes mellitus*, where autonomic spinal and cranial nerves are often involved, the pupils are affected in the majority of cases. They are smaller than would be expected for age because of involvement of pupillodilator sympathetic fibers, and mydriasis is excessive upon instillation of sympathomimetic drugs. The light reflex, mediated by parasympathetic fibers (which are also damaged), is reduced, usually to a greater degree than constriction on accommodation (Smith and Smith, 1987). Some of these abnormalities require special methods for their demonstration.

Argyll Robertson Pupil (Table 14-6)

In almost all the forms of late syphilis, particularly *tabes dorsalis*, the pupils are bilaterally small, irregular, and unequal; they fail to react to light, although they do constrict on accommodation (light-near dissociation) and

do not dilate properly in response to mydriatic drugs. Atrophy of the iris is associated in some cases. This is known as the *Argyll Robertson pupil*. The exact locality of the lesion is not certain but it is generally believed to be in the tectum of the midbrain proximal to the oculomotor nuclei where the descending pupillodilator fibers are in close proximity to the light reflex fibers (Fig. 14-9). This putatively explains the sparing of the afferent accommodative pathways from the retina to the Edinger-Westphal nuclei. The possibility of a partial third-nerve lesion extending to the ciliary ganglion seems as plausible to us. A similar pupillary abnormality has been observed in the meningoradiculitis of Lyme disease and in diabetes. A dissociation of the light reflex from the accommodation-convergence reaction is also sometimes observed with a variety of midbrain lesions—e.g., pinealoma, multiple sclerosis; in these diseases, miosis, irregularity of pupils, and failure to respond to a mydriatic are usually not present. S.A.K. Wilson referred to this condition as the *Argyll Robertson pupillary phenomenon*.

Adie Tonic Pupil (Holmes-Adie Syndrome)

(Table 14-6)

Another interesting pupillary abnormality is the tonic reaction, also referred to as the *Adie pupil*. This syndrome is caused by a degeneration of the ciliary ganglia and the postganglionic parasympathetic fibers that normally constrict the pupil and effect accommodation. The patient may complain of unilateral blurring of vision or photophobia or may have noticed that one pupil is larger than the other. The affected pupil is slightly enlarged in ambient light and the reaction to light is absent at the outset of the syndrome or greatly reduced if tested in the customary manner, although the pupil will slowly constrict with prolonged bright light stimulation. Characteristically, there is a light-near dissociation, i.e., like the Argyll Robertson pupil, the Adie pupil responds better to near (accommodation) than it does to light. The most characteristic feature is that once the pupil has constricted, it tends to remain tonically constricted and redilates very slowly (the “tonic” aspect of the syndrome). Once dilated, the pupil remains in this state for many seconds, up to a minute or longer. Light and near paralysis of a segment or segments of the pupillary sphincter is also characteristic of the syndrome; this segmental irregularity can be seen with the high plus lenses of an ophthalmoscope. The affected pupil constricts promptly in response to the common miotic drugs and is unusually sensitive to a 0.1 percent solution of pilocarpine,

Table 14-6

CHARACTERISTICS OF ARGYLL ROBERTSON AND ADIE PUPILS

	SIZE AND SIDE	LIGHT REACTION	ACCOMMODATIVE REACTION	SPECIAL FEATURES
Argyll Robertson pupil	Small, irregular, asymmetrical	No	Yes	Syphilitic, but also diabetic
Adie tonic pupil	Initially fixed, later enlarged to medium size; bilateral	No or poor; only with sustained bright light	Yes, with tonic reaction	Tonic contraction to prolonged accommodation; associated areflexia

a concentration that has only minimal effect on a normal pupil (due to denervation supersensitivity).

The tonic pupil usually appears during the third or fourth decade of life and is much more common in women than in men; it may be associated with absence of knee or ankle jerks (*Holmes-Adie syndrome*) and hence be mistaken for tabes dorsalis. From all available data, it represents a special form of mild inherited polyneuropathy. There is a familial tendency to the syndrome, in some cases associated with a mutation in the myelin protein zero (MP0) gene that is implicated in one of the less-common forms of Charcot-Marie-Tooth inherited polyneuropathy (see Chap. 46).

An acquired type of tonic pupil has also been associated, sometimes on uncertain grounds, with diabetes, viral infection, and trauma. We have observed it in migraine and following recovery from the Guillain-Barré syndrome.

Springing Pupil

Mention should be made of this rare pupillary phenomenon characterized by transient episodes of unilateral mydriasis for which no cause can be found (the *springing*

pupil). Episodes of mydriasis, which are more common in women, last for minutes to days and may recur at random intervals. Oculomotor palsies and ptosis are notably lacking, but sometimes the pupil is distorted during the attack. Some patients complain of blurred vision and head pain on the side of the mydriasis, suggesting an atypical ophthalmoplegic migraine. In children, following a minor or major seizure, one pupil may remain dilated for a protracted period of time. The main consideration in an awake patient is that the cornea has inadvertently (or purposefully) been exposed to mydriatic solutions, among them vasopressor agents used in cardiac resuscitation.

Differential Diagnosis of Anisocoria

(Figure 14-11)

In regard to pupillary disorders, there are two main issues with which the neurologist has to contend. One is the problem of unequal pupils (anisocoria), and determining whether this abnormality is derived from sympathetic or parasympathetic denervation. The second problem is the relative afferent pupillary defect, and how to recognize it; this was discussed earlier.

Figure 14-11. A schematic approach for sorting out the nature of anisocoria. (Adapted by permission from Thompson and Pilley.)

In dealing with anisocoria, 20 percent of normal persons show an inequality of 0.3 to 0.5 mm or more in pupillary diameter. This is "simple," or *physiologic, anisocoria*, and it may be a source of confusion in patients with small pupils. Its main characteristic is that the same degree of asymmetry in size is maintained in low, ambient, and bright light conditions. It is also variable from day to day and even from hour to hour, and often will have disappeared at the time of a second examination (Loewenfeld; Lam et al).

The first step in the analysis of pupillary asymmetry is to determine which of the pupils is abnormal. An abnormal larger pupil can be identified by a reduced direct and consensual light reaction. If the smaller pupil is causing asymmetry, it will fail to enlarge in response to shading both eyes or reducing ambient light. More simply stated, *light exaggerates the anisocoria caused by a third-nerve lesion, and darkness accentuates the anisocoria in the case of a Horner syndrome.*

A *persistently small pupil* always raises the question of a Horner syndrome, a diagnosis that may be difficult if the ptosis is slight. In darkness, the Horner pupil dilates more slowly and to a lesser degree than the normal one because it lacks the pull of the dilator muscle (dilation lag). The diagnosis in the past had been confirmed by placing 1 or 2 drops of 2 to 10 percent cocaine in each eye; the Horner pupil dilates not at all or much less than the normal one. A more recently introduced approach that is more dependable and obviates the difficulties in obtaining cocaine is to apply the alpha-agonist apraclonidine to both eyes and observe the *reversal of miosis* on the affected side of Horner syndrome (the opposite effect to cocaine). Such responses to either drug will occur with a lesion at any point along the sympathetic pathway because lesions of the first- or second-order sympathetic neurons eventually deplete norepinephrine at

the synapses with third-order neurons. The reduction of neurotransmitter at the nerve endings in the ciliary dilator muscle greatly reduces the reuptake blocking effects of cocaine. If the subsequent (24 h after cocaine) application of the adrenergic mydriatic hydroxyamphetamine (1 percent) has no effect, the lesion can be localized to the postganglionic portion of the pathway as this drug releases any norepinephrine that may remain in the third-order neuron. Localization of the lesion to the central or preganglionic parts of the sympathetic pathway depends upon the associated symptoms and signs (see Chap. 26).

A variety of lesions, some of them purely ocular, such as uveitis, may also give rise to a *dilated pupil*.

Drug-induced iridoplegia is another cause of anisocoria. Not infrequently, particularly among nurses and pharmacists, a mydriatic fixed pupil is the result of accidental or deliberate application of an atropinic or sympathomimetic drug. We have observed this in house officers after they had participated in resuscitation from a cardiac arrest and been inadvertently sprayed with a sympathomimetic drug. Failure of 1 percent pilocarpine drops to contract the pupil provides proof that the iris sphincter has been blocked by atropine or some other anticholinergic agent. This is particularly the case when only one eye is affected.

As a rule, bilateral smallness of pupils does not pose a difficult diagnostic problem. The clinical associations, acute and chronic, have already been discussed. Long-standing bilateral Adie pupils tend to be small and show tonic near responses. They can be readily distinguished from Argyll Robertson pupils, which constrict quickly to near (accommodation) and redilate quickly on release from the near stimulus.

Figure 14-11 is a useful schematic, devised by Thompson and Pilley, for sorting out the various types of anisocoria.

Deafness, Dizziness, and Disorders of Equilibrium

Sounds alert us to danger; spoken words are the universal means of communication; music is one of our most exalted aesthetic pleasures. The loss of hearing excludes the individual from much of what is happening, and adjustment to this deprivation imposes profound challenge. Prevention of deafness is a goal toward which medicine strives. Likewise, vestibular function ensures one's ability to stand steadily, stabilize eye position during head movement, and move about gracefully. Hence an understanding of the functions of the eighth cranial nerves and their derangements by disease is as much the concern of the neurologist as the otologist. As a general rule, the association of vertigo and deafness signifies a disease of the end organs for hearing and vestibular function, or of the eighth nerve. The precise locus of the disease is determined by tests of labyrinthine and auditory function, described further on, and by findings on neurologic examination and imaging studies that implicate the primary and secondary connections of the eighth cranial nerve.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The vestibulocochlear, or eighth, cranial nerve has two separate components: the cochlear nerve, which subserves hearing, and the vestibular nerve, which is concerned with equilibrium (balance) and orientation of the body and eyes to the surrounding world. The acoustic division has its cell bodies in the spiral ganglion of the cochlea. This ganglion is composed of bipolar cells, the peripheral processes of which convey auditory impulses from the specialized neuroepithelium of the inner ear, the spiral organ of Corti. This is the end organ of hearing, wherein sound is transduced into nerve impulses. It consists of approximately 15,000 neuroepithelial (hair) cells that rest on the basilar membrane, which extends along the entire 2.5 turns of the cochlea. Projecting from the inner surface of each hair cell are approximately 60 very fine filaments, or stereocilia, which are embedded in the tectorial membrane, a gelatinous structure overlying the organ of Corti (Fig. 15-1). Sound causes the basilar membrane to vibrate; upward displacement of the basilar

membrane bends the relatively fixed stereocilia and provides a stimulus adequate for activating the hair cells. The stimulus is then transmitted to the sensory fibers of the cochlear nerve, which end synaptically at the base of each hair cell.

Each afferent auditory fiber and the hair cell with which it is connected have a minimum threshold at one frequency ("characteristic" or "best" frequency). The basilar membrane vibrates at different frequencies throughout its length, according to the frequency of the sound stimulus. In this way, the fibers of the cochlear nerve respond to the full range of audible sound and can differentiate and resolve complexes of sounds.

The inner hair cells, numbering about 3,500, are of particular importance, because they synapse with approximately 90 percent of the 30,000 afferent cochlear neurons. The central processes of the primary auditory neurons constitute the cochlear division of the eighth cranial nerve. In addition, the nerve contains approximately 500 efferent fibers, which arise from the superior olivary nuclei (80 percent from the contralateral nucleus and 20 percent from the ipsilateral one) and synapse with the afferent neurons from the hair cells (Rasmussen). The function of this efferent pathway is not clear. It is thought to play some part in the auditory processing generated in the ear itself, possibly to enhance the sharpness of sound perception by a feedback mechanism. The eighth nerve also contains adrenergic postganglionic fibers that are derived from the cervical autonomic chain and innervate the cochlea and labyrinth. Their function has been the subject of investigation.

The semicircular ducts, utricle, and saccule, collectively comprising the vestibular apparatus, contain the sense organs for the detection of angular and linear acceleration. They are filled with an intracellular fluid, endolymph, and are surrounded by cerebrospinal fluid (perilymph) within excavated spaces of the temporal bone, the semicircular canals. The latter term, canal, is used interchangeably with the proper description, ducts, to describe the vestibular apparatus.

The vestibular division of the eighth nerve arises from cells in the vestibular, or Scarpa ganglion, which is situated in the internal auditory meatus. This ganglion is also composed of bipolar cells, the peripheral processes of which terminate in hair cells of the specialized sensory

Figure 15-1. The auditory and vestibular systems. **A.** The right ear, viewed from the front, showing the external ear and auditory canal, the middle ear and its ossicles, and the inner ear. **B.** The main parts of the right inner ear, viewed from the front. The *perilymph* is located between the wall of the bony labyrinth and the membranous labyrinth. In the cochlea, the perilymphatic space takes the form of two coiled tubes—the *scala vestibuli* and *scala tympani*. The *endolymph* is located within the membranous labyrinth, which includes the three semicircular canals, utricle, and saccule. **C.** The *organ of Corti*. This is the end organ of hearing; it consists of a single row of inner hair cells and three rows of outer hair cells. The stereocilia of the hair cells are embedded in the tectorial membrane. **D.** Diagram of a crista ampulla, the specialized sensory epithelium of a semicircular canal. The crista senses the displacement of endolymph during head rotation. The direction of head rotation is indicated by the *large arrow*, and endolymph flow by the *small arrow*. The *macula* is the locus of the sensory epithelium in the utricle and saccule. Note that the tips of the hair cells are in contact with the otoliths (calcareous material), which are embedded in a gelatinous mass called the *cupula*.

epithelium of the labyrinthine apparatus. The sensory epithelium is located on hillocks (*cristae*) in the dilated openings or ampullae of the semicircular ducts, where they are called the *cristae ampullaris*, and in the utricle and saccule, where they are called *maculae acusticae*. The hair cells of the maculae are covered by the *otolith membrane*, or *otolith*, which is composed of calcium carbonate crystals embedded in a gelatinous matrix. The sensory cells of the cristae are covered by a sail-shaped gelatinous mass called a *cupula* (Fig. 15-1). The labyrinthine semicircular ducts transduce angular acceleration of the head, and the otoliths transduce linear acceleration, including the effects of gravity.

The central fibers from the cells of the spiral and vestibular ganglia travel in a common trunk, the eighth cranial nerve, which enters the cranial cavity through the internal auditory meatus (accompanied by the facial and

intermediate nerves). They traverse the cerebellopontine angle and enter the lateral brainstem at the junction of the pons and medulla. Here the cochlear and vestibular fibers become separated. The cochlear fibers bifurcate and terminate almost at once in the dorsal and ventral cochlear nuclei. The fibers from each cochlear nucleus pursue separate crossing and ascending pathways; they pass to both inferior colliculi (mainly to the opposite side) via the lateral lemnisci. Secondary acoustic fibers project via the trapezoid body and lateral lemniscus to the medial geniculate bodies, a special component of the thalamic sensory system (Fig. 15-2). Some fibers terminate in the trapezoid body and superior olivary complex and sub-serve such reflex functions as auditory attention, sound localization, auditory startle, and oculopostural orientation to sound.

Both excitatory and inhibitory neurons are located at every level of these pathways. At all levels there are

Figure 15-2. The ascending auditory pathways. The lower part of the diagram is a horizontal section through the upper medulla. (Reproduced with permission from Noback CR: *The Human Nervous System*, 3rd ed. New York, McGraw-Hill, 1981.)

strong commissural connections through which auditory signals come to be represented bilaterally in the cerebrum. From the medial geniculate bodies, fibers project to the cortex via the auditory radiations—relatively compact bundles that course ventrolaterally through the posterior parts of the putamen before dispersing and ending in the *transverse gyri of Heschl* and other auditory cortical areas (Tanaka et al).

The auditory cortical field comprises the superior temporal gyrus and the upper bank of the sylvian fissure (Brodmann area 41; see Fig. 22-1), or *primary auditory cortex*, and the surrounding secondary and tertiary cortices in the adjacent temporal lobe. The latter are of particular importance in the interpretation of sound (Ceesia) including spoken language. Bilateral temporal lobe lesions involving the geniculocortical fasciculi result in cortical deafness, although such lesions are rare. Unilateral cortical lesions do not affect hearing, but defects in function such as dichotic listening can be detected by specialized tests. At several levels of these ascending fiber systems, there is feedback to lower structures.

The vestibular fibers of the eighth nerve terminate in the four vestibular nuclei: superior (Bechterew), lateral (Deiters), medial (triangular, or Schwalbe), and inferior (spinal, or descending). In addition, some of the fibers from the semicircular canals project directly to the cerebellum via the juxtarestiform body and terminate in the flocculonodular lobe and adjacent vermian cortex (consequently, these structures are called the “vestibulocerebellum,” as noted in Chap. 5). Efferent fibers from this portion of the cerebellar cortex, in turn, project ipsilaterally to the vestibular nuclei and to the fastigial nucleus; fibers from the fastigial nucleus project back to the contralateral vestibular nuclei, again via the juxtarestiform body. Thus each side of the cerebellum exerts an influence on the vestibular nuclei of both sides (Fig. 15-3; see also Chap. 5).

The lateral and medial vestibular nuclei also have important connections with the spinal cord, mainly via the uncrossed lateral vestibulospinal tract and the crossed and uncrossed medial vestibulospinal tracts (Fig. 15-4). Presumably, vestibular effects on posture are mediated via these pathways—the axial muscles being acted upon

Figure 15-3. A simplified diagram of the vestibulocerebellar and vestibulospinal pathways and connections between vestibular and ocular motor nuclei. The medial longitudinal fasciculi (blue lines) are the main pathways for ascending vestibular impulses. (See text and also Fig. 14-1.)

Figure 15-4. The vestibular reflex pathways. (Reproduced by permission from House EL: *A Systematic Approach to Neuroscience*. New York, McGraw-Hill, 1979.)

predominantly by the medial vestibulospinal tract and the limb muscles, by the lateral tract. The nuclei of the third, fourth, and sixth cranial nerves come under the influence of the vestibular nuclei through the projection pathways, mainly the medial longitudinal fasciculus described in Chap. 14. In addition, all the vestibular nuclei have afferent and efferent connections with the pontine reticular formation (Fig. 15-4). The latter connections subserv vestibuloocular and vestibulospinal reflexes that are essential for clear vision and stable posture.

Finally, there are projections from the vestibular nuclei to the cerebral cortex, specifically to the regions of the intraparietal sulcus and superior sylvian gyrus. In the monkey, these projections are almost exclusively contralateral, terminating near the “face area” of the first somatosensory cortex (area 2 of Brodmann). Lesions in the posterior insula impair the sense of verticality, body orientation, and movement. Whether the vestibular nuclei project to the thalamus in humans is not entirely settled; most anatomists indicate that there are no such direct connections.

These brief remarks convey some notion of the complexity of the anatomic and functional organization of the vestibular system (for a full discussion, see the monographs of Brodal and of Baloh and Honrubia). In view of the proximity of cochlear and vestibular elements, it is understandable that acoustic and vestibular functions are often affected together in the course of disease although each may also be affected separately.

DEAFNESS, TINNITUS, AND OTHER DISORDERS OF AUDITORY PERCEPTION

Deafness

Figures from a National Health Survey (National Institute on Deafness and Other Communication Disorders) indicated that approximately 28 million Americans of all ages had a significant degree of deafness and that 2 million were profoundly deaf. More than one-third of persons older than age 75 years were handicapped to some extent by hearing loss.

Deafness is of three general types: (1) *conductive deafness*, caused by a defect in the mechanism by which sound is transformed (amplified) and conducted to the cochlea. These are disorders of the external or middle ear—obstruction of the external auditory canal by atresia or cerumen, thickening of the tympanic membrane from infection or trauma, chronic otitis media, otosclerosis (the main cause of deafness in early adult life), and obstruction of the eustachian tube. (2) *Sensorineural deafness* (also called, imprecisely, *nerve deafness*), which is caused by disease of the cochlea or of the cochlear division of the eighth cranial nerve. Although cochlear and eighth nerve causes of deafness have conventionally been combined in one (sensorineural) category, the neurologist recognizes that the symptoms and causes of the two are quite different and that it is more practical to think of them as cochlear (end organ) and retrocochlear (nerve) deafness. (3) *Central deafness*, caused by lesions of the cochlear nuclei and their connections with the primary auditory receptive areas in the temporal lobes. For example, complete tone deafness, which is probably inherited as an autosomal dominant trait, is a central disorder.

The two peripheral forms of deafness—conductive and sensorineural deafness—must be distinguished from each other, because important remedial measures are available, particularly for the former. In differentiating them, the tuning-fork tests are often of value. When a vibrating fork, preferably of 512-Hz frequency, is held about 2.5 cm from the ear (test for air conduction), sound waves can be appreciated only as they are transmitted through the middle ear; they will be reduced with disease in this location. When the vibrating fork is applied to the skull (test for bone conduction), the sound waves are conveyed directly to the cochlea, without intervention of the sound-transmission apparatus of the middle ear, and will therefore not be reduced or lost in outer or middle ear disease. Normally air conduction is better than bone conduction, and the sound transmitted through the air

is appreciated for about twice as long as that passing through the bone.

These principles form the basis for several simple tests of auditory function. In the *Weber test*, the vibrating fork is applied to the forehead in the midline (or to a central incisor). A normal person hears the bone-conducted sound equally in both ears. In nerve deafness, the sound is localized to the normal ear for the reasons noted above; in conductive deafness, the sound is perceived as louder in the affected ear because interference from ambient sounds is muted on the affected side. In the *Rinne test*, the fork is applied to the mastoid process. At the moment the patient indicates that the sound ceases, the fork is held at the auditory meatus. In middle ear deafness, the sound cannot be heard by air conduction after bone conduction has ceased (abnormal Rinne test). In nerve deafness, the reverse may be true (normal Rinne test), but more saliently, both air and bone conduction are quantitatively decreased. The *Schwabach test* consists of comparing the patient's bone conduction with that of the normal examiner.

In general, early sensorineural deafness is characterized by a partial loss of perception of high-pitched sounds and conductive deafness by a partial loss of low-pitched sounds. This can be ascertained by the use of tuning forks of different frequencies but most accurately by the use of an audiometer and the construction of an audiogram, which reveals the entire range of hearing at a glance. The audiogram is the one essential test in the evaluation of hearing loss and the point of departure for subsequent diagnostic evaluation. A ticking watch (infrequently found on doctor's wrists or pockets any longer) or rubbing the patient's hair together near the ear can be used as a surrogate test of gross hearing for the bedside, but these maneuvers emit mostly high-frequency noise and will not detect low-frequency conductive loss.

A cochlear type of hearing loss can be recognized by the presence of the symptoms of recruitment and diplacusis. *Recruitment* refers to a heightened perception of loudness once the threshold for hearing has been exceeded; thus the patient's retort "You don't have to shout" when the examiner raises his voice (see below). *Diplacusis* refers to a defect in frequency discrimination that is manifest by a lack of clarity of spoken syllables or by the perception that music is out of tune and unpleasant (described by patients as a "mushiness" of sounds).

Because each cochlear nucleus is connected with the cortex of both temporal lobes, hearing is unaffected by unilateral cerebral lesions as already mentioned. Deafness caused by brainstem lesions is observed only rarely, as a massive lesion is required to interrupt both the crossed and uncrossed projections from the cochlear nuclei—so massive, as a rule, that other neurologic abnormalities usually make the testing of hearing impossible.

Special Audiologic Procedures

A number of special tests prove to be helpful in distinguishing cochlear from retrocochlear (nerve) lesions. Although an absolute distinction cannot be made on the basis of any one test, the results taken together

(particularly loudness recruitment and threshold tone decay) make it possible to predict the site of the lesion with considerable accuracy. These tests, usually carried out by an otologist or audiologist, include the following:

1. *Loudness recruitment.* This phenomenon, mentioned above, is thought to depend on the selective destruction of low-intensity elements subserved by the external hair cells of the organ of Corti. The high-intensity elements are preserved, so that loudness is appreciated only at high intensities. In testing for loudness recruitment, the difference in hearing between the two ears is estimated and the loudness of the pure-tone stimulus of a given frequency delivered to each ear is then increased by regular increments. In *nonrecruiting deafness* (characteristic of a nerve lesion), the original difference in hearing persists in all comparisons of loudness, since both high- and low-intensity fibers are affected. In *recruiting deafness* (which occurs with a lesion in the organ of Corti—e.g., Ménière disease), the more affected ear gains in loudness and may finally be equal to the better one. In bilateral disease, recruitment is assessed by the intensity of the stimulus that causes discomfort, about 100 dB (decibels) in normal persons.
2. *Speech discrimination.* This consists of presenting the patient with a list of 50 phonetically balanced monosyllabic words (e.g., *thin, sin*) at suprathreshold levels. The speech-discrimination score is the percentage of the 50 words correctly repeated by the patient. Marked reduction (less than 30 percent) in the speech-discrimination scores is characteristic of eighth nerve (retrocochlear) lesions.
3. *Audiometry.* Continuous and interrupted tones are presented at various frequencies. Tracings are made, measuring the increments by which the patient must increase the volume in order to continue to hear the continuous and interrupted tones just above threshold. Clinically, analysis has shown that there are four basic configurations, referred to as types I to IV Békésy audiograms. Type III or IV usually indicate the presence of a retrocochlear lesion, the type II response points to a lesion of the cochlea itself, and type I is considered normal. Related tests, such as threshold tone decay and the short increment sensitivity index, were formerly used to a greater extent than they are currently; therefore, we have not described them here.
4. *Brainstem auditory evoked potentials, or response.* See Chap. 2 (BAEP, or BAER). This method provides very refined information as to the integrity of primary and secondary auditory pathways from the cochlea to the superior colliculus. It has the advantage of being accurate in uncooperative and even comatose patients as well as infants who cannot cooperate with audiometry. It is of some value in detecting small acoustic and vestibular schwannomas; in localizing brainstem lesions such as those caused by demyelination; in corroborating the state of brain death, in which all waves, except occasionally the eighth nerve (wave I), responses are abolished; and in assessing

sensorineural damage in neonates who have had meningitis or been exposed to ototoxic medications.

5. The *acoustic-stapedial reflex* can be used as a measure of conduction in the auditory (and the facial) nerve. This reflex normally protects the cochleas from excessively loud sound. When sound of intensity greater than 70 to 90 dB above threshold hearing reaches the inner ear, the stapedius muscles on both sides contract reflexively, relaxing the tympanum and offering impedance to further sound. It may be tested by insufflating the external auditory canal with pressured air and measuring the change in pressure that follows immediately after a loud sound. The response is muted in patients with conductive hearing loss because of the mechanical restriction of ossicular movement, but otherwise the test is sensitive to cochlear and acoustic nerve lesions.

Tinnitus

This is the other major manifestation of cochlear and auditory disease. Tinnitus aurium literally means “ringing of the ears” (Latin *tinnire*, “to ring or jingle”) and refers to sounds originating in the ear, although they need not be ringing in character. Buzzing, humming, whistling, roaring, hissing, clicking, chirping, or pulse-like sounds are also reported. Some otologists use the term *tinnitus cerebri* to distinguish other head noises from those that arise in the ear, but the term *tinnitus* when used without qualification refers to *tinnitus aurium*.

Tinnitus is a remarkably common symptom, affecting more than 37 million Americans, according to Marion and Cevette. It may be defined as any sensation of sound for which there is no source outside the individual. Two basic types are recognized, *tonal* and *nontonal* (nonvibratory and vibratory, in the terminology of Fowler). The tonal type is by far the more common and is what is meant when the unqualified term *tinnitus* is used. It is also called *subjective tinnitus*, because it can be heard only by the patient. The nontonal form is sometimes *objective*, in the sense that under certain conditions the tinnitus can be heard by the examiner as well as by the patient. In either case, whether tinnitus is produced in the inner ear or in some other part of the head and neck, sensory auditory neurons must be stimulated, for only the auditory neural pathways can transmit an impulse that will be perceived as sound.

According to a large survey conducted by Stouffer and Tyler, about one-third of patients report that persistent tinnitus is unilateral; the others experience it bilaterally or with a lateralized predominance. Many more patients have brief episodes of tinnitus and are concerned enough to bring the symptom to the attention of a physician; some are produced by loud noises or by the ingestion of common drugs, such as aspirin but most such cases are transient and innocuous.

Nontonal and Pulsatile Tinnitus

These head noises are mechanical in origin and are conducted to the inner ear through the various hard or soft structures or the fluid or gaseous media of the body.

They are not caused by a primary dysfunction of the auditory neural mechanism but have their origin in the contraction of muscles of the eustachian tube, middle ear (stapedius, tensor tympani), palate (palatal myoclonus), or pharynx (muscles of deglutition), or in vascular structures near the ear. One of the common forms of subjective tinnitus is a self-audible bruit, the source of which is the turbulent flow of blood in the large vessels of the neck or in an arteriovenous malformation or glomus jugulare tumor. The sound is pulsatile and appreciated by the patient as emanating from one side of the cranium, but it is only sometimes detectable by the examiner.

Other noteworthy causes of pulsatile tinnitus are pseudotumor cerebri or raised intracranial pressure of any type, in which the noise is attributed to a pressure gradient between the cranial and cervical venous structures and the resulting venous turbulence; thyroid enlargement with increased venous blood flow. Other causes include intracranial aneurysm; aortic stenosis; and vascular tumors of the skull, such as histiocytosis X. In the case of a vascular tumor or a large arteriovenous malformation, the examiner may hear the bruit over the mastoid process. Obliteration of the sound by gentle compression of the jugular vein on the symptomatic side is a useful indicator of a venous origin. It has been suggested that diseases that raise the cardiac output markedly (such as severe anemia) may cause pulsatile tinnitus. A flow-related carotid bruit—originating from fibromuscular dysplasia, atherosclerotic stenosis, carotid dissection, and enhanced blood flow in a vessel contralateral to a carotid occlusion—has also been incriminated. However, carotid artery stenosis is infrequently causes a self-audible bruit. The same holds for diseases of the vertebral artery. In 100 consecutive cases of pulsatile tinnitus collected by Sismanis and Smoker, the most common causes were intracranial hypertension, glomus tumors, and carotid disease. One must be cautious in overinterpreting this symptom, because normal persons can hear their pulse when lying with one ear on a pillow, and introspective individuals may become excessively worried about it. We have suggested that normal variations in the size and location of the jugular bulb may explain some benign cases (Adler and Ropper).

Another type of tinnitus is the rhythmic clicking of palatal myoclonus caused by intermittent contraction of the tensor tympani or stapedius muscles, termed *middle ear myoclonus* as discussed in Chap. 6 with other forms of tremor. This process has been treated with a variety of medications, including diazepam or, in extremely annoying cases, by section of the offending muscles (Badia et al). Clicking noises caused by palatal myoclonus have also been successfully treated by the injection of botulinum toxin into the soft palatal tissues (Jamieson et al).

Tonal Tinnitus

This is the common persistent form of tinnitus that arises in the middle or inner ear and is associated in a proportion of patients with cochlear damage. For this reason, the first step in analysis after the clinical examination is an audiogram. Under ideal acoustic circumstances (in a soundproof room having an ambient noise level of 18 dB or less), slight tinnitus is present in 80 to 90 percent of

adults (“physiologic tinnitus”). The ambient noise level in ordinary living conditions usually exceeds 35 dB and is of sufficient intensity to mask physiologic tinnitus. Tinnitus because of disease of the middle ear and auditory neural mechanisms may also be masked by environmental noise and hence becomes troublesome only in quiet surroundings—at night, in the country, etc.

Most often, subjective tinnitus signifies a disorder of the tympanic membrane, ossicles of the middle ear, inner ear, or eighth nerve. As already remarked, a majority of patients who complain of persistent tinnitus have some degree of deafness as well. Tinnitus that is localized to one ear and is described as having a tonal character (such as a ringing, bell-like, or like a high and steady musical tone) is particularly likely to be associated with impairment of cochlear or neural function. Tinnitus associated with sensorineural hearing loss of high frequency is often described as “chirping,” and that of low frequency as “whooshing” or blowing (Marion and Cevette). Tinnitus as a result of middle ear disease (e.g., otosclerosis) tends to be more constant than the tinnitus of sensorineural disorders; it is of variable intensity and lower pitch and is characterized by clicks, pops, and rushing sounds.

As remarked above, the pitch of tinnitus associated with a conductive hearing loss is generally of low frequency (median frequency of 490 Hz, with a range of 90 to 1,450 Hz). That which accompanies sensorineural loss is higher (median frequency of 3,900 Hz, with a range of 545 to 7,500 Hz). This rule does not apply to Ménière disease, in which the tinnitus is usually described as a low-pitched whoosh, buzz, or roar (median frequency of 320 Hz, with a range of 90 to 900 Hz), thus resembling the tinnitus that accompanies a conductive rather than a sensorineural hearing loss (Nodar and Graham). The tinnitus of Ménière disease often fluctuates in intensity, like the hearing loss.

The mechanism of tonal tinnitus has not been established although a number of theories have been postulated. One supposition attributes tinnitus to an overactivity or disinhibition of hair cells adjacent to a part of the cochlea that has been injured. Another postulates a decoupling of hair cells from the tectorial membrane. Yet a third theory is based on the finding of an abnormal discharge pattern of afferent neurons, attributed to ephaptic transmission between nerve fibers that have been damaged by vascular compression (Møller).

Treatment

Relief of unilateral tinnitus in certain selected cases has reportedly been achieved by vascular decompression of the eighth nerve in a manner comparable to hemifacial spasm, superior oblique myokymia, and some cases of trigeminal neuralgia (Jannetta). However, for most forms of tinnitus, there is little effective treatment (see the review by Lockwood et al). Many patients become reconciled to its presence once the benign nature of the disorder is explained to them. It is possible to fit some patients with a special audiologic instrument, like a hearing aid, that masks the tinnitus by delivering a sound of like pitch and intensity. Patients who are likely to benefit can be identified during the audiogram by noting improvement

in tinnitus with the application of superimposed tones. Also, a hearing aid that improves audition may suppress or diminish tinnitus. Antiepileptic drugs and tocainide hydrochloride have been suggested as treatments, but have not been helpful in our experience. Some success in reducing the symptom has been achieved with small doses of amitriptyline at night. In extreme circumstances some groups have experimented with implanted stimulators on the temporal cortex.

If bilateral tinnitus is the basis of persistent complaints, one often discovers that the patient is anxious or depressed, in which case a careful history will reveal the other features of these disorders. Treatment then must be directed to the psychiatric symptoms. In their review, Lockwood and colleagues suggest that all patients with undifferentiated tinnitus be protected from loud sounds and ototoxic drugs (the main ones being aminoglycoside antibiotics, certain loop diuretics, neurotoxic chemotherapies such as cisplatin, and perhaps high doses of aspirin). The American Tinnitus Association website may be helpful to some patients as a source of reassurance (<http://www.ata.org>).

Tinnitus that is unilateral, pulsatile, or fluctuating and associated with vertigo should be investigated by appropriate neurologic and audiologic studies.

Other Disorders of Auditory Perception

On occasion, pontine lesions may be accompanied by complex auditory illusions, sometimes with the qualities of true hallucinations (pontine auditory hallucinosis) as in the patients, one of whom was ours, described by Cascino and Adams. These consist of alternating musical tones, like those of an organ; a jumble of sound, like a symphony orchestra tuning up; or siren-like or buzzing sounds, like a swarm of bees. These auditory sense disturbances are more complex than neurosensory tinnitus but less formed than temporal lobe hallucinations. They are usually associated with impairment of hearing in one or both ears and other neurologic signs related to the pontine lesion. An unpleasant degree of hyperacusis in the contralateral ear has also been reported with upper pontine tegmental lesions. BAEPs reveal intact cochlear, auditory nerve, and cochlear nuclear responses. As in the case of peduncular visual hallucinosis, patients realize that the sounds are unreal, i.e., they have insight into their illusory nature.

Another well-recognized but inexplicable type of auditory hallucinosis occurs in elderly patients with longstanding neurosensory deafness. All day long, or for several hours at a time, they hear songs, symphonies, choral music, or familiar or unfamiliar melodies interrupted only by other ambient noise, sleep, or conversations that engage their attention. The "choice" of music has been referable, not surprisingly, to the individual's earlier life. Our patients, like those reported by Hammeke and colleagues, have been neither depressed nor demented, and antiepileptic and neuroleptic drugs have had no effect. Activation of the right auditory cortex on single-photon emission tomography (SPECT) and magnetoencephalography has been reported in such a case by Kasai and colleagues. The problem may be analogous to the one of Charles Bonnet syndrome, in which elderly individuals with failing vision

experience rich visual hallucinations. We find it puzzling that pontine lesions are implicated in some cases, as mentioned above.

Complex auditory hallucinations may occur as part of temporal lobe seizures arising from a variety of temporal lobe lesions. Conversely, seizures may be induced by musical sounds as well as by other auditory stimuli. These topics are discussed in Chaps. 16 and 22. Paracusis, a condition in which a sound, tune, or a voice is repeated for several seconds, is also a cerebral auditory phenomenon, similar in a sense to the visual phenomenon of palinopsia. The precise anatomy is unknown. The auditory hallucinations of schizophrenia have been extensively studied in relation to activity of the temporal lobes, as discussed in Chap. 53.

Middle Ear Deafness

The common causes are otosclerosis, otitis media, and trauma. Of the various types of progressive conductive deafness, otosclerosis is the most frequent, being the cause of about half the cases of bilateral (but not necessarily symmetrical) deafness that have their onset in early adult life, usually in the second or third decade. A predilection to otosclerosis is transmitted as an autosomal dominant trait with variable penetrance. Pathologically, it is characterized by an overgrowth of labyrinthine capsular bone around the oval window, leading to progressive fixation of the stapes. The remarkable advances in microotologic surgery designed to mobilize or replace the stapes and to reconstruct the ossicular chain, have greatly altered the prognosis in this disease; significant improvement in hearing can now be achieved in the majority of patients.

The use of antibiotic drugs has markedly reduced the incidence of purulent otitis media, both the acute and chronic forms, which in former years were common causes of conductive hearing loss in children. Repeated attacks of serous otitis media are, however, still an important cause of this type of deafness.

Fractures of the temporal bone, particularly those in the long axis of the petrous pyramid, may damage middle ear structures; frequently there is bleeding into the middle ear as well, and a ruptured tympanic membrane. Transverse fractures through the petrous pyramid are more likely to damage both the cochlear-labyrinthine structures and the facial nerve. Other diseases of the temporal bone—such as Paget disease, fibrous dysplasia, and osteopetrosis—may impair hearing by compression of the cochlear nerve. It should be noted that rupture of the tympanic membrane, as for example from blast injury does not cause much hearing loss; in the case of a blast, the cause of reduced hearing is cochlear damage.

Sensorineural Deafness

This has many causes. The common high-frequency sensorineural type of hearing loss in the aged (presbycusis) is probably a result of neuronal degeneration, i.e., progressive loss of spiral ganglion neurons (Suga and Lindsay). Explosions or intense, sustained noise in certain industrial settings or from gun blasts or even rock music may result

in a high-tone sensorineural hearing loss from cochlear damage. Certain antimicrobial drugs (namely, the aminoglycoside group and vancomycin) damage cochlear hair cells and, after prolonged use, can result in severe hearing loss. If these drugs have been used to treat bacterial meningitis, it may be difficult to determine whether the antibiotic or the infection is the cause. A variety of other commonly used drugs are ototoxic, including certain neurotoxic cancer chemotherapies, especially platinum containing drugs, usually in a dose-dependent fashion (see Nadol). Quinine and acetylsalicylic acid may impair sensorineural function transiently.

The cochlea of a neonate may have been damaged in utero by rubella in the pregnant mother. Mumps, acute purulent meningitis (particularly from *Pneumococcus* and *Haemophilus*), or chronic infection spreading from the middle to the inner ear may cause nerve deafness in childhood. The meningeal infection spreads along the cochlear aqueduct, a structure that connects the cerebrospinal fluid (CSF) space with the perilymph of the cochlea. Measles vaccination, *Mycoplasma pneumoniae* infection, and scarlet fever have been associated with acute deafness, with or without vestibular symptoms. It is uncertain whether the deafness in these cases is due to direct infection of the cochlea or represents an autoimmune reaction directed to the inner ear. Also, the inner ear contains melanocytes, and their involvement in Vogt-Koyanagi-Harada disease adds dysacusis, tinnitus, and sensorineural deafness to the usual manifestations of vitiligo of the eyebrows, poliosis (depigmented forelock of hair), iritis, retinal depigmentation, and recurrent meningitis. Meningeal hemosiderosis, a rare process that results from repeated bouts of subarachnoid hemorrhage, also causes eighth nerve damage and deafness, presumably as a toxic effect of iron deposition in the meninges adjacent to the nerve. Cases of acute sensorineural hearing loss or reduced acuity have occurred following CSF drainage or lumbar puncture, likely either the result of traction on the cochlear nerve due to pressure gradients, or endolymphatic hydrops (see further on) through a patent cochlear aqueduct. Most cases are transient.

Episodic deafness in one ear, even without vertigo, proves in most instances to be the result of *Ménière disease* (see further on).

Otologists have described a progressive sensorineural type of hearing loss as a late manifestation of congenital syphilis, sometimes occurring despite prior treatment with adequate doses of penicillin. It has been claimed that the long-term administration of steroids may be useful in such cases. The pathologic basis of the hearing loss has not been determined and the causal relationship to congenital syphilis remains to be established.

The *auditory* nerve may be involved by tumors of the cerebellopontine angle or by mycotic, lymphomatous, carcinomatous, tuberculous, *Listeria*, melioidosis, or other types of chronic meningitis and rarely, in sarcoidosis. Lymphomatous meningitis has a particular predilection to cause unilateral hearing loss; we have seen several such cases in which no other cranial nerves were infiltrated. Carcinomatous meningitis may do the same but almost always in the context of other cranial

and spinal nerve palsies (see Chap. 31). Of the solid tumors, the ones that involve the auditory nerve most frequently are schwannomas, neurofibromas, meningiomas, dermoids, and metastatic carcinoma. In neurofibromatosis type II, the involvement by vestibular and acoustic schwannomas is typically bilateral as discussed in Chap. 37. Unilateral deafness may also result from demyelinating plaques, infarction, or tumor involving the cochlear nerve fibers or nuclei in the brainstem. Rarely, deafness is the result of bilateral lesions of the temporal lobes (Chap. 22). The condition called *pure word deafness*, a type of aphasia, is also caused by left temporal lobe disease; despite normal pure-tone perception and audiometry and normal brainstem auditory evoked potentials, spoken words cannot be understood. This condition is discussed in Chap. 23.

Sudden idiopathic hearing loss

Of equal concern to neurologists is the onset in an adult of sudden and permanent unilateral hearing loss without vertigo and lacking all the other features of Ménière disease. Little is known about the pathogenesis of this (idiopathic) syndrome. A vascular causation (occlusion of the cochlear artery or presumed arterial spasm in the course of migraine) has been postulated, on uncertain grounds. We do not know how to interpret the findings of DeFelice and colleagues as well as others, who report that the posterior communicating arteries are absent in a disproportionate number of patients with sudden hearing loss. A few cases are due to complicated herpes zoster and mumps parotitis, but aside from these there is no proven relationship to the usual viral respiratory infections. An immune-mediated cause may also be operative in some patients, a hypothesis that has led some neurologists and otologists to treat such patients with a brief course of orally administered corticosteroids. In a prospective report of the natural history of 88 cases of acute sensorineural hearing loss, two-thirds recovered their hearing completely within a few days or a week or two (Mattox and Simmons). In the remaining patients, recovery was much slower and often incomplete; in this latter group, the hearing loss was predominantly for high tones and in some cases was associated with varying degrees of vertigo and hypoactive caloric responses.

The same problem has been reported to follow cardiopulmonary bypass surgery and has been ascribed, without confirmation, to microemboli. Less often, such an event follows general anesthesia for nonotologic surgery (Evan et al); the pathogenesis is obscure. None of the currently popular therapeutic agents—such as histamine, calcium channel blockers, anticoagulants, inhalation of carbon dioxide (30 percent carbon dioxide), and corticosteroids—seems to clearly affect the outcome of sudden unilateral or bilateral deafness without vertigo. Nonetheless, as mentioned, corticosteroids are often prescribed, based on the uncertain theory that this illness is analogous to an immune form of vestibular neuritis.

Hereditary Deafness (Table 15-1)

A large number of *genetically determined syndromes* that feature a neural or conductive type of deafness—some

Table 15-1

REPRESENTATIVE GENETIC FORMS OF HEARING LOSS

DESIGNATION	INHERITANCE	GENE DEFECT	TYPE OF HEARING LOSS	ASSOCIATED DEFECTS	FREQUENCY
<i>I. Nonsyndromic</i>					
DFN A	AD	GJB2 (connexin), MYO7, USH, SLC26A4, and allelic variants of these genes; GJB2 accounts for half of cases in most populations (AD)	Progressive sensorineural	Same loci as cause syndromic hearing loss such as Usher and Pendred syndromes, as noted below; 80% of hereditary deafness from recessive gene	Accounts for half of non-syndromic recessive deafness (connexin)
DFN B	AR (most common)	—	—	—	—
DFN X	X-linked	—	—	—	—
<i>Familial otosclerosis</i>	AD with reduced penetrance	COLIA1	Conductive	—	—
<i>II. Syndromic</i>					
Waardenburg	AD	PAX3 and some due to SOX, WSIV (transcription factors)	Variable sensorineural	Dystopic canthi, heterochromia, iritis, poliosis	Most common dominant syndromic hearing loss; accounts for 3% of childhood hearing loss
Type I	—	—	—	—	—
Type II	—	—	—	Same as type I but no dystopia	—
Type III	—	—	—	Upper limb defects	—
Type IV	—	EDN (receptors in endothelin pathways)	—	Pigmentary defects and Hirschsprung disease	—
Branchio-oto-renal syndrome	AD	EYA1 in half (transcription factor involved in development of inner ear and kidney)	Conductive (75%), sensorineural and mixed	Second most common dominant form of hearing loss. Brachial cleft cysts, cleft palate, malformations of external ear and of kidney	2%
Stickler	AD	STL 1-3	Progressive sensorineural hearing loss	Cleft palate, epiphyseal dysplasia; severe myopia and retinal detachment in types 1 and 3	—
Neurofibromatosis type 2	AD	NF 2	Acoustic neuromas	Evident on MRI; proclivity to other tumors	—
Usher	AR	USH genes (unconventional myosin and adhesion molecules)	Severe congenital sensorineural hearing loss, vestibular dysfunction; retinitis pigmentosa	Most common recessive types; retinitis pigmentosa after first decade; type 1 has abnormal vestibular function	3-6%
Type I	—	—	—	—	—
Type II	—	—	Moderate to severe hearing loss, late retinitis	—	—

Type III	—	—	Progressive hearing loss and variable retinitis	—	—
Pendred	AR	SLC13A4 in half (same mutation causes nonsyndromic hearing loss)	Profound congenital sensorineural hearing loss; abnormal bony labyrinth (Mondini dysplasia)	Euthyroid goiter	4%
Jervell and Lange-Nielsen	AR	KVQT, KCNE (delayed potassium rectifier inner ear)	Congenital deafness	Prolonged QT interval on ECG; syncope, sudden death	<1%
Refsum	AR	—	Progressive sensorineural deafness	Retinitis pigmentosa, sensory polyneuropathy; elevated phytanic acid	—
Alport	X-linked	X-linked in 85% but also autosomal dominant and recessive forms (basement membrane formation in cochlea, eye, and kidney)	Progressive sensorineural hearing loss	Glomerulonephritis and renal failure	1%
Mohr-Tranebjerg	X-linked	TIMMBA (a translocation protein from cytoplasm to mitochondria)	Progressive childhood deafness	Visual disability, dystonia, mild retardation	—
Kearns-Sayre	Mitochondrial	MTRNT 1 at 3243 site and MTTTS 1 of mitochondrial genome	Late-onset progressive sensorineural hearing loss	Diabetes, other features typically associated with mitochondrial mutations—see Chap. 37	—
Bartter IV	—	BSND; Cl ⁻ channel	Congenital, severe	Salt wasting	—

AD, autosomal dominant; AR, autosomal recessive.

congenital and others having their onset in childhood or early adult life—have come to light (see articles by Tekin et al and Gorlin et al). The majority of cases of congenital deafness are inherited as an autosomal recessive trait with no other syndromic features. In most of the remainder, inheritance is autosomal dominant in type and in a small number, it is sex linked.

The singular genetic advance in this field has been the identification in recessive nonsyndromic deafness of a mutation of the connexin-26 gene on chromosome 13 (designated GJB2). This mutation is found in half of recessive familial cases of pure deafness; what is more striking is that the same gene abnormality occurs in 37 percent of cases of sporadic congenital deafness, almost certainly from a spontaneous mutation (Estivill et al and Morell et al). The connexin protein is a component of gap junctions and the mutation is theorized to interfere with the recycling of potassium from the cochlear hair cells to the endolymph. As a result of the human genome project, more than 20 other gene loci have been detected that may be related to congenital deafness syndromes; these have been summarized by Tekin and colleagues, but none, except the one for connexin, accounts for more than a very small proportion of cases. These unattached, nonsyndromic types of congenital deafness are denominated by genes in a family called DFN (for DeaFNess); for example, the connexin mutation is in DFNB1. The mutations in this gene can be recessive, dominant or X-linked. The genetic errors involve either cytoskeletal or structural proteins of the organ of Corti or the ion channel apparatus.

It is remarkable that deafness is a component of over 400 more complex different genetic syndromes (e.g., Waardenburg, branchio-oto-renal, Stickler, Pendred, Usher, Alport, Bartter, among many others listed in the table and those omitted because of their rarity). Among these, the finding of a mutation in a gene called PAX3 in the Waardenburg syndrome in the early 1990s began a flood of other gene defects underlying the many disorders that had been described on clinical grounds over the previous century. The mutations that give rise to some of these diseases, particularly the Usher syndrome, may also cause nonsyndromic congenital deafness. The syndromic forms of genetic deafness have been classified largely on the basis of their associated defects: retinitis pigmentosa, malformations of the external ear; integumentary abnormalities such as hyperkeratosis, hyperplasia or scantiness of eyebrows, albinism, large hyperpigmented or hypopigmented areas, ocular abnormalities such as hypertelorism, severe myopia, optic atrophy, and congenital and juvenile cataracts, cerebellar ataxia, myoclonus, and mental deficiency; skeletal abnormalities; and renal, thyroid, or cardiac abnormalities. Deafness is also a feature of several mitochondrial disorders, particularly the Kearns-Sayre syndrome and occasionally the MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) syndrome. The Wolfram syndrome, of which sensorineural deafness is a major feature, can have either a nuclear or mitochondrial genetic origin. Table 15-1 summarizes this and the other main hereditary syndromes. Chinnery et al have summarized the mitochondrial causes of deafness. Chapters 37 and 39

discuss further the association of neurosensory deafness with degenerative and developmental neurologic disease.

Differing from the degenerations is a group of acoustic aplasias. Four types of inner ear aplasia have been described: (1) *Michel defect*, a complete absence of the otic capsule and eighth nerve; (2) *Mondini defect*, an incomplete development of the bony and membranous labyrinths and the spiral ganglion; (3) *Scheibe defect*, a membranous cochleosaccular dysplasia with atrophy of the vestibular and cochlear nerves; and (4) rare chromosomal aberrations (trisomies) characterized by abnormality of the end organ and absence of the spiral ganglion.

Hysterical Deafness

It is possible to distinguish hysterical and feigned deafness from that caused by structural disease in several ways. In the case of bilateral deafness, the distinction can be made by observing a blink (cochleo-orbicular reflex) or an alteration in skin sweating (psychogalvanic skin reflex) in response to loud sound. Unilateral hysterical deafness may be detected by an audiometer, with both ears connected, or by whispering into the bell of a stethoscope attached to the patient's ears, closing first one and then the other tube without the patient's knowledge. The elicitation of the first two waves of the brainstem auditory evoked potentials provides indisputable evidence that sounds are reaching the receptive auditory structures and that the patient should be capable of hearing sounds. A brief episode of deafness with fully preserved consciousness may rarely be caused by seizure activity in one temporal lobe (epileptic suppression of hearing).

DIZZINESS AND VERTIGO

Dizziness and other sensations of imbalance are, along with headache, back pain, and fatigue, among the most frequent complaints in medicine (Kroenke and Mangelsdorff). The significance of these complaints varies greatly. For the most part they are benign, but there is always the possibility that they signal an important neurologic disorder. Diagnosis of the underlying disease demands that the complaint of dizziness be analyzed correctly—the nature of the disturbance of function being determined first and then its anatomic localization. This approach to neurologic diagnosis is invaluable in the patient whose main complaint is dizziness.

The term *dizziness* is applied by the patient to a number of different sensory and psychic experiences—a feeling of rotation or whirling as well as nonrotatory swaying, weakness, faintness, light-headedness, or unsteadiness. Blurring of vision, feelings of unreality, syncope, and even petit mal or other seizure phenomena may be called “dizzy spells.” These experiences fall into four categories: (1) vertigo, a physical sensation of motion of self or the environment; (2) near syncope, a sensation of faintness; (3) disequilibrium, a disorder of imbalance of stance or gait; and (4) ill-defined light-headedness, or “giddiness,” a symptom that often

accompanies anxiety. Hence, close questioning of the patient as to how he is using the term *dizziness* is a necessary first step in clinical work.

Physiologic Considerations

Several mechanisms are responsible for the maintenance of a balanced posture and for awareness of the position of the body in relation to its surroundings and to gravity. Continuous afferent impulses from the eyes, labyrinths, muscles, and joints inform us of the position of different parts of the body. In response to these impulses, the adaptive movements necessary to maintain equilibrium are carried out. Normally, we are unaware of these adjustments because they operate largely at a reflex level. The most important of the afferent impulses are the following.

1. *Visual information* from the retinae and possibly proprioceptive impulses from the ocular muscles, enable us to judge the distance of objects from the body. This information is coordinated with sensory information from the labyrinths and neck (see below) to stabilize gaze during movements of the head and body.
2. *Impulses from the labyrinths*, which function as highly specialized spatial proprioceptors and register changes in the velocity of motion (either acceleration or deceleration) and position of the body in relation to the gravitational vertical. The cristae of the three semicircular canals sense angular acceleration of the head in the three planes of roll, pitch and yaw, and the maculae of the saccule and utricle sense linear acceleration and gravitational pull. In each of these structures, displacement of sensory hair cells is the effective stimulus. In the semicircular ducts, this is accomplished by movement of the endolymphatic fluid, which, in turn, is induced by rotation of the head. In the utricle and saccule, the hairs are displaced by the movement of the otoliths in response to gravity, thus generating a force that displaces the otoliths. This end organ is a force transducer that converts the generated force into neural impulses that are conducted down the vestibular nerve to the vestibular nuclei. In either case (angular and linear acceleration), the force causes depolarization of the nerve terminals and initiation of impulses in the vestibular nerve, with the production of two main reflex responses: the vestibuloocular, which stabilizes the eyes, and the vestibulospinal, which stabilizes the position of the head and body.
3. *Impulses from the proprioceptors* of the joints and muscles are essential to all reflex, postural, and volitional movements. Those from the neck are of special importance in relating the position of the head to the rest of the body. The sense organs listed above are connected with the cerebellum and pathways in the brainstem, particularly the vestibular nuclei and, via the medial longitudinal fasciculi, with the ocular motor nuclei. These cerebellar and brainstem structures are the important coordinators of the sensory data and provide for postural adjustments and the maintenance of equilibrium. They are the basis of the

mechanisms whereby the perceptions of one's self (the body schema) and one's surroundings (the environmental schema) are matched. Accordingly, any disease that disrupts these neural mechanisms may give rise to vertigo and disequilibrium. The interdependence of the two schemata (self and environment) is ascribed to the fact that the various sense organs—retinal, labyrinthine, and proprioceptive—are usually activated simultaneously by any body movement.

One element of the sense of stable equilibrium derives from the ability to match visual and positional information during motion. Through reflex mechanisms, we come to see objects as stationary, while we are moving (mainly the ocular fixation reflex) and moving objects as having motion when we are either moving or stationary (vestibuloocular reflex). At times, especially when our own sensory information is incomplete, we mistake movement of our surroundings for movements of our own body. A well-known example is the feeling of movement that one experiences in a stationary train when a neighboring train is moving.

A factor that influences equilibrium is the effect of aging on all the afferent structures that subserve stability. The elderly may lose their balance on extending the neck, and their peripheral sensory afferents are often impaired, as are the protective postural mechanisms, making falls more frequent. A destructive lesion of one or both labyrinths may leave an elderly person permanently unbalanced, whereas a younger person largely compensates for the loss.

Clinical Characteristics of Vertigo

A careful history and physical examination usually afford the basis for separating true vertigo from the dizziness caused by near syncope, gait disorder, and anxiety. Any illusion or hallucination of motion in any plane qualifies as vertigo. The recognition of vertigo is usually not difficult when the patient states that objects in the environment have spun around or moved rhythmically in one direction or that a sensation of whirling of the head and body was experienced. A distinction is sometimes drawn between subjective vertigo, meaning a sense of turning of one's body, and objective vertigo, an illusion of movement of the environment, but its significance is limited.

Often, however, the patient is not so explicit and a number of related experiences may be described. The feeling may be described as to-and-fro or up-and-down movement of the body, usually of the head, or the patient may compare the feeling to that imparted by the pitch and roll of a ship. Or the floor or walls may seem to tilt or to sink or rise up. In walking, the patient may have felt unsteady and veered to one side, or may have had a sensation of leaning or being pulled to the ground or to one side or another (pulsion or static tilt), as though being drawn by a strong magnet. This feeling is particularly characteristic of vertigo. Oscillopsia, a rhythmic, jerking, illusory movement of the environment, is another effect of vestibular disorder, especially if induced by movement of the head. Observant patients may actually note this rhythmic movement of the environment due to nystagmus.

Some patients may be able to identify their symptoms only when asked to compare them with the feeling of movement they experience when they come to a halt after rapid rotation. If the patient is unobservant or imprecise in descriptions, a helpful tactic is to provoke a number of dissimilar sensations by rapid rotation, or by asking the patient to stoop for a minute and straighten up; having him stand relaxed for 3 min and checking his blood pressure for orthostatic effect; and, particularly, having him hyperventilate for 3 min. Should the patient be unable to distinguish among these several types of induced dizziness or to ascertain the similarity of one of the types to his own condition, the history is probably too inaccurate for purposes of diagnosis.

When the patient's symptoms are mild or poorly described, small items of the history—a desire to keep still and a disinclination to stoop or walk during an attack, a tendency to list to one side, an aggravation of symptoms by turning over in bed or closing his eyes, a sense of imbalance when making a quick turn on foot or in a car, and a preference for one position of the body or head—help to identify them as vertigo. At the other end of the scale are attacks of such abruptness and severity as to virtually throw the patient to the ground. Independently occurring vertiginous attacks of the usual variety mark these falling episodes as part of Ménière disease (see further on). On the other hand, a dizzy sensation that is not made worse markedly by vigorous shaking of the head is unlikely to relate to vertigo, particularly that type due to peripheral vestibular disease.

All but the mildest forms of vertigo are accompanied by some degree of nausea, vomiting, pallor, perspiration, and some difficulty with walking. The patient may simply be disinclined to walk or may walk unsteadily and veer to one side, or he may be unable to walk at all if the vertigo is intense. Forced to lie down, the patient realizes that one position, usually on one side with eyes closed, reduces the vertigo and nausea, and that the slightest motion of the head aggravates them. One common form of vertigo, benign positional vertigo (see further on), occurs with the repositioning that accompanies lying down, sitting up, turning, or looking upwards. The source of the gait ataxia associated with vertigo (vertiginous ataxia) is recognized by the patient as being “in the head,” not in the control of the legs and trunk. It is noteworthy that the coordination of individual movements of the limbs is not impaired in these circumstances—a point of difference from most instances of cerebellar disease. Loss of consciousness as part of a vertiginous attack nearly always signifies another type of disorder (seizure or faint).

Nonvertiginous Types of Dizziness

It is important to distinguish vertigo from the more common complaints for which the term dizziness is used by patients. These include the feeling of impending fainting (near syncope), a disorder of gait (disequilibrium), and an ill-defined feeling of lightheadedness. Many patients in the last category who initially complain of dizziness will, on closer questioning, describe his symptoms as a

“distant feeling,” “walking on air,” “inability to focus,” or some other unnatural sensation in the head. These sensory experiences are particularly common in states characterized by anxiety or panic attacks—often, but not always, with depression.

This constellation of nonvertiginous symptoms has been loosely referred to as “phobic,” “functional,” and “psychogenic” vertigo. Every clinician encounters numerous such patients. In Brandt's (1996) extensive experience, phobic vertigo (his term) was second only to benign positional vertigo (described below) as a cause of consultation in his dizziness clinic. He relates the disorder to anxiety and panic spells, but finds that it exists more often as an independent entity that is subject to improvement after careful explanation and reassurance. We agree with Furman and Jacobs that the term *psychiatric dizziness*, if used at all, should be restricted to dizziness that occurs as part of a recognized psychiatric syndrome, notably extreme anxiety disorder. Often, there is a component of avoidance of crowds, open spaces and tight circumstances. There seems to be little point in signifying the nonvertiginous symptoms with separate designations based on the settings in which they commonly occur (“supermarket syndrome,” “motorist disorientation syndrome,” “phobic postural vertigo,” “street neurosis”) but they do emphasize the psychogenic nature and may facilitate recognition of the syndrome. Furman and Jacobs have related anxiety-type dizziness to minor degrees of vestibular dysfunction, but we have not found it possible to determine whether there is a genuine labyrinthine disorder in all of these patients.

Oculomotor disorders, such as ophthalmoplegia with diplopia, may be a source of spatial disorientation and brief sensations of vertigo, mild nausea, and staggering. These symptoms are maximal when the patient looks in the direction of action of the paralyzed muscle; it is attributable to the receipt of two conflicting visual images. Some normal persons may experience such symptoms for brief periods when first adjusting to bifocal glasses.

In a peculiar symptom called the *Tullio phenomenon*, a loud sound, or yawning, produces a brief sensation of vertigo or tilting of the environment. Some patients with this symptom are found to have an absence or thinning of the bony roof of the superior semicircular canal, which can be detected by thin (1 mm) slice CT. This disorder, which is a form of perilymphatic fistula, is caused by a spontaneous or traumatic dehiscence of the bone of the superior canal. Occasionally, patients with Ménière disease report this symptom.

Other causes of dizziness are more difficult for the physician and patient to define. In severe anemic states, particularly pernicious anemia, and in aortic stenosis, easy fatigability and languor may be attended by lightheadedness, related particularly to postural change and exertion. In the emphysematous patient, physical effort may be associated with weakness and peculiar cephalic sensations, and violent paroxysms of coughing may lead to giddiness and even fainting (tussive syncope) because of impaired venous return to the heart. The dizziness that often accompanies acute hypertension is difficult to evaluate; sometimes it is an expression of anxiety, or it

may conceivably be the result of an unstable adjustment of cerebral blood flow. It is doubtful that chronic hypertension causes dizziness, although many of the medications for its treatment certainly can cause the symptom.

Postural nonvertiginous dizziness is another state in which inadequate vasomotor reflexes prevent a constant cerebral circulation; it is notably frequent in persons with orthostatic hypotension of any cause, for example, in those taking antihypertensive drugs, as well as in patients with a polyneuropathy that has an autonomic component. Such persons, on rising abruptly from a recumbent or sitting position, experience a swaying type of dizziness, dimming of vision, and spots before the eyes that last for several seconds. The patient is forced to stand still and steady himself by holding onto a nearby object. Occasionally, a syncopal attack may occur at this time (see Chap. 18). Hypoglycemia gives rise to yet another form of dizziness, marked by a sense of hunger and attended by trembling, sweating, and other autonomic symptoms. Drug intoxication—particularly with alcohol, sedatives, and antiepileptic drugs—may induce a nonspecific dizziness and, at advanced stages of intoxication, true vertigo.

In practice, it may nonetheless be difficult to separate these types of dizziness from vertigo, for there may, or may not be, feelings of rotation, impulsion, up-and-down movement, oscillopsia, or other disturbance of motion. The ancillary symptoms of true vertigo—namely, nausea, vomiting, tinnitus and deafness, staggering, and the relief obtained by sitting or lying still—are also absent. Furthermore, it is not an uncommon circumstance to find more than one type of dizziness in an individual who is carefully tested.

The Neurologic and Otologic Causes of Vertigo

The fact that vertigo may constitute the aura of an epileptic seizure supports the view that this symptom may have a cerebrocortical origin. Indeed, electrical stimulation of the cerebral cortex in an unanesthetized patient, either of the posterolateral aspects of the temporal lobe or the inferior parietal lobule adjacent to the sylvian fissure, may evoke intense vertigo. The occurrence of vertigo as the initial symptom of a seizure is, however, infrequent. In such cases, a sensation of movement—either of the body away from the side of the lesion or of the environment in the opposite direction—lasts for a few seconds before being submerged in other seizure activity. Vertiginous epilepsy of this type should be differentiated from vestibulogenic seizures, in which an excessive vestibular discharge serves as the stimulus for a seizure. The latter is a rare form of reflex epilepsy, in which tests that induce vertigo may provoke the seizure (see Chap. 16).

The issue of *migraine* as a cause of vertigo has occasioned much discussion. Several authoritative clinicians attribute many instances of otherwise unexplained dizziness and vertigo to migraine with aura, but it is not entirely clear whether they are referring to an attack of basilar migraine, usually in children (migrainous vertigo), or to episodes of vague disequilibrium or vertigo at various times in migraineurs, which has been more typical in

our experience. A survey by Neuhauser and colleagues found that 7 to 9 percent of patients had conventional migrainous symptoms during or before a vertiginous attack, and in half of those the vertigo was regularly associated with migraine. This number is certainly higher than in most practices, but it does support the idea that migraine can cause vertigo as discussed further on.

Lesions of the cerebellum produce vertigo depending on which part of this structure is involved. Large, destructive processes in the cerebellar hemispheres and vermis, such as cerebellar hemorrhage may, or at times may not, cause vertigo. However, strokes in the territory of the medial branch of the posterior inferior cerebellar artery (which arises distal to the branches to the medulla, and therefore does not involve the lateral medulla) causes intense vertigo and vomiting that is *indistinguishable from that caused by labyrinthine disorder*. In two such pathologically studied cases, a large zone of infarction extended to the midline and involved the flocculonodular lobe (Duncan et al). Falling in these cases was toward the side of the lesion; nystagmus was present on gaze to each side but was more prominent on gaze to the side of the infarct. These findings have been confirmed by CT and MRI (Amarenco et al). Early in the course of an acute attack of vertigo, when it may be difficult to assess the gait and the quality of nystagmus, it may be necessary to exclude a cerebellar infarct or hemorrhage by use of imaging procedures.

Labyrinthine disease, on the other hand, causes predominantly unidirectional nystagmus to the side opposite the impaired labyrinth and swaying or falling toward the involved side—i.e., the direction of the nystagmus is opposite to that of the falling and past pointing (the latter referring to overshooting a target by the patient's finger with eyes closed, as originally described by Bárány [1921]). Ataxia and dysarthria are, of course, typical of many forms of cerebellar disease but may be minimal or absent in cerebellar hemorrhage and some infarctions as well as being lacking in all forms of vestibular disease.

The topic of vertigo with fluctuating ischemia in the territory of the basilar and vertebral arteries (transient ischemic attack [TIA]) and the problem of subclavian steal syndrome are discussed further on under "Vertigo of Brainstem Origin" and in Chap. 34. Also common in practice is vertigo caused by the demyelinating lesions of multiple sclerosis, as noted in the later section.

Biernand and DeJong described a kind of nystagmus and vertigo originating in the upper cervical roots and the muscles and ligaments that they innervate (so-called cervical vertigo). Spasm of the cervical muscles, trauma to the neck, and irritation of the upper cervical sensory roots were said to produce asymmetrical spinovestibular stimulation and thus to evoke nystagmus, prolonged vertigo, and disequilibrium. Toole and Tucker demonstrated a reduced flow through these vessels (in cadavers) when the head was rotated or hyperextended. In our view, the existence of "cervical vertigo," or at least these interpretations of it, is open to question. However, we acknowledge having encountered patients with cervical dystonia who describe something akin to vertigo, and this may speak to a relationship between cervical proprioceptors and vertigo.

Causes of vertigo other than Ménière disease that originate in the vestibular nerve are discussed further on.

In summary, for all practical purposes, vertigo indicates a disorder of the vestibular end organs, the vestibular division of the eighth nerve, or the vestibular nuclei in the brainstem and their immediate connections, including the inferior cerebellum. Although lesions of the cerebral cortex, eyes, and perhaps the cervical muscles may give rise to vertigo, they are not common sources of the symptom, and vertigo is rarely the dominant manifestation of disease in these structures. The clinical problem resolves by deciding which portion of the labyrinthine-vestibular apparatus is involved. Usually this determination can be made on the basis of the form of the vertiginous attack, the nature of the ancillary symptoms and signs, and tests of labyrinthine function. These tests are described below, followed by a description of the common labyrinthine-vestibular syndromes.

Tests of Labyrinthine Function

The most rudimentary test of labyrinthine function is simply to have the patient shake his head from side-to-side in an attempt to elicit symptoms that simulate the dizziness that has been described and to observe the degree of postural instability during this maneuver. Falling and marked intensification of the dizziness is almost always an indication of labyrinthine disease. Also, nystagmus may be evoked, indicating a vestibular instability. More informative in identifying a diseased labyrinth is the "rapid head impulse" test, which is conducted by asking the patient to fixate on a target and then for the examiner to rotate the patient's head quickly by 10 degrees (an explanation must be given to encourage the patient to relax the neck muscles and remain focused on the fixation point). The eyes are observed for a slippage from the target; this is most evident by a quick saccadic return to the point of focus. Ocular instability is observed when the patient turns his head toward the side of the affected labyrinth. This use of the vestibuloocular reflex is said by Halmagyi and Crener to be among the most dependable bedside tests of labyrinthine function.

Maneuvers designed to elicit positional vertigo by rapidly changing from a seated to a supine position with the head turned to one side bring about vertigo in a number of conditions but are specifically intended to detect benign positional vertigo and are described further on.

A number of other interesting but less validated tests that bring out instabilities in station and gait may be used to supplement the conventional tests for vestibular dysfunction. The Unterberger maneuver requires the patient to march in place with eyes closed and arms outstretched. Normally, less than 15 degrees or so of rotation is displayed; asymmetry of labyrinthine function is manifest as excessive rotation away from the diseased side. A related test involves having the patient walk around a chair with eyes closed; an increasing or decreasing radius is indicative of an imbalance between the two sides of the labyrinthine apparatus. Both of

these tests, however, often show abnormalities with cerebellar disease as well, in which the patient veers to the affected side. The sensitivity of maneuvers such as these has been questioned. We can only comment that they seem in our experience to demonstrate vestibulo-cerebellar lesions.

Vestibular (labyrinthine) stimulation can also be produced by rotating the patient in a Bárány chair or any type of swivel chair. The patient is asked not to fixate or is defocused with Frenzel lenses during rotation to avoid the effects of optokinetic nystagmus. The normal response is nystagmus in the direction opposite to rotation. In contrast, if the patient is asked to focus on his own thumb in an outstretched arm, there should be no nystagmus if the rotational velocity is slow; the ability to suppress this vestibuloocular response reflects the integrity of the vestibular organ and nerve on the side toward the direction of rotation. Electronystagmography (ENG) provides a more refined method of detecting disordered labyrinthine function because it permits the accurate recording of eye movements without visual fixation. ENG is usually coupled with caloric stimulation or with modern devices for rotational testing that allow precise control of the velocity, acceleration, and extent of rotation beyond what can be done with a traditional chair.

Irrigation of the ear canal alternately with cold and warm water (caloric testing) may be used to disclose a reduction in labyrinthine function in the form of an impairment or loss of thermally induced nystagmus on the involved side. Caloric testing is accomplished by having the patient lay supine on the examining table with the head tilted forward 30 degrees to bring the horizontal semicircular canal into a vertical plane, the position of maximal sensitivity of this canal to thermal stimuli. Each external auditory canal is irrigated for 30 s, first with water at 30°C (86°F) and then at 44°C (111.2°F), with a pause of at least 5 min between each irrigation. In normal persons, cold water induces a slight tonic deviation of the eyes to the side being irrigated, followed, after a latent period of about 20 s, by nystagmus to the opposite side (direction of the fast phase). Warm water induces nystagmus to the irrigated side. (As noted in Chap. 14, this is the basis for the mnemonic COWS: cold opposite, warm same, referring to the direction of fast phase of the nystagmus.) In normal subjects, the nystagmus usually persists for 90 to 120 s, although the range is considerably larger. Nausea and symptoms of excessive reflex vagal activity may occur in sensitive individuals.

Simultaneous irrigation of both canals with cold water causes a tonic downward deviation of the eyes with nystagmus (quick component) upward. Bilateral irrigation with warm water yields a tonic upward movement and nystagmus in the opposite direction ("cold upward, warm down, referring again to the fast phase of nystagmus; "CUWD"). Caloric testing will reliably answer whether the vestibular end organs react, and comparison of the responses from the two ears will indicate which one is parietic. Recording of eye movements during the test allows quantification of these responses.

Galvanic stimulation of the labyrinths is effective but offers no particular advantage over caloric stimulation.

Ménière Disease and Other Forms of Labyrinthine Vertigo

Labyrinthine disorders are the most common causes of true vertigo. Ménière disease is characterized by paroxysmal attacks of vertigo associated with fluctuating tinnitus and deafness. One or the other of the latter two symptoms may be absent during the initial attacks of vertigo, but invariably they assert themselves as the disease progresses and increase in severity during acute attacks. Ménière disease affects the sexes about equally and has its onset most frequently in the fifth decade of life, although it may begin earlier or later. Cases of Ménière disease usually occurs as a sporadic trait, but hereditary forms, both autosomal dominant and recessive, have been described (see reviews by Königsmark). The main pathologic changes consist of an increase in the volume of endolymph and distention of the endolymphatic system (endolymphatic hydrops). It had been speculated several decades ago that the paroxysmal attacks of vertigo are related to ruptures of the membranous labyrinth and release of potassium-containing endolymph into the perilymph, changes that have a paralyzing effect on vestibular nerve fibers and lead to degeneration of the delicate cochlear hair cells (Friedmann). An immune pathogenesis has also been proposed, based tentatively on the presence of circulating antibodies putatively against heat shock protein in some patients.

In typical Ménière disease, the attacks of vertigo are abrupt and last for several minutes to an hour or longer. The vertigo is unmistakably whirling or rotational and usually so severe that the patient cannot stand or walk. Varying degrees of nausea and vomiting, low-pitched tinnitus, a feeling of fullness in one ear and a diminution in hearing are practically always associated. Nystagmus is present during the acute attack; it is horizontal in type, usually with a rotary component and with the slow phase to the side of the affected ear. On attempting to touch a target with the eyes closed, there is past pointing as well as a tendency to fall toward the affected ear when standing or walking. The patient prefers to lie with the faulty ear uppermost and is disinclined to look toward the normal side, which exaggerates the nystagmus and dizziness. As the attack subsides, hearing improves, as does the sensation of fullness in the ear; with further attacks, however, there is a progressive increase in deafness.

The attacks vary considerably in frequency and severity. They may recur several times weekly for many weeks on end, or there may be remissions of several years' duration. Frequently recurring attacks may give rise to a mild chronic state of disequilibrium and a reluctance to move the head or to turn quickly. With milder forms of the disease, the patient may complain more of head discomfort and of difficulty in concentrating than of vertigo and then may be considered to signify anxiety. Symptoms of anxiety are common in patients with Ménière disease, particularly in those with frequent severe attacks.

A small proportion of patients with Ménière disease experience sudden, violent falling attacks. These episodes have been referred to by the quaint name "otolithic catastrophe of Tumarkin" who attributed them to deformation of the otolithic membrane of the utricle and saccule. Patients characteristically describe a sensation of being pushed or knocked to the ground without warning, or there may be a sudden movement or tilt of the environment just before the fall. Consciousness is not lost, and vertigo of the usual type and its accompaniments are not part of the falling attack, although some patients become aware of these symptoms after falling. The attacks may occur early or late in the course of the disease. Typically, several attacks occur over a period of a year or less and remit spontaneously (Baloh et al). An initial attack must be distinguished from other types of drop attacks, but the occurrence of the more typical vertiginous attacks of Ménière disease, with deafness and tinnitus, clarifies the diagnosis.

The hearing loss in Ménière disease usually precedes the first attack of vertigo but it may appear later. Episodic deafness without vertigo has been called *cochlear Ménière syndrome*. As already mentioned, with recurrent attacks, there is a saltatory progressive unilateral hearing loss (in most series only 10 percent of cases involve both ears, but Baloh places the figure closer to 30 percent). Early in the disease, deafness affects mainly the low tones and fluctuates in severity; actually, tones below 500 Hz are affected early on, and this loss is not evident to the patient. Without measurable fluctuations in pure-tone audiometric thresholds, the diagnosis is left uncertain. Later the fluctuations cease and high tones are affected. Speech discrimination is relatively preserved. The attacks of vertigo usually cease when the hearing loss is complete but there may be an interval of months or longer before this occurs. Audiometry reveals a sensorineural type of deafness, with air and bone conduction equally depressed. Provided that deafness is not complete, loudness recruitment can be demonstrated in the involved ear (see earlier).

Treatment

During an acute attack of Ménière disease, rest in bed is effective treatment, as the patient can usually find a position in which vertigo is minimal. The antihistaminic agents—cyclizine, meclizine, or transdermal scopolamine—are useful in the more protracted cases. Promethazine is an effective vestibular suppressant, as is trimethobenzamide (given in 200-mg suppositories), which also suppresses nausea and vomiting. For many years, a low-salt diet in combination with ammonium chloride or potassium and diuretics has been used in the treatment of Ménière disease, but the value of this regimen has never been established. The same is true for dehydrating agents such as oral glycerol and more recently introduced calcium channel blockers. Mild sedative drugs may help the anxious patient between attacks. The administration of corticosteroids was at one time popular but they have never been proven effective; transtympanic irrigation with dexamethasone is still practiced by some otologists but neither of these approaches is currently popular.

If the attacks are very frequent and disabling, permanent relief can be obtained by surgical means. Destruction of the labyrinth should be considered only in patients with strictly unilateral disease and who have reached the point of complete or nearly complete loss of hearing. In patients with bilateral disease or significant retention of hearing, the vestibular portion of the eighth nerve can be sectioned. Currently, an endolymphatic-subarachnoid shunt is the operation favored by some surgeons, and selective destruction of the vestibule by a cryogenic probe or transtympanic injection of gentamicin is favored by others. Decompression of the eighth cranial nerve, by separating it from an adjacent vessel, as suggested by Janetta, is still a controversial measure and probably better suited to the treatment of sustained and disabling but unexplained vertigo, rather than the treatment of Ménière disease. The decision to undertake any surgical procedure must be tempered by the fact that a majority of the patients, who are middle-aged, stabilize spontaneously in a few years.

Benign Paroxysmal Positional Vertigo (BPPV)

This disorder of labyrinthine function is more frequent than Ménière disease and—while it does not have the same implications in the long-term, an acute attack can be quite disabling. It is characterized by *paroxysmal vertigo* and nystagmus that occur *only with the assumption of certain positions of the head*, particularly lying down or rolling over in bed, bending over and straightening up, or tilting the head backward. It is common for the patient to report that the paroxysm of vertigo began in the middle of the night or early morning, presumably while shifting position during sleep and rapidly making one ear dependent, on rolling over to get out of bed, or to turn off an alarm. Brandt (1994) prefers the descriptive adjective *positioning vertigo* to *positional vertigo*, insofar as the symptoms are induced not by a particular head position but only by rapid changes in head position. This disorder was first described by Bárány (1921) but Dix and Hallpike emphasized its benign nature and were responsible for its further characterization, particularly the discrete positional movements that provoke it. Individual episodes last for less than a minute, but these may recur periodically for several days or for many months—rarely for years. As a rule, examination discloses no abnormalities of hearing or other identifiable lesions in the ear or elsewhere. A thorough summary of the condition has been given by Furman and Cass.

The diagnosis of this disorder is settled at the bedside by moving the patient from the sitting position to recumbency, with the head tilted 30 to 40 degrees over the end of the table and 30 to 45 degrees to one side, as originally described by Dix and Hallpike (Fig. 15-5). This need not be done abruptly but should occur in one smooth motion over a few seconds or less. After a latency of a few seconds, this maneuver provokes a paroxysm of vertigo; the patient may become frightened and grasp the examiner or the table or struggle to sit up. The dysfunctional ear is the one that is downward when vertigo is elicited. We cannot refute the contention made

by von Brevern and colleagues that the right labyrinth is more often responsible. The vertigo is accompanied by oscillopsia and nystagmus with the rapid components away from the affected (dependent) ear. The nystagmus is predominantly torsional with an additional vertical component in the eye opposite the affected ear according to Baloh and colleagues. The induced vertigo and nystagmus last no more than 30 to 40 s and usually less than 15 s. *Changing from a recumbent to a sitting position reverses the direction of vertigo and nystagmus* (position-changing nystagmus), and this is perhaps the most certain sign that the disorder originates in the labyrinth. With repetition of the maneuver, vertigo and nystagmus become less apparent, and after three or four trials, they can no longer be elicited (referred to as “fatigue”); they can be reproduced in their original severity only after a protracted period of rest. The head-hanging maneuver does not always evoke vertigo and nystagmus in patients whose histories are otherwise consistent with the diagnosis of benign paroxysmal vertigo; therefore Froehling and coworkers do not insist on it for diagnosis if the history is compatible but without the sign, we are uncertain how to confirm the diagnosis. It may still be appropriate to prescribe the corrective exercises as a trial.

Such attacks of vertigo may come and go for years, particularly in the elderly, and require no treatment. At the other end of the scale is the rare patient with positional vertigo of such persistence and severity as to require surgical intervention.

Baloh and colleagues, in their study of 240 cases of benign positional vertigo, found that 17 percent had their onset within several days or weeks after cerebral trauma and 15 percent after presumed viral neurolabyrinthitis. The significance of these preceding events is unclear, insofar as they did not appear to influence the clinical symptoms or course of the disorder. The provocative suggestion has been made on the basis of small epidemiologic studies such as the one by Jeong and colleagues that osteoporosis is associated with an increased frequency of the disorder.

Sudden changes in position, particularly of the head, may induce vertigo and nystagmus or cause a worsening of these symptoms in patients with all types of vestibular-labyrinthine disease, including Ménière disease and the types associated with vertebrobasilar stroke, trauma, and posterior fossa tumors. However, only if the paroxysm has the special characteristics noted above—namely, elicitation by change in head position, latency of onset, brevity, reversal of direction of nystagmus on sitting up, fatigability with repetition of the test, and the presence of distressing subjective symptoms of vertigo or its recurrence for months or years without other symptoms—can it be regarded as “benign paroxysmal” in type.

Schuknecht is credited with demonstrating that benign positional vertigo was caused by cupulolithiasis, in which otolithic crystals become detached and attach themselves to the cupula of the posterior semicircular canal. It is now generally believed that the debris, probably detached from the otolith, forms a free-floating clot in the endolymph of the canal (canalolithiasis) and gravitates to the most dependent part of the canal during changes in the position of the head (see Brandt et al).

Figure 15-5. Dix-Hallpike maneuver to elicit benign positional vertigo (originating in the right ear). *A.* The maneuver begins with the patient seated and the head turned to one side at 45 degrees, which aligns the right posterior semicircular canal with the sagittal plane of the head. *B.* The patient is then helped to recline rapidly so that the head hangs over the edge of the table, still turned 45 degrees from the midline. Within several seconds, this elicits vertigo and nystagmus that is right beating with a rotary (counterclockwise) component. An important feature of this type of “peripheral” vertigo is a change in the direction of nystagmus when the patient sits up again with his head still rotated. If no nystagmus is elicited, the maneuver is repeated after a pause of 30 s, with the head turned to the left. Treatment with the canalith repositioning maneuver is shown in Fig. 15-6.

In 90 percent of cases, the posterior semicircular canal is implicated; the remaining 10 percent are caused by cupulolithiasis in the *lateral canal*. As mentioned, the conventional maneuver to elicit BPPV may not only fail to induce symptoms in cases of lateral canal cupulolithiasis but the corrective maneuver may even inadvertently produce it. The disorder of the lateral canal is nicely summarized by De la Meillere and coworkers.

Treatment

The debris is thought to act by inducing currents on the cupula and triggering an attack of vertigo. Based on this presumed mechanism, several canalith repositioning maneuvers have been devised (Semont et al; Epley), allowing the debris to gravitate out of the semicircular canal and into the vestibule, where it will not induce a current during angular acceleration.

The first part of the Epley canalith repositioning maneuver (Fig. 15-6) is similar to the diagnostic Hallpike maneuver, the only difference being that the patient is

positioned without extending the head into the hanging position of the Dix-Hallpike diagnostic maneuver, first with one ear down and the head turned, then the other ear, in order to establish the side responsible for symptoms. Next, with the patient in the position that causes symptoms, the head is turned in a series of three steps, each separated by about 20 s: first the head is turned 45 to 60 degrees toward the opposite ear; the patient is then turned onto his side and the head turned an additional 45 degrees, until the head is parallel to the ground; then the head is turned once more until it more nearly faces the floor. We have become aware that this last step, which is a necessary part of the maneuver, is sometimes omitted by neurologists. After about 20 s, the patient is returned to the upright position. It was formerly believed that the patient should be instructed to avoid the head-down position for 24 hours, but recent studies have demonstrated that this is probably not necessary. Often a single treatment sequence suffices to terminate a period of positional vertigo (approximately 80 percent respond), but a second sequence carried out immediately after

Figure 15-6. Bedside maneuver for the treatment of a patient with benign paroxysmal positional vertigo affecting the right ear. The presumed position of the debris within the labyrinth during the maneuver is shown on each panel. The maneuver is a four-step procedure. First, a Dix-Hallpike test is performed with the patient's head rotated 45 degrees toward the (affected) right ear and the neck slightly extended with the chin pointed slightly upward. *A.* This position results in the patient's head hanging to the right. *B.* Once the vertigo and nystagmus provoked by this maneuver cease, the patient's head is rotated about the rostral-caudal body axis until the left ear is down. *C.* Then the head and body are further rotated until the head is almost facing down. The vertex of the head is kept tilted upward throughout the rotation. The patient should be kept in the final, face down position for about 10 to 15 s. *D.* With the head kept turned toward the left shoulder, the patient is brought into the seated position.

the first probably gains another small group who derive benefit. Additional treatments carried out in the same session are said to add no further benefit. In recalcitrant cases, our otolaryngology colleagues have applied a large vibrator to the temporal bone while the Epley maneuver was being performed, after which the episodes ceased; presumably this mobilizes the crystals and aids in moving them out of the canal. An incompletely implemented Epley maneuver risks converting the usual posterior semicircular canal cupulolithiasis to one involving the lateral canal, which may be more difficult to treat.

Patients who fail to respond to the Epley maneuver may respond to variations of repositioning such as the Semont maneuver (the patient begins in a sitting position with the head turned 45 degrees to one side, then drops laterally to a side lying position on the opposite ear, followed by a brisk swing of the body to drop the opposite side lying position) or the similar Brandt-Daroff exercises (sitting, to side lying, to sitting, performed repeatedly).

Positional vertigo caused by lateral canalolithiasis causes a purely horizontal nystagmus rather than the torsional and vertical type described above. In this case, another repositioning maneuver that involves rolling from one side to the other is used to liberate and reposition the otolithic debris.

It is important to reiterate that in some patients with positional vertigo, the disorder is neither benign nor paroxysmal. Jannetta and colleagues have described a group of patients in whom symptoms of vertigo and disequilibrium were almost constant (even in the upright position) and disabling and unresponsive to habituation and other medical therapy (*disabling positional vertigo*). They attributed this disorder to cross-compression of the root entry zone of the eighth cranial nerve by an adjacent blood vessel and have reported that decompression of the nerve provides lasting relief of symptoms.

Toxic and Idiopathic Bilateral Vestibulopathy

The common and serious ototoxic effects of the aminoglycoside antibiotics have already been mentioned—both on the cochlear hair cells, with loss of hearing and independently, on the vestibular labyrinths. Prolonged exposure to these agents produces a bilateral vestibulopathy without vertigo. Instead, there tends to be a disequilibrium associated with oscillopsia. The symptoms are especially troublesome when the patient moves. Often the disequilibrium is not discovered until a bedbound patient tries to walk.

Less-well appreciated is the occurrence of a slowly progressive vestibulopathy for which no cause can be discerned. The disorder affects men and women alike, with onset in middle or late adult life with the main abnormalities being unsteadiness of gait, which is worse in the dark or with eyes closed, and oscillopsia, which occurs with head movements and is particularly noticeable when walking. Vertigo and hearing loss are absent, as are other neurologic abnormalities. Bilateral vestibular loss can be documented with caloric and rotational testing. Baloh and colleagues, in a report of

22 patients with idiopathic vestibulopathy of this type, found that a significant proportion (9 of 22 cases) had a prior history of prolonged episodes of vertigo consistent with the diagnosis of bilateral sequential vestibular neuritis (see below).

Vestibular Neuritis (Neuronitis)

This was the term applied originally by Dix and Hallpike to a distinctive disturbance of vestibular function, characterized clinically by a paroxysmal and usually a prolonged single attack of vertigo and by a conspicuous absence of tinnitus and deafness. The entity is, however, more nebulous than most discussions indicate.

This disorder occurs mainly in young to middle-aged adults (children and older individuals also may be affected), without preference for either sex. The patient frequently gives a history of an antecedent upper respiratory infection of nonspecific type, but it is not clear whether this is requisite for the diagnosis. Usually, the onset of vertigo is fairly abrupt, although some patients describe a prodromal period of several hours or days in which they felt “top-heavy” or “off balance.” Persistence of the symptoms for a day or more differentiates the process from Ménière disease. The vertigo is severe as a rule and is associated with nausea, vomiting, and the need to remain immobile.

Nystagmus (quick component) and a sense of body motion are to the opposite side, whereas falling and past pointing are to the side of the affected labyrinth. In some patients, the caloric responses are abnormal bilaterally, and in some, the vertigo may recur, affecting the same or the other ear. Auditory function is normal. Examination discloses vestibular paresis on one side, i.e., an absent or diminished response to caloric stimulation of the horizontal semicircular canal. If the patient will tolerate small head movements, the previously described rapid-head-impulse test of Halmagyi and Cremer is one of the best means of demonstrating absent function of one lateral semicircular canal.

Although the symptoms can be quite disabling for a short period, vestibular neuritis is an ostensibly benign disorder. The severe vertigo and associated symptoms subside in a matter of several days, but lesser degrees of these symptoms, made worse by rapid movements of the head, may persist for months. The caloric responses are gradually restored to normal as well. In some patients, there has been a recurrence months or years later, as already mentioned.

The portion of the vestibular pathway that is primarily affected in this disease is thought to be the superior part of the vestibular nerve trunk, which was observed to show degenerative changes by Schuknecht and Kitamura. Earlier, Dix and Hallpike had reasoned that the lesion was located central to the labyrinth, as hearing is spared and vestibular function usually returns to normal. They used the term *vestibular neuritis* because of the uncertainty of more precise localization within the peripheral vestibular pathway. The cause of vestibular neuritis is still uncertain, but many authorities have attributed it to a viral infection of the

vestibular nerve, analogous to Bell's palsy, and from time to time, enhancement of the eighth nerve or the membranous labyrinth is seen after gadolinium administration on MRI. For want of more specific etiologic or pathologic data, many neurologists prefer the term *vestibular neuropathy* or *neuritis* or *acute unilateral peripheral vestibulopathy*. It is likely that the conditions described under the terms *epidemic vertigo*, *epidemic labyrinthitis*, and *acute labyrinthitis* or *neuro labyrinthitis* refer to the same process. Certainly, herpes zoster oticus causes this syndrome (as well as affecting the seventh nerve); this characterizes the Ramsay Hunt syndrome described in Chaps. 10 and 47.

During the acute stage, antihistamine drugs, promethazine, clonazepam, and scopolamine may be helpful in reducing the symptoms. Vestibular exercises are recommended by Baloh (2003) in his review of the subject. One clinical trial has demonstrated a more rapid recovery with the use of methylprednisolone, 100 mg orally, tapered over 3 weeks; valacyclovir did not have this effect (Strupp et al).

Other Causes of Vertigo of Vestibular Nerve Origin

Vertigo may occur with diseases that involve the eighth nerve in the petrous bone or at the cerebellopontine angle. Aside from vestibular neuritis, discussed above, the two most common causes of vertigo of eighth nerve origin are probably an acoustic or vestibular schwannoma and vascular irritation or compression by a small branch of the basilar artery. The frequency of the vascular compression syndrome as a cause of otherwise undifferentiated vertigo is not known (see earlier).

Regarding vestibular schwannoma, vertigo is rarely the initial symptom; the usual sequence is deafness affecting the high-frequency tones initially, followed some months or years later by mild chronic imbalance rather than vertigo and by impaired caloric responses, and then, if untreated, by additional cranial nerve palsies (the seventh, fifth, and tenth nerves), ipsilateral ataxia of limbs, and headache. Variations in the sequence of development of symptoms are frequent, and probably many vestibular schwannomas discovered in the process of an evaluation for vertigo are incidental; i.e., almost 1 percent of the general population harbors small tumors. In the diagnosis of vestibular and acoustic schwannoma, MRI and BAEP are the most important ancillary examinations. Bilateral vestibular/acoustic Schwannomas are almost always a manifestation of neurofibromatosis type 2.

Labyrinthine infarction can be a component of the stroke syndrome from occlusion of the anterior inferior cerebellar artery (AICA). In the complete syndrome there is hearing loss, cerebellar ataxia, and sometimes "screaming tinnitus" or lesser degrees of tonal tinnitus. Also reported is a clinical syndrome of unknown nature consisting of a single abrupt attack of severe vertigo, nausea, and vomiting without tinnitus or hearing loss but with permanent ablation of labyrinthine function on one side. It has been suggested that this syndrome

is a result of occlusion of the labyrinthine division of the internal auditory artery, but so far, anatomic confirmation has not been obtained. Labyrinthine hemorrhage has been demonstrated by MRI in some of these patients; others are attributed, speculatively, to viral infection.

Basser described a particular form of paroxysmal vertigo that occurs in childhood. The attacks occur in a setting of good health and are of sudden onset and brief duration. Pallor, sweating, and immobility are prominent manifestations; occasionally, vomiting and nystagmus occur. No relation to posture or movement has been observed. The attacks are recurrent but tend to cease spontaneously after a period of several months or years. The outstanding abnormality is demonstrated by caloric testing, which shows impairment or loss of vestibular function, bilaterally or unilaterally, frequently persisting after the attacks have ceased. Cochlear function is unimpaired. The pathologic basis of this disorder has not been determined, and a suggested connection with migraine is tenuous. The special case of basilar artery migraine is discussed below.

Cogan has described an infrequent syndrome in young adults in which a *nonsyphilitic interstitial keratitis* is associated with vertigo, tinnitus, nystagmus, and rapidly progressive deafness. The prognosis for vision is good, but the deafness and loss of vestibular function are usually permanent. The cause and pathogenesis of this syndrome are unknown, although approximately half of the patients later develop aortic insufficiency or a systemic vasculitis that resembles polyarteritis nodosa. These vascular complications proved fatal in 7 of 78 cases reviewed by Vollertsen and colleagues.

There are many other causes of aural vertigo, such as purulent labyrinthitis complicating mastoiditis or meningitis; serous labyrinthitis caused by infection of the middle ear; "toxic labyrinthitis" caused by intoxication with alcohol, quinine, or salicylates; motion sickness; and hemorrhage into the inner ear. Bárány (1911) was the first to draw attention to the nystagmus and positional vertigo, worse on closing the eyes that occurs at a certain level of intoxication with alcohol and lasts a few hours. Such an episode of alcohol-induced vertigo tends to last longer than a vertiginous attack of Ménière disease, but in other respects, the symptoms (excepting tinnitus) are similar.

Vertigo with varying degrees of spontaneous or positional nystagmus and reduced vestibular responses is a frequent complication of *cranial trauma*. Vertigo, often of the nonrotatory, to-and-fro type, may follow cerebral concussion or whiplash injury, in which the head has not been impacted. Brandt has attributed this syndrome to a loosening or dislodgement of the otoconia in the otoliths. The vertigo in these circumstances usually improves in a few days or weeks and is rarely accompanied by impairment of hearing—in distinction to the vertigo that follows fractures of the temporal bones (as described earlier in this chapter in the discussion of deafness). Dizziness is also a prominent complaint as part of the syndrome of a postconcussion syndrome as

described in Chap. 35, but usually this proves to be ill-defined giddiness rather than true vertigo.

There is, nonetheless, a type of vestibular concussion accompanying closed head trauma that may leave the patient with imbalance or positional vertigo. Otolaryngologists are familiar with a syndrome resulting from a perilymph fistula after traumatic injury. The trauma may be minor, even forceful coughing, sneezing, or lifting; some cases are a result of chronic ear infection or cholesteatoma. Disruption of the oval or round windows causes a leak of perilymph into the middle ear. Vertigo and nystagmus can be induced by pressure in the external ear canal (the fistula test). If enough perilymph migrates to the middle ear, a conductive hearing loss may also be detected. Superior canal dehiscence, in which loud sounds induce brief vertigo and nystagmus (Tullio phenomenon) is another result of perilymphatic fistula, as discussed earlier. A perilymph fistula may be pronounced enough to also cause low pressure of the spinal fluid with the characteristic enhancement of the dura on MRI.

Vertigo of Brainstem Origin

Reference was made above to the occurrence of vertigo and nystagmus with lower and upper brainstem lesions. In these cases, vestibular nuclei and their connections are implicated. Auditory function is nearly always spared, because the vestibular and cochlear fibers diverge upon entering the brainstem at the junction of the medulla and pons. The vertigo of brainstem origin, as well as the accompanying nausea, vomiting, nystagmus, and disequilibrium, is generally more protracted but less severe than with labyrinthine lesions, but one can think of exceptions to this statement. Nevertheless, with brainstem lesions, one often observes marked nystagmus without the slightest degree of vertigo—which does not happen with labyrinthine disease. The nystagmus of brainstem origin may be uni- or bidirectional, purely horizontal, vertical or rotary, and is characteristically worsened by attempted visual fixation. In contrast, nystagmus of labyrinthine origin is unidirectional, usually with a rotary component, and past pointing and falling are in the direction of the slow phase; purely vertical nystagmus does not occur, and a purely horizontal nystagmus without a rotary component is unusual. Furthermore, labyrinthine nystagmus is inhibited by visual fixation and reverses direction with changes in the position of the head; nystagmus of brainstem origin generally displays none of these features. Either may have a positional- or movement-induced worsening, but this finding is more prominent in labyrinthine disease. Table 15-2 summarizes these findings.

The central localization of vertigo is confirmed mainly by finding signs of involvement of other structures within the brainstem (cranial nerves, sensory and motor tracts, etc.). The mode of onset, duration, and other features of the clinical picture depend on the nature of the causative disease, which may be vascular, demyelinating, or neoplastic.

Table 15-2

DIFFERENTIATION OF PERIPHERAL FROM CENTRAL NYSTAGMUS (SEE TEXT)

	PERIPHERAL	CENTRAL
Vertigo and nausea	Pronounced	Mild
Direction of nystagmus	<ul style="list-style-type: none"> • Mixed torsional-vertical • Mixed torsional-horizontal • May be pure horizontal 	<ul style="list-style-type: none"> • Pure horizontal • Pure vertical • Pure torsional
Influence of gaze	Does not change direction with gaze	Direction changes with gaze
Visual fixation	Inhibits nystagmus	Does not affect nystagmus
Latency following repositioning maneuver	Up to 20 s	Brief
Direction changing with reversal of head position	Present and characteristic	Absent
Hearing loss/tinnitus	Variably present	Absent
Signs of brainstem or cerebellar disease	Absent	Generally present

Vertigo is a prominent symptom of ischemic attacks and of brainstem infarction occurring in the territory of the verteobasilar arteries, particularly the Wallenberg syndrome of lateral medullary infarction.

On the other hand, our colleague C.M. Fisher had pointed out that vertigo as the *sole* manifestation of brainstem ischemia from basilar arterial disease is rare. Unless other symptoms and signs of a brainstem disorder appear contemporaneously or soon after the vertigo, one can usually postulate an aural origin and nearly always exclude vascular disease of the brainstem. However, we have encountered rare patients with repeated brief attacks of vertigo that later proved to be caused by basilar artery stenosis, but in whom only a few episodes were associated with signs of brainstem disease such as dysarthria, facial numbness, or diplopia. In other words, frequent and sudden episodes of vertigo lasting a minute or so may infrequently be related to transient brainstem ischemia.

Vertigo of cerebellar origin is exceptional in this respect in that it may rarely be the sole manifestation of cerebellar infarction or hemorrhage, as described earlier in the introductory sections of the chapter and in Chap. 34. It follows that isolated vertigo may be the result of occlusion of the posterior inferior cerebellar artery or its parent vertebral artery although most often, there are additional features related to damage to the lateral medulla. In instances of isolated vertigo, one seeks confirmation that there are no features pointing to a central origin or conversely, if there are signs such as nystagmus in more than one direction of gaze with a single position of the head, or vertical nystagmus, there is concern for ischemia of the brainstem. The nystagmus and ataxia of gait (more of a

propelling, or pulsion, to one side) that accompany acute cerebellar lesions are toward the same side (the side of the lesion), while in acute vestibulopathies, nystagmus beats away from the side of the lesion and pulsion is still toward the affected side.

Multiple sclerosis may be the explanation of persistent vertigo in an adolescent or young adult, sometimes with little or no nystagmus.

The relationship of migraine to vertigo was mentioned earlier. This refers to otherwise mundane migraine in which the vertigo is perhaps an aura, or to episodes of paroxysmal vertigo in adults that are considered to be migraine equivalents. In addition, attacks of vertigo followed by an intense unilateral and often suboccipital headache and vomiting are the characteristic features of *basilar artery migraine*. The prodromal visual symptoms take the form of blindness or of photopsia that occupies all of the visual fields. Between headaches, tests of cochlear and vestibular function in these patients are normal. Some authorities have stated that most cases of recurrent vertigo without hearing loss over many years can be attributed to migraine and not to Ménière disease. An instructive series of such cases has been published by Dieterich and Brandt.

Finally, mention should be made of a *familial vestibulocerebellar syndrome*, beginning in childhood or early adult life and characterized by recurrent episodes of vertigo and imbalance. Diplopia and dysarthria complicate some attacks, which seem to be precipitated by extreme exertion and emotion. Repeated attacks are followed by a mild, persistent ataxia, mainly of the trunk. This disorder was first described by Farmer and Mustian and more recently by Baloh and Winder, who have pointed out that both the episodic vertigo and ataxia are markedly reduced or abolished by the administration of acetazolamide. This process is most likely related to the inherited acetazolamide-responsive ataxic channelopathy syndrome described in Chap. 5. A form that is kinesigenic, i.e., brought on by activity, has a similar appearance.

In summary, the nature of the nystagmus, instability of the eyes during the head impulse test, and the other features of the neurologic examination allow a distinction to be made between central and peripheral cases of vertigo. Associated hearing loss favors a vestibular cause of vertigo. Tables 15-2 and 15-3 summarize the features of the various vertiginous syndromes.

Table 15-3

VERTIGINOUS SYNDROMES WITH LESIONS OF DIFFERENT PARTS OF THE VESTIBULAR SYSTEM

SYNDROME	NEUROLOGIC FINDINGS	DISORDERS OF EQUILIBRIUM	TYPE OF NYSTAGMUS ^a	HEARING	LABORATORY EXAM
Labyrinths (postural vertigo, trauma, Ménière disease, aminoglycoside toxicity, labyrinthitis)	None	Ipsilateral past pointing and lateral propulsion to side of lesion	Horizontal or rotary to side opposite lesion, positional and position changing, fatigable	Normal or conduction or neurosensory deafness with recruitment	Vestibular paresis by caloric testing, directional preponderance
Vestibular nerve and ganglia (vestibular neuronitis, herpes zoster)	Auditory eighth and seventh cranial nerve abnormalities; abnormal head impulse test to affected side	Ipsilateral past pointing and lateral propulsion to side of lesion	Unidirectional positional	Sometimes sensorineural deafness, without recruitment (vestibulolabyrinthitis)	Imaging may be normal or abnormal Vestibular paresis on caloric testing Directional preponderance
Cerebellopontine angle (acoustic neuroma, glomus and other tumors)	Ipsilateral fifth, seventh, ninth, tenth cranial nerves, cerebellar ataxia Increased intracranial pressure (late)	Ataxia and falling ipsilaterally	Gaze-paretic, positional, coarser to side of lesion	Sensorineural deafness without recruitment	Imaging abnormal Vestibular paresis on caloric testing BAEPs abnormal Increased CSF protein
Brainstem and cerebellum (infarcts, tumors, viral infections)	Multiple cranial nerves, brainstem tract signs, cerebellar ataxia	Ataxia present with eyes open	Coarse horizontal and vertical, gaze-paretic	Usually normal	Hyperactive labyrinths or directional preponderance on caloric testing Imaging, and BAEPs abnormal in most cases
Higher (cerebral) connections	Aphasia, visual field, hemimotor, hemisensory, and other cerebral abnormalities, seizures	No change	Usually absent	Normal	No change in caloric responses Imaging and electroencephalogram may be abnormal

^aSee text and Chap. 14 for description of types of nystagmus.

Epilepsy and Disorders of Consciousness

Epilepsy and Other Seizure Disorders

The prevalence and importance of epilepsy, i.e., recurrent cerebral cortical seizures, can hardly be overstated. From the epidemiologic studies of Hauser and colleagues, one may extrapolate an incidence of approximately 2 million individuals in the United States who are subject to epilepsy and predict about 44 new cases per 100,000 persons each year. These figures are exclusive of patients in whom seizures transiently complicate febrile and other illnesses or injuries. It has also been estimated that slightly less than 1 percent of persons in the United States will have epilepsy by the age of 20 years (Hauser and Annegers). Over two-thirds of all epileptic seizures begin in childhood (most in the first year of life), and this is the period when seizures assume the widest array of forms. In the practice of pediatric neurology, epilepsy is one of the most common disorders, and the chronicity of childhood forms adds to their importance. The incidence increases again after age 60 years. For all these reasons, physicians should know something of the nature of seizure disorders and their treatment. It is notable that, in striking contrast to the many treatments available for epilepsy, as pointed out by J. Engel, 80 to 90 percent of persons with epilepsy in the developing world never receive medical attention.

In 1870, Hughlings Jackson, the eminent British neurologist, postulated that seizures were due to "an excessive and disorderly discharge of cerebral nervous tissue on muscles." The discharge may result in an almost instantaneous loss of consciousness, alteration of perception or impairment of psychic function, convulsive movements, disturbance of sensation, or some combination thereof.

Terminologic difficulty arises from the diversity of the clinical manifestations of seizures. The term *convulsion*, referring as it does to an intense paroxysm of involuntary repetitive muscular contractions, is inappropriate for a disorder that may consist only of an alteration of sensation or consciousness. *Seizure* is preferable as a generic term, because it embraces all paroxysmal electrical discharges of the brain, and also because it lends itself to qualification. The term *motor* or *convulsive seizure*, therefore, is not tautologic, and one may likewise speak of a *sensory seizure* or *psychic seizure*. The word *epilepsy* is derived from Greek words meaning "to seize upon" or a "taking hold of." Our predecessors referred to it as the "falling sickness" or the "falling evil." Although a useful

medical term to denote recurrent seizures, the words *epilepsy* and *epileptic* may still have unpleasant connotations and should be used advisedly in dealing with patients. There is also a curious, but common entity of "nonconvulsive seizure" that may impair consciousness, but not manifest any abnormal bodily movement. This represents an important and potentially treatable form of a confusional state.

A first solitary seizure or brief outburst of seizures may occur during the course of many medical illnesses. It indicates that the cerebral cortex has been affected by disease, either primarily or secondarily. If prolonged or repeated every few minutes, the condition termed *status epilepticus*, may threaten life. Equally important, a seizure or a series of seizures may be the manifestation of an ongoing neurologic disease that requires special diagnostic, and therapeutic measures. Status epilepticus may be of the nonconvulsive type, and continuously impair consciousness and is difficult to detect clinically because of the absence of characteristic movements.

A more common and less-grave circumstance is for a seizure to be but one in an extensive series recurring over a long period of time, with most of the attacks being more or less similar in type. In this instance, they may be the result of an inactive lesion that remains as a scar in the cerebral cortex. The original disease may have passed unnoticed, or perhaps had occurred in utero, at birth, in infancy, or in parts of the brain inaccessible for examination or too immature to manifest signs. The increasingly refined techniques of MRI now also reveal small zones of developmental cortical dysplasia and hippocampal sclerosis, both of which tend to be epileptogenic. Patients with such long-standing but subtle lesions probably make up a large portion of those with recurrent seizures. If there is no underlying lesion, the condition is classified as idiopathic or primary, but in the modern era, this is come to be almost synonymous with a genetic cause. In this category, there are a large number of important types of epilepsy for which no pathologic basis has been established, and for which there is no apparent underlying cause except perhaps a genetic one. Included here are special hereditary forms including types of generalized tonic-clonic (grand mal), and "absence" seizure states as suggested in classifications many years ago by Lennox and Forster. Persistent seizures, whether idiopathic or

not, can secondarily damage cortical tissue by several mechanisms that may include excitotoxicity and, in the setting of prolonged tonic seizures, systemic hypoxia.

CLASSIFICATION OF SEIZURES AND EPILEPSIES

Seizures have been grouped in several ways: according to their presumed etiology, i.e., idiopathic (primary) or symptomatic (secondary); their site of origin; their clinical form (generalized or focal); their frequency (isolated, cyclic, or repetitive, or the closely spaced sequence of status epilepticus); or by special electrophysiologic correlates. A distinction must be made between the classification of *seizures* (the clinical manifestations of epilepsy: generalized tonic clonic (grand mal), absence (petit mal), myoclonic, partial, and others), and the classification of the *epilepsies*, or *epileptic syndromes*, which are specific diseases, most of which may manifest several seizure types. These are discussed later in the chapter. A further distinction is made by clinical and EEG features. This approach allows for the reasonable predictability of response to specific medications and to some extent, in prognosis. Basically, this classification divides seizures into two types—*focal* (formerly termed *partial*), in which a focal or localized onset can be discerned clinically or by EEG, and *generalized*, in which the seizures appear to begin bilaterally.

Generalized seizures are of two types—*convulsive* and *nonconvulsive*. (This dichotomy is not part of the main classification, but it is fundamental.) The common convulsive type is the *tonic-clonic (grand mal) seizure*. Less common is a purely tonic, purely clonic, or clonic-tonic-clonic generalized seizure. The typical nonconvulsive generalized seizure is the brief lapse of consciousness or absence (*petit mal*); included also under this heading are minor motor phenomena such as brief myoclonic, atonic, or tonic seizures.

The classification followed here was first proposed by Gastaut in 1970 and has been refined repeatedly by the Commission on Classification and Terminology of the International League Against Epilepsy. This nomenclature, based mainly on the clinical form of the seizure, and its electroencephalographic (EEG) features, has been adopted worldwide and is generally referred to as the “International Classification”. A modified version of it is reproduced in Table 16-1.

It is also useful clinically, and etiologically to separate epilepsies that originate as truly generalized electrical discharges in the brain from those that spread secondarily from a focus to become generalized. The *primary generalized epilepsies* are a group of somewhat diverse, age-dependent phenotypes that are characterized by generalized 2.5- to 4-Hz bifrontally predominant spikes or polyspike-and-slow-wave discharges that arise without underlying structural abnormalities. In most instances, these individuals have normal intelligence. What is most significant is that a genetic component underlies many of these disorders. By contrast, epilepsies manifesting as

Table 16-1

INTERNATIONAL CLASSIFICATION OF EPILEPTIC SEIZURES

- I. Generalized seizures (bilaterally symmetrical and without focal onset)
 - A. Tonic, clonic, or tonic-clonic (grand mal)
 - B. Absence (petit mal)
 1. typical
 2. atypical
 3. special features
 - a. eyelid myoclonia
 - b. myoclonic absence
 - C. Clonic
 - D. Tonic
 - E. Atonic
 - F. Myoclonic including atonic and tonic types
- II. Focal (formerly “partial”); characterized by main feature(s). See Table 16-2
 - A. Simple (*without* loss of consciousness or alteration in psychic function)
 1. Aura; somatosensory or special sensory (visual, auditory, olfactory, gustatory, vertiginous)
 2. Motor
 3. Autonomic
 4. Awareness retained (formerly (“simple”) or impaired (formerly “complex”))
- III. Unclassifiable; cannot be characterized as focal, generalized or both, including epileptic spasms

Table 16-2

COMMON FOCAL SEIZURE PATTERNS

CLINICAL TYPE	LOCALIZATION
<i>Somatic motor</i>	
Jacksonian (focal motor)	Prerolandic gyrus
Masticatory, salivation, speech arrest	Amygdaloid nuclei, opercular
Simple contraversive	Frontal
Head and eye turning associated with arm movement or atetoid-dystonic postures	Supplementary motor cortex
<i>Somatic and special sensory (auras)</i>	
Somatosensory	Contralateral postrolandic
Unformed images, lights, patterns	Occipital
Auditory	Heschl gyri
Vertiginous	Superior temporal
Olfactory	Mesial temporal
Gustatory	Insula
Visceral: autonomic	Insular-orbital-frontal cortex
<i>Focal seizure with altered consciousness</i>	
Formed hallucinations	Temporal neocortex or amygdaloid-hippocampal complex
Illusions	—
Dyscognitive experiences (déjà vu, dreamy states, depersonalization)	—
Affective states (fear, depression, or elation)	Temporal
Automatism (ictal and postictal)	Temporal and frontal
Staring	Frontal cortex, amygdaloid-hippocampal complex, reticular-cortical system

seizures that begin locally and may evolve into generalized tonic-clonic seizures, termed *secondarily generalized tonic clonic seizures* (termed bilateral convulsive in Fig. 16-1), generally have no such genetic component and are usually the result of underlying brain disease, either acquired or a result of congenital malformations or metabolic defects. Quite often, the initial focal phase is not appreciated, leading to misdiagnosis. An increasing frequency and severity of this group of disorders with age reflects the accumulation of focal cerebral damage from trauma, strokes, and other damage.

Focal seizures are further classified according to their additional features such as a specific subjective experience (*aura*), motor, autonomic, and most importantly, whether awareness or consciousness is disturbed; the latter was formerly called *partial complex seizure*. A prominent component of such seizures is a *dyscognitive state*. In reality, an *aura* represents the initial phase of a focal seizure; in some instances, it may constitute the entire epileptic attack.

The classification of seizures and of the epilepsies is constantly being modified. In an older but still useful version, the so-called syndromic classification (*Epilepsia* 30:389, 1989), an attempt had been made to incorporate all of the seizure types and epileptic syndromes and to categorize them not only as partial and generalized but also according to their age of onset, their primary (generalized) or secondary nature, the evidence of cortical loci of the epileptogenic lesions, and the many clinical settings in which they occur. This classification is semantically difficult and, in our view, too complicated for general clinical application; it has been replaced with current classifications already mentioned. Because many

epileptic syndromes share overlapping features, it is often not possible to fit a newly diagnosed case of epilepsy into a specific category in this new classification. The Commission is continuously engaged in revision of terminology and classification in the field of epilepsy.

We begin our discussion with a practical approximation of the most recent classification that was given in 2010 (see Berg and colleagues) and is shown in Fig. 16-1, followed by consideration of a number of well-defined epilepsies and epileptic syndromes.

It is also useful to view the various types of seizures and epilepsies in the context of the age at which they occur. A proposed current classification based on the age of onset of the seizure disorder is shown in Fig. 16-2, and the distribution of the seizure types for each age epoch, obtained and aggregated from several sources is shown in Fig. 16-3. There has also been substantial progress in defining the molecular basis of familial and hereditary epilepsies over the last decade; it is likely that these insights will lead to modification of both the clinical classifications and management of the epilepsies.

GENERALIZED SEIZURES

Generalized Tonic-Clonic Seizures (Grand Mal)

In the common primary type of seizure, most often a convulsion starts with little or no warning. Sometimes the patient senses the approach of a seizure by several subjective phenomena (*prodrome*) even prior to an epileptic aura, which represents a focal seizure. For some hours, the patient may feel apathetic, depressed, irritable, or,

Figure 16-1. ILAE proposal for revised terminology for organization of seizures and epilepsies 2010 classification of seizures. (From http://www.ilae.org/Visitors/Centre/ctf/documents/ILAEHandoutV10_000.pdf/.)

Figure 16-2. ILAE proposal for revised terminology for organization of seizures and epilepsies 2010 electroclinical syndromes and other epilepsies grouped by specificity of diagnosis. (From http://www.ilae.org/Visitors/Centre/ctf/documents/ILAEHandoutV10_000.pdf.)

rarely, the opposite—ecstatic. In a patient with generalized epilepsy (juvenile myoclonic epilepsy being one typical type), one or more myoclonic jerks of the trunk or limbs on awakening may herald a seizure later in the day. Abdominal pains or cramps, a sinking, rising, or gripping feeling in the epigastrium, pallor or redness of the face, throbbing headache, constipation, or diarrhea have been given prodromal status, but they do not occur

consistently enough to be predictive of an oncoming seizure.

In more than half of cases of generalized seizure, there is some type of movement for a few seconds before consciousness is lost (turning of the head and eyes or whole body or intermittent jerking of a limb), although the patient often fails to form a memory of this and such information is obtained only from an observer. As has

Figure 16-3. The distribution of the main types of epilepsy by age. The overrepresentation of absence and myoclonic seizures in childhood and of complex partial seizures in older individuals is evident. (Adapted from Hauser and Annegers and the texts of Engel and of Pedley.)

already been pointed out, it is useful, whenever possible, to distinguish between a primary (generalized) type of seizure with widespread EEG abnormalities at the onset, and a secondarily generalized type, which begins as a focal seizure and then becomes generalized. The secondary generalized type implicates a focal brain lesion. More often, the seizure strikes without warning, beginning with a sudden loss of consciousness and a fall to the ground that may lead to facial and dental injuries.

The initial motor signs are a brief flexion of the trunk, an opening of the mouth and eyelids, and upward deviation of the eyes. The arms are elevated and abducted, the elbows semiflexed, and the hands pronated. These are followed by a more protracted extension (*tonic*) phase, involving first the back and neck, then the arms and legs. There may be a piercing cry as the whole musculature is seized in a spasm with biting of the lateral margin of the tongue, and air is forcibly emitted through the closed vocal cords. Because the respiratory muscles are caught up in the tonic spasm, breathing is suspended and after some seconds the skin and lips may become cyanotic. The pupils are dilated and unreactive to light. The bladder may empty at this stage or later, during the postictal coma. This is the tonic phase of the seizure and lasts for 10 to 20 s.

There then occurs a transition from the tonic to the *clonic phase* of the convulsion. At first, there is a mild generalized tremor, which is, in effect, a repetitive relaxation of the tonic contraction. It begins at a rate of 8 per second and coarsens to 4 per second; then it rapidly gives way to brief, violent flexor spasms that come in rhythmic salvos and agitate the entire body. The face becomes violaceous and contorted by a series of grimaces. Autonomic signs are prominent: the pulse is rapid, blood pressure is elevated, pupils are dilated, and salivation and sweating are prominent; bladder pressure may increase sixfold during this phase. The clonic jerks decrease in amplitude and frequency over a period of about 30 s. The patient remains apneic until the end of the clonic phase, which is often marked by a deep inspiration. Instead of the whole dramatic sequence described above, the seizures may be abbreviated or limited in scope by anticonvulsive medications.

In the terminal phase of the seizure, all movements have ended and the patient is motionless and limp in a deep coma. The pupils now begin to contract to light. Breathing may be quiet or stertorous. This state persists for several minutes, after which the patient opens his eyes, begins to look about, and is obviously bewildered and confused and may be quite agitated. The patient may speak and later not remember anything that has been said and undisturbed becomes drowsy and falls asleep, sometimes for several hours, then often awakens with a pulsatile headache. When fully recovered, such a patient has no memory of any part of the spell but knows that something has happened because of the strange surroundings (in ambulance or hospital), the obvious concern of those around him, and often, a sore, bitten tongue and aching muscles from the violent movements. The contractions, if violent enough, may crush a vertebral body or result in a serious injury; a fracture, periorbital

hemorrhages, subdural hematoma, posterior shoulder dislocation, or burn may have been sustained in the fall.

Each of these phases of the generalized tonic-clonic seizure has its characteristic EEG accompaniment. Initially, movement artifacts obscure the EEG tracing; sometimes there are repetitive spikes or spike-wave discharges lasting a few seconds, followed by an approximately 10-s period of 10-Hz spikes. As the clonic phase asserts itself, the spikes become mixed with slow waves and then the EEG slowly assumes a polyspike-and-wave pattern. When all movements have ceased, the EEG tracing is nearly flat for a variable time, and then the brain waves gradually resume their pre-seizure pattern.

Convulsions of this type ordinarily come singly or in groups of two or three and may occur when the patient is awake and active or during sleep, or when falling asleep or awakening. It is useful to know that seizures on awakening usually signify a generalized type, whereas those occurring during the period of sleep are more often focal in nature. Some 5 to 8 percent of such patients will at some time have a prolonged series of such seizures without resumption of consciousness between them; this is called *status epilepticus* and demands urgent treatment. The first outburst of seizures may take the form of status epilepticus.

Aside from psychogenic episodes that imitate seizures, few clinical states simulate a generalized tonic-clonic seizure, but several are worthy of mention. One is a clonic jerking of the extended limbs (usually less severe than those of a grand mal seizure) that occurs with vasodepressor syncope or a Stokes-Adams hypotensive attack. In contrast to an epileptic type of EEG, the brain waves are slow in frequency and low in amplitude during the jerking movements. A rarer phenomenon that may be indistinguishable from a generalized convulsion occurs as part of the syndrome of basilar artery occlusion. This presumably has its basis in ischemia of the corticospinal tracts in the pons (Ropper); a similar ischemic mechanism in the cortex has been invoked for "limb-shaking TIAs" (transient ischemic attacks), in which there are clonic movements of one limb or one side of the body during an episode of cerebral ischemia. Clonic limb movements occur immediately after a traumatic concussion and an observer who arrives at this moment will be unable to determine if the inciting event was a seizure or a collision. In infants, a breath-holding spell may closely simulate the tonic phase of a generalized seizure. Another disorder that simulates a seizure, albeit self-induced, is the "fainting lark" (or in the British, the "mess trick). By hyperventilating in a squatting position and standing rapidly combined with a Valsalva maneuver, a syncopal episode is induced that ends with generalized convulsive movements (see Lempert and colleagues).

Absence, Petit Mal Seizures

In contrast to major generalized seizures, absence seizures (formerly referred to as *petit mal* or *pyknoepilepsy*) are notable for their brevity, rapid onset and cessation, and frequency and the paucity of motor activity. Indeed, they may be so brief that the patients themselves are

sometimes not aware of them; to an onlooker, they resemble a moment of absentmindedness or daydreaming. The attack, coming without warning, consists of a sudden interruption of consciousness, for which the French word *absence* (“not present,” “not in attendance”) has been retained. The patient stares and briefly stops talking or ceases to respond. Only about 10 percent of such patients are completely motionless during the attack; in the remainder, one observes a brief burst of fine clonic (myoclonic) movements of the eyelids, facial muscles, or fingers or small synchronous movements of both arms, all at a rate of 3 per second. This rate corresponds to that of the EEG abnormality, which takes the form of a generalized 3-per-second spike-and-wave pattern (Fig. 2-3E). Absence seizures are said to be “typical” if they have a rapid onset and offset, typical three per second spike and wave, and complete loss of awareness.

Minor automatisms—in the form of lip-smacking, chewing, and fumbling movements of the fingers—are common during an attack but may be subtle. Postural tone may be slightly decreased or increased, and occasionally there is a mild vasomotor disorder. As a rule, such patients do not fall; they may even continue complex acts such as walking or riding a bicycle. After 2 to 10 s, occasionally longer, the patient reestablishes full contact with the environment and resumes his pre-seizure activity. Only a loss of the thread of conversation or the place in reading betrays the occurrence of the momentary “blank” period (the absence). In many such patients, voluntary hyperventilation for 2 to 3 min is an effective way of inducing absence attacks.

Typical absence seizures constitute the most characteristic epilepsy of childhood (“childhood absence”); rarely do the seizures begin before 4 years of age or after puberty. Another attribute is their great frequency (hence, the old term *pykno*, meaning “compact” or “dense”). As many as several hundred may occur in a single day, sometimes in bursts at certain consistent times of the day. They produce periods of inattention and may appear in the classroom when the child is sitting quietly rather than participating actively in his lessons. If frequent, they disturb attention and thinking to the point that the child’s performance in school is impaired. Less frequently, such attacks may last for hours with no interval of normal mental activity between them—so-called *absence* or *petit mal status*. Absence epilepsy of adolescent onset (“juvenile absence”) does not have the very high seizure frequency of the childhood type. Cases of absence status have also been described in adults with frontal lobe epilepsy (see below). In contrast to childhood absence seizures, the disorder may last well into adulthood and be punctuated by generalized tonic-clonic seizures or a burst of seizures. Akinesia (motionlessness) is not unique to any seizure type.

The typical absence, with or without myoclonic jerks, rarely causes the patient to fall. Absence should be considered a separate entity because of its relative benignity. It may be the only type of seizure during childhood. The attacks tend to diminish in frequency in adolescence and then often disappear, only to be replaced in many instances by major generalized seizures. About one-third of children with absence attacks will, in addition, display

symmetrical or asymmetrical myoclonic jerks without loss of consciousness, and about half will at some time have major generalized (tonic-clonic) convulsions.

Absence Variants

Distinguished from typical absence seizures are variants in which the loss of consciousness is less complete or in which myoclonus is prominent, and others in which the EEG abnormalities are less regularly of a 3-per-second spike-and-wave type (they may occur at the rate of 2 to 2.5 per second or take the form of irregular 4- to 6-Hz polyspike-and-wave complexes). *Atypical absence* is a term that was introduced to describe long runs of slow spike-and-wave activity, usually with no apparent loss of consciousness. External stimuli, such as asking the patient to answer a question or to count, interrupt the run of abnormal EEG activity. The current classification (Fig. 16-1) separates the disorder into groups that are identified as typical, atypical, and having special features, namely, myoclonic jerks or eyelid myoclonus.

Lennox-Gastaut Syndrome

In sharp contrast to the typical absence epilepsies, is a form that has its onset between 2 and 6 years of age and is characterized by atonic, or astatic, seizures (i.e., falling attacks), often succeeded by various combinations of minor motor, tonic-clonic, and partial seizures and by progressive intellectual impairment in association with a distinctive, slow (1- to 2-Hz) spike-and-wave EEG pattern. This is the *Lennox-Gastaut syndrome*. Often it is preceded in earlier life by infantile spasms, a characteristic high-amplitude chaotic EEG picture (“hypsarrhythmia”), and an arrest in mental development, a triad sometimes referred to as the *West syndrome* (see further on). The early onset of atonic seizures with abrupt falls, injuries, and associated abnormalities nearly always has a grave implication—namely, the presence of serious neurologic disease. Prematurity, perinatal injury and metabolic diseases of infancy are the most common underlying conditions. This is essentially a form of symptomatic generalized epilepsy, in contrast to the foregoing idiopathic types such as typical absence epilepsy (*petit mal*). The Lennox-Gastaut syndrome may persist into adult life and is one of the most difficult forms of epilepsy to treat.

Myoclonic Seizures

The phenomenon of myoclonus was discussed in Chap. 6, where the relationship to seizures was emphasized. Characterized by a brusque, brief, muscular contraction, some myoclonic jerks may be so small as to involve only one muscle or part of a muscle; others are so large as to displace a limb on one or both sides of the body or the entire trunk musculature. Many are brief, lasting 50 to 100 ms; they may occur intermittently and unpredictably or present as a single jerk or a brief salvo.

As mentioned earlier, a series of several small, rhythmic myoclonic jerks may appear with varying frequency as part of atypical absence seizures, and as isolated events in patients with generalized clonic-tonic-clonic or

tonic-clonic seizures. As a rule, seizure-associated myoclonus, when occurring in isolation, is relatively benign and usually responds well to medication. In contrast, there are diseases in which myoclonus is progressive in severity or very frequent. These disorders have their onset in childhood and raise the suspicion of entities such as the myoclonus-opsoclonus-ataxia syndrome, lithium or other drug toxicity or, if lasting a few weeks, subacute sclerosing panencephalitis. Chronic progressive polymyoclonus with dementia characterizes the group of juvenile lipidosis, Lafora-type familial myoclonic epilepsy, certain mitochondrial disorders, and other chronic familial degenerative diseases of undefined type (paramyoclonus multiplex of Friedreich) as noted in Table 16-3.

The large number of adult diseases causative of myoclonus and seizure disorders are discussed in Chaps. 33, 37, and 39. Myoclonus as a phenomenon is described in Chap. 6.

Juvenile Myoclonic Epilepsy

This is the most common form of idiopathic generalized epilepsy in older children and young adults. It begins in adolescence, typically around age 15 years, with a range that essentially spans all of the teenage years. The patient comes to attention because of a generalized tonic-clonic seizure, often upon awakening or because of myoclonic jerks in the morning that involve the entire body; sometimes absence seizures are prominent. The family reports that the patient has occasional myoclonic jerks of the arm and upper trunk that is brought out with fatigue, early stages of sleep, or alcohol ingestion. A few patients in our experience have had only the myoclonic phenomena and rare absence or tonic-clonic seizures that persisted unnoticed for years. The EEG shows characteristic bursts of 4- to 6-Hz irregular polyspike activity. A linkage has been established to chromosome 6 in some cases of this illness, and in some other forms of juvenile-onset epilepsy, and several are the result of mutations in ion channel genes.

The disorder does not impair intelligence and tends not to be progressive, for which reason it has been called “benign”, but a proclivity to infrequent seizures usually continues throughout life. A report by Bakan and colleagues has indicated that, over an average of two decades, the majority of patients have long seizure-free periods and a great reduction in myoclonic seizures. Valproic acid in particular and some other antiepileptic drugs are highly effective in eliminating the seizures and myoclonus but they should be continued indefinitely as discontinuation of medication is associated with a high rate of relapse. Owing to the potential teratogenicity of valproate, women of childbearing age are often given levetiracetam or lamotrigine, acknowledging that they may not be as effective as the first choice of drug.

FOCAL SEIZURES

As indicated earlier, the International Classification divides all seizures into two types—generalized, in which the clinical and EEG manifestations indicate

bilateral and diffuse cerebral cortical involvement from the onset, and focal, in which the seizure is often the product of a demonstrable focal lesion or EEG abnormality in some part of the cerebral cortex. Partial seizures vary with the locale of the lesion and are conventionally qualified based their specific clinical characteristics and on whether consciousness is retained or impaired. Focal seizures with sensory or motor features at the onset most often arise from foci in the sensorimotor cortex. Those with impairment of consciousness, which occurs in many forms, most often have their focus in the limbic and autonomic areas or in the temporal lobe, but a frontal localization is also known. Table 16-2, on a previous page, lists the common sites of the lesions and the types of seizures to which they give rise.

Relatively few focal seizures can be localized precisely from clinical data alone. However, when combined with scalp and intracranial EEG recording and MRI, the localization is reasonably accurate.

Frontal Lobe Seizures (Focal Motor and Jacksonian Seizures)

Focal or partial motor seizures are attributable to a discharging lesion of the frontal lobe. The most common type, originating in the supplementary motor area, takes the form of a turning movement of the head and eyes to the side opposite the irritative focus, often associated with a tonic extension of limbs, also on the side contralateral to the affected hemisphere. This may constitute the entire seizure, or it may be followed by generalized clonic movements. The extension of the limbs may occur just before or simultaneously with loss of consciousness but a lesion in one frontal lobe may give rise to a major generalized convulsion without an initial turning of the head and eyes. It has been postulated that in both types of seizures, the one with and the one without turning movements, there is an immediate spread of the discharge from the frontal lobe to integrating centers in the thalamic or high midbrain reticular formation, accounting for the loss of consciousness.

The frontal lobe, being so large, can give rise to numerous forms of seizure. In addition to the typical Jacksonian type described above, there are *adversive*, speech arrest, frontal, absence types, and a number of unusual disorders related to discharges from the supplementary motor area including hyperkinetic and postural tonic varieties. In practice, it is often difficult to distinguish such seizures from parasomnic (sleep related) events (see Chap. 18).

Jacksonian seizures begin with forceful, sustained deviation of the head and eyes, and sometimes of the entire body, are referred to as *versive* or *adversive*. Because the turning movements are usually to the side opposite the irritative focus (sometimes to the same side), *contraversive* and *ipsiversive*, respectively, might be preferable terms. Nonforceful, unsustained, or seemingly random lateral head movements during the ictus do not have localizing value. The same is true for the head and eye turning that occurs at the end of the generalized tonic-clonic phase of seizures (Wylie et al). Contraversive deviation of only the head and eyes can

Table 16-3

MONOGENIC EPILEPTIC DISORDERS

	GENE	PROTEIN INVOLVED
<i>Channelpathies</i>		
Sodium channels		
Familial generalized seizures with febrile seizures "plus"; see text	SCN1A,B, (GABA _A)	Sodium channel subunits; less often, GABA receptor
Benign familial neonatal convulsions	SCN2A	Sodium channel subunits
Dravet syndrome (severe myoclonic epilepsy of infancy)	SCN1A	Sodium channel α -subunit
Potassium channels		
Benign infantile epilepsy	KCNQ2,3	Potassium channel subunits
Episodic ataxia type 1 with partial epilepsy	KCNA1	
Ligand-gated channels		
Autosomal dominant nocturnal frontal seizures	CHRNA 2,4	Nicotinic acetylcholine receptor subunits
Familial generalized and febrile seizures	GABRG2	GABA _A receptor subunit
Juvenile myoclonic epilepsy	GABRA1 (CACNB4)	GABA _A receptor subunit; less often, calcium channel subunit
Glucose transporter-1 deficiency	SLC2A1	GLUT1 (responsive to ketogenic diet)
Calcium channels		
Episodic ataxia type 2 with spike-wave seizures	CACNA1A	Calcium channel subunit
<i>Malformations of cortical development</i>		
Holoprosencephaly, generalized epilepsy	SHH, PTCH, ZIC2, SIX3, TGIF	Sonic hedgehog, SHH receptor, transcription factors
Schizencephaly, generalized epilepsy	EMX2	Homeodomain protein
Tuberous sclerosis, generalized epilepsy	TSC1, 2	Hamartin, tuberlin
Lissencephaly, generalized epilepsy	LIS1	Platelet-activating factor acid hydrolase
Double-cortex syndrome, generalized epilepsy	DCX	Doublecortin
Heterotopia, focal epilepsy	FLN1	Filamin1
Fukuyama muscular dystrophy, lissencephaly, generalized epilepsy	FCMD	Fukutin
Walker-Warburg syndrome, generalized epilepsy	POMT1	O-mannosyl transferase
Muscle-eye-brain disease, generalized epilepsy	MEB	Glycosyltransferase, PMGnT1
Angelman syndrome: myoclonic, tonic-clonic, atonic seizures	UBE3A	Ubiquitin-protein ligase
<i>Progressive myoclonic epilepsies (PME)</i>		
Unverricht-Lundborg disease with PME	EPM1	Cystatin B
Lafora body disease with PME	EPM2A	Laforin, protein tyrosine phosphatase
Myoclonic epilepsy with ragged red fibers	tRNA ^{Lys}	Mitochondrial lysine tRNA
Dentatorubro-pallidoluysian atrophy with PME	DRPLA	Atrophin-1
Gaucher disease	PSAP	β -Glucocerebrosidase
Sialidosis type I	NEU1	Sialidase
Ceroid lipofuscinosis (CLN) and PME	CLN	CLN2, CLN3, CLN5, CLN6 also cause generalized, atonic and atypical absence seizures
<i>Mixed seizure types</i>		
Lipoid proteinosis and temporal lobe epilepsy	ECM1	Extracellular matrix protein 1
Autosomal dominant lateral temporal lobe epilepsy	LGI1	Leucine-rich glioma inactivated protein
CLN8; progressive nonmyoclonic epilepsy with retardation	CLN8	Membrane protein in endoplasmic reticulum
Pyridoxine deficiency	ALDH7A1	Antiquitin (ATQ-1)

be induced most consistently by electrical stimulation of the superolateral frontal region (area 8), just anterior to area 6 (see Figs. 22-1 and 22-2). In seizures of temporal lobe origin, early in the seizure, there may be head turning ipsilaterally followed by forceful, contraversive head (and body) turning. These head and body

movements, if they occur, are preceded by quiet staring or automatisms.

The *Jacksonian motor seizure* may also begin with a tonic contraction of the fingers of one hand, the face on one side, or the muscles of one foot. This transforms into clonic movements in these parts in a fashion analogous to that in

a generalized clonic-tonic-clonic convulsion. Sometimes a series of clonic movements of increasing frequency build up to a tonic contraction. The movements spread (“march”) from the part first affected to other muscles on the same side of the body. In this typical Jacksonian form, the seizure spreads from the hand, up the arm, to the face, and down the leg; or if the first movement is in the foot, the seizure marches up the leg, down the arm, and to the face, usually in a matter of 20 to 30 s. Interestingly, spontaneously occurring focal motor seizures, e.g., those beginning in the toes or fingers, may sometimes be arrested (inhibited) by applying a ligature above the affected part or, in the case of focal sensory seizures, by applying a vigorous sensory stimulus ahead of the advancing sensory aura. Rarely, the first muscular contraction is in the abdomen, thorax, or neck. In some cases, the one-sided seizure activity is followed by turning of the head and eyes to the convulsing side, occasionally to the opposite side, and then by a generalized seizure with loss of consciousness. Consciousness is not lost if the sensorimotor symptoms remain confined to one side.

Following convulsions that have a prominent focal motor signature, there may be a transient paralysis of the affected limbs. This “Todd’s paralysis” persists for minutes or at times for hours after the seizure, usually in proportion to the duration of the convulsion. Continued focal paralysis beyond this time usually indicates the presence of a focal brain lesion as the underlying cause of the seizure or persisting seizures in a nonconvulsive form. A similar Todd phenomenon is found in cases of focal epilepsy that involve the language, somesthetic, or visual areas; here the persistent deficit corresponds to the region of brain affected.

The high incidence of focal motor epilepsy that originates with movements in the face, hands, and toes is probably related to the disproportionately large cortical representation of these parts. The disease process or focus of excitation is usually in or near the rolandic (motor) cortex, i.e., area 4 of Brodmann (Figs. 3-3 and 22-2); in some cases, and especially if there is a sensory accompaniment, it has been found in the postrolandic convolution. Lesions confined to the motor cortex are reported to assume the form of clonic contractions, and those confined to the premotor cortex (area 6), tonic contractions of the contralateral arm, face, neck, or all of one side of the body. Tonic elevation and extension of the contralateral arm (“fencing posture”) and choreoathetotic and dystonic postures have been associated with high medial frontal lesions (area 8 and supplementary motor cortex), as have complex, bizarre, and flailing movements of a contralateral limb, but this always raises the suspicion of hysterical seizure. Perspiration and piloerection occur occasionally in parts of the body involved in a focal motor seizure, suggesting that these autonomic functions have a cortical representation in or adjacent to the rolandic area. Focal motor and Jacksonian seizures have essentially the same localizing significance.

Seizure discharges arising from the cortical language areas may give rise to a brief aphasic disturbance (*ictal aphasia*) and ejaculation of a word or, more frequently, a vocal arrest. Ictal aphasia is usually succeeded by other

focal or generalized seizure activity but may occur in isolation, without loss of consciousness, in which case it can later be described by the patient. Postictal aphasia is more common than ictal aphasia, which typically takes the form of complete speech arrest. Verbalization at the onset of a seizure has no consistent lateralizing significance and, paradoxically, is usually associated with an origin in the nondominant hemisphere. These disturbances should be distinguished from the stereotyped repetition of words or phrases or the garbled speech that characterizes some complex partial seizures or the postictal confusional state and, of course, Wernicke aphasia.

Somatosensory, Visual, and Other Types of Sensory Seizures

Somatosensory seizures, either focal or “marching” to other parts of the body on one side, are nearly always indicative of a focus in or near the postrolandic convolution of the opposite cerebral hemisphere. Penfield and Kristiansen found the seizure focus in the postcentral or precentral convolution in 49 of 55 such cases. The sensory disorder is usually described as numbness, tingling, or a “pins-and-needles” feeling and occasionally as a sensation of crawling (formication), electricity, or movement of the part. Pain and thermal sensations may occur but are exceedingly rare. In the majority of cases, the onset of the sensory seizure is in the lips, fingers, or toes, and the spread to adjacent parts of the body follows a pattern determined by sensory arrangements in the postcentral (postrolandic) convolution of the parietal lobe. If the sensory symptoms are localized to the head, the focus is in or adjacent to the lowest part of the convolution, near the sylvian fissure; if the symptoms are in the leg or foot, the upper part of the convolution, near the superior sagittal sinus or on the medial surface of the hemisphere, is involved.

Olfactory hallucinations, perhaps the most important of the sensory seizures because they signify a particular localization, are associated with disease of the inferior and medial parts of the temporal lobe, usually in the region of the parahippocampal convolution or the uncus (hence Jackson’s term *uncinate seizures* [see also Chap. 12]). Usually the perceived odor is exteriorized, i.e., projected to someplace in the environment, and is described as disagreeable or foul, though otherwise unidentifiable. *Gustatory hallucinations* also have been recorded in proven cases of temporal lobe disease and less often with lesions of the insula and parietal operculum; salivation and a sensation of thirst may be associated. Electrical stimulation in the depths of the sylvian fissure, extending into the insular region, has produced peculiar sensations of taste.

Visual seizures are relatively rare but also have localizing significance. Lesions in or near the striate cortex of the occipital lobe usually produce elemental visual sensations of darkness or sparks and flashes of light, which may be stationary or moving and colorless or colored. According to Gowers, red is the most frequently reported color, followed by blue, green, and yellow. These images may be referred to the visual field on the side opposite of the lesion or may appear straight ahead. If they occur on one side of the visual field, patients perceive that only

one eye is affected (the one opposite the lesion), probably because most persons are aware of only the temporal half of a homonymous field defect. Curiously, a seizure arising in one occipital lobe may cause momentary blindness in both fields. It has been noted that lesions on the lateral surface of the occipital lobe (Brodmann areas 18 and 19) are likely to cause a sensation of twinkling or pulsating lights. More complex or formed visual hallucinations are usually caused by a focus in the posterior part of the temporal lobe, near its junction with the occipital lobe, and may be associated with auditory hallucinations. The localizing value of visual auras has been confirmed by Bien and colleagues in a group of 20 surgically treated patients with intractable seizures. They found that elementary visual hallucinations and visual loss were typical of occipital lobe epilepsy but could also occur with seizure foci in the anteromedial temporal and occipitotemporal regions.

Auditory hallucinations are infrequent as an initial manifestation of a seizure and usually represent a psychotic disorder or one of several more benign conditions. Occasionally, a patient with a focus in one superior temporal convolution will report a buzzing or roaring in the ears. A human voice, sometimes repeating unrecognizable words, or the sound of music has been noted a few times with lesions in the more posterior part of one temporal lobe. Some people with epilepsy and a strong family history of seizures with auditory auras, may have normal imaging but turn out to have mutations in the LGI1 gene.

Vertiginous sensations of a type suggesting a vestibular origin may on rare occasions be the first symptom of a seizure. The lesion is usually located in the superoposterior temporal region or the junction between parietal and temporal lobes. In one of the cases reported by Penfield and Jasper, a sensation of vertigo was evoked by stimulating the cortex at the junction of the parietal and occipital lobes. Occasionally with a temporal focus, the vertigo is followed by an auditory sensation. Giddiness, or light-headedness, is a frequent prelude to a seizure, but this symptom, as discussed in Chap. 15, has so many different connotations that it is of little diagnostic value.

Vague and often indefinable *visceral sensations* arising in the thorax, epigastrium, and abdomen are among the most frequent of auras, as already indicated. Most often they have a temporal lobe origin, although in several such cases the seizure discharge has been localized to the upper bank of the sylvian fissure, in the upper or middle frontal gyrus, or in the medial frontal area near the cingulate gyrus. Palpitation and acceleration of the heart rate at the beginning of the attack have also been related mainly to a temporal lobe focus.

Focal Seizures Characterized by Altered Awareness or Responsiveness (Formerly Termed Complex Partial Seizures, Psychomotor Seizures, Temporal Lobe Seizures)

These differ from the major generalized and absence seizures discussed above in that (1) they signify a focal onset in the temporal lobe as reflected by an aura that may be

a hallucination or perceptual illusion, and (2) instead of a complete loss of control of thought and action, there is a period of altered behavior and consciousness, for which the patient is later found to be amnesic.

Although it is difficult to enumerate all the psychic experiences that may occur during these types of seizures, they may be categorized into a somewhat arbitrary hierarchy of illusions, hallucinations, depersonalization states, and affective experiences. Sensory illusions, or distortions of ongoing perceptions, are the most common. Objects or persons in the environment may shrink or recede into the distance, or they may enlarge (micropsia and macropsia), or perseverate as the head is moved (palinopsia). Tilting of the visual environment has been reported. Hallucinations are most often visual or auditory, consisting of formed or unformed visual images, sounds, and voices; less frequently, they may be olfactory (usually unpleasant, unidentifiable sensations of smell), gustatory, or vertiginous. Among the altered psychic states are a feeling of intense perception of familiarity in an unfamiliar circumstance or place (*déjà vu*) or, conversely, of strangeness or unfamiliarity (*jamais vu*) in a previously known place or circumstance. There may be the experience of autoscopy, a type of depersonalization, or dream-like state in which the patient views himself as an external observer. Fragments of certain old memories or scenes may insert themselves into the patient's mind and recur with striking clarity, or there may be an abrupt interruption of memory. (See Gloor for a more detailed description of the experiential phenomena of temporal lobe epilepsy.) Associated epigastric and abdominal sensations have been alluded to above and likely have their origin in autonomic and limbic structures.

Emotional experiences as a result of seizure, while less common, may be dramatic—fear, sadness, loneliness, anger, happiness, and sexual excitement have all been recorded. Fear and anxiety are the most common affective experiences, while occasionally the patient describes a feeling of rage or intense anger as part of a complex partial seizure. Ictal fear has no apparent connection to objective experience and is generally not related to the situation in which the patient finds himself during the seizure.

Each of these subjective psychic states may constitute the entire seizure or some combination may occur and immediately precedes a period of altered awareness. These "auras" represent electrical seizures as already mentioned and have the same localizing significance as motor convulsions do for the frontal cortex.

The motor components of a focal temporal lobe or limbic seizure, if they occur, arise during the later phase of the seizure and take the form of *automatisms* such as lip-smacking, chewing or swallowing movements, salivation, fumbling of the hands, or shuffling of the feet. Patients may walk around in a daze or act inappropriately (undressing in public, speaking incoherently, etc.). Certain complex acts that were initiated before the loss of consciousness—such as walking, chewing food, turning the pages of a book, or even driving—may continue. However, when asked a specific question or given a command, the patients are obviously out of contact with their surroundings. There may be no response at all, or

the patient may look toward the examiner in a perplexed way or utter a few stereotyped phrases. The patient may walk repetitively in small circles (*volvular epilepsy*), run (*epilepsia prokursiva*), or simply wander aimlessly, either as an ictal or postictal phenomenon (*poriomania*). These forms of seizure, according to some epileptologists, are actually more common with frontal lobe than with temporal lobe foci of origin.

In a very small number of patients with temporal lobe seizures (7 of 123 patients studied by Ebner et al), some degree of responsiveness (to simple questions and motor commands) is preserved in the presence of prominent automatisms such as lip-smacking and swallowing. Interestingly, in this small group of partially responsive patients, the seizures originate in the right temporal lobe.

The patient, in a confused and irritable state, may resist or strike out at the examiner. These types of behaviors, which occur in a limited number of patients with temporal lobe or frontal seizures, usually take the form of nondirected oppositional resistance to restraint. These behaviors manifest during a period of automatic behavior (so called because the patient presumably acts like an automaton) or, more often, in the postictal period. Unprovoked assault or outbursts of intense rage or blind fury are very unusual; Currie and associates found such outbursts in only 16 of 666 patients (2.4 percent) with temporal lobe epilepsy. Penfield once commented that he had never observed a rage state as a result of temporal lobe stimulation. It is exceedingly unlikely that an organized violent act requiring several sequential steps in its performance, such as obtaining a weapon and using it in a directed manner, could represent a temporal lobe seizure.

Rarely, laughter may be the most striking feature of a seizure (*gelastic epilepsy*). A particular combination of gelastic seizures and precocious puberty has been traced to a hamartoma of the hypothalamus. Crying, on the other hand, is very infrequent as a component of seizure and usually indicates a psychogenically induced episode.

Dystonic stiffness of the arm and leg contralateral to the seizure focus is found to be an accompaniment of temporal lobe seizures (more often this is from the supplementary motor of the frontal than the temporal lobes).

The patient with temporal lobe seizures may exhibit only one of the foregoing manifestations of seizure activity or various combinations. In a series of 414 patients studied by Lennox, 43 percent displayed some of the motor changes; 32 percent, automatic behavior; and 25 percent, alterations in psychic function. Because of the frequent concurrence of these symptom complexes, he referred to them as the *psycho-motor triad*. Probably the clinical pattern varies with the precise locality of the lesion and the direction and extent of spread of the electrical discharge.

After the attack, the patient usually has no memory or only fragments of recall for what was said or done. Any type of complex partial seizures may proceed to other forms of secondary generalized seizures. The tendency to generalization holds true for all types of partial or focal epilepsy.

Temporal lobe seizures are not peculiar to any period of life, but they do show an increased incidence in adolescence and the adult years and have an uncertain

relationship to febrile seizures. The topic of febrile seizures is broader than this association suggests; it is taken up in a later section of the chapter. Neonatal convulsions, head trauma, and various other non-progressive perinatal neurologic disorders are other antecedents that place a child at risk of developing complex partial seizures (Rocca et al). Two-thirds of patients with temporal lobe seizures also have generalized tonic-clonic seizures or have had them in early childhood, and it has been theorized that the generalized seizures may have led to secondary excitotoxic damage to the hippocampal portions of the temporal lobes. In the latter cases, carefully performed and quantitated MRI in the coronal plane may disclose a loss of volume in the hippocampi and adjacent gyri on one or both sides—i.e., *medial temporal sclerosis* (Fig. 16-4).

Temporal lobe seizures are highly variable in duration. Behavioral automatisms rarely last longer than a minute or two, although postictal confusion and amnesia may persist for a considerably longer time. Some consist only of a momentary change in facial expression and a blank spell, resembling an absence. Almost always, however, temporal lobe events are characterized by distinct ictal and postictal phases, whereas patients with absence attacks usually have an instantaneous return of full consciousness following the ictus.

Postictal behavior after temporal lobe seizures is often accompanied by widespread or focal slowing in the EEG. Prolonged disorientation for time and place suggests a right-sided source. Automatisms in the postictal period have no lateralizing connotation (Devinsky et al). However, postictal posturing and paresis of an arm (*Todd's paralysis*) or an aphasic difficulty are helpful in determining the side of the lesion (Cascino). Postictal nose wiping, which is reported on video recording to occur in half of patients with temporal lobe seizures, is carried out by the hand ipsilateral to the seizure focus according to Leutzmezer and colleagues, but we are in no position to confirm this.

Amnesic Seizures (Transient Epileptic Amnesia)

Rarely, recurrent attacks of transient amnesia are the only manifestations of temporal lobe epilepsy, although it is unclear whether the amnesia in such patients represents an ictal or postictal phenomenon. These attacks of pure amnesia have been referred to as *transient epileptic amnesia* (TEA; Palmieri et al; Zeman et al). If the patient functions at a fairly high level during the attack, as may happen, there is a resemblance to transient global amnesia (described in Chap. 20). However, in contrast to transient global amnesia, the relative brevity and frequency of the amnesic spells, their tendency to occur on awakening, the impaired performance on complex cognitive tasks, and the absence of repetitive stereotyped questions help to make the distinction.

Behavioral and Psychiatric Disorders with Epilepsy

Some comments are in order concerning the issues of *behavioral and psychiatric disorders* in patients who have seizures. Data as to prevalence of these disorders have been

Figure 16-4. Medial temporal sclerosis. *A.* T1-weighted MRI in the coronal plane, showing reduced volume of the left hippocampus (shown by arrow) and secondary enlargement of the adjacent temporal horn of the lateral ventricle. *B.* Coronal T2-FLAIR image showing abnormal hyperintense signal within the left hippocampus (shown by arrow).

derived mainly from studies of selected groups of patients attending university hospitals and other specialty clinics that tend to treat the most difficult and complicated cases. In one such study (Victoroff), approximately one-third of epileptic patients had a history of major depressive illness, and an equal number had symptoms of anxiety disorder; psychotic symptoms were found in 10 percent. Similar figures, also from a university-based epilepsy center, have been reported by Blumer et al. It must be emphasized that these remarkably high rates of psychiatric morbidity do not reflect the prevalence in the entire population of patients with epilepsy. Epidemiologic studies provide only limited evidence of an association with psychosis in the overall population of epileptics (see Trimble and Schmitz and the review by Trimble for a critical discussion of this subject). Furthermore, it should be borne in mind that many chronic medical conditions are associated with psychiatric reactions. On the other hand, the unpredictability and stigma of the epileptic disorders may contribute to depression and anxiety.

The postictal state in patients with temporal lobe epilepsy rarely incorporates a protracted *paranoid-delusional* or *amnesic psychosis* lasting for days or weeks. The EEG during this period may show no seizure discharge, although this does not exclude repeated seizures in temporal lobe structures that are remote from the recording electrodes. This disorder, virtually indistinguishable from psychosis, may also present in the interictal period.

It had been observed that some patients with temporal lobe seizures may exhibit a number of personal peculiarities. It was stated that they are slow and rigid in their thinking, verbose, circumstantial and tedious in conversation, inclined to mysticism, and preoccupied with rather naive religious and philosophical ideas. Obsessionalism, humorless sobriety, emotionality (mood swings, sadness, and anger), and a tendency to paranoia are other frequently described traits. Diminished sexual interest and potency in men and menstrual problems in women, not readily attributable to antiepileptic drugs, are common among patients with complex partial seizures of temporal lobe origin. Geschwind proposed that a triad of behavioral abnormalities—hyposexuality, hypergraphia, and hyperreligiosity—constitutes a characteristic syndrome.

Bear and Fedio suggested that certain personality traits were more common with *right* temporal lesions, and that anger, paranoia, and cosmologic or religious conceptualizing are more characteristic of *left* temporal lesions. However, Rodin and Schmaltz found no features that would distinguish foci on either side and they found no behavioral changes that would distinguish patients with temporal lobe epilepsy from other groups of epileptics. The problem of personality disturbances in epilepsy has not been clarified and modern clinicians no longer identify these traits as parts so the epileptic syndrome, having in the past been imputed to these

patients by societal and medical biases (see review by Trimble).

Sudden Unexplained Death in Epilepsy (SUDEP)

In the past few decades, sudden death has been emphasized as an underappreciated problem in the epileptic population. Certainly, the mortality in individuals with epilepsy is increased ostensibly from accidents, suicide, and the underlying cause of seizures. However, the main contributor to the increased mortality rate in healthy people with epilepsy is unexpected death outside of circumstances such as drowning, trauma from a fall, myocardial infarction, and automobile accidents during the seizure. It is to this group that the acronym "SUDEP" has been applied. Surprisingly, unexpected death is predominantly an issue of adulthood more than of childhood. The rate of unexpected death increases with the duration and severity of epilepsy and several population studies suggest that the rate may be as high as 9% lifetime incidence but others cite a much lower figure. Most patients affected have a history of generalized tonic-clonic seizures and die in bed. In children, those with treatment resistant epilepsy, developmental delay and several syndromes such as tuberous sclerosis are at particular risk.

Several factors have emerged as risks from population-based and cohort case controlled studies; the postictal period immediately after a tonic clonic seizure, increasing seizure frequency (including three generalized seizures in the preceding year), lack of successful treatment (i.e., patients not in remission as documented in a 40 year follow up of childhood epilepsy by Sillanpää and Shinnar), or subtherapeutic levels of antiepileptic drugs, the period of early adulthood, long-standing epilepsy, and mental retardation.

Most instances of SUDEP occur when the patient is unattended or during sleep. Although respiratory difficulty and cardiac changes including asystole and ventricular arrhythmias are known to occur during and immediately after seizures, none of these has been a consistent factor and usually, the precise mechanism of death has been difficult to determine. A postictal "shutdown" of brainstem activity resulting in hypercapnia or hypoxemia has been suggested.

One approach to preventing sudden death is adequate treatment with antiepileptic drugs. The risk of sudden death is as high as 20 times greater for untreated patients. Some specialists in the field of epilepsy have suggested that an open conversation be undertaken about the problem with patients and their families. More often, neurologists raise the issue only in high risk patients or when specifically asked. A review of this subject has been provided by Devinsky.

SPECIAL EPILEPTIC SYNDROMES

There remain to be considered several epileptic syndromes and other seizure states that cannot be readily classified with the usual types of generalized or partial seizures.

Benign Epilepsy of Childhood with Centrotemporal Spikes (Rolandic Epilepsy, Sylvian Epilepsy)

This common focal motor epilepsy is unique among the focal epilepsies of childhood in that it is self-limiting despite a very abnormal EEG pattern. It is usually transmitted in families as an autosomal dominant trait and begins between 5 and 9 years of age. It typically announces itself by a nocturnal tonic-clonic seizure with focal onset. Thereafter, the seizures take the form of clonic contractions of one side of the face, less often of one arm or leg, and the interictal EEG shows high-voltage spikes in the contralateral lower rolandic or centrotemporal area. Seizures are readily controlled by a single anticonvulsant drug and gradually disappear during adolescence. The relation of this syndrome to developmental dyslexia is unsettled.

Epilepsy with Occipital Spikes

A similar type of epilepsy, usually benign in the sense that there is no intellectual deterioration and the seizures often cease in adolescence, has been associated with spike activity over the occipital lobes as identified by Panayiotopoulos. Visual hallucinations, while not invariable, are the most common clinical feature, according to the review by Taylor and colleagues; sensations of movements of the eyes, tinnitus, or vertigo are also reported in cases of occipital epilepsy. These authors point out symptomatic causes of the syndrome, mainly cortical heterotopias. In both of these types of childhood epilepsy the observation that spikes are greatly accentuated by sleep is a useful diagnostic sign.

Infantile Spasms (West Syndrome)

This term is applied to a special and particularly dramatic form of epilepsy of infancy and early childhood. West, in the mid-nineteenth century, described the condition in his son in great detail. This disorder, which in most cases appears during the first year of life, is characterized by recurrent, single or brief episodes of gross flexion movements of the trunk and limbs and, less frequently, by extension movements (hence the alternative terms *infantile spasms* or *salaam* or *jackknife seizures*). Most but not all patients with this disorder show major EEG abnormalities consisting of continuous multifocal spikes and slow waves of large amplitude. However, this pattern, named by Gibbs and Gibbs as *hypsarhythmia* ("mountainous" dysrhythmia), is not specific for infantile spasms, being frequently associated with other developmental or acquired abnormalities of the brain. As the child matures, the seizures diminish and usually disappear by the fourth to fifth year. If MRI and CT scans are more or less normal, the usual pathologic findings according to Jellinger are cortical dysgeneses. Both the seizures and the EEG abnormalities may respond dramatically to treatment with adrenocorticotrophic hormone (ACTH), corticosteroids, or the benzodiazepine drugs, of which clonazepam is probably the most widely used. A type of West syndrome that

is caused by tuberous sclerosis also responds dramatically to gamma-aminobutyric acid (GABA)-inhibiting drugs such as vigabatrin, as noted below. However, most patients, even those who were apparently normal when the seizures appeared, are left mentally impaired. Infantile spasms may later progress to the *Lennox-Gastaut syndrome*, a seizure disorder of early childhood of graver prognosis as discussed in a previous section.

Febrile Seizures

The well-known uncomplicated *febrile seizure*, specific to infants and children between 6 months and 5 years of age (peak incidence ages 9 to 20 months) and with a strong inherited tendency, is generally regarded as a benign condition. It usually takes the form of a single, generalized motor seizure occurring as the patient's core temperature rises or reaches its peak. Seldom does the seizure last longer than a few minutes and by the time an EEG can be obtained, there is no abnormality and recovery is complete. The temperature is usually above 38°C (100.4°F). Any viral or bacterial illness, or, rarely, an immunization, may be the precipitant of the fever; herpesvirus 6 is one of the common precipitants, probably because of its tendency to cause high fever. Prophylactic antiepileptic drugs have not been found to be helpful in preventing febrile seizures. Except for a presumed genetic relationship with benign epilepsy of childhood (Luders et al), which in itself is transient in nature, these patients' risk of developing epilepsy in later life is only slightly greater than that of the general population. In some families, such as those studied by Nabbout and colleagues, febrile seizures alone, without generalized epilepsy, have been associated with a particular gene by linkage analysis. Presumably, when the gene products are identified, some insight into the nature of defects that lower the seizure threshold will be forthcoming.

This benign type of febrile seizure should not be confused with more serious illnesses in which a febrile acute encephalitic or encephalopathic state causes focal or prolonged seizures, generalized or focal EEG abnormalities, and repeated episodes of febrile convulsions during a febrile illness (*complicated febrile seizures*). In these cases, these seizures may recur not only with infections but also at other times. When patients with both types are combined together under the rubric of *febrile convulsions*, it is not surprising that a high percentage are complicated by later atypical petit mal, atonic, and astatic spells followed by tonic seizures, mental retardation, and partial complex epilepsy. In a study of 67 patients with medial temporal lobe epilepsy by French and colleagues, 70 percent had a history of complicated febrile seizures during the first 5 years of life, although many did not again develop seizures until their teens. Bacterial meningitis was an important risk factor; head and birth trauma were less-common factors. Epidemiologic studies have substantiated this clinical point of view. Annegers and colleagues observed a cohort of 687 children for an average of 18 years after their initial febrile convulsion. Overall, these children had a five-fold excess of unprovoked seizures in later life. Among the children with simple febrile convulsions,

the risk was only 2.4 percent. By contrast, children with what Annegers and colleagues called complex febrile convulsions (focal, prolonged, or repeated episodes of febrile seizures) had a greatly increased risk—8, 17, or 49 percent, depending on the association of one, two, or three of the complicating features.

Reflex Epilepsies

It has been appreciated for a long time that seizures can be evoked in certain individuals by a discrete physiologic or psychologic stimulus. The term *reflex epilepsy* is reserved for this small subgroup. Forster classified these seizures in accordance with their evocative stimuli into five types: (1) *visual*—flickering light, visual patterns, and specific colors (especially red), leading to rapid blinking or eye closure; (2) *auditory*—sudden unexpected noise (startle), specific sounds, musical themes, and voices; (3) *somatosensory*—either a brisk unexpected tap or sudden movement after sitting or lying still, or a prolonged tactile or thermal stimulus to a certain part of the body; (4) *writing or reading* of words or numbers; and (5) *eating*.

Visually induced seizures are by far the most common type. The seizures are usually myoclonic but may be generalized and triggered by the photic stimulation of television or an EEG examination or by the photic or pattern stimulation of video games. In other types of reflex epilepsy, the evoked seizure may be focal (beginning often in the part of the body that was stimulated) or generalized and may take the form of one or a series of myoclonic jerks or of an absence or tonic-clonic seizure. Seizures induced by reading, voices, or eating are most often of the complex partial type; seizures induced by music are usually myoclonic, simple, or complex partial. A few such instances of reflex epilepsy have been caused by focal cerebral disease, particularly occipital lesions.

Clonazepam, valproate, carbamazepine, and phenytoin (as well as many of the new antiepileptic drugs) are all effective in controlling individual instances of reflex epilepsy. Some patients learn to avert the seizure by undertaking a mental task, e.g., thinking about some distracting subject, counting, etc., or by initiating some type of physical activity. Forster has demonstrated that in certain types of reflex epilepsy, the repeated presentation of the stimulus may eventually render the trigger innocuous but this requires a great deal of time and reinforcement, which limits its therapeutic value.

Epilepsia Partialis Continua

This is a special type of focal motor epilepsy characterized by persistent rhythmic clonic movements of one muscle group—usually of the face, arm, or leg—which are repeated at fairly regular intervals every few seconds and continue for hours, days, weeks, or months without spreading to other parts of the body. Thus *epilepsia partialis continua* is, in effect, a highly restricted and very persistent focal motor status epilepticus. The distal muscles of the leg and arm, especially the flexors of the hand and fingers, are affected more frequently than the proximal ones. In the face, the recurrent contractions involve either the corner

of the mouth or one or both eyelids. Occasionally, isolated muscles of the neck or trunk are affected on one side. The clonic activity may be accentuated by active or passive movement of the involved muscles and may be reduced in severity but not abolished during sleep.

First described by Kozhevnikov in patients with Russian spring-summer encephalitis, these ongoing partial seizures may be induced by a variety of acute or chronic cerebral lesions. In some cases the underlying disease is not apparent (this has applied to most of the cases in our experience), and the clonic movements may be mistaken for some type of slow tremor or extrapyramidal movement disorder. Most patients with epilepsy partialis continua show focal EEG abnormalities, either repetitive slow-wave abnormalities or sharp waves or spikes over the central areas of the contralateral hemisphere. In some cases, the spike activity can be related precisely in location and time to the clonic movements (Thomas et al). In the series collected by Obeso and colleagues, there were various combinations of epilepsy partialis continua and cutaneous reflex myoclonus (cortical myoclonus occurring only in response to a variety of afferent stimuli).

As would be expected, a wide range of causative lesions has been implicated—developmental anomalies, encephalitis, demyelinating diseases, tumors, metabolic abnormalities, particularly hyperosmolarity, and degenerative diseases; but in many instances, as already emphasized, the underlying cause is not found even after extensive investigation. Epilepsy partialis continua is particularly common in patients with the rare condition, Rasmussen encephalitis (see further on).

Whether cortical or subcortical mechanisms are responsible for epilepsy partialis continua is an unresolved question. The electrophysiologic evidence adduced by Thomas and colleagues favors a cortical origin; the pathologic evidence is less definite. In each of eight cases in which the brain was examined postmortem, they found some degree of involvement of the motor cortex or adjacent cortical area contralateral to the affected limbs. However, all but one of these patients also had some involvement of deeper structures on the same side as the cortical lesion, on the opposite side, or on both sides.

Rasmussen Syndrome

In rare cases, a lesion, usually identified by MRI and confirmed by biopsy, and in some cases by special auto-antibodies, takes the form of a chronic focal encephalitis. In 1958, Rasmussen described three children in whom the clinical problem consisted of intractable focal epilepsy in association with a progressive hemiparesis. The cerebral cortex disclosed a mild meningeal infiltration of inflammatory cells and an encephalitic process marked by neuronal destruction, gliosis, neuronophagia, some degree of tissue necrosis, and perivascular cuffing. Many additional cases were soon uncovered and Rasmussen was able to summarize the natural history of 48 personally observed patients (see the often cited monograph by Andermann).

An expanded view of the syndrome has added several interesting features. The affected children are typically ages 3 to 15 years, more girls than boys. Half of

them have epilepsy partialis continua. The progression of the disease leads to hemiplegia or other deficits and focal brain atrophy in most cases. The neuropathology of five fully examined cases has revealed extensive destruction of the cortex and white matter with intense gliosis and lingering inflammatory reactions.

The CSF shows a pleocytosis and sometimes oligoclonal bands but these are not uniform findings. Focal cortical and subcortical lesions are usually visualized by MRI and are bilateral in some cases. The finding of antibodies to glutamate receptors (GluR3) in a proportion of patients with Rasmussen encephalitis has raised interest in an immune causation (see review by Antel and Rasmussen). An autoimmune hypothesis has been supported by the findings of Twyman and colleagues that these antibodies cause seizures in rabbits and lead to the release of the neurotoxin kainate in cell cultures. However, Wendl's group and others have found these antibodies in many types of focal epilepsy and have questioned their specificity.

The unrelenting course of the disease had in the past defied medical therapy. In some patients the process eventually burns out, but in those with continuous focal epilepsy the seizures continued despite all antiepileptic drugs. The use of high doses of corticosteroids, when started within the first year of the disease, proved beneficial in 5 of the 8 patients treated by Chinchilla and colleagues. Repeated plasma exchanges and immune globulin have also been tried, but the results are difficult to interpret. When the disease is extensive and unilateral, neurosurgeons have resorted to partial hemispherectomy.

PSYCHOGENIC NONEPILEPTIC SEIZURES (PNES, PSEUDOSEIZURES)

These common episodes, which simulate convulsive or nonconvulsive seizures, are not the result of an abnormal neuronal discharge. They have been termed psychogenic non-epileptic seizures (PNES) and comprise a heterogeneous group of disorders that are easily mistaken for epileptic spells. Moreover, they comprise a large proportion of treatment resistant epilepsy and often are treated with multiple antiepileptic drugs, to which they are unresponsive. It has been estimated that 70% of people diagnosed with PNES have been previously diagnosed and treated for epilepsy. In large series, non-epileptic seizures comprise 4% of cases of transient loss of consciousness, 20% of referrals to specialist epilepsy services, and 50% of apparent status epilepticus. It should be emphasized that patients with true epileptic seizures can exhibit psychogenic ones as well, making the distinction between the two particularly difficult. It is this population that proves most vexing (and common) in specialty epilepsy services.

Our current conceptualization is that the condition arises as a behavioral response to underlying emotional or psychological distress. Episodes may be derived from traumatic experiences in early life, particularly physical, sexual, and mental abuse during childhood. Many experts consider them to be allied with hysteria (*Briquet disease*,

conversion disorder, as discussed in Chap. 56) or malingering. Recent studies suggest that a conversion-hysterical disorder accounts for most cases, even in males, and that malingering is rare but this has certainly not been our experience.

Three broad categories of psychogenic states seem to generate pseudoseizures: (1) panic disorder that is itself common in people with epilepsy; (2) dissociative disorders, in which convulsions are typically prolonged, resembling generalized tonic-clonic seizures, or alternatively, swooning as in a faint or presyncopal spell, or blank spells that closely simulate absence seizure; and (3) malingering, the deliberate feigning of seizures to avoid certain situations, e.g., imprisonment.

Usually, the unconventional motor display in the course of a nonepileptic seizure is sufficient to identify it as such: completely asynchronous thrashing of the limbs and repeated side-to-side movements of the head; striking out at a person who is trying to restrain the patient; hand-biting, kicking, trembling, and quivering; pelvic thrusting and opisthotonic arching postures; and screaming or talking during the ictus. It is helpful to observe that the eyes are kept quietly or forcefully closed in pseudoseizure whereas the lids are open or show clonic movement in epilepsy. Psychogenic spells are likely if attacks are prolonged (many minutes, even hours), if there is rapid breathing (whereas apnea is typical during and after a seizure), or if there is tearfulness after an episode. Pseudoseizures tend to occur in the presence of observers, to be precipitated by emotional factors. With few exceptions, tongue-biting, incontinence, hurtful falls, or postictal confusion are lacking but if the tongue is bitten in a pseudoseizure it is usually the front, compared to the lateral tongue injury that is characteristic of an epileptic attack. Incontinence does not assist in making a clear distinction from epileptic seizures.

Another clue to non-epileptic seizures in our experience has been highly resistant epilepsy in an individual with normal intellect and normal brain imaging. Often in these persons in particular, there has been a background of unexplained medical problems, previous psychological problems (depression, panic disorder, overdose, self harm, addiction), and a life story that includes intense emotional trauma. Prolonged *fugue states* usually prove to be manifestations of hysteria or a psychopathy, even in a known epileptic.

The serum creatine kinase levels are normal after nonepileptic seizures; this may be helpful in distinguishing them from epilepsy. Where doubt remains, a recording of the ictal or postictal EEG or the prolonged combined video and EEG recording of an attack may settle the issue.

THE NATURE OF THE DISCHARGING LESION IN EPILEPSY

Physiologically, the epileptic seizure has been defined as a sudden alteration of central nervous system (CNS) function resulting from a paroxysmal high-frequency

or synchronous low-frequency, high-voltage electrical discharge. This discharge arises from an assemblage of excitable neurons in any part of the cerebral cortex and possibly in secondarily involved subcortical structures as well. Of course, there need not be a visible lesion in the brain. In the proper circumstances, a seizure discharge can be initiated in an entirely normal cerebral cortex, as when the cortex is activated by ingestion of drugs, or by withdrawal from alcohol or other sedative drugs. A special mechanism that ostensibly creates a secondary seizure focus, "kindling," is the result of repeated stimulation with subconvulsive electrical pulses from an established focus elsewhere; it is known to occur in animal models but is a controversial entity in humans.

Viewed from a larger physiologic perspective, seizures require three conditions: (1) a population of pathologically excitable neurons; (2) an increase in excitatory, mainly glutaminergic, activity through recurrent connections in order to spread the discharge; and (3) a reduction in the activity of the normally inhibitory GABAergic projections. Each of these has been challenged but is supported by considerable data and together they serve as a reasonable model, as noted below. Understanding of the initial discharges and their spread has been advanced by the identification of several rare forms of familial epilepsy that are the result of mutations in sodium, potassium, acetylcholine receptor, or GABA channels on neurons. These are discussed further on under "Role of Genetics."

Just why the neurons in or near a focal cortical lesion discharge spontaneously and synchronously is not fully understood. Some of the electrical properties of a cortical epileptogenic focus suggest that its neurons have been deafferented. Neurons in these circumstances are hyperexcitable, and they may chronically remain in a state of partial depolarization, able to fire irregularly at rates as high as 700 to 1,000 per second. The cytoplasmic membranes of such cells have an increased ionic permeability, which renders them susceptible to activation by hyperthermia, hypoxia, hypoglycemia, hypocalcemia, and hyponatremia, as well as by repeated sensory (e.g., photic) stimulation and during certain phases of sleep (where *hypersynchrony* of neurons occurs).

As an example, epileptic foci induced in the animal cortex by the application of penicillin are characterized by spontaneous interictal discharges, during which the neurons of the discharging focus exhibit large, calcium-mediated paroxysmal depolarizations (depolarizing shifts), followed by prolonged afterhyperpolarizations. The latter are caused in part by calcium-dependent potassium currents, but enhanced synaptic inhibition also plays a role. The depolarizing shifts occur synchronously in the penicillin focus and summate to produce surface-recorded interictal EEG spikes; the afterpolarizations correspond to the slow wave of the EEG spike-and-wave complex (see Engel). The neurons surrounding an epileptogenic focus are hyperpolarized and release inhibitory GABA. The spread of seizures depends on factors that activate neurons in the focus or inhibit those surrounding it. Beyond this, the precise mechanism that governs the transition from a circumscribed

interictal discharge to a widespread seizure state is not understood.

Biochemical studies of neurons from a seizure focus have not greatly clarified the problem. Levels of extracellular potassium are elevated in glial scars near epileptic foci, and a defect in voltage-sensitive calcium channels has also been postulated. Epileptic foci are known to be sensitive to acetylcholine and to be slower in binding and removing it than is normal cerebral cortex. A deficiency of the inhibitory neurotransmitter GABA, increased glycine, decreased taurine, and either decreased or increased glutamic acid have been variously reported in excised human epileptogenic tissue, but whether these changes are the cause or result of seizure activity has not been determined. The interpretation of reported abnormalities of GABA, biogenic amines, and acetylcholine in the cerebrospinal fluid (CSF) of epileptic patients poses great difficulties.

Concurrent EEG recordings from an epileptogenic cortical focus and subcortical, thalamic, and brainstem centers in the animal model have enabled investigators to construct a sequence of electrical and clinical events that characterize an evolving focal seizure. Firing of the involved neurons in the cortical focus is reflected in the EEG as a series of periodic spike discharges, which increase progressively in amplitude and frequency. Once the intensity of the seizure discharge exceeds a certain point, it overcomes the inhibitory influence of surrounding neurons and spreads to neighboring cortical regions via short corticocortical synaptic connections. If the abnormal discharge remains confined to the cortical focus and the immediate surrounding cortex, there are probably no clinical symptoms or signs of seizure, and the EEG abnormality that persists during the interseizure period reflects this restricted type of abnormal cortical activity.

A provocative finding, based on sophisticated mathematical analysis of EEG tracings, indicates that subtle electrographic changes arise several minutes before the ictal discharge (see LeVan Quyen et al). This suggests that seizures could be triggered either by a change in central thalamic rhythm generators or a subtle alteration in the electrical activity in the region of a focal lesion. Of interest are the findings of Litt and colleagues that in a small number of patients there are prolonged bursts of seizure-like activity detected by sophisticated techniques even days before the onset of temporal lobe seizures. Their proposal is that these events cause a cascade of electrophysiologic changes that very gradually culminate in a seizure.

If unchecked, cortical excitation spreads to the adjacent cortex and to the contralateral cortex via interhemispheric pathways, and also to anatomically and functionally related pathways in subcortical nuclei (particularly the basal ganglionic, thalamic, and brainstem reticular nuclei). It is at this time that the clinical manifestations of the seizure begin. The excitatory activity from the subcortical nuclei is conceived to feed back to the original focus and to other parts of the cerebrum, a mechanism that serves to amplify their excitatory activity and to give rise to the characteristic high-voltage polyspike discharge in the EEG. The spread of excitation to the

subcortical, thalamic, and brainstem centers corresponds to the tonic phase of the seizure and to loss of consciousness as well as to the signs of autonomic nervous system overactivity (salivation, mydriasis, tachycardia, increased blood pressure). Breathing may be arrested, but usually for only a few seconds. The development of unconsciousness and the generalized tonic contraction of muscles are reflected in the EEG by a diffuse high-voltage discharge pattern appearing simultaneously over the entire cortex.

Soon after the spread of excitation, a diencephalic inhibition begins and intermittently interrupts the seizure discharge, changing it from the persistent tonic phase to the intermittent bursts of the clonic phase. In the surface EEG, a transition occurs from a continuous polyspike to a spike-and-wave pattern. The intermittent clonic bursts become decreasingly frequent and finally cease altogether, leaving in their wake an "exhaustion" (paralysis) of the neurons of the epileptogenic focus and a regional increase in permeability of the blood-brain barrier and regional edema in magnetic resonance images. An excess of these inhibitory mechanisms and metabolic exhaustion are thought to be the basis of *Todd's postepileptic paralysis* and of postictal stupor, sensory loss, aphasia, hemianopia, headache, and diffuse slow waves in the EEG. Plum and associates observed a two- to threefold increase in glucose utilization during seizure discharges and suggested that the paralysis that follows might be a result of neuronal depletion of glucose and an increase in lactic acid. However, inhibition of epileptogenic neurons may occur in the absence of neuronal exhaustion. The exact roles played by each of these factors in postictal paralysis of function are not settled.

Insights to absence seizures have been obtained from animal models of bilaterally synchronous 3-per-second high-voltage spike-and-wave discharges. The spike-and-wave complex, which represents brief excitation followed by slow-wave inhibition, is the type of EEG pattern that characterizes the clonic (inhibitory) phase of the focal motor or grand mal seizure. By contrast, this strong element of inhibition is present diffusely throughout an "absence" attack, a feature that perhaps accounts for the failure of excitation to spread to lower brainstem and spinal structures (tonic-clonic movements do not occur). However, the absence seizure can also at times activate the mechanism for rhythmic myoclonus, probably at an upper brainstem level.

Current physiologic data indicate that the characteristic EEG patterns of generalized forms of epilepsy are generated entirely in the neocortex but are enhanced by the synchronizing influences of subcortical structures. The generalization of the clinical and electrical manifestations depends upon activation of a deep, centrally located physiologic mechanism, which, as outlined in Chap. 17, includes the midbrain reticular formation and its diencephalic extension, the intralaminar and nonspecific thalamic projection systems (originally referred to by Penfield as the "centrencephalon"). There is little evidence, however, that seizure activity originates in these deep structures; thus the term *centrencephalic* has been replaced by *corticoreticular epilepsy*.

Of theoretical importance is the observation that a seizure focus may establish, via commissural connections, a persistent secondary focus in the corresponding cortical area of the opposite hemisphere (*mirror focus*). The nature of this phenomenon is obscure; it may be similar to the “kindling” phenomenon mentioned earlier in animals, where a repeated nonconvulsive electrical stimulation of normal cortex induces a permanent epileptic focus. No morphologic change is visible in the mirror focus, at least by light microscopy. The mirror focus may be a source of confusion when trying to identify the side of the primary discharging lesion by EEG. However, there is only limited evidence that mirror foci of the kindling phenomenon produce seizures in humans (see Goldensohn).

Severe seizures may be accompanied by a systemic lactic acidosis with a fall in arterial pH, reduction in arterial oxygen saturation, and rise in P_{CO_2} . These effects are secondary to the respiratory arrest and excessive muscular activity. If prolonged, they may cause hypoxic-ischemic damage to remote areas in the cerebrum, basal ganglia, and cerebellum. In paralyzed and artificially ventilated subjects receiving electroconvulsive therapy, these changes are less marked and the oxygen tension in cerebral venous blood may actually rise. Heart rate, blood pressure, and particularly CSF pressure rise briskly during an ECT-induced seizure. According to Plum and colleagues, the rise in blood pressure evoked by a seizure usually causes a sufficient increase in cerebral blood flow to meet the increased metabolic needs of the brain.

EEG AND LABORATORY TESTING IN EPILEPSY

The origins of EEG activity of an epileptic focus and the generalization of seizures are discussed in Chap. 2 and earlier in this chapter. The EEG provides confirmation of Hughlings Jackson’s concept of epilepsy—that it represents a recurrent, sudden, excessive discharge of cortical neurons. The EEG is the most sensitive, indeed indispensable, tool for the diagnosis of epilepsy; but like other ancillary tests, it must be used in conjunction with clinical data. In patients with idiopathic generalized seizures, and in a high proportion of their relatives, interictal spike-and-wave abnormalities without any clinical seizure activity are common, especially if the EEG is repeated several times or taken over long periods. By contrast, a proportion of epileptic patients have a perfectly normal interictal EEG. Using standard methods of scalp recording, the EEG may even be normal during the experiential aura of a simple or complex partial seizure. Furthermore, interpretation of EEG abnormalities must take into account that a small number of healthy persons (approximately 2 to 3 percent) show paroxysmal EEG abnormalities.

A single EEG tracing obtained during the interictal state is abnormal to some degree in 30 to 50 percent of epileptic patients; this figure rises to 60 to 70 percent

if patients are subjected to several recordings. Many EEG patterns are possible in seizures. One consistent observation, however, has been that the region of earliest spike activity corresponds best to the epileptogenic focus, a rule that has come to guide epilepsy surgery. The postseizure or postictal state also has an EEG correlate, taking the form of random generalized slow waves after generalized seizures and focal slowing following partial seizures. With clinical recovery, the EEG returns to normal or to the pre-seizure state.

A higher yield of abnormalities and a more precise definition of seizure types can be obtained by the use of several special EEG procedures, as described in Chap. 2. Here it is restated that activating procedures such as hyperventilation, photic stroboscopic stimulation, and sleep increase the yield of EEG recordings. EEG recording during sleep is particularly helpful because focal abnormalities, particularly in the temporal lobes, may become prominent in slow-wave and stage II sleep. Sphenoidal leads have been used to detect inferomedial temporal seizure activity, but they are uncomfortable and probably add little more information than can be obtained by the placement of additional subtemporal scalp electrodes. Nasopharyngeal electrode recordings are too contaminated by artifact to be clinically useful.

Beyond dependably identifying artifacts in the EEG recording, one of the main challenges for the electroencephalographer is to differentiate between normal patterns that simulate seizures and true epileptic or interictal discharges. These paroxysmal but ostensibly normal patterns appear mostly during sleep, each with a highly characteristic morphology. These include small sharp spikes, “14 and 6” polyspike activity, lambda and posterior occipital mu rhythm, and occipital sharp transients. These are pictured in most standard textbooks on the subject of EEG and discussed in Chap 2.

Several methods of *long-term EEG monitoring* are now in common use and are of particular value in the investigation of patients with surgically removable epileptogenic foci and of non-epileptic spells. The most common of these makes use of telemetry systems, in which the patient is attached to the EEG machine by cable or radio transmitter without unduly limiting freedom of movement. The telemetry system is joined to an audiovisual recording system, making it possible to record seizure phenomena (even at night, under dim infrared light) and to synchronize them with the EEG abnormalities. An alternative is the use of a small digital recording device that is attached to a miniature EEG machine worn by the patient at home and at work (“ambulatory EEG”). The patient is instructed to push a button if he experiences an “event,” which can later be correlated with EEG activity.

Other Laboratory Abnormalities Associated with Seizures

MRI is the most useful tool for the detection of structural abnormalities underlying epilepsy. Medial temporal sclerosis, heterotopias and other disorders of neuronal migration, glial scars, and porencephaly can be clearly visualized.

After a seizure, particularly one with a focal component, MRI sometimes discloses subtle focal cortical swelling and signal change in the FLAIR (fluid-attenuated inversion recovery) and diffusion-weighted sequences, or, if a contrast agent is administered, an ill-defined cortical blush may be visible on MRI. There is an approximate relationship between the duration of seizure activity and the intensity and extent of these secondary changes. Likewise, angiography or perfusion imaging performed soon after a seizure may show a focal area of enhanced blood flow or elevated blood volume. All of these imaging abnormalities are thought to reflect transient disruption of the blood–brain barrier, and they rarely persist for more than a day or two. Less-well understood is the findings on MRI of increased T2 signal or restricted diffusion in the hippocampi after a prolonged seizure or status epilepticus. In some cases, a thalamic or cerebellar signal change is seen on MRI after a seizure; these may also persist for days. There are also imaging changes in the white matter, particularly the splenium of the corpus callosum that may occur soon after the withdrawal of certain antiepileptic medications as discussed in the later section on the use of these drugs and by Gürtler and colleagues).

The CSF after a seizure occasionally contains a small number of white blood cells (rarely up to $50/\text{mm}^3$, but more often in the range of $10/\text{mm}^3$) in about 15 percent of patients. A slight increase in protein is also possible. Like the imaging abnormalities these findings may lead to spurious conclusions about the presence of an active intracranial lesion, particularly if polymorphonuclear leukocytes predominate; a larger pleocytosis should always be construed as a sign of inflammatory or infectious disease.

Systemic (lactic) acidosis is a common result of convulsive seizures, and it is not unusual for the serum pH to reach levels near or below 7 if taken immediately after a convulsion. Of more practical value is the fact that almost all generalized convulsions produce a rise in serum creatine kinase activity that persists for hours, a finding that could be used to greater advantage in emergency departments to assist in distinguishing seizures from fainting. Of course, extensive muscle injury from a fall or prolonged compression during a period of unconsciousness can produce the same abnormality.

Concentrations of serum prolactin, like those of other hypothalamic hormones, rise for 10 to 20 min after all types of generalized seizures, including complex partial types, but not in absence or myoclonic types. An elevation may help differentiate a psychogenic seizure from a genuine one; however, serum prolactin may also be slightly elevated after a syncopal episode. Testing is facilitated by collecting capillary blood from the finger on filter paper for analysis (Fisher et al). There is also a post-ictal rise in ACTH and serum cortisol, but these changes have a longer latency and briefer duration. If elevations in these hormonal levels are used as diagnostic tests, one must have information about normal baseline levels, diurnal variations, and the effects of concurrent medications. Changes in body temperature, which are said to

sometimes precede a seizure, may reflect hypothalamic changes but are far less consistent and difficult to use in clinical work.

PATHOLOGY OF EPILEPSY

In most autopsied cases of primary generalized epilepsy of the genetic variety, the CNS is grossly and microscopically normal. MRI, which has been used as a surrogate for pathology, has not improved matters much except to expose some cortical heterotopias that had been previously difficult to detect, and to highlight the frequency of gliosis in the medial temporal lobes. Not surprisingly, there are also no visible lesions in the seizure states complicating drug intoxication and withdrawal, transient hyper- and hyponatremia, and hyper- and hypoglycemia, which presumably represent derangements at the cellular level.

In contrast, symptomatic epilepsies have definable lesions. These include zones of neuronal loss and gliosis (scars) or other lesions such as heterotopia, dysgenic cortex, hamartoma, vascular malformation, porencephaly, and tumor. Vascular malformations, hamartomas, gangliogliomas and related dysembryoplastic neuroectodermal tumors (DNET), which are important causes of drug resistant epilepsy, and low-grade astrocytomas were less frequent; again, in a small number, no abnormalities could be found. Certainly the focal epilepsies are associated with the highest incidence of structural abnormalities, although in certain cases no morphologic change is visible. With reference to the focal epilepsies, it has not been possible to determine which component of the lesion is responsible for the seizures. Gliosis, fibrosis, vascularization, and meningocerebral cicatrix have all been incriminated, but they are found in nonepileptic foci as well. The Scheibels' Golgi studies of neurons from epileptic foci in the temporal lobe showed distortions of dendrites, loss of dendritic spines, and disorientation of neurons near the scars, but these findings have dubious status because they were not usually compared with similar nonepileptic lesions. Once a gliotic focus of whatever cause becomes epileptogenic, it may remain so throughout the patient's lifetime.

Medial Temporal Sclerosis

In several series of cases of temporal lobe excisions in prior decades, such as the often cited one described by Falconer, a specific pattern of neuronal loss with gliosis (sclerosis) in the hippocampal and amygdaloid region was found in the majority, and this abnormality is being increasingly recognized with MRI, as already noted (*medial temporal sclerosis*; Fig. 16-4). The associated histologic finding is loss of neurons in the CA1 segment (Sommer sector) of the pyramidal cell layer of the hippocampus, often unilateral, extending into contiguous regions of both the pyramidal layer and the underlying dentate gyrus. It is still undetermined whether this

neuronal loss is primary or secondary and, if the latter, whether it was incurred at birth or happened later as the consequence of recurrent seizures.

However, early life head trauma, infections, and a variety of less-common perturbations may also cause the ensemble of neuron loss and mild gliosis of medial temporal sclerosis. The cessation of seizures in many patients following surgical resection of the medial temporal lobe favors the first interpretation that the pathologic change is primary in most cases (see further on under "Surgical Treatment of Epilepsy"). Attesting to the uncertainty of cause or effect are numerous surgical series that favor one view or the other (see editorial by Sutula and Pitkänen).

Role of Genetics

Most primary epilepsies have a genetic basis and, as in many other diseases such as diabetes and atherosclerosis, the mode of inheritance is complex, i.e., some are likely to be polygenic but increasingly, single mutations are being found. That a genetic factor is operative in the primary generalized epilepsies is suggested by a familial incidence in 5 to 10 percent of such patients and, in certain families, the inheritance of a seizure disorder through specific genes (Gourfinkel-An et al). The importance of genetic factors in the primary epilepsies is also underscored by evidence from twin studies; in six major series, the overall concordance rate was 60 percent for monozygotic twins and 13 percent for dizygotic pairs.

Of course, epilepsy is a component of many genetic syndromes that are defined by their dysmorphic appearance or neurocutaneous disorder with or without mental retardation. What we consider here are the few idiopathic seizure disorders that are inherited by a simple (mendelian) pattern. These include a subgroup of benign neonatal familial convulsions inherited as an autosomal dominant trait (Leppert et al), and a similar disorder of infantile onset and a benign myoclonic epilepsy of childhood (autosomal recessive). Particularly informative are a special group of epileptic disorders in which monogenic genetic defects are related to abnormalities of ion channels or neurotransmitter receptors (Table 16-3). These were mentioned earlier in the discussion of the physiology of seizures and despite their rarity they suggest that idiopathic epilepsy may be caused by a disruption in the function of these same channels.

The consequences of almost all of these mutations are to enhance overall neuronal excitability. Examples include autosomal dominant nocturnal frontal lobe epilepsy, which may present as a partial seizure (in which the offending mutations are in subunits of the nicotinic acetylcholine receptor subunit); "generalized epilepsy with febrile seizures plus" (subunits of a neuronal sodium channel associated with various combinations of uncomplicated febrile seizures, febrile seizures persisting beyond childhood, generalized, absence, myoclonic, atonic, and complex partial seizures.); benign familial neonatal convulsions (two different potassium channels); and forms of juvenile myoclonic epilepsy and childhood absence epilepsy (subunits of the brain GABA_A receptor).

Some of these are summarized in Table 16-3, and their number will almost certainly expand in the next few years. As with numerous other genetic neurologic disorders, a single mutation may produce different epilepsy and seizure types, and a single type may be the result of one of several different mutations. Also notable is the low penetrance of some monogenic epileptic disorders, particularly the autosomal dominant one associated with nocturnal frontal seizures.

Another group of epilepsies with mendelian inheritance has been ascribed to genetic defects that do not implicate ion channels. Most of these are primarily myoclonic disorders in which the epilepsy is one component. Two forms of progressive myoclonic epilepsy, Unverricht-Lundborg disease and Lafora body disease, are the result, respectively, of mutations in genes encoding cystatin B and tyrosine phosphatase. To these inherited forms of epilepsy may be added diseases such as tuberous sclerosis and ceroid lipofuscinosis (Chap. 37), which have a strong proclivity to cause seizures and genetically determined heterotopias such as FLN1 (this and other developmental aberrations are discussed in Chap. 38).

A more complex genetic element is also identified in several childhood seizure disorders—absence epilepsy with 3-per-second spike-and-wave discharges and benign epilepsy of childhood with centrotemporal spikes—both of which are transmitted as autosomal dominant traits with incomplete penetrance or perhaps in a more complicated manner. In the partial, or focal, epilepsies the role of heredity is not nearly so clear. Yet in numerous studies there has been a greater-than-expected incidence of seizures, EEG abnormalities, or both among first-degree relatives. Among the familial cortical epilepsies, both a temporal and frontal lobe type, are inherited in a polygenic fashion or in an autosomal dominant pattern. Undoubtedly also inherited, is the tendency to develop simple febrile convulsions, though the mode of inheritance is uncertain.

CLINICAL APPROACH TO EPILEPSY

The physician faced with a patient who seeks advice about an episodic disorder of nervous function must determine first, whether the episode in question is a seizure. In the diagnosis of epilepsy, history is the key; in most adult cases the physical examination is relatively unrevealing. The examination in infants and children is of greater value, as the finding of dysmorphic and cutaneous abnormalities allow the diagnosis of a number of highly characteristic cerebral diseases that give rise to epilepsy.

Paramount in establishing that there has been a seizure is a description from a witness. A detailed account of the event is required and in particular, the type and duration of bodily movements, level of alertness and responsiveness during and immediately after the episode, skin color and breathing, and incontinence. If a witness is not

available, then a telephone call to observers and family may give more information than does sophisticated laboratory testing. From the patient, information can be obtained regarding tongue biting, incontinence, and recollection of the event of the immediately preceding epoch. If the patient is able to provide information, previous events that may have been misinterpreted as other than a seizure, for example, brief losses of consciousness, myoclonic jerks, rumpled bedsheets with incontinence, unexplained falls with injury and so forth, may hint at preceding seizures. The family history, developmental milestones, neonatal events and the circumstances of birth are useful additional aspects of the evaluation of epilepsy.

The conditions most likely to simulate an epileptic seizure are psychogenic nonepileptic seizures and other paroxysmal events such as panic attack and syncope but also, unexplained falls (drop attacks), transient ischemic attacks, particularly those associated with limb shaking, sleepwalking and rapid eye movement (REM) sleep behavior disorder, subarachnoid hemorrhage, migraine, hypoglycemia, cataplexy, paroxysmal ataxia and choreoathetosis, and transient global amnesia. In emergency departments it is often difficult to differentiate the postictal effects of an unwitnessed seizure from the confusion and amnesia following cerebral concussion.

The clinical differences between a seizure and a *syncope attack* are considered in Chapter 18; there it was emphasized that no single criterion stands inviolate. Particularly emphasized because of their potential gravity are episodes of cardiac syncope from a serious arrhythmia, especially ventricular tachycardia. Cardiac arrhythmias may present as episodes of unheralded loss of consciousness, sometimes with associated convulsive movements that simulate epileptic disorders and the failure to pursue the diagnosis of arrhythmia may have important consequences. Palpitations, previous myocardial infarction, EKG abnormalities, valvular disease, and thoracic trauma may direct attention to the proper diagnosis.

Absence attacks may be difficult to identify because of their brevity. Helpful maneuvers are to have the patient hyperventilate to evoke an attack or to observe the patient counting aloud for several minutes. Those with frequent absence attacks will pause or skip one or two numbers. The diagnosis of temporal lobe epilepsy is similarly difficult. These attacks are so variable and so often induce disturbances of behavior and psychic function—rather than overt interruptions or loss of consciousness—that they may be mistaken for temper tantrums in children, drug ingestion, hysteria, panic attacks, or acute psychosis. These seizures may include verbalizations that cannot be remembered, walking aimlessly, repetitive olfactory and gustatory hallucinations, stereotyped hand movements or automatism such as lip smacking. The nature of the patient's report of a psychic experience is often helpful in distinguishing seizures from psychogenic events. In the former, patients attempt to focus with great effort on the description of the experience, although the term "indescribable" is often included in the report, whereas vague and imprecise descriptions of "something being

wrong" or resorting to a friend or family member to describe the event usually implicates a psychogenic seizure. We place emphasis on amnesia for the events of at least part of the seizure as an important criterion for the diagnosis of temporal lobe epilepsy.

Migraine may be mistaken for a seizure. One feature of the focal neurologic disorder of typical migraine is particularly helpful—namely, the pace of the sequence of cerebral malfunction over a period of minutes rather than seconds, as in focal epilepsy. Even this criterion may fail occasionally, especially if both migraine and partial seizures are joined, e.g., as expressions of a vascular malformation of the brain.

Identification of a TIA and its separation from focal epilepsy are aided by considering that most paroxysmal vascular disorders are characterized by loss of function that can be attributed to one area of the cortex such as paralysis, blindness, diplopia, or aphasia. If the ischemic attack is marked by an evolution of symptoms, they tend to develop more slowly than those of a seizure. The patient's age and presence of vascular risk factors, evidence of disease of the heart and carotid arteries, and the lack of disorder of consciousness or amnesia may be supportive of the diagnosis of vascular disease. However, a "limb-shaking" TIA and convulsive phenomena at the outset of basilar artery occlusion may be nearly impossible to distinguish from epilepsy.

Regarding the distinction of seizures from odd disorders such as cataplexy, paroxysmal ataxia or choreoathetosis, transient global amnesia, it is sufficient to be aware of the diagnostic features for each of these conditions. Hysterical fugues can cause substantial difficulty in diagnosis. They may be recognized by the loss of personal identity and by episodes that are longer than typical or seizures, sometimes up to a few days. REM sleep behavior disorder tend to occur later in the sleep cycle, as they require REM, whereas frontal epileptic seizures with violent motions or acts that might be mistaken for REM sleep behavior disorder, can occur at any time of the night and tend to be briefer than the sleep disorder. *Drop attacks* (falling to the ground without loss of consciousness as discussed in Chap. 7) remain an enigma. In most cases, it has not been possible to substantiate an association with circulatory disturbances of the vertebrobasilar system and seldom have we observed drop attacks to be an expression of atonic or myoclonic epilepsy.

Several laboratory studies are usually included in the initial diagnostic evaluation—complete blood count (CBC), blood chemistries, EKG, EEG, and imaging study of the brain, preferably MRI. CT scanning gives limited information on major problems that may underlie epilepsy but MRI is vastly superior in detecting the various structural causes of epilepsy. Nonetheless, CT may be the only feasible study when MRI is not available or in emergency circumstances. If blood is tested after the episode in question, elevation in creatine kinase (persistent for hours) and formerly, elevation of prolactin (for up to 10 min) may occur after an unwitnessed convulsive seizure but the test is not specific enough to be useful in general practice. Other forms of testing—e.g., cardiac stress tests, Holter monitor, tilt-table testing, long-term

patient-activated cardiac monitors, and sleep studies—are sometimes indicated in order to exclude some of the nonepileptic disorders listed earlier. Some patients may need prolonged EEG monitoring, either in the hospital or with portable equipment at home. In all forms of epilepsy, prolonged EEG and video monitoring in a hospital unit may prove diagnostic.

Seizures in Each Age Period

(Table 16-4 and Fig. 16-5)

Having concluded that the neurologic disturbance under consideration is one of seizure, the next issue is to identify its type. Indeed, in most cases this determines the nature of treatment. Because there are so many seizure types, especially in childhood and adolescence, each one tending to predominate in a certain age period, a clinical advantage accrues to considering seizures from just this point of view. A broader approach includes consideration of the neurologic and EEG findings, the response to drugs, etiology, and prognosis.

Table 16-4

CAUSES OF RECURRENT SEIZURES IN DIFFERENT AGE GROUPS

AGE OF ONSET	PROBABLE CAUSE*
Neonatal	Congenital maldevelopment, birth injury, anoxia, metabolic disorders (hypocalcemia, hypoglycemia, vitamin B ₆ deficiency, biotinidase deficiency, phenylketonuria, and others)
Infancy (1–6 months)	As above; infantile spasms (West syndrome)
Early childhood (6 months–3 years)	Infantile spasms, febrile convulsions, birth injury and anoxia, infections, trauma, metabolic disorders, cortical dysgenesis, accidental drug poisoning
Childhood (3–10 years)	Perinatal anoxia, injury at birth or later, infections, thrombosis of cerebral arteries or veins, metabolic disorders, cortical malformations, Lennox-Gastaut syndrome, “idiopathic,” probably inherited, epilepsy (Rolandic epilepsy)
Adolescence (10–18 years)	Idiopathic epilepsy, including genetically transmitted types, juvenile myoclonic epilepsy, trauma, drugs
Early adulthood (18–25 years)	Idiopathic epilepsy, trauma, neoplasm, withdrawal from alcohol or other sedative drugs
Middle age (35–60 years)	Trauma, neoplasm, vascular disease, alcohol or other drug withdrawal
Late life (older than 60 years)	Vascular disease (usually postinfarction), tumor, abscess, degenerative disease, trauma

*Meningitis or encephalitis and their complications may be a cause of seizures at any age. This is true also of severe metabolic disturbances. In tropical and subtropical countries, parasitic infection of the CNS is a common cause.

(See also Fig. 16-5.)

Figure 16-5 displays the frequency of each seizure type and the main causes of seizures by age group. These data are assembled from various sources and are approximate, but they highlight several points of clinical importance.

Neonatal Seizures

The neonatologist is often confronted by an infant who begins to convulse in the first days of life. In most instances, the seizures are fragmentary—an abrupt movement or posturing of a limb, stiffening of the body, rolling up of the eyes, a pause in respirations, lip-smacking, chewing, or bicycling movements of the legs. Even the experienced observer may have difficulty at times in distinguishing seizure activity from the normal movements of the neonate. If manifest seizures are frequent and stereotyped, the diagnosis is less difficult. The seizures correlate with focal or multifocal cortical discharges; however, as is the case with most EEG changes in neonates, these are poorly formed and less distinct than seizure discharges in later life. Presumably the immaturity of the cerebrum prevents the development of a fully organized seizure pattern, and the incomplete corticocortical myelination prevents bihemispheric spread. The EEG is nonetheless helpful in diagnosis. For example, periods of EEG suppression may alternate with sharp or slow waves, or there may be discontinuous theta activity that represents electrographic seizure activity. Conversely, electrical seizure activity in the neonate may be unattended by clinical manifestations.

An early onset of myoclonic jerks, either fragmentary or massive, with an EEG pattern of alternating suppression and complex bursts of activity is particularly ominous. Ohtahara described another unfavorable form of neonatal seizure evolving in infancy into infantile spasms (West syndrome) and Lennox-Gastaut syndrome and leaving in its wake severe brain damage. Most reported patients have been left developmentally delayed.

Neonatal seizures occurring within 24 to 48 h of a difficult birth are usually indicative of severe cerebral damage, usually anoxic, either antenatal or parturitional. Such infants often succumb, and about half of the survivors are seriously handicapped. *Seizures having their onset several days or weeks after birth* are more often an expression of acquired or hereditary metabolic disease. In the latter group, hypoglycemia is the most frequent cause; another, hypocalcemia with tetany, has become infrequent. A hereditary form of pyridoxine deficiency is a rare cause, sometimes also inducing seizures in utero and characteristically responding promptly to massive doses (100 mg) of vitamin B₆ given intravenously. Biotinidase deficiency is a rare but correctable cause. Nonketotic hyperglycemia, maple syrup urine disease, as well as other metabolic disorders may lead to seizures in the first week or two of life and are expressive of a more diffuse encephalopathy.

In contrast, benign forms of neonatal seizures have also been identified. Plouin described a form of benign neonatal clonic convulsions beginning on days 2 and 3, up to day 7, (“fifth day seizures”) in which there were no specific EEG changes. The seizures then remit and have a

Figure 16-5. Distribution of the main causes of epilepsy at different ages. Evident is the prevalence of congenital causes in childhood and the emergence of cerebrovascular disease in older patients. (Adapted from several sources including Hauser and Annegers and the texts of Engel and of Pedley.)

good prognosis. The inheritance is autosomal dominant. There are other nonfamilial cases with onset on days 4 to 6, wherein the partial seizures may even increase to status epilepticus; the EEG consists of discontinuous theta activity. In both these groups, the outlook for normal development is good and seizures seldom recur later in life. There are also benign forms of polymyoclonus without seizures or EEG abnormality in this age period. Some occur only with slow-wave sleep or feeding. They disappear after a few months and require no treatment. A form of benign nocturnal myoclonus in the neonate is also well known.

Infantile Epilepsies

Neonatal seizures may continue into the infantile period, or seizures may begin in an infant who seemed to be normal up to the time of the first convulsive attack. While the most common type of convulsion is the febrile seizure, not strictly a type of epilepsy, the most characteristic epilepsy at this age is the massive sudden myoclonic jerk of head and arms leading to flexion or, less often, to extension of the body (*infantile spasms*, *salaam spasms*). This form, which characterizes the West syndrome as described earlier, has many underlying causes. The same seizure type occurs in infants with tuberous sclerosis (diagnosed in infancy by the presence of hypopigmented macules, or “ash-leaf spots”), phenylketonuria, or Sturge-Weber angiomatosis, but most often it is associated with other diseases beginning in this age period. Some instances of infantile spasms may be due to a metabolic encephalopathy of unknown type or, a cortical dysgenesis (Jellinger). West syndrome is characterized by an EEG picture of large bilateral slow waves and multifocal spikes (*hypsarrhythmia*).

The recently clarified Dravet syndrome, which includes myoclonic and focal seizures, occurs in this age group but has become relevant to adult practice as patients are recognized with resistant epilepsy and learning disability or developmental delay. In the past the epilepsy and developmental delay were attributed to a febrile illness or vaccination in infancy but it has become clear that the syndrome has a genetic underpinning and a resultant abnormality of a sodium channel protein (SCN1A) and the manifestations have simply been bought forward by the initial neonatal event.

When myoclonus begins in infancy with fever and unilateral or bilateral clonic seizures or with focal seizures followed by focal neurologic abnormalities, there is a likelihood of developmental delay. The latter types are sometimes referred to as *complicated febrile seizures*, but, as indicated above, they must be distinguished from the benign familial febrile seizure syndrome discussed earlier in the chapter. Infantile spasms cease by the end of the second year and are replaced by focal and secondarily generalized seizures. They do not respond well to the usual antiepileptic medications. While myoclonic activity with seizures in this age group raises concern of a serious condition, there is a common benign form that has a heritable component and does not lead to developmental delay.

Seizures Presenting in Early Childhood

A number of focal epilepsies may appear for the first time during this age period and carry a good prognosis, i.e., the neurologic and intellectual capacities remain relatively unimpaired and seizures may cease in adolescence. These disorders begin between 3 and 13 years of age and there is often a familial predisposition. Most are marked by distinctive focal spike activity that is accentuated by sleep (see above, in reference to benign childhood epilepsy with centrotemporal or occipital spikes). Several of these have been discussed earlier under the Special Epileptic Syndromes. In one form, benign childhood epilepsy with centrotemporal spikes, unilateral tonic or clonic contractions of the face and limbs recur repeatedly with or without paresthesia; anarthria may follow the seizure. There are central and temporal spikes in the EEG interictally. Less commonly, the focus originates in an occipital lobe with EEG spiking on eye closure. An acquired aphasia characterizes another disorder that was described by Landau and Kleffner to mark the beginning of an illness in which there are partial or generalized motor seizures and multifocal spike or spike-and-wave discharges in the EEG and deterioration of language function.

Among the generalized epilepsies, childhood absence epilepsy arises in children of this age, as described earlier as well. As in any age group, there are structural causes of seizures that include medial temporal sclerosis, described

in several places in this chapter, tumor and arteriovenous malformation.

The convulsive state in this age group may present around the age of 4 years as a focal myoclonus with or without astatic seizures, atypical absence, or generalized tonic-clonic seizures. The EEG, repeated if initially normal, is most helpful in diagnosis; it reveals a paroxysmal 2- to 2.5-per-second spike-and-wave pattern on a background of predominant 4- to 7-Hz slow waves. Many of these cases qualify as the Lennox-Gastaut syndrome, are difficult to treat, and are likely to be associated with developmental delay. At this age, perhaps more than any other, the first burst of seizures may take the form of status epilepticus and, if not successfully controlled, may end fatally.

In contrast to the Lennox-Gastaut group, the more typical absence, with its regularly recurring 3-per-second spike-and-wave EEG abnormality, also begins in this age period (rarely before age 4 years) and carries a good prognosis. This seizure disorder responds well to medications, as indicated further on. Its features are fully described in "Absence Variants." The special case of Rasmussen encephalitis and intractable seizures has already been discussed under the Special Epileptic Syndromes.

Seizures in Later Childhood and Adolescence

These represent a common problem in practice but present a special difficulty because this is the age at which syncope and psychogenic seizures begin to occur and alcohol and drug abuse may begin. Here, we face the frequent issue relating to the nature and management of the first seizure in an otherwise normal young person. As in other age groups, the history often discloses the likely cause of seizures, as for example, in young person has been sleep deprived or imbibing alcohol or one of many abused drugs and has a first seizure. A search for a cause is necessary by MRI, EKG, and EEG but these tests infrequently disclose hippocampal sclerosis, cortical heterotopia, tumor, infection, or a vascular malformation and the epilepsy, if there are certain characteristic other features such as myoclonic jerks or more than one seizure, is then classified as idiopathic and genetic. If there has only been a single event and no clinical or EEG features to corroborate epilepsy, the diagnosis must remain uncertain. However, the type of seizure that first brings the child or adolescent to medical attention is most likely to be a generalized tonic-clonic convulsion and often marks the beginning of idiopathic generalized epilepsy or juvenile myoclonic epilepsy, as described an earlier section. As described there the latter syndrome is identified by intermittent myoclonic jerks when the patient is tired or after the ingestion of alcohol. Seizures are usually grand mal but a few have had a history of absence. The EEG shows a characteristic polyspike pattern, about one-third with a photomyoclonic response, and treatment with certain anticonvulsants is very successful at suppressing seizures and myoclonus.

In a case where there had been some type of seizure at an earlier period, one should suspect a developmental disorder, parturitional hypoxic-ischemic encephalopathy (birth injury), or one of the hereditary metabolic diseases.

When the seizures are an expression of a long-standing epileptic focus or foci that is associated with developmental delay or scholastic failure, the diagnostic and therapeutic problem becomes much more demanding. Some patients of this group will eventually fall into the category of epilepsy with complex partial seizures. In this age period in particular, as the adolescent strives for independence, the social disruption caused by seizures are likely to take a toll on the relationships and educational progress of the emerging adult.

In the special group of younger individuals with *long-standing seizures*, nearly half have temporal lobe epilepsy. Huttenlocher and Hapke, in a follow-up study of 145 infants and children with intractable epilepsy, found that the majority had borderline or subnormal intelligence.

Opinion is divided on whether treatment is required for the older child or adolescent who comes to medical attention because of a first seizure that appears to be idiopathic. When such cases have been left untreated, such as in the series reported by Hesdorfer and colleagues, the risk of another seizure over 10 years was 13 percent unless the first episode was status epilepticus, in which case the risk was 41 percent. Age, sex, and the circumstances of the seizure (withdrawal from drugs or alcohol, myoclonic episodes, family history) all figure into the risk. Attention to what had in the past been called "hygiene" can be all that is required until the problem has ceased or clarified itself as an epileptic disorder, namely regularizing sleep and minimizing alcohol and stimulants.

Seizures Due to Underlying Medical Disease

Several diseases announce themselves by an acute convulsion. Here we focus on generalized medical disorders as causes of single and episodic seizures, in contrast to structural lesions of the brain that cause focal or generalized epilepsy.

Withdrawal Seizures

The possibility of abstinence seizures in patients who abuse alcohol, barbiturates, or benzodiazepine and related sedative drugs must be considered when seizures occur for the first time in adult life or in adolescence. Suspicion is raised by the stigmata of alcohol abuse or a history of prolonged anxiety and depression requiring sedative drugs. Also, sleep disturbance, tremulousness, disorientation, illusions, and hallucinations can be associated with the convulsive phase of the illness. Seizures in this setting may occur singly, but as often, in a brief flurry, the entire convulsive period lasting for several hours and rarely for a day or longer, during which time the patient may display twitchiness or myoclonus and be unduly sensitive to photic stimulation. Chapter 42 discusses alcohol and other drug-related seizures in detail.

Infections and Inflammatory-immune Conditions

An outburst of seizures is also a prominent feature of all varieties of *bacterial meningitis*, more so in children than in adults. Fever, headache, and stiff neck provide the

clues to diagnosis, and lumbar puncture yields the salient data. Myoclonic jerking and seizures may appear early in acute *herpes simplex encephalitis* and other forms of viral, treponemal, and parasitic encephalitis, including those derived from HIV infection, both directly and indirectly such as toxoplasmosis and brain lymphoma; and in subacute sclerosing panencephalitis. In tropical countries, cysticercosis and tuberculous granulomas of the brain are very common causes of epilepsy. Seizure(s) without fever or stiff neck may be the initial manifestation of syphilitic meningitis, a fact worth noting as this process reemerges in AIDS patients.

A special case of autoimmune encephalitides may cause seizures as, for example, those caused by the anti-NMDA receptor antibody that is associated with ovarian and other teratomas and other paraneoplastic conditions such as the antibody syndrome directed at the voltage-gated potassium channel complex (see Chap. 31).

Seizures in Metabolic Encephalopathy

Uremia has a strong convulsive tendency. Of interest is the relation of seizures to the development of acute anuric renal failure, generally from acute tubular necrosis but occasionally due to glomerular disease. Total anuria may be tolerated for several days without the appearance of neurologic signs, and then there is an abrupt onset of twitching, trembling, myoclonic jerks, and brief generalized motor seizures; acute hypertension probably plays a role. The entire motor constellation, one of the most dramatic in medicine, lasts several days until the patient sinks into terminal coma or recovers by dialysis. When this *twitch-convulsive syndrome* accompanies lupus erythematosus, seizures of undetermined cause, or generalized neoplasia, one should suspect its basis in renal failure.

Other acute metabolic illnesses and electrolytic disorders complicated by generalized and multifocal motor seizures are hyponatremia and its opposite, the hypernatremic, hyperglycemic and other hyperosmolar states, thyrotoxic storm, porphyria, hypoglycemia, hypomagnesemia, and hypocalcemia. In all these cases, *rapidly evolving electrolyte abnormalities are more likely to cause seizures than those occurring gradually*. For this reason it is not possible to assign absolute levels of sodium, blood urea nitrogen (BUN), osmolarity, or glucose concentrations above or below which seizures are likely to occur. Lead (in children) and mercury (in children and adults) are the most frequent of the metallic poisons that cause convulsions. The presence of these heavy metals in culturally based homeopathic treatments should not be overlooked.

In most cases of seizures caused by metabolic and withdrawal states, treatment with antiepileptic drugs is not necessary as long as the underlying disturbance is rectified. Indeed, antiepileptic drugs are usually ineffective in halting the seizures if the metabolic disorder persists.

Generalized seizures, with or without twitching, occur in the advanced stages of many other illnesses, such as *hypertensive encephalopathy*, the posterior reversible encephalopathy syndrome from causes other than hypertension (PRES as discussed in Chap. 34), sepsis—especially

gram-negative septicemia with shock—hepatic stupor, and intractable congestive heart failure. Usually, seizures in these circumstances can be traced to an associated metabolic abnormality and are revealed by appropriate studies of the blood. Seizures are a central feature of the eclamptic syndrome as discussed in a separate section below.

Medications as a Cause of Seizures

A large number of medications are capable of causing seizures, usually when toxic blood levels are attained. The antibiotic imipenem and excessive doses of other penicillin congeners and linezolid may be responsible, particularly if renal failure leads to drug accumulation. Cefepime, a fourth-generation cephalosporin, widely used for the treatment of gram-negative sepsis, can result in status epilepticus, if given in excessive dosage (Dixit et al). The tricyclic antidepressants, bupropion, and lithium may cause seizures, particularly in the presence of a structural brain lesion. Lidocaine and aminophylline are known to induce an unheralded single convulsion if administered too quickly or in excessive doses. The use of the analgesic tramadol has also been associated with seizures. Curiously, the anesthetic propofol, which is discussed further on as a potent anticonvulsant in the treatment of status epilepticus, has caused marked myoclonic phenomena in some patients and, rarely, seizures. These may occur during induction or emergence from anesthesia or as a delayed effect (Walder et al).

The list of medications that at one time or another have been associated with a convulsion is long and, if no other explanation for a single seizure is evident, the physician is advised to look up in standard references the side effects of the drugs being administered to the patient. In a few of our otherwise healthy adult patients, extreme *sleep deprivation* coupled with ingestion of large doses of antibiotics or adrenergic medications or other remedies that are used indiscriminately for the symptomatic relief of colds has been the only plausible explanation for a single or doublet seizure.

Global Arrest of Circulation

Cardiac arrest, suffocation or respiratory failure, carbon monoxide poisoning, or other causes of *hypoxic encephalopathy* tend to induce diffuse myoclonic jerking and generalized seizures as cardiac function resumes. The myoclonic-convulsive phase of this condition may last only a few hours or days, in association with coma, stupor, and confusion; or it may persist indefinitely as an intention myoclonus state (Lance-Adams syndrome).

Cerebrovascular Diseases

Convulsive seizures are quite uncommon in the acute or evolving phases of an arterial stroke. The ischemic convulsive phenomena of a “limb-shaking TIA” and a burst of generalized clonic motor activity during basilar artery occlusion have been mentioned earlier, but are uncommon and are not epileptic phenomena. Only exceptionally will acute embolic infarction of the brain cause a focal seizure at the onset. Otherwise, a new seizure should not be attributed to an acute arterial occlusion in the cerebrum.

However, embolic infarcts involving the cortex become epileptogenic in fewer than 10 percent of cases and only after an interval of several months or longer. It has been stated in texts that thrombotic infarcts involving the cortex are almost never convulsive at their onset but any distinction in seizure frequency between stroke types seems to us to be based on limited data. Lacunar infarction, being deep and not involving the cortical surface, of course, does not produce convulsions.

In contrast, *cortical venous thrombosis* with underlying ischemia and infarction acts as a highly epileptogenic lesion (see Chap. 34). The same is true for hypertensive encephalopathy (including the above mentioned reversible posterior encephalopathy and eclampsia) and thrombotic thrombocytopenic purpura (TTP), which has a strong tendency to cause nonconvulsive status epilepticus. The rupture of a saccular aneurysm is sometimes marked by one or two generalized convulsions that are not epileptic in nature and are probably predicated on the arrest of cerebral circulation. Deep cerebral hemorrhages, spontaneous or traumatic, also occasionally become sources of recurrent focal seizures.

The use of anticonvulsants as prophylaxis for seizures after a typical cortical stroke of embolic or thrombotic type or cerebral hemorrhage is not necessary. The rate of such seizures has been estimated to be 3 percent or less in the first year. This subject is addressed further in Chap. 34.

Seizures with Acute Head Injury

It is not uncommon for severe concussion to be attended by brief convulsive movements (see Chap. 35). The appearance is in most cases of clonic twitching but may include a momentary tonic phase. Rarely, a prolonged clonic convulsion occurs. The nature of this event, whether originating in the reticular formation as a component of concussion, or from some disruption of cortical activity, is not clear. Almost invariably in our experience, the EEG recorded hours or a day later is normal, and imaging studies are likewise normal or show a small contusion. There is little to guide one in treatment of these patients; we tend to give a course of antiepileptic medications for several weeks but it is not established if this is the correct approach. Aside from penetrating brain trauma, the risk of delayed seizures is low. Further details on this subject can be found in Chap. 35.

Seizures during Pregnancy

Here one contends with two problems: one, the woman with epilepsy who becomes pregnant; the other, the woman who has her first seizure during pregnancy. According to the extensive EURAP study, about two-thirds of epileptic women who become pregnant have no change in seizure frequency or severity (the majority remain seizure free); the remainder are evenly split between those in whom the frequency increases and in an equal number, it lessens. In a large cohort of such women, there was a slight increase in the number of stillbirths and a doubling in the expected incidence of developmental delay and nonfebrile seizures in their offspring (see later).

Issues regarding a coagulopathy in the fetus exposed to phenobarbital (now infrequently used for adult seizure disorders) and certain of the other drugs are well known to obstetricians and pediatric specialists and are treated with the oral administration of vitamin K, 20 mg/d during the eighth month or 10 mg IV 4 h before birth and 1 mg IM to the neonate. The conventional anticonvulsants also seem to be safe for the baby during breast-feeding in that only small amounts are excreted in lactated milk. For example, carbamazepine in human milk is found to be 40 percent of the mother's serum concentration which results in a neonatal blood level that is below the conventionally detectable amount. Phenytoin is excreted at 15 percent of maternal serum concentration, and valproate, being highly protein bound, is virtually absent in breast milk. No adverse effects have been attributed to these small amounts of drug.

The special issue of the teratogenicity of antiepileptic drugs is addressed further on.

Seizures with Eclampsia (See also Chap. 34.)

This syndrome appears during the last trimester of pregnancy or soon after delivery and may announce itself by hypertension and convulsions; the latter are generalized and tend to occur in clusters. The standard practice is to induce labor or perform a cesarean section and manage the seizures as one would manage those of hypertensive encephalopathy (of which this is one type). The administration of magnesium sulfate continues to be the favored treatment by obstetricians for the prevention of eclamptic seizures; two randomized trials have reestablished its value in preventing seizures in preeclamptic women (Lucas et al) and in avoiding a second convulsion once one had occurred (Eclampsia Trial Collaborative Group). Magnesium sulfate, 10 g IM, followed by 5 g every 4 h, proved comparable to standard doses of phenytoin as prophylaxis for seizures. Our colleagues use a regimen of 4 g IV over 5 to 10 min followed by a maintenance dose of 5 g every 4 h IM or 1 to 2 g/h IV. In nontoxic gestational epilepsy, approximately 25 percent of patients are found to have some disease (neoplastic, vascular, or traumatic) that will persist.

Epilepsy in Late Adult Life

Seizures in this age group present special problems in diagnosis. Often, these individuals live alone so there is no witness to the event, they have multiple medical problems, they may have cognitive difficulty that impedes an accurate history, multiple medications are almost the rule, and cerebral imaging is likely to show abnormalities that may not be referable to the problem at hand.

Nonetheless, Hauser and Kurland reported an increase in the incidence of seizures as the population ages—from 11.9 per 100,000 in the 40- to 60-year-old age group to 82 per 100,000 in those 60 years of age or older. It is possible that these are overestimates due to the complicating factors alluded to in the paragraph above. A person in the latter age group who begins to have seizures of either partial or generalized type is always to be suspected of harboring a primary or secondary tumor or a past cerebral infarct that had not declared itself clinically.

Recent published series suggesting that the majority of seizures in this age group are caused by infarction and a small number by tumor are not in accord with our experience. For example, according to Sung and Chu, previous infarcts are by far the most common lesions underlying status epilepticus in late adult life, but our experience has been that old trauma is considerably more common. Probably the nature of the population in a given clinic determines the relative frequency of underlying causes. In any case, cerebral imaging usually settles the issue.

However, many apparent seizures in this age group are the result of a primary cardiac event, particularly an arrhythmia such as ventricular tachycardia. Therefore, a 12 lead EKG and further monitoring of heart rhythm are important ancillary tests if the episode remains unexplained.

Cortical and subcortical lesions, the result of previous traumatic contusions, are a particularly important cause of seizures among older alcoholics; the lesions are revealed by brain imaging and are typically located in the anterior frontal and temporal lobes. Brain abscess and other inflammatory and infectious illnesses remain common causes of adult seizures in tropical regions. In the elderly, seizures as a result of Alzheimer and other degenerative diseases occur in up to 10 percent of cases, but are not a source of diagnostic challenge; nonetheless, these patients are subject to falls, subdural hematoma, and all other illnesses of old age, such as cancer, that affect the brain.

In the common case of an adult with a first unexplained seizure, it has been our practice not to administer an antiepileptic medication unless there is an underlying structural lesion or an abnormality on a single EEG or with prolonged monitoring and to reevaluate the situation in 6 to 12 months. Usually, a second MRI and EEG are performed to exclude focal abnormalities that were not appreciated during the initial evaluation, but often these studies are again unrevealing. This approach has been prompted by data such as those of Hauser and colleagues, who found that about one-third of patients with a single unprovoked seizure will have another seizure within 5 years; the risk is even greater if there is a history of seizures in a sibling, a complex febrile convulsion in childhood, or a spike-and-wave abnormality in the EEG. Moreover, the risk of recurrence is greatest in the first 24 months. In patients with two or three unexplained seizures, a far higher proportion, about 75 percent, have further seizures in the subsequent 4 years.

TREATMENT OF EPILEPSY

The treatment of epilepsy of all types can be divided into four parts: the use of antiepileptic drugs, the surgical excision of epileptic foci and other surgical measures, the removal of causative and precipitating factors, and the regulation of physical and mental activity.

Antiepileptic Drugs—General Principles

The goal of drug treatment is to create a seizure-free state if possible and with the fewest side effects. In the past, a few seizures a year had been considered adequate control

but with the bevy of newer medications it is advisable to aspire to the goal of eliminating seizures. On the other hand, it is an error to make the patients so mentally dulled as to interfere with function at work or school. The choice and dose of medication depends on many factors including sex, age, other medications being used by the individual, and renal or hepatic dysfunction or other medical conditions and psychiatric that might be favorably influenced by a particular agent. As a general rule, starting in the lower dose range and attempting to provide twice daily or daily administration are favored.

In approximately 70 percent of all patients with epilepsy, the seizures are controlled completely or almost completely by medications; in an additional 20 to 25 percent, the attacks are significantly reduced in number and severity. Table 16-5 lists the most commonly used drugs along with their dosages, effective blood levels, and serum half-lives. Because of the long half-lives of phenytoin, phenobarbital, and ethosuximide, these drugs need be taken only once daily, preferably at bedtime. Valproate and carbamazepine have shorter half-lives, and their administration should be spaced during the day. It is useful to be familiar with the serum protein-binding characteristics of antiepileptic drugs and the interactions among these drugs, and between antiepileptic and other drugs.

Certain drugs are somewhat more effective in one type of seizure than in another, and it is necessary to use the proper drugs in optimum dosages for different circumstances. Initially, only one drug should be used and the dosage increased until sustained therapeutic levels have been attained. If the first drug does not control seizures, a different one should be tried, but frequent shifting of drugs is not advisable; each should be given an adequate trial before another is substituted. A general approach to the choice of drug in certain common forms of epilepsy is given in Tables 16-6 for adults and 16-7 for children, but it must be noted that there are a number of drugs that may be appropriate in each circumstance.

It is difficult to give definitive guidance on combining medications for refractory seizures. Several general principles are, however, worth noting. First, it is sensible to avoid drugs combinations with similar putative mechanisms because their side effects may be additive, for example, the addition of lamotrigine to carbamazepine or of phenytoin to carbamazepine may not be ideal but at the same time, it should be mentioned that the mechanism of action has little influence on clinical effectiveness. Second, the clinician should be aware of known interactions through metabolic pathways such as valproate combined with either lamotrigine or phenobarbital as they share the cytochrome P450 degradation pathway. Third, although it is appropriate to use drugs that are known to be effective for the class of seizures under treatment, it is often necessary to extend the choices beyond these restrictions.

The therapeutic dose for any given patient must be determined, to some extent by clinical effect, guided by measurement of serum levels, as described below. Inquiry regarding seizure control and drug side effects is more valuable than adjustment of medication based solely on drug concentrations. Blood for

Table 16-5

COMMON ANTIPILEPTIC DRUGS

GENERIC NAME	TRADE NAME	USUAL DOSAGE		PRINCIPAL THERAPEUTIC INDICATIONS	SERUM HALF-LIFE, H	EFFECTIVE BLOOD LEVEL, ^a μG/ML
		CHILDREN, MG/KG	ADULTS, MG/D			
Major antiepileptic used as monotherapy						
Valproic acid	Depakote	30–60	1,000–3,000	Generalized tonic-clonic, partial, absence, myoclonic	6–15	50–100
Phenytoin	Dilantin	4–7	300–400	Generalized tonic-clonic, partial, absence, myoclonic	12–36	10–20
Carbamazepine	Tegretol	20–30	600–1,200 ^b	Generalized tonic-clonic, partial	14–25	4–12
Oxcarbazepine	Trileptal	10–40	900–2,400	Partial	1–5	—
Phenobarbital	Luminal	3–5 (8 for infants)	90–200	Generalized tonic-clonic, partial	40–120	15–40
Lamotrigine	Lamictal	0.5	300–500	Generalized, partial	15–60	2–7
Levetiracetam	Keppra	20–60	500–3,000 ^b	Partial, myoclonic	6–8	—
Adjuvant and special-use anticonvulsants						
Topiramate	Topamax	—	400	Generalized tonic-clonic, atypical absence, myoclonic, partial	20–30	—
Lacosamide	Vimpat	—	—	—	—	—
Zonisamide	Zonegren	—	—	—	—	—
Primidone	Mysoline	10–25	750–1,500 ^b	Generalized tonic-clonic, partial	6–18	5–12
Ethosuximide	Zarontin	20–40	750–1,500	Absence	20–60	50–100
Methsuximide	Celontin	10–20	500–1,000	Absence	28–50	40–100
ACTH	—	40–60 Units daily	—	Infantile spasms	—	—
Clonazepam	Klonopin	0.01–0.2	2–10	Absence, myoclonus	18–50	0.01–0.07
Anticonvulsants for status epilepticus (initial loading or continuous infusion doses shown)^c—phenytoin and phenobarbital used in doses higher than shown above						
Diazepam	Valium	0.15–2	2–20	Status epilepticus	—	—
Lorazepam	Ativan	0.03–0.22	2–20	Status epilepticus	—	—
Midazolam	Versed	—	0.1–0.4 mg/kg/h	Status epilepticus	—	—
Propofol	Diprivan	2.5–3.5	2–8 mg/kg/h	Status epilepticus	—	—
Fosphenytoin	Cerebyx	30–50 mg	1,000–1,500	Status epilepticus	—	10–20

^cAdministered intravenously.

serum levels is ideally drawn in the morning before breakfast, before the first ingestion of anticonvulsants (“trough levels”), a practice that introduces consistency in measurement. Not uncommonly, a drug is discarded as being ineffective when a slight increase in dosage would have led to suppression of attacks. On the other hand, drug levels can be helpful in detecting non-compliance or poor absorption in instances of inadequate seizure control. The management of seizures is facilitated by having

patients chart their daily medication and the number, time, and circumstances of each episode. Some patients find it helpful to use a dispenser that is filled with medications with sufficient pills to last the week. This indicates to the patient whether a dose had been missed and whether the supply of medications is running low.

Table 16-5 indicates the effective serum levels for each of the commonly used antiepileptic drugs. In general, higher serum concentrations of drugs are necessary

Table 16-6

CHOICES OF ANTIPILEPTIC DRUGS BY TYPE OF ADULT SEIZURE DISORDER

SEIZURE TYPE	INITIAL CHOICE	SECOND LINE
Generalized tonic-clonic	Valproate, phenytoin	Lamotrigine, levetiracetam, carbamazepine, oxcarbazepine
Myoclonic	Valproate	Topiramate, levetiracetam, zonisamide
Focal (with or without secondary generalized)	Carbamazepine, phenytoin	Valproate, lamotrigine, oxcarbazepine, levetiracetam, lacosamide,
Absence	Valproate	Ethosuximide
Status epilepticus	Diazepines	Phenytoin, fosphenytoin, propofol, levetiracetam

Table 16-7

CHOICES OF ANTIPILEPTIC DRUGS IN CHILDHOOD SEIZURE DISORDERS

SEIZURE TYPE	INITIAL CHOICE	SECOND	THIRD
Generalized tonic-clonic	Valproate, carbamazepine	Lamotrigine, oxcarbazepine	Phenytoin
Myoclonic	Valproate, levetiracetam	Lamotrigine	Phenobarbital, clobazam
Absence	Valproate	Topiramate, levetiracetam, ethosuximide	Lamotrigine
Focal	Carbamazepine, phenytoin	Valproate, levetiracetam, oxcarbazepine	Lamotrigine, vigabatrin, topiramate
Infantile spasms	ACTH, vigabatrin,	Valproate	Lamotrigine
Lennox-Gastaut	Valproate	Topiramate, lamotrigine	Levetiracetam

for the control of focal seizures than for generalized ones. The usual blood level assay is of the total concentration of the drug; this is not a precise reflection of the amount of drug entering the brain, because—in the case of the most widely used anticonvulsants—the large proportion of drug is bound to albumin and does not penetrate nervous tissue. Also, in patients who are malnourished or chronically ill or who have a constitutional reduction in proteins, there may be intoxication at low total serum levels. Certain antiepileptic drugs also have active metabolites that are not measured by methods ordinarily used to determine serum concentrations but nonetheless produce toxicity. This is particularly true for the epoxide of carbamazepine. The situation may be further complicated by interactions between one anticonvulsant and the metabolites of another, as, for example, the inhibition of epoxide hydrolase by valproic acid, leading to toxicity through the buildup of carbamazepine epoxide. In circumstances of unexplained toxicity in the face of conventionally obtained serum levels that are normal, measurement may be undertaken of the levels of free drug and the concentration of active metabolites by chromatographic techniques.

The use of saliva for measurement of free drug levels has merit but has not been adopted frequently in practice. The measurements correlate with free drug levels. It has the advantage of allowing the patient to collect a sample before breakfast and avoid venipuncture.

Finally, the pharmacokinetics of each drug plays a role in toxicity and the serum level that is achieved with each alteration in the dose. This is particularly true of phenytoin, which, as the result of saturation of liver enzymatic capacity, has nonlinear kinetics once serum concentration exceeds 10 mg/mL. For this reason, a typical increase in dose from 300 to 400 mg daily results in a disproportionate elevation of the serum level and toxic side effects. Elevations in drug concentrations are also accompanied by prolongation of the serum half-life, which increases the time to reach a steady-state concentration of phenytoin after dosage adjustments. Contrariwise, carbamazepine is known to induce its own metabolism, so that doses adequate to control seizures at the outset of therapy are no longer effective several weeks later.

Antiepileptic Drug Interactions

Antiepileptic drugs have manifold interactions with each other and with a wide variety of other drugs. Although

many such interactions are known, only a few are of clinical significance and most pertain to older generations of medications, requiring adjustment of drug dosages (see Kutt). Among interactions between anticonvulsant drugs, valproate often leads to accumulation of active phenytoin and of phenobarbital by displacing them from serum proteins, as well as slightly elevating serum total levels. Agents that alter the concentrations of antiepileptic medications are chloramphenicol, which causes the accumulation of phenytoin and phenobarbital, and erythromycin, which causes the accumulation of carbamazepine. Antacids reduce the blood phenytoin concentration, whereas histamine blockers used to reduce gastric acid output do the opposite. Salicylates reduce the total plasma levels of anticonvulsant drugs but elevate the free fraction by displacing the drug from its protein carrier. More importantly, warfarin levels are decreased by the addition of phenobarbital or carbamazepine and may be increased by phenytoin although, with this last drug there may be unexpected alterations of the international normalized ratio (INR) in either direction. Enzyme-inducing drugs such as phenytoin, carbamazepine, and barbiturates can greatly increase the chance of breakthrough menstrual bleeding in women taking oral contraceptives and may lead to failure of contraceptive medications, and adjustments in the amount of estradiol must be made. These interactions are emphasized further below under the discussions of each agent.

Hepatic function greatly affects antiepileptic drug concentrations, since most of these drugs are metabolized in the liver. Serum levels must be checked more frequently than usual if there is liver failure, and with hypoalbuminemia it is advisable to obtain free drug levels for reasons just mentioned. Renal function has an indirect effect on the concentrations of the commonly used antiepileptics, but some newer agents, such as levetiracetam, gabapentin, and pregabalin, are excreted through the kidneys and require dosage adjustment in cases of renal failure. The main renal effects have to do with alterations in protein binding that are induced by uremia. In end-stage renal failure, serum levels are not an accurate guide to therapy and the goal should be to attain adequate free concentrations of, for example, 1 to 2 mg/mL. In addition, uremia causes the accumulation of phenytoin metabolites, which are measured with the parent drug by enzyme-multiplied immunoassay techniques. In patients who are being dialyzed, total blood levels of phenytoin

tend to be low because of decreased protein binding; in this situation it is also necessary to track free (unbound) phenytoin levels. Because dialysis removes phenobarbital and ethosuximide, dosage of these drugs may have to be increased. Decreased phenytoin levels are also known to occur during viral illnesses, and supplementary doses are occasionally necessary.

Teratogenic Effects of Antiepileptic Medications

Because it is essential to prevent convulsions in the pregnant epileptic woman, anticonvulsant medication should not be discontinued or arbitrarily reduced, particularly if there have been recent convulsions. The conventional drugs (phenytoin, carbamazepine, phenobarbital, valproate, lamotrigine) are all tolerated in pregnancy. Plasma levels of most of these drugs, both the free and protein-bound fractions, fall slightly in pregnancy and are cleared more rapidly from the blood. The main practical issue pertains to the potential teratogenicity of most of the drugs with valproate having slightly more risk than the others, and a slight reduction in IQ in children born of mothers who had been exposed to valproate during pregnancy.

The most common teratogenic effects have been cleft lip and cleft palate, but infrequently also a subtle facial dysmorphism (“fetal anticonvulsant syndrome”), similar to the fetal alcohol syndrome. The risks are highest with valproate. In general, the risk of major congenital defects is low; it increases to 4 to 5 percent in women taking anticonvulsant drugs during pregnancy, in comparison to 2 to 3 percent in the overall population of pregnant women. These statistics are essentially confirmed in the large study by Holmes and colleagues, conducted among several Boston hospitals. When all types of malformations were included, both major and minor, 20 percent of infants born to mothers who took anticonvulsants during pregnancy showed abnormalities, compared to 9 percent of mothers who had not taken medications. These authors identified “midface hypoplasia” (shortened nose, philtrum, or inner canthal distance) and finger hypoplasia as characteristic of anticonvulsant exposure; these changes were found in 13 and 8 percent of exposed infants, respectively. However, it should be emphasized that in large surveys, major malformations have occurred in only 5 percent of infants exposed to antiepileptic drugs. The infants born of a group of women with epilepsy who had not taken anticonvulsants during pregnancy showed an overall rate of dysmorphic features comparable to that in control infants, but there was still a 2 to 3 percent rate of facial and finger hypoplasia. This risk is shared more or less equally by all the major anticonvulsants again, with concern that valproate is associated with a higher rate. Aggregating eight databases, Jetnik and colleagues found a number of malformations of the nervous and somatic systems to be increased in comparison to other antiepileptic drugs.

Of equal or greater concern has been the findings by Meador and colleagues that in utero exposure to valproate was associated with lower IQs (by 9 points) compared to lamotrigine in children at the age of 4. It is not clear if the effect persists after this age. Children who had been exposed to phenytoin or to carbamazepine also

had slightly lower IQs but this difference was ostensibly accounted for by lower maternal IQ. Some studies, including the one by Meador and colleagues (2011) suggest that folate may have an ameliorating effect on this detrimental effect at age 3, whereas there is an uncertain benefit in preventing fetal malformations.

The risk of neural tube defects is also slightly increased by anticonvulsants during pregnancy, and greatest for the use of valproate. It had been considered to be reduced by giving folate before pregnancy has begun (it is not clear if this is true for valproate), but epilepsy experts avoid the use of valproate during pregnancy altogether. These risks are greater in women taking more than one anticonvulsant, so that monotherapy is a desirable goal. Furthermore, the risk is disproportionately increased in families with a history of these defects. Some of the newer anticonvulsants should probably be used cautiously until greater experience has been obtained. As each new anticonvulsant has been introduced over the years, there has usually been a tentative claim of reduced teratogenic effects, often proven later to be incorrect. Claims have been made of safety in this regard for lamotrigine, causing many specialists to change from the more conventional drugs to this one in women who anticipate becoming pregnant, but lamotrigine levels tend to fall precipitously during pregnancy. A report by Cunningham and colleagues using registry information suggests that the incidence of major birth defects in the fetuses exposed to lamotrigine during the first trimester is just under 3 percent, similar to risk estimates for the general population but also close to the 3 to 4 percent risk derived from most registries of women on anticonvulsants. Polytherapy with lamotrigine and valproate raised the estimate of risk to 12 percent.

If a woman with seizure disorder has been off epilepsy medications for a time before getting pregnant and seizes during the pregnancy, the best choice of medication currently may be phenytoin for its advantage in rapid seizure control, or levetiracetam. Exposure of the fetus late in gestation poses few teratogenic risks. If a woman discovers she is pregnant while on an antiepileptic drug, changing medications is unlikely to reduce the chances of birth defects, even for valproate, but this drug retains the risk of lower IQ in the child. The special case of eclamptic seizures is managed by infusion of magnesium. Epileptic women of childbearing age should be advised that higher doses of the estradiol component of birth control agents are required or they may be exposed to the issues of becoming pregnant while antiepileptic medications.

Skin Eruptions from Antiepileptic Drugs

Rashes are the most frequent idiosyncratic reactions to the drugs used to treat epilepsy. The aromatic compounds (phenytoin, carbamazepine, phenobarbital, primidone, and lamotrigine) are the ones most often responsible. Furthermore, there is a high degree of cross-reactivity within this group, particularly between phenytoin, carbamazepine, and phenobarbital, and, possibly, lamotrigine. The problem arises most often in the first month of use. The typical eruption is maculopapular, mainly on the trunk; it usually resolves within days of discontinuing the

medication. More severe rashes may develop, sometimes taking the form of erythema multiforme and Stevens-Johnson syndrome, or even toxic epidermal necrolysis, especially with lamotrigine.

Certain polymorphisms in HLA genes (HLA-B*1502) have been associated with an increased risk of these types of severe skin reactions, particularly those of Asian ancestry but probably also in Caucasians, in whom this genotype is rare. Another allele HLA-A* 3101 may be associated with skin eruptions in Caucasians (McCormack et al), but it (HLA-B 1502) does not seem reasonable at this time to screen non-Asian patients for such an infrequent complication. Another rare systemic hypersensitivity syndrome associated with the use of antiepileptic medications is one of high fever, rash, lymphadenopathy, and pharyngitis. Eosinophilia and hepatitis (or nephritis) may follow.

If any of these reactions require that one of the aromatic drugs be replaced, valproate, gabapentin, topiramate, or levetiracetam are reasonable substitutes, depending, of course, on the nature of the seizures.

Discontinuation of Anticonvulsants

Withdrawal of anticonvulsant drugs may be undertaken in patients who have been free of seizures for a prolonged period. There are few firm rules to guide the physician in this decision. One plan, applicable to most forms of epilepsy, is to obtain an EEG whenever withdrawal of medication is contemplated. We have taken the approach that if the tracing is abnormal by way of showing paroxysmal activity, it is generally better to continue treatment. However, a normal EEG may not be helpful in making the decision to discontinue medications. A prospective study by Callaghan and colleagues showed that in patients who had been seizure-free during 2 years of treatment with a single drug, one-third relapsed after discontinuation of the drug, and this relapse rate was much the same in adults and children and whether the drug was reduced over a period of weeks or months. The relapse rate was lower in patients with absence and generalized-onset seizures than in patients with focal seizures. Another study by Specchio and colleagues gave results similar to those of the large Medical Research Council Antiepileptic Drug Withdrawal Study—namely, that after 2 years on a single anticonvulsant during which no seizures had occurred, the rate of relapse was 40 percent 2.5 years later and 50 percent at 5 years after discontinuation; this compared to a seizure recurrence rate of 20 percent for patients remaining on medication. Other epileptologists have suggested that a longer seizure-free period is associated with a lesser rate of relapse.

Often in practice, the suggestion to stop medications after a lengthy seizure free period comes from the patient, for example if pregnancy is planned or there are untoward side effects but otherwise, the change is never risk free and therefore is infrequently impelled by the physician. Decisions regarding the cessation of medication are also tempered by patient's desire to continue driving and their concern that another seizure may prevent a return to driving.

Patients with juvenile myoclonic epilepsy, even those with long seizure-free periods, should probably continue

medication life-long, but there have been no thorough studies to support this dictum. In young women with this disorder who plan or a likely to become pregnant, changing from valproate to levetiracetam may be sensible. The appropriate duration of treatment for postinfection epilepsy has not been studied, and most neurologists continue to use one drug indefinitely. Interestingly, epilepsy caused by military brain wounds tends to wane in frequency or to disappear in 20 to 30 years, thereafter no longer requiring treatment (Caveness). In contrast, childhood uncomplicated absence seizures do not require lifelong treatment.

A curious and unexplained lesion in the splenium of the corpus callosum has been detected in patients who have had their antiepileptic drug(s) withdrawn in the previous few days. A review of 16 patients by Gürtler and colleagues did not find a clinical correlate for this change. A broad range of drugs was implicated and the lesion was most prominent on FLAIR MRI.

Specific Drugs in the Treatment of Seizures

General Comments

Phenytoin, carbamazepine, levetiracetam, and *valproate* are representative antiepileptic drugs and are more or less equally effective in the treatment of both generalized and partial seizures (see Table 16-5 for typical initial dosages). Valproate is probably less effective in the treatment of complex partial seizures. The first two of these drugs putatively act by blocking sodium channels, thus preventing abnormal neuronal firing and seizure spread. Lamotrigine is emerging as a popular alternative for partial seizures with a different side effect profile from the other three.

Because carbamazepine (or the related oxcarbazepine) and levetiracetam have somewhat fewer side effects, one or the other is preferred as the initial drug by many neurologists, though phenytoin and valproate have very similar therapeutic and side-effect profiles. Carbamazepine and valproate are probably preferable to phenytoin for epileptic children because they do not coarsen facial features and do not produce gum hypertrophy or breast enlargement. In many cases, phenytoin or carbamazepine alone will control the seizures. If not, the use of valproate (which facilitates GABA activity) alone, or the combined use of phenytoin and carbamazepine, produces better control. In others, the addition of valproate to carbamazepine may prove effective. Because of the high incidence of myoclonic epilepsy in adolescence, it has been our practice to use valproate as the first drug in this age group. Weight gain, menstrual irregularities (see below) during the period of initiation of valproate, and its teratogenic effects may also figure into the decision regarding the choice of initial drug for otherwise uncomplicated seizures in young women.

Most of the commonly used antiepileptic drugs cause, to varying degrees, a decrease in bone density and an increased risk of fracture from osteoporosis in older patients, particularly in women. Several mechanisms are probably active, among them, induction of the cytochrome P450 system, which enzymatically degrades vitamin D.

No specific recommendations have been offered to counteract this effect of bone loss, but we have advised patients to take calcium supplements or one of the bisphosphonates if there is no contraindication, or to check bone density at regular intervals.

Finally, several reports and meta analyses over the past decades have suggested that antiepileptic drugs might increase the incidence of suicide, both in individuals with epilepsy and psychiatric patients. The issue may never be entirely resolved because of confounding factors but a patient level-analysis performed by Arana and colleagues showed no such relationship in epilepsy once underlying depression was accounted for.

Phenytoin Oral, intramuscular, and intravenous forms are available. Rash, fever, lymphadenopathy, eosinophilia and other blood dyscrasias, and polyarteritis are manifestations of idiosyncratic *phenytoin hypersensitivity*; their occurrence calls for discontinuation of the medication. *Overdose with phenytoin* causes ataxia, diplopia, and stupor. The prolonged use of phenytoin often leads to hirsutism (mainly in young girls), hypertrophy of gums, and coarsening of facial features in children. A clinical trial conducted by Arya and colleagues suggests that folate supplementation may prevent gingival hyperplasia in children. Chronic phenytoin use over several decades may occasionally be associated with peripheral neuropathy and probably with a form of cerebellar degeneration (Lindvall and Nilsson); it is not clear if these are strictly dose-related effects or idiosyncratic reactions. An antifolate effect on blood and interference with vitamin K metabolism have also been reported, for which reason pregnant women taking phenytoin (and in fact most other antiepileptic drugs) should be given folate supplementation and vitamin K before delivery and the newborn infant also should receive vitamin K to prevent bleeding. Phenytoin should not be used together with disulfiram (Antabuse), chloramphenicol, sulfamethizole, phenylbutazone, or cyclophosphamide, and the use of either phenobarbital or phenytoin is not advisable in patients receiving warfarin (Coumadin) because of the undesirable interactions already described. Choreoathetosis is a rare idiosyncratic side effect. Fosphenytoin for intramuscular and intravenous administration allows somewhat faster attainment of serum levels and may have minor advantages in special circumstances, especially the availability of the IM route. Intravenous phenytoin and fosphenytoin are discussed further in the section on status epilepticus.

Carbamazepine This drug causes many of the same side effects as phenytoin, but to a slightly lesser degree. Mild leukopenia is common, and there have been rare instances of pancytopenia, hyponatremia (inappropriate antidiuretic hormone [ADH]), and, rarely, diabetes insipidus as idiosyncratic reactions. It is advisable therefore, that a complete blood count be done before or soon after treatment is instituted and that counts are rechecked regularly. *Oxcarbazepine*, a more recently introduced analogue of carbamazepine, has fewer of these side effects than the parent drug, especially marrow toxicity, but its long-term therapeutic value is not as well established. Hyponatremia has been reported in 3 percent of patients

taking oxcarbazepine. Should drowsiness or increased seizure frequency occur, this complication should be suspected.

Valproate All preparations of this drug are occasionally hepatotoxic, an adverse effect that is usually (but not invariably) limited to children 2 years of age and younger. The use of valproate with hepatic enzyme-inducing drugs increases the risk of liver toxicity. However, mild elevations of serum ammonia and mild impairments of liver function tests in an adult do not require discontinuation of the drug. An increasingly emphasized problem with valproate has been weight gain during the first months of therapy. In one study there was an average addition of 5.8 kg, and even more in those disposed to obesity. In addition, menstrual irregularities and polycystic ovarian syndrome may appear in young women taking the drug, perhaps as a consequence of the aforementioned weight gain. Pancreatitis is a rare but important complication of valproate. Tremor and slight bradykinesias have been seen and they vaguely simulate parkinsonism. The major issues, however, pertain to its use in pregnancy as discussed earlier.

An intravenous form of valproate is available and may be useful in status epilepticus. The maximum recommended rate of administration is 3 mg/kg per min.

Phenobarbital Introduced as an antiepileptic drug in 1912, phenobarbital is still highly effective, but because of its toxic effects—drowsiness and mental dullness, nystagmus, and staggering, as well as the availability of better alternatives—it is seldom used in adults. The adverse effects of *primidone* are much the same. Both drugs may provoke behavioral problems in developmentally delayed children and they are still used to advantage as an adjunctive anticonvulsant and as primary therapy in infantile seizures.

Lamotrigine *Lamotrigine* closely resembles phenytoin in its antiseizure activity but has different features relating to toxicity. It functions by selectively blocking the slow sodium channel, thereby preventing the release of the excitatory transmitters glutamate and aspartate. It is effective as a first-line and adjunctive drug for generalized and focal seizures, and may be an alternative to valproate in young women because it does not provoke weight gain and ovarian problems. The main limitation to its use has been a serious rash in approximately 1 percent of patients, requiring discontinuation of the drug, and lesser dermatologic eruptions in 12 percent. It should be pointed out that some registries have reported considerably lower rates of these complications. The slow introduction of the medication may reduce the incidence of drug eruptions (see below). Rare cases of reversible chorea have been reported, especially with the concurrent use of phenytoin. Combined use with valproate greatly increases the serum level of lamotrigine.

Levetiracetam This is a relatively novel drug with uncertain mechanism that has been useful in the treatment of both partial and generalized seizures. The agent affects the SV2A synaptic vesicle protein, but how this relates to its antiepileptic properties is still being investigated. It is well tolerated if initiated slowly, but produces considerable sleepiness and dizziness otherwise and if used at high doses. It also may produce irritability and depression.

A major advantage is that there are no important interactions with other antiepileptic drugs for which reason it is often chosen as a first-line agent in patients who have organ failure and require numerous medications, as well as those receiving hepatically-metabolized chemotherapeutics.

Other Antiepileptic Drugs Two other drugs, *gabapentin* and *vigabatrin*, were synthesized specifically to enhance the intrinsic inhibitory system of GABA in the brain. Gabapentin is chemically similar to GABA, but its anticonvulsant mechanism is not known; it has an apparent effect on calcium channels. It is moderately effective in partial and secondary generalized seizures and has the advantage of not being metabolized by the liver. Vigabatrin inhibits GABA transaminase. Vigabatrin is no longer used in adults because of the side effect or retinal damage. *Tiagabine* is considered to be an inhibitor of GABA reuptake.

Topiramate, has much the same mode of action and probably a broader effectiveness as tiagabine. It will rarely cause serious dermatologic side effects, especially if used with valproate, and appears to induce renal stones in 1.5 percent of patients. Angle-closure glaucoma has also been reported as a complication. A minor problem has been the development of hyperchloremic metabolic acidosis.

Lacosamide, a potent drug for seizures that have a focal onset and generalize or remain focal, is currently used currently mainly as an adjunctive therapy. Like levetiracetam, its mechanism of action is not entirely known but it has been shown to modulate voltage-gated sodium channel activity. The main but infrequent side effects are headache and diplopia. The drug may prolong the P-R interval and worsen heart failure.

Ethosuximide and valproate are equally effective for the treatment of absence seizures, the former having fewer cognitive side effects according to a study by Glauser and colleagues. It is good practice, so as to avoid excessive sleepiness, to begin with a single dose of 250 mg of ethosuximide per day and to increase it every week until the optimum therapeutic effect is achieved. *Methsuximide* (Celontin) is useful in individual cases where ethosuximide and valproate have failed. In patients with benign absence attacks that are associated with photosensitivity, myoclonus, and clonic-tonic-clonic seizures (including juvenile myoclonic epilepsy), valproate is the drug of choice. Valproate is particularly useful in children who have both absence and grand mal attacks, as the use of this drug alone often permits the control of both types of seizures. The concurrent use of valproate and clonazepam has been known to produce absence status.

Zonisamide, similar to topiramate, seems to be useful for myoclonic epilepsy but its main use is currently as an adjuvant in al epilepsy. It is not a sodium channel blocker and can be taken in parallel with carbamazepine. Some clinicians have found it to produce fewer cognitive side effects than topiramate.

Treatment of Seizures in the Neonate and Young Child

This specialized area of neonatal seizures is discussed by Fenichel and by Volpe and in children by Guerrini. In general, phenobarbital has been preferred for seizure

control in infancy. Probably the form of epilepsy that is most difficult to treat is the childhood *Lennox-Gastaut* syndrome. Some of these patients have as many as 50 or more seizures per day, and there may be no effective combination of anticonvulsant medications. Valproic acid (900 to 2,400 mg/d) will reduce the frequency of spells in approximately half the cases. The newer drugs—lamotrigine, topiramate, vigabatrin—are each effective in approximately 25 percent of cases. Clonazepam also has had limited success. In the special case of Dravet syndrome, a disorder of the sodium channel, antiepileptic drugs that block that same channel are avoided.

In the treatment of infantile spasms, ACTH or adrenal corticosteroids had been used, but vigabatrin is now found to be as effective, including in patients with underlying tuberous sclerosis (see Elterman et al).

Status Epilepticus

Recurrent generalized convulsions at a frequency that precludes regaining of consciousness in the interval between seizures (convulsive status) constitutes the most serious problem in epilepsy, with an overall mortality of 20 to 30 percent, according to Towne and colleagues, but probably lower in recent years. Some patients who die of epilepsy do so because of uncontrolled seizures of this type, complicated by the effects of the underlying illness or an injury sustained as a result of a convulsion. Rising temperature, acidosis, hypotension, and renal failure from myoglobinuria is a sequence of life-threatening events that may be encountered in cases of convulsive status epilepticus. Prolonged convulsive status (for longer than 30 min) also carries a risk of serious neurologic sequelae (“epileptic encephalopathy”). The MRI during and for days after a bout of status epilepticus may show signal abnormalities in the region of a focal seizure or in the hippocampi, most often reversible, but we have had several such patients who awakened and were left in a permanent amnesic state. The MRI changes are most evident on FLAIR and diffusion-weighted sequences. With regard to acute medical complications, from time to time a case of neurogenic pulmonary edema is encountered during or just after the convulsions, and some patients may become extremely hypertensive, making it difficult to distinguish the syndrome from hypertensive encephalopathy.

The etiologies of status epilepticus vary among age groups but all the fundamental causes of seizures are able to produce the syndrome. The most recalcitrant cases we have encountered in adults have been associated with viral or paraneoplastic encephalitis, old traumatic injury, and epilepsy with severe mental retardation. Stroke and brain tumor have, in contrast, been infrequent causes.

Treatment of Convulsive Status Epilepticus (Table 16-8)

The many regimens that have been proposed for the treatment of status epilepticus attest to the fact that no one of them is altogether satisfactory and none is clearly superior (Treiman et al).

We have had the most success with the following program: When the patient is first seen, an initial

Table 16-8

APPROACH TO THE TREATMENT OF STATUS EPILEPTICUS IN ADULTS**Initial assessment**

- Ensure adequate ventilation, oxygenation, blood pressure
- Intubate if necessary, based on low oxygen saturation and labored breathing
- Insert intravenous line
- Administer glucose and thiamine in appropriate circumstances
- Send toxic screen
- Assess quickly for cranial and cervical injury if onset of seizures is unwitnessed

Immediate suppression of convulsions

- Lorazepam or diazepam, 2 to 4 mg/min IV to a total dose of 10 to 15 mg with blood pressure monitoring when higher rates or doses are used

Initiation or reloading with anticonvulsants

- Phenytoin 15–20 mg/kg IV at 25–50 mg/min in normal saline or fosphenytoin at 50 to 75 mg/min

General anesthetic doses of medication for persistent status epilepticus

- Midazolam 0.2 mg/kg loading dose followed by infusion at 0.1 to 0.4 mg/kg/h or propofol 2 mg/kg/h

Further treatment if convulsions or electrographic seizures persist after several hours

- May add valproate or phenobarbital 10 mg/min to total dose of 20 mg/kg as additional anticonvulsants intravenously, or carbamazepine or levetiracetam by nasogastric tube if there is gastric and bowel activity
- Consider neuromuscular paralysis with EEG monitoring if convulsions persist
- Pentobarbital 10 mg/kg/h
- Inhalational anesthetics (isoflurane)

assessment of cardiorespiratory function is made and an oral airway established. A large-bore intravenous line is inserted; blood is drawn for glucose, BUN, electrolytes, and a metabolic and drug screen. A normal saline infusion is begun and a bolus of glucose is given (with thiamine if malnutrition and alcoholism are potential factors). To rapidly suppress the seizures, we have used diazepam intravenously at a rate of about 2 mg/min until the seizures stop or a total of 20 mg has been given; alternatively, lorazepam, 0.1 mg/kg given by intravenous push at a rate not to exceed 2 mg/min, is now favored, being marginally more effective than diazepam because of its clinically longer duration of action (see Table 16-8).

Immediately thereafter, a loading dose (20 mg/kg) of phenytoin is administered by vein at a rate of less than 50 mg/min. More rapid administration risks hypotension and heart block; consequently, it is recommended that the blood pressure and electrocardiogram be monitored during the infusion. Phenytoin must be given through a freely running line with normal saline (it precipitates in other fluids) and should not be injected intramuscularly. A study by Treiman and colleagues has demonstrated the superiority of using lorazepam instead of phenytoin as the first drug to control status, but this is not surprising considering the longer latency of onset of phenytoin.

In the field, emergency medical technicians can administer lorazepam drug or midazolam. Attesting to the benefit of rapidly treating seizures, Silbergleit and colleagues have shown that intramuscular administration is slightly superior to the intravenous route simply

because of the delay in inserting an intravenous line. Allredge and colleagues showed that diazepam can be administered by paramedical workers in nursing homes with good effect in status epilepticus, terminating the seizures in about half of cases.

Nonetheless, a long-acting antiepileptic such as phenytoin must be given immediately after a diazepam has controlled the initial seizures. An alternative is the water-soluble drug fosphenytoin, which is administered in the same dose equivalents as phenytoin but can be injected at twice the maximum rate. Moreover, it can be given intramuscularly in cases where venous access is difficult. However, the delay in hepatic conversion of fosphenytoin to active phenytoin makes the latency of clinical effect approximately the same for both drugs.

In an epileptic patient known to be taking seizure medications chronically but in whom the serum level of drug is unknown, it is probably best to administer the full-recommended dose of phenytoin. If it can be established that the serum phenytoin is above 10 mg/mL, a lower loading dose may be advisable. If seizures continue, an additional 5 mg/kg is indicated. If this fails to suppress the seizures and status has persisted for 20 to 30 min, an endotracheal tube should be inserted and O₂ administered.

Having emphasized the dangers of this syndrome, at each stage of treatment it is worthwhile considering if a refractory convulsive episode is of psychogenic, non-epileptic nature. The reader is referred to the previous section on this subject.

Several approaches have been suggested to control status epilepticus that persists after these efforts. At this stage we have resorted to the approach suggested by Kumar and Bleck of giving high doses of midazolam (0.2 mg/kg loading dose followed by an infusion of 0.1 to 0.4 mg/kg/h as determined by clinical and EEG monitoring). If seizures continue, the dose can be raised as blood pressure permits. We have used in excess of 20 mg/h because of a diminishing effect over days. This regimen of midazolam and phenytoin may be maintained for several days without major ill effect in previously healthy patients. Propofol given in a bolus of 2 mg/kg and then as an intravenous drip of 2 to 8 mg/kg/h is an effective alternative to midazolam, but after 24 h the drug behaves like a high dose of barbiturate and there may be hypotension. Prolonged use of propofol may precipitate hypertriglyceridemia-associated pancreatitis or a fatal shock and acidosis ("propofol syndrome").

Valproate and levetiracetam are available as intravenous preparations, making them suitable for administration in status, but their role in this circumstance has not been extensively studied. Another dependable approach is infusion of either pentobarbital, starting with 5 mg/kg, or phenobarbital, at a rate of 100 mg/min until the seizures stop or a total dose of 20 mg/kg is reached; a long period of stupor must be anticipated after. Hypotension often limits the continued use of the barbiturates, but Parviainen and colleagues were able to manage this problem by fluid infusions, dopamine, and neosynephrine.

If none of these measures controls the seizures, a more aggressive approach is taken to subdue all brain

electrical activity by the use of general anesthesia. The preferred medications for this purpose have been pentobarbital or propofol, which, despite their moderate efficacy as primary anticonvulsants, are easier to manage than the alternative inhalational anesthetic agents. An initial intravenous dose of 5 mg/kg pentobarbital or 2 mg/kg propofol is given slowly to induce an EEG burst-suppression pattern, which is then maintained by the administration of pentobarbital, 0.5 to 2 mg/kg/h, or propofol, up to 10 mg/kg/h. Every 12 to 24 h, the rate of infusion is slowed to determine whether the seizures have stopped. The experience of Lowenstein and colleagues, like our own, is that most instances of status epilepticus that cannot be controlled with the combination of standard anticonvulsants and midazolam will respond to high doses of barbiturates or to propofol, but that these infusions cause hypotension and cannot be carried out for long periods.

Should the seizures continue, either clinically or electrographically, despite all these medications, one is justified in the assumption that the convulsive tendency is so strong that it cannot be checked by reasonable quantities of medications. However, a few patients in this predicament have survived and awakened, even at times with minimal neurologic damage depending on the underlying cause.

The volatile anesthetic agent isoflurane has also been used in these circumstances with good effect, as we have reported (Ropper et al), but the continuous administration of inhalational anesthetic agents is impractical in most critical care units. Halothane has been relatively ineffective as an anticonvulsant, but ether, although impractical, has in the past been effective in some. In the end, in patients with truly intractable status, one usually depends on phenytoin, phenobarbital (smaller doses in infants and children than are shown in Table 16-8), and on measures that safeguard the patient's vital functions. Ketamine infusions have been a last resort, in combination with a midazolam infusion. A few times over the years, we have also resorted to inducing ketosis in adults by manipulating the nutrition given through a nasogastric tube.

A word is added here concerning neuromuscular paralysis and continuous EEG monitoring in status epilepticus. With failure of aggressive anticonvulsant and anesthetic treatment, there may be a temptation to paralyze all muscular activity, an effect easily attained with drugs such as pancuronium, while neglecting the underlying seizures. The use of neuromuscular blocking drugs without a concomitant attempt to suppress seizure activity is inadvisable. If such measures are undertaken, continuous or frequent intermittent EEG monitoring is essential; this may also be helpful in the early stages of status epilepticus in that it guides the dosages of anticonvulsants required to suppress the seizures.

In the related but less-serious condition of *acute repetitive seizures*, in which the patient awakens between convulsions, a diazepam gel, which is well absorbed if given rectally, is available and has been found useful in institutional and home care of epileptic patients, although it is quite expensive. A similar effect has been

attained by the nasal or buccal (transmucosal) administration of midazolam, which is absorbed from these sites (5 mg/mL, 0.2 mg/kg nasally; 2 mL to 10 mg buccally). Midazolam may be preferred among the diazepamines for transmucosal use because it produces somewhat less respiratory depression than the others in the class and has been more effective at controlling seizures according to a study by McIntyre and colleagues. Still, only half were controlled. These approaches have found their main use in children with frequent seizures who live in supervised environments, where a nurse or parent is available to administer the medication.

Absence status should be managed by intravenous lorazepam, valproic acid, or both, followed by ethosuximide. Nonconvulsive generalized status is treated along the lines of grand mal status, usually stopping short of using anesthetic agents (see Meierkord). In the case of *epilepsia partialis continua*, typically a difficult condition to control, a balance must be found between stopping the phenomenon and the risk of overuse of medications that can produce stupor. The patient must be involved by way of determining how troubling the movements are to him.

Surgical Treatment of Epilepsy

The surgical excision of epileptic foci that have not responded to intensive and prolonged medical therapy is being used with increasing effectiveness in a growing number of specialized epilepsy units. At these centers, it has been estimated that approximately 25 percent of all patients with epilepsy are candidates for surgical therapy and more than half of these may benefit from extirpation of the epileptic cortical focus. With increasing experience and standardized approaches, especially in patients with temporal lobe epilepsy, it has been suggested that many patients are waiting too long before the surgical option. A perspective that may promote surgery in even more patients is the observation that approximately 60 percent of patients with focal seizures will respond to a conventional anticonvulsant, but that among the remainder, few will respond to the addition of a second or third drug.

However, considerable effort, time and technology are required to determine the site of epileptic discharge and the method of safe removal of the cortical tissue. To locate the discharging focus requires a careful analysis of clinical, imaging, and EEG findings, often including those obtained by long-term video/EEG monitoring and, sometimes, intracranial EEG recording by means of intraparenchymal depth electrodes, subdural strip electrodes, and subdural grids. Recently, functional imaging, magnetoencephalography, and specialized EEG analysis have been introduced to supplement these methods.

The most favorable candidates for surgery are those with focal seizures that induce altered consciousness and a unilateral temporal lobe focus, in whom rates of cure and significant improvement approach 90 percent in some series but overall, are probably closer to 50 percent after 5 years. A randomized trial conducted by Wiebe and colleagues gave representative results after temporal

lobectomy of 58 percent of 40 carefully studied patients remaining seizure-free after 1 year, in contrast to 8 percent on medication alone. Furthermore, as reported by Yoon and colleagues, among those patients who remain free of seizures for 1 year after surgery, more than half are still free of seizures after 10 years and most of the remainder had one or fewer episodes per year. It should be emphasized that most of the patients who underwent surgery in these studies still required anticonvulsant medication. Excision of cortical tissue that contains a structural lesion outside of the temporal lobe accomplishes complete seizure-free states in approximately 50 percent. Taking all seizure types together, only approximately 10 percent of patients obtain no improvement at all and less than 5 percent are worse. The matter of resection of areas of focal cortical dysplasias in children is a highly specialized area. It has been indicated that the histologic features of the dysplasia are important determinants of the success of surgery (Fauser et al).

Other surgical procedures of value in highly selected cases are sectioning of the corpus callosum, which is for the most part palliative, and hemispherectomy, which may be curative in special circumstances. The most encouraging results with callosotomy have been obtained in the control of intractable partial and secondarily generalized seizures, particularly when atonic drop attacks are the most disabling seizure type. Removal of the entire cortex of one hemisphere, in addition to the amygdala and hippocampus, has been of value in children, as well as in some adults with severe and extensive unilateral cerebral disease and intractable contralateral motor seizures and hemiplegia. Rasmussen encephalitis, Sturge-Weber disease, and large porencephalic cysts at times fall into this category. Surgical, focused radiation, or endovascular reduction of arteriovenous malformations may reduce the frequency of seizures, but the results in this regard are somewhat unpredictable (see Chap. 34).

Vagal Nerve Stimulation

This technique has found some favor in cases of intractable partial and secondarily generalizing seizures. A pacemaker-like device is implanted in the anterior chest wall and stimulating electrodes are connected to the vagus at the left carotid bifurcation. The procedure is well tolerated except for hoarseness in some cases. Several trials have demonstrated an average of 25 percent reduction in seizure frequency among patients who were resistant to all manner of anticonvulsant drugs (see Chadwick for a discussion of clinical trials). The mechanism by which vagal stimulation produces its effects is unclear, and its role in the management of seizures is still being defined. Stimulation of the cerebellum and of other sites in the brain has also been used in the control of seizures, with no clear evidence of success. They must currently be considered to be experimental.

Ketogenic Diet

Since the 1920s, interest in this form of seizure control has varied, being revived periodically in centers caring for many children with intractable epilepsy. Despite the

absence of controlled studies showing its efficacy or an agreed upon hypothesis for its mechanism, several trials in the first half of the twentieth century, and again more recently, demonstrated a reduction in seizures in half of the patients, including handicapped children with severe and sometimes intractable episodes. The diet is used mainly in children between the ages of 1 and 10 years. The regimen is initiated during hospitalization by starvation for a day or two in order to induce ketosis, followed by a diet in which 80 to 90 percent of the calories are derived from fat (Vining). The difficulties in making such a diet palatable leads to its abandonment by about one-third of children and their families.

A summary of experience from the numerous trials of the ketogenic diet can be found in the review by Lefevre and Aronson and in the report of its use in 58 children by Kinsman and colleagues. They both concluded that the diet is effective in refractory cases of epilepsy in childhood, reducing seizure frequency in two-thirds of children and allowing a reduction in the amount of anticonvulsant medication in many. It has also been commented that some benefit persists even after the diet has been stopped. Nephrolithiasis is a complication in somewhat less than 10 percent of children, and this risk is particularly high if topiramate is being used.

Ketogenic diet is the main treatment for children with GLUT1 deficiency syndrome, as discussed earlier.

Safety and Regulation of Physical and Mental Activity

Driving and Epilepsy

A person with incompletely controlled epilepsy should not be allowed to drive an automobile. Only a few states in the United States and most provinces of Canada mandate that physicians report patients with seizures under their care to the state motor vehicle bureau. Nonetheless, physicians should counsel such a patient regarding the obvious danger to himself and others if a seizure should occur while driving (the same holds for the risks of swimming unattended). What few data are available suggest that accidents caused directly by a seizure are rare and, in any case, 15 percent have been the result of a first episode of seizure that could not have been anticipated. In some states where a driver's license has been suspended on the occurrence of a seizure, there is usually some provision for its reinstatement—such as a physician's declaration that the patient is under medical care and has been seizure-free for some period of time (usually 6 months or 1 to 2 years). The Epilepsy Foundation website can be consulted for updated information regarding restrictions on driving, and this serves as an excellent general resource for patients and their families (<http://www.efa.org>).

General Health Hygiene

The most important factors in seizure breakthrough, next to the abandonment of medication or a natural reduction of serum levels of medication, are loss of sleep and abuse of alcohol or other drugs. The need for moderation in

the use of alcohol must be stressed, as well as the need to maintain regular hours of sleep. Advice to colleagues about moderating alcohol is particularly important.

With proper safeguards, even potentially more dangerous sports, such as swimming, may be permitted. However, operating unguarded machinery, climbing ladders, or taking baths behind locked doors are not advisable; such a person should swim only in the company of a good swimmer. There is concern about epileptic mothers bathing their infants without additional safety guards.

Psychosocial difficulties are common and must be identified and addressed early. The stigma of epilepsy remains an issue in society. Advice and reassurance to attempt to pursue a normal life will aid in preventing or overcoming any feelings of inferiority and self-consciousness of many younger patients with epilepsy. However, the situation is rarely so simple and patients and their families may benefit from more extensive counseling.

Coma and Related Disorders of Consciousness

In hospital and emergency neurology, the clinical analysis of unresponsive and comatose patients becomes a practical necessity. There is always an urgent need to determine the underlying disease and the direction in which it is evolving in order to protect the brain against more serious or irreversible damage. When called upon, the physician must therefore be prepared to implement a rapid, systematic investigation of the comatose patient and prompt therapeutic and diagnostic action that allows little time for deliberate, leisurely investigation.

Some idea of the dimensions of the problem of coma can be obtained from published statistics. Eighty years ago, in two large municipal hospitals, it was estimated that 3 percent of all admissions to the emergency wards were for diseases that had caused coma. Alcoholism, cerebral trauma, and cerebrovascular diseases were the most common, accounting for 82 percent of the comatose patients admitted to the Boston City Hospital (Solomon and Aring). Epilepsy, drug intoxication, diabetes, and severe infections were the other major causes for admission. It is perhaps surprising to learn that more contemporary figures from large city hospitals are much the same; they emphasize that the common conditions underlying coma are relatively invariant in general medical practice. For example, in the series collected by Plum and Posner (Table 17-1), only 25 percent proved to have cerebrovascular disease, and in only 6 percent was coma the consequence of trauma. Indeed, all intracranial masses and their secondary effects—such as tumors, abscesses, hemorrhages, and infarcts—made up less than one-third of the coma-producing diseases. A majority was the result of exogenous (drug overdose) and endogenous (metabolic) intoxications and hypoxia. Subarachnoid hemorrhage, meningitis, and encephalitis accounted for another 5 percent of the total. Thus, intoxication, stroke, and cranial trauma stand as the “big three” of coma-producing conditions. Equally common in some series, although obvious and usually transient, is the coma that follows seizures or resuscitation from cardiac arrest.

The terms *consciousness*, *confusion*, *stupor*, *unconsciousness*, and *coma* have been endowed with so many different meanings that it is almost impossible to avoid ambiguity in their usage. They are not strictly medical terms but are also literary, philosophic, and psychologic ones. The word *consciousness* is the most difficult of all.

William James remarked that everyone knows what consciousness is until he attempts to define it. To the psychologist, consciousness denotes a state of continuous awareness of one's self and environment. Knowledge of self includes all “feelings, attitudes and emotions, impulses, volitions, and the active or striving aspects of conduct”; in short, a near continuous self-awareness of a person's mental functioning, particularly of cognitive processes and their relation to memories and experience. These can be judged only by the individual's verbal account of his introspections and indirectly, by his actions.

Physicians, being more practical and objective for the most part, give greater credence to the patient's behavior and reactions to overt stimuli than to what the patient says. For this reason, they use the term *consciousness* in its broadest operational meaning—namely, the state of awareness of self and environment, and responsiveness to external stimulation and inner need. This narrow definition has an advantage in that *unconsciousness* has the opposite meaning: a state of unawareness of self and environment or a suspension of those mental activities by which people are made aware of themselves and their environment, coupled always with a diminished responsiveness to environmental stimuli.

Arousal, or the level of consciousness, refers to the appearance of being *awake* as displayed by the facial muscles, eye opening, fixity of gaze, and body posture, i.e., wakefulness. A clear distinction is made in medicine between the *level* of consciousness and the *content* of consciousness, the latter reflecting the quality and coherence of thought and behavior. For neurological purposes, the loss of normal arousal is by far the more important and dramatic aspect of disordered consciousness and the one identified by laypersons and physicians as being the central feature of coma.

Much more could be said about the history of our ideas concerning consciousness, and the theoretical problems with regard to its definition. There has been an ongoing polemic among philosophers of mind as to whether it will ever be possible to understand mind and consciousness in terms of reductionist physical entities, such as cellular and molecular neural systems. Although it serves little practical purpose to review these subjects in detail here, we note that contemporary investigations indicate that one constructive approach is to define the

Table 17-1

FINAL DIAGNOSIS IN 500 PATIENTS ADMITTED TO HOSPITAL WITH "COMA OF UNKNOWN ETIOLOGY"

Metabolic and other diffuse disorders	326 (65%)
Drug poisoning	149
Anoxia or ischemia	87
Hepatic encephalopathy	17
Encephalomyelitis and encephalitis	14
Subarachnoid hemorrhage	13
Endocrine disorders (including diabetes)	12
Acid–base disorders	12
Temperature regulation	9
Uremic encephalopathy	8
Pulmonary disease	3
Nutritional	1
Nonspecific metabolic coma	1
Supratentorial mass lesions	101 (20%)
Intracerebral hematoma	44
Subdural hematoma	26
Cerebral infarct	9
Brain tumor	7
Brain abscess	6
Epidural hematoma	4
Thalamic infarct	2
Pituitary apoplexy	2
Closed head injury	1
Subtentorial lesions	65 (13%)
Brainstem infarct	40
Pontine hemorrhage	11
Cerebellar hemorrhage	5
Cerebellar tumor	3
Cerebellar infarct	2
Brainstem demyelination	1
Cerebellar abscess	1
Posterior fossa subdural hemorrhage	1
Basilar migraine	1
Psychiatric disorders	8 (2%)

Note: Listed here are only those patients in whom the initial diagnosis was uncertain, and a final diagnosis was established. Thus, obvious poisonings and closed head injuries are underrepresented.

Source: Adapted from Plum and Posner.

neurobiologic correlates of those elements of consciousness that are subject to observation by behavioral, electrical, and particularly imaging methods. Importantly, these controversies are informed in neurology by analyses of unusual neurologic disorders, such as those that disturb perception and consciousness of perception (phantom limb, "blindsight," etc.). The interested reader is referred to the discussions of consciousness by Crick and Koch, Plum and Posner, Young, and Zeman listed in the references.

STATES OF NORMAL AND IMPAIRED CONSCIOUSNESS

The following definitions are of service to clinicians and provide a convenient terminology for describing the states of awareness and responsiveness of patients.

Normal Consciousness

This is the condition of the normal person when awake. In this state the individual is fully responsive to a thought

or perception and indicates by his behavior and speech the same awareness of self and environment as that of the examiner. There is attention to, and interaction with, the immediate surroundings. This normal state may fluctuate during the day from one of keen alertness or deep concentration with a marked constriction of the field of attention to one of mild general inattentiveness, but even in the latter circumstances, the normal individual can be brought immediately to a state of full alertness and function.

Confusion

The term *confusion* lacks precision, but in general it denotes an inability to think with customary speed, clarity, and coherence. Almost all states of confusion are marked by some degree of inattentiveness and disorientation. In this condition the patient does not take into account all elements of his immediate environment. This state also implies a degree of imperceptiveness and distractibility, referred to traditionally as "clouding of the sensorium." Here, one difficulty is to define *thinking*, a term that refers variably to problem solving or to coherence of ideas. Confusion results most often from a process that influences the brain globally, such as a toxic or metabolic disturbance or a dementia. In addition, any condition that causes drowsiness or stupor, including the natural state that comes from sleep deprivation, results in some degradation of mental performance and the emergence of inattentiveness and a state of confusion. In this way, confusion, which exists along the axis of *content* of consciousness, is linked to alertness and the *level* of consciousness.

A confusional state can also accompany focal cerebral disease in various locations, particularly in the right hemisphere, or result from disorders that disturb mainly language, memory, or visuospatial orientation, but a distinction is made between these isolated disruptions in mental function and the global confusional state. They represent special states that are analyzed differently, matters discussed further in Chaps. 20 and 23.

The mildest degree of confusion may be so slight that it can be overlooked unless the examiner searches for deviations from the patient's normal behavior and ability to carry on a coherent conversation. The patient may even be roughly oriented as to time and place, with only occasional irrelevant remarks betraying a lack of clarity and slowness of thinking. Their responses are inconsistent, attention span is reduced, and they are unable to stay on one topic, together suggesting a fundamental flaw in attention. Usually, they are disoriented and distractible, at the mercy of every stimulus. Sequences of movement may reveal impersistence and poor planning.

Severely confused and inattentive persons are unable to do more than carry out the simplest commands, and these only inconsistently and in brief sequence. Speech may be limited to a few words or phrases; or the opposite pertains—namely, some confused individuals are voluble. They give the appearance of being unaware of much that goes on around them, are disoriented in time and place, do not grasp their immediate situation or the predicament of their own confusion, and may misidentify

people or objects. These illusions may lead to fear or agitation. Occasionally, hallucinatory, illusionary, or delusional experiences impart a psychotic cast to the clinical picture, obscuring the deficit in attention.

Many events that involve the confused patient leave no trace in memory; in fact, the capacity to recall events of the past hours or days is one of the most delicate tests of mental clarity. Another is the use of “working memory,” which requires the temporary storage of the solution of one task for use in the next. A deficit in working memory, which is such a common feature of the confusional states, can be demonstrated by tests of serial subtraction, and the spelling of words (or repeating a phone number) forward and then backward. Careful analysis will show these defects to be tied to inattention and impaired perception or registration of information rather than to a fault in retentive memory. These phenomena that betray inattention are the central features of most confusional states. As already stated, the observed behavior of a confused person transcends inattention alone. It may incorporate elements of clouded interpretation of internal and external experience, and an inability to integrate and attach symbolic meaning to experience (apperception). The degree of confusion often varies from one time of day to another. It tends to be least pronounced in the morning and increases as the day wears on, peaking in the early evening hours (“sundowning”) when the patient is fatigued, and environmental cues are not as clear.

In some medical writings, particularly in the psychiatric literature, the terms *delirium* and *confusion* are used interchangeably, the former connoting nothing more than a nondescript confusional state. However, in the syndrome of delirium tremens (observed most often but not exclusively in alcoholics), the vivid hallucinations; extreme agitation; trembling, startling easily, and convulsion; and the signs of overactivity of the autonomic nervous system suggest to us that the term *delirium* should be retained for this type of highly distinctive confusional syndrome (elaborated in Chap. 20).

As commented earlier in the discussion of the term “confusion,” a relationship between the level of consciousness and disordered thinking or, content of consciousness, is evident as patients pass through states of inattention, drowsiness, confusion, stupor, and coma.

Drowsiness and Stupor

In these states, mental, speech, and physical activity are reduced. *Drowsiness* denotes an inability to sustain a wakeful state without the application of external stimuli. Furthermore, in distinction to stupor discussed later, alertness is sustained spontaneously for at least some brief period, without the further necessity of stimuli. As a rule, some degree of inattentiveness and mild confusion are coupled with drowsiness, both improving with arousal. The patient still shifts positions somewhat naturally and without prompting. The lids droop; there may be snoring, the jaw and limb muscles are slack, and the limbs are relaxed. This state is indistinguishable from light sleep, sometimes with, slow arousal elicited by speaking to the patient or applying a tactile stimulus.

Stupor describes a state in which the patient can be roused only by vigorous and repeated stimuli and in which arousal cannot be sustained without repeated stimulation. Responses to spoken commands are either absent, curtailed, or slow and inadequate. Restless or stereotyped motor activity is common, and there is a reduction or elimination of the natural shifting of body positions. When left unstimulated, these patients quickly drift back into a deep sleep-like state. The eyes move outward and upward, a feature that is shared with sleep (see further on). Tendon and plantar reflexes, and the breathing pattern may or may not be altered, depending on how the underlying disease has affected the nervous system. In psychiatry, the term *stupor* has been used in a second sense—to denote an uncommon condition in which the perception of sensory stimuli is presumably normal but activity is suspended and motor activity is profoundly diminished (catatonia, or catatonic stupor).

However, these states, including coma, exist in a continuum, and an alternative practical method of making distinctions between them was given by Fisher, who suggested that a verbal command is required to overcome drowsiness whereas a noxious stimulus is required to overcome stupor. This allows for further gradations in the level of consciousness based on the intensity of stimulation that is necessary to produce arousal. Also encompassed in this continuum is the observation that stuporous and drowsy patients may not always be aroused to a fully awake state.

Coma

The patient who is incapable of being aroused by external stimuli or inner need, is in a state of coma. There are variations in the degree of coma, and the findings and signs depend on the underlying cause of the disorder. In its deepest stages, no meaningful or purposeful reaction of any kind is obtainable and corneal, pupillary, pharyngeal responses are diminished. In lighter stages, sometimes referred to by the ambiguous terms *semicoma* or *obtundation*, most of the above reflexes can be elicited, and the plantar reflexes may be either flexor or extensor (Babinski sign). As mentioned, the depth of coma and stupor may be gauged by the response to externally applied stimuli and is most useful in assessing the direction in which the disease is evolving, particularly when compared in serial examinations.

Relationship of Sleep to Coma

Persons in sleep give little evidence of being aware of themselves or their environment; in this respect, they are unconscious. Sleep shares a number of other features with the pathologic states of drowsiness, stupor, and coma. These include yawning, closure of the eyelids, cessation of blinking and reduction in swallowing, upward deviation or divergence or roving movements of the eyes, loss of muscular tone, decrease or loss of tendon reflexes, and even the presence of Babinski signs and irregular respirations, sometimes Cheyne-Stokes in type. Upon being awakened from deep sleep, a normal person

may be confused for a few moments, as every physician knows from personal experience. Nevertheless, sleeping persons may still respond to unaccustomed stimuli and are capable of some mental activity in the form of dreams that leave traces of memory, thus differing from stupor or coma. The most important difference, of course, is that persons in sleep, when stimulated, can be roused to normal and persistent consciousness. There are important physiologic differences as well. Cerebral oxygen uptake does not decrease during sleep, as it usually does in coma. Recordable electrical activity—electroencephalographic (EEG) and cerebral evoked responses—and spontaneous motor activity differ in the two states, as indicated later in this chapter and in Chap. 19. The anatomic and physiologic bases for these differences are only partly known.

THE VEGETATIVE AND MINIMALLY CONSCIOUS STATES, LOCKED-IN SYNDROME, AND AKINETIC MUTISM

Vegetative State

With increasing refinements in the treatment of severe systemic diseases and cerebral injury, larger numbers of patients, who formerly would have died, have survived for indefinite periods without regaining any meaningful mental function. For the first week or two after the cerebral injury, these patients are in a state of deep coma. Then they begin to open their eyes, at first in response to painful stimuli, and later spontaneously and for increasingly prolonged periods. The patient may blink in response to threat or to light and intermittently the eyes move from side to side, seemingly following objects or fixating momentarily on the physician or a family member and giving the erroneous impression of recognition. Respiration may quicken in response to stimulation, and certain automatisms—such as swallowing, bruxism, grimacing, grunting, and moaning—may be observed (Zeman). However, the patient remains unresponsive and, for the most part, unconscious, does not speak, and shows no signs of awareness of the environment or inner need; motor activity is limited to primitive postural and reflex movements of the limbs. There is loss of sphincter control. There may be arousal or wakefulness in alternating cycles as reflected in partial eye opening, but the patient regains neither awareness nor purposeful behavior. These features define the *vegetative* state. One sign of the vegetative state is a lack of *consistent* visual following of objects; brief observation of ocular movements is subject to misinterpretation, and repeated examinations are required. These perspectives have been altered by the findings of some conscious activity that can be detected by functional imaging in relation to certain commands and verbal cues such as the individual's name as detailed below.

This state is characterized by one of a number of EEG abnormalities. There may be predominantly low-amplitude delta-frequency background activity, burst suppression, widespread alpha and theta activity, an

alpha coma pattern, and sleep spindles, all of which have been described in this syndrome, as summarized by Hansotia (see Chap. 2). One important feature is a lack of—or minimal change in—the background EEG activity during and after stimulating the patient.

In the initial days and weeks, this syndrome of unconscious awakening has been referred to as the vegetative state and, if lasting 3 months after nontraumatic and 12 months after traumatic injury, the syndrome has been termed the *persistent vegetative state* (PVS; Jennett and Plum). These terms have gained wide acceptance and apply to this clinical appearance whatever the underlying cause.

The most common pathologic bases of this state are diffuse cerebral injury as a result of closed head trauma, widespread necrosis of the cortex after cardiac arrest, and thalamic necrosis from a number of causes. Most often, the prominent pathologic changes are in the thalamic and subthalamic nuclei, as in the widely known Quinlan case (Kinney et al) rather than solely in the cortex; this holds for postanoxic as well as traumatic cases. A review by J.H. Adams and colleagues found these thalamic changes, but attributed them to secondary degeneration from white matter and cortical lesions. However, in several of our cases the thalamic damage stood almost alone as the cause of persistent “awake coma.” In traumatic cases, the pathologic findings are often of diffuse subcortical white matter degeneration (described as *diffuse axonal injury*), prominent thalamic degeneration, and ischemic damage in the cortex. Taken together, these anatomic findings suggest the concept that PVS is a state in which the cortex is either diffusely injured or effectively disconnected and isolated from the thalamus, or the thalamic nuclei are destroyed. In either the traumatic or anoxic types of PVS, atrophy of the cerebral white matter may lead to ventricular enlargement and thinning of the corpus callosum.

The vegetative state or the minimally conscious state described further on, may also be the terminal phase of progressive cortical degenerative processes such as Alzheimer and Creutzfeldt-Jakob disease (where the pathologic changes may include the thalamus).

In all these clinical states, the profound and widespread dysfunction of the cerebrum is reflected by extreme reductions in cerebral blood flow and metabolism, measured with positron emission tomography (PET) and other techniques. On the basis of PET studies in a patient with carbon monoxide poisoning, Laureys and colleagues observed that the main difference between the vegetative state and the later recovered state was the degree of hypometabolism in the parietal lobe association areas. Anatomic changes in this same cortical region have been implicated in the transition from minimally conscious to a more awake state. The finding in this PET study that noxious somatosensory stimulation fails to activate the association cortices is consistent with the concept that large regions of cortex are isolated from thalamic input or that the critical parietal interpretive areas are isolated from the rest of the cortex.

Of practical value is the observation that the CT and MRI may show progressive and profound cerebral atrophy in cases of vegetative state. In the absence of this

atrophy after several months or more, it may be unwise to offer a pessimistic prognosis. One patient with clinical features of the traumatic vegetative state but lacking cerebral atrophy on imaging studies regained normal cognitive ability after a year, although he remained paralyzed (R. Cranford, personal communication).

These observations notwithstanding, there is little doubt that the neuroanatomic and neurophysiologic basis of the vegetative state will prove to be complex or at least separable into categories defined by the locus of brain damage. In particular, a striking observation has been made by Owen and colleagues in a 23-year-old woman who had been vegetative for 5 months after a head injury (thus not strictly speaking a “persistent” vegetative state). They observed localized cortical activity in the middle and superior temporal gyri in response to the presentation of spoken sentences that was comparable to the brain activity in normal individuals. Di and colleagues have similarly demonstrated brain activation only to the patient’s own name and not to other names in vegetative patients. These data suggest that some forms of mental processing can go on during a vegetative state but it is not clear if this situation is representative nor does it provide information about self-awareness, a requisite for consciousness. The most compelling demonstration of cognitive processing in vegetative and minimally conscious patients has been provided by Monti and colleagues as displayed by functional MRI. Five of their 54 patients, all with traumatic brain injury but none after anoxic ischemic damage, could on command, willfully modulate focal brain activity by playing tennis (frontal lobe activation) or mentally navigating a familiar place such as their home (temporal lobe activation). In one patient, this activity could be used as a means of communication.

At a minimum, these demonstrations emphasize the care that must be taken in establishing diagnoses of PVS and minimally conscious states. Whether these findings with functional imaging simply reflect preserved islands of function in severe brain injury that were not examinable clinically or whether they require an entire rethinking of the neurologic examination that determines the state of consciousness cannot yet be stated (see editorial by Ropper, 2010).

An additional observation of some consequence is the finding of purported axonal growth over time in a patient with traumatic brain injury who had been in a minimally conscious state (see below) for 19 years and then began to speak and comprehend, while remaining virtually quadriplegic. Voss and colleagues, using sophisticated MRI diffusion tensor imaging, have shown axonal sprouting in the posterior parietal and midline cerebellar regions. They compared the results of tensor imaging to a patient who had been in a minimally conscious state for 6 years without improvement and to 20 normal individuals. Their findings are subject to several interpretations, but axonal growth in the parietal lobes offers a potential explanation for the few instances in which recovery from severe injury does occur. When combined with the findings of Laureys and colleagues, a case can be made for the posterior parietal regions as necessary for integrated consciousness. This further raise

the possibility that certain islands of limited awareness may be dissociated from global brain function.

Additional terms that have been used to describe this syndrome of preserved autonomic and respiratory function without cognition include *apallic syndrome* and *neocortical death*. A position paper has codified the features of the PVS and suggests dropping a number of related ambiguous terms, although some, such as *akinetic mutism*, discussed further on, have a more specific neurologic meaning and are still useful (see Multi-Society Task Force on PVS).

It is difficult to predict which comatose patients will later fall permanently into the vegetative or minimally conscious categories (see Chap. 40). Plum and Posner reported that of 45 patients with signs of the vegetative state at 1 week after onset, 13 had awakened and 5 of these had satisfactory outcomes. After being vegetative for close to 2 weeks, only 1 recovered to a level of moderate disability; after 2 weeks, the prognosis was uniformly poor. Larger studies by Higashi and colleagues have given similar results. As a rough guide to prognosis specifically in head injury, Braakman and colleagues found that among a large group of comatose patients, 59 percent regained consciousness within 6 h, but of those in a vegetative state at 3 months, none became independent. At no time before 3 or 6 months was it possible to distinguish patients who would remain in a vegetative state from those who would die. Further comments regarding recovery are made in the next section on the minimally conscious state.

A study by the Multi-Society Task Force on PVS concluded that the outcome from a vegetative state is better in traumatic as compared to nontraumatic cases. J.H. Adams and coworkers have proposed that this reflects differences in the state of thalamic neurons in the two situations. They suggested that after acute hypoxia, neurons subjected to ischemic necrosis are liable to be permanently lost; by contrast, in trauma, the loss of thalamic neurons is more frequently secondary to transsynaptic degeneration following diffuse axonal injury, allowing a greater potential for recovery. Many of these ideas are speculative.

Minimally Conscious State

The vegetative state blends into a less severe but still profound dementia that has been termed the “minimally conscious state,” wherein the patient is capable of some rudimentary behavior such as following a simple command, gesturing, or producing single words or brief phrases, always in an inconsistent way from one examination to another (see Giacino et al). Here, there is preservation of the ability to carry out basic motor behaviors that demonstrate a degree of awareness, at least at some times. The minimally conscious state is found as either a transitional or permanent condition and is sometimes difficult to separate from akinetic mutism discussed further on. Any notion of such a patient’s self-awareness is purely conjectural, but there may be an impressive array of behaviors and activation of associative cortex that suggest at least some relationship to processing of external information beyond a rudimentary level (see discussion

by Bernat). The causes and pathologic changes underlying the minimally conscious state are identical to those of the vegetative state, including the frequent finding of thalamic and multiple cerebral lesions, and the distinction between them is one of degree.

It is useful to maintain a critical view of reports of remarkable recuperation after months or years of prolonged coma or the vegetative state. When the details of such cases become known, it is evident that recovery might reasonably have been expected. There are, however, numerous reported instances of partial recovery in patients—particularly children and young adults—who display vegetative features for several weeks or, as Andrews and Childs and Mercer describe, even several months after injury. Such observations cast doubt on unqualified claims of success with certain therapies, such as sensory stimulation. Nevertheless, the occurrence of very late recovery in adults must be acknowledged (see Andrews; Higashi et al; and Rosenberg et al, 1977) and a relation of awakening to the recovery of connections to the parietal lobes has already been mentioned. Cases of improvement from the “minimally conscious state” are more plausible than those from the vegetative state. More recent reports, for example by Estraneo and colleagues and by Luaté and coworkers, may be more instructive but still not entirely directive. In contrast to the notion that late recovery is exceptional, the first case series of 50 consecutive patients in a PVS for a year, 10 showed late improvement an average of 2 years later, but all were severely impaired. In the second series, none of the 12 vegetative patients improved at 5 years but 13 of 39 MCS cases emerged to consciousness with severe disability. Of course, the assignment of a poor prognosis by the application of these terms to an individual patient often leads to the withdrawal of care, and the self-fulfilling poor prognosis. This is a much discussed problem that has not been satisfactorily but it emphasizes that simply labeling patients with certain diagnoses has implications for accurately assessing the natural history of some diseases.

Among the interesting recent therapeutic observations, one observation has come from Schiff and colleagues, who were able to improve function by stimulating the medial (interlaminar) thalamic nuclei through implanted electrodes in a patient who had been initially vegetative and made a natural transition to a minimally conscious state after traumatic brain injury. Longer periods of eye opening and increased responses to execute commands, such as bringing a cup to his mouth, were observed, including, for the first time since his injury, intelligible verbalization. The authors point out that this individual had preserved language cortex and connections between thalamus and cortex. Whether this remarkable result is generalizable is not known.

It cannot go without comment that the degree of disability that families find acceptable varies greatly and leads to difficult decisions regarding the continuation of medical care. The knowledgeable, sympathetic, and flexible physician is in the best position to offer perspective and guide these matters as discussed at the end of this chapter.

Locked-in Syndrome

The states of coma described above and the vegetative state must be distinguished from a syndrome in which there is little or no disturbance of consciousness, but only an inability of the patient to respond adequately. The latter is referred to as the *locked-in syndrome* or the *deafferented state*. The term *pseudocoma* as a synonym for this state is best avoided, because it is used by some physicians to connote the unconsciousness of the hysteric or malingeringer, the dissociative state, or catatonia. The locked-in syndrome is most often caused by a lesion of the ventral pons (basis pontis) as a result of occlusion of the basilar artery. Such an infarction spares both the somatosensory pathways, and the ascending neuronal systems responsible for arousal and wakefulness, as well as certain midbrain elements that allow the eyelids to be raised in wakefulness; the lesion essentially interrupts the corticobulbar and corticospinal pathways, depriving the patient of speech and the capacity to respond in any way except by vertical gaze and blinking. Severe motor neuropathy (e.g., Guillain-Barré syndrome), pontine myelinolysis, or periodic paralysis may have a similar effect.

Akinetic Mutism

One could logically refer to the locked-in state as *akinetic mutism* insofar as the patient is akinetic (motionless) and mute, but this is not the sense in which the term was originally used by Cairns and colleagues, who described a patient who appeared to be awake but was unresponsive (actually their patient was able to answer in whispered monosyllables). Following each of several drainings of a third ventricular cyst, the patient would become aware and responsive but would have no memory for any of the events that had taken place when she was in the akinetic mute state. This state of apparent vigilance in an imperceptive and unresponsive patient has been referred to by French authors as *coma vigile*, but the same term has been applied to the vegetative state.

The term *akinetic mutism* has been applied to yet another group of patients who are silent and inert as a result of bilateral lesions usually of the anterior parts of the frontal lobes, leaving intact the motor and sensory pathways; the patient is profoundly apathetic, lacking to an extreme degree the psychic drive or impulse to action (abulia). However, the abulic patient, unlike Cairns' patient, registers most of what is happening about him and is intensely stimulated, may speak normally, relating events observed in the recent and distant past.

Catatonia

The patient with *catatonia* appears unresponsive, in a state that simulates stupor, light coma, or akinetic mutism. There are no signs of structural brain disease, such as pupillary or reflex abnormalities. Oculocephalic responses are preserved, as in the awake state—i.e., the eyes move concurrently as the head is turned. There is usually resistance to eye opening, and some patients display a waxy flexibility of passive limb movement that

gives the examiner a feeling of bending a wax rod (*flexibilitas cerea*); there is also the retention for a long period of seemingly uncomfortable limb postures (*cataplexy*). Peculiar motor mannerisms or repetitive motions, seen in a number of these patients, may give the impression of seizures; choreiform jerking has also been reported, but the latter sign should also suggest the possibility of seizure activity. The EEG shows normal posterior alpha activity that is attenuated by stimulation. Catatonia is discussed further in Chaps. 20 and 53.

Because there is considerable imprecision in the use of terms by which various states of reduced consciousness are designated, the physician would be better advised to supplement designations such as *coma* and *akinetic mutism* by simple descriptions indicating whether the patient appears awake or asleep, drowsy or alert, aware or unaware of his surroundings, and responsive or unresponsive to a variety of stimuli. This requires that the patient be observed more frequently or over a longer period than the several minutes usually devoted to this portion of the neurologic examination. The aforementioned findings of apparent limited responsiveness reflected with functional imaging only further emphasizes the care with which these clinical diagnoses should be determined.

BRAIN DEATH

In the late 1950s, European neurologists called attention to a state of coma in which the brain was irreversibly damaged and had ceased to function, but pulmonary and cardiac function could still be maintained by artificial means. Mollaret and Goulon referred to this condition as *coma dépassé* (a state beyond coma). A Harvard Medical School committee, in 1968, called it *brain death* and established a set of clinical criteria by which it could be recognized (Beecher et al). R.D. Adams, who was a member of the committee, defined the state as one of complete unresponsiveness to all modes of stimulation, arrest of respiration, and absence of all EEG activity for 24 h. The concept that a person is dead if the brain is dead and that death of the brain may precede the cessation of cardiac function has posed a number of important ethical, legal, and social problems, as well as medical ones. All aspects of brain death have since been the subject of close study by several professional committees, which for the most part have confirmed the 1968 guidelines for determining that the brain is dead. The American Academy of neurology published guidelines on this subject in 1995 and affirmed them with some refinements in 2010. The monograph by Wijdicks is a thorough modern source on the subject of brain death and also addresses the subject from an international perspective.

The philosophical underpinnings of the equating of brain death to death, giving it the same status as cessation of cardiorespiratory death, a utilitarian approach, are complex.

The ethical and moral dimensions of brain death are complex and subject to differing interpretations in various

societies, religions, and cultures. One justification for equating brain death with somatic death is the general inevitability of cardiorespiratory failure in patients who fulfill the standard criteria. This tenet has exceptions, the most striking of which is a well-studied case of 20-year survival in a boy who had meningitis reported by Reptinger and colleagues, and other cases of long survival have been described with varying degrees of documentation. These have been collected by Shewmon who makes the further point that the arguments equating brain death with death on the basis of the brain's role in creating "somatic unity" are weakened by the existence of such cases as well as by delivery of live babies from brain-dead mothers. In the end, these philosophical concerns matter but the operational state called brain death serves both patients and society well and is compatible with most of the world's religions.

The central considerations in the diagnosis of brain death are (1) absence of all cerebral functions; (2) absence of all brainstem functions, including spontaneous respiration; and (3) irreversibility of the state. Following from the last of these criteria, it is necessary to demonstrate an irrefutable cause of the underlying catastrophic brain damage (e.g., trauma, cardiac arrest, cerebral hemorrhage) and to exclude reversible causes such as drug overdose and extreme hypothermia.

In the diagnosis of brain death, the absence of cerebral function is demonstrated by the presence of deep coma and total lack of spontaneous movement and of motor and vocal responses to all visual, auditory, and cutaneous stimulation. Spinal reflexes may persist, and the toes often flex slowly in response to plantar stimulation; but a well-developed Babinski sign is unusual in our experience (although its presence does not exclude the diagnosis of brain death). Extensor or flexor posturing is seen from time to time as a transitional phenomenon just before or after brain death becomes evident, and the status of these movements in the diagnosis is ambiguous, but the physician should proceed cautiously in declaring a patient dead in the presence of posturing and should consider conducting the examination again at a later time.

The absence of brainstem function is judged by the loss of spontaneous eye movements, midposition of the eyes, and lack of response to oculocephalic and caloric (oculovestibular) testing; the presence of dilated or midposition fixed pupils (not smaller than 3 mm); paralysis of bulbar musculature (no facial movement or gag, cough, corneal, or sucking reflexes); an absence of motor and autonomic responses to noxious stimuli; and absence of respiratory movements. The clinical findings should show complete absence of brain function, not an approximation that might be reflected, e.g., by small or poorly reactive pupils, slight eye deviation with oculovestibular stimulation, posturing of the limbs, as mentioned earlier.

As a demonstration of destruction of the medulla, it has become customary to perform an "apnea test" to demonstrate unresponsiveness of the medullary centers to a high carbon dioxide tension. This test is conducted by first employing preoxygenation for several minutes

with high inspired oxygen tension, the purpose of which is to displace nitrogen from the alveoli and create a reservoir of oxygen that will diffuse along a gradient into the pulmonary circulation. The patient can then be disconnected from the respirator for several minutes during which time 100 percent oxygen is being delivered by cannula or ventilator that has its pumping mechanism turned off; this allows the arterial P_{CO_2} to rise to 50 to 60 mm Hg (typically, CO_2 rises approximately 2.5 mm Hg per minute at normal body temperature—slower if the patient is hypothermic). The hypercarbia serves both as a stimulus to breathing and a confirmation that spontaneous ventilation has failed. If no breathing is observed and examination of the blood gases shows that an adequate level of P_{CO_2} has been attained, the presence of this component of brain death is corroborated. Several sets of formal criteria have chosen a level of CO_2 of 60 mm Hg (7.98 kPa [kilopascals]) as adequate to stimulate the medulla, even under circumstances in which it has been badly damaged. In our experience, patients who have a severely damaged brainstem but nonetheless breathe, have done so at a P_{CO_2} well below 50 mm Hg, but there are exceptions in which higher levels were required as a stimulus.

The risks of apnea testing are minimal, as discussed in the American Academy of Neurology's 2010 document, but hypotension, hypoxemia, cardiac arrhythmias, and barotrauma may occasionally occur. In patients who cannot tolerate the test for more than a brief period, initially raising the CO_2 rapidly by insufflation of this gas has been suggested, but this approach has not been studied extensively. Delivering oxygen during the test with a low tidal volume and a ventilator rate of 1 to 2 breaths per minute or by continuous positive airway pressure may ameliorate hypoxia and resultant hypotension to allow apnea to continue for a period long enough to reach the target P_{CO_2} , but this technique has also not been adequately studied.

Most, but not all, brain-dead patients have diabetes insipidus. The absence of this syndrome in some cases reflects the imprecision of clinical signs in detecting a total loss of brain function. Other ancillary bedside tests may be conducted. Among the ones we use from time to time is the inability to produce tachycardia in response to the injection of atropine; this reflects the loss of innervation of the heart by the medullary vagal neurons.

The authors have observed a number of dramatic spontaneous movements when severe hypoxia is attained upon terminal disconnection from the ventilator for several minutes. These include opisthotonos with chest expansion that simulates a breath, elevation of the arms and crossing them in front of the chest or neck (termed the Lazarus sign by Ropper, 1984), head-turning, shoulder-shrugging, and variants of these posturing-like movements. For this reason the advice that the family not be in attendance immediately after mechanical ventilation has been discontinued.

The EEG provides confirmation of cerebral death, and many institutions prefer this corroboration by the demonstration of electrocerebral silence ("flat" or, more accurately, isoelectric EEG, shown first by Schwab).

However, most U.S. institutions do not require an EEG for the confirmation of death. Electroencephalographic silence is considered to be present if there is no electrical potential of more than 2 mV during a 30-min recording except for artifacts created by the ventilator, electrocardiograph, and surrounding electrical devices; the absence of these artifacts suggests a technical problem with the recording.

There are cases on record in which a patient with an isoelectric EEG has had preserved brainstem reflexes so that cerebral unresponsiveness and a flat EEG do not alone signify brain death; both may also occur and may be reversible in states of profound hypothermia or intoxication with sedative-hypnotic drugs and immediately following cardiac arrest. Therefore, it has been recommended that the diagnosis of brain death not be entertained until several hours have passed from the time of initial observation. If the examination is performed at least approximately 6 h after the precipitating event, and there is prima facie evidence of overwhelming brain injury from trauma, or massive cerebral hemorrhage (the most common conditions causing brain death), there is no need for serial testing. If cardiac arrest was the antecedent event, or the cause of neurologic damage is unclear, or drug or alcohol intoxication could reasonably have played a role in suppressing the brainstem reflexes, it is advisable to wait about 24 h before repeating the testing and pronouncing the patient dead. Toxicologic screening of the serum or urine is requisite in the latter circumstances.

The impact of any requirement to perform a second brain death examination at some interval such as 6 hours has been studied by Lustbader and coworkers. Their extensive survey in New York State, where a second examination had been recommended by a panel, was instructive; of 1,311 adult and pediatric cases, none who were found to be brain dead regained brainstem function on a second test that was performed about 18 hours later. However, 12 percent had cardiac arrest and in others, consent for organ donation was withheld during the time between examinations. Several authoritative authors have argued against a second test on this basis.

Because evoked potentials show variable abnormalities in brain-dead patients, they are not of primary value in the diagnosis. Some centers use nuclide brain scanning or cerebral angiography to demonstrate an absence of blood flow to the brain, equating this with brain death; but there are technical pitfalls in the use of these methods, and it is preferable to establish the diagnosis of death primarily on clinical grounds. The specificity of radionuclide scanning is close to 100 percent but there is a self-referential aspect to this statement as the clinical diagnosis has been used as a gold standard. An additional problem arises in the observation that the sensitivity may be only about 75 percent (Joffe et al). Others take the view that demonstrating absent cerebral blood flow equates with brain death. False-negative tests are possible if a small amount of filling of the intracranial vertebral arteries or nuclide uptake in the inferior cerebellum is revealed. The same can be said for transcranial Doppler sonography, which in brain death shows a to-and-fro, *pendelfluss* blood-flow pattern in the basal vessels.

The main difficulties that arise in relation to brain death are not the technical ones, but those involving the sensitive conversations with the family of the patient and, to some extent, with other medical professionals. These tasks often fall to the neurologist. It is best not to embark on clinical or EEG testing for brain death unless there is a clear intention on the part of the physician to remove the ventilator or follow through with organ donation at the end of the process. The nature of testing for brain death and its intended outcome should be explained to the family in plain language. The family's desires regarding organ transplantation should be sought after adequate time has passed for them to absorb the shock of the circumstances. Neurologists must, of course, resist pressures from diverse sources that might lead them to the premature designation of a declaration of brain death. To avoid the appearance of conflict of motivations, most centers have a separate team, often from an organ bank, to address the issues of organ transplantation after brain death has been established. The complex matter of a family's desire to maintain ventilation and other medical support in a brain-dead relative is best addressed with kind consideration and counseling by clergy, ethics ("optimal care") committees, and hospital staff so as to avoid confrontation. Time often allows such situations to be defused.

At the same time, it should be clarified that while brain death is an operational state that allows transplantation to proceed, and mandates withdrawal of ventilation and blood pressure support, patients with overwhelming brain injuries need not fulfill these absolute criteria in order for medical support to be withdrawn.

A task force for the determination of *brain death in children* has recommended the adoption of essentially the same criteria as for adults. However, the great difficulty in evaluating the status of nervous function in relation to perinatal insults, has led them to suggest that the determination not be made before the seventh postnatal day and that the period of observation should be extended to 48 h. As with adults, the possibility of reversible brain dysfunction from toxins, drugs, hypothermia, and hypotension must always be considered.

THE ELECTROENCEPHALOGRAM AND DISTURBANCES OF CONSCIOUSNESS

The EEG provides one of the most delicate confirmations of the fact that states of impaired consciousness are expressions of neurophysiologic changes in the cerebrum. Some change of brain electrical activity occurs in all disturbances of consciousness except for the milder degrees of confusion, delirium tremens, and in catatonia. These alterations usually consist of a disorganization of the EEG background pattern, including disappearance of the normal alpha rhythm and replacement by random slow waves of low to moderate voltage in the initial stages of confusion and drowsiness; a more regular pattern of slow, 2- to 3-per-second waves of high voltage occurs in stupor; slow low-voltage

waves or intermittent suppression of organized electrical activity in the deep coma of hypoxia and ischemia; and, ultimately, a complete absence of electrical activity in brain death.

In some deeply comatose patients, the EEG may transiently show diffuse and variable alpha (8- to 12-Hz) activity, which may be mistaken for the physiologic alpha rhythm. However, this pattern (alpha coma), unlike normal alpha, is not limited to the posterior cerebral regions, is not monorhythmic like normal alpha activity, and displays no reactivity to sensory stimuli. Alpha coma is usually associated with pontine or diffuse cortical lesions and has a poor prognosis (see Iragui and McCutchen). A rarer EEG abnormality is "spindle coma," in which sleep spindles dominate the record (see "Disorders of Sleep Related to Neurologic Disease" in Chap. 19).

The EEG accurately reflects the depth of certain metabolic comas, particularly those caused by hepatic or renal failure. In these conditions, the slow waves become higher in amplitude as coma deepens, ultimately assuming a high-voltage rhythmic delta pattern and a triphasic configuration. Not all cerebral disorders that cause confusion, stupor, and coma have the same effects on the EEG. In cases of intoxication with sedatives, exemplified by barbiturates and diazepam, fast (beta) activity initially replaces normal rhythms. Coma in which myoclonus or twitching is a major clinical feature may show frequent sharp waves or a sharpness of the background slowing of the EEG. A relatively normal EEG in delirium tremens has already been commented on. The differences in EEG changes among metabolic derangements probably represent biologic distinctions at the neuronal level that have not yet been elucidated (see also Chap. 2).

THE ANATOMY AND NEUROPHYSIOLOGY OF ALERTNESS AND COMA

Our current understanding of the anatomy and physiology of alertness comes largely from the elegant experiments of Bremer and of Moruzzi and Magoun in the 1930s and 1940s. Observing cats in whom he had sectioned the brainstem between the pons and midbrain and at the level of the lower medulla, Bremer found that the rostral section caused a sleep-like state and "synchronized" EEG rhythms that were characteristic of sleep; animals with the lower section remained awake with appropriate "desynchronized" EEG rhythms. He interpreted this to mean, in large part correctly, that a constant stream of sensory stimuli, provided by trigeminal and spinal sources, was required to maintain the awake state. More recently, a system of "nonspecific" projections from the thalamus to all cortical regions, independent of any specific sensory nucleus has been demonstrated. A critical refinement of this concept resulted from the observation by Moruzzi and Magoun that electrical stimulation of the medial midbrain tegmentum and adjacent areas just above this level caused a lightly anesthetized animal to become suddenly alert and its EEG to change

correspondingly, i.e., to become “desynchronized,” in a manner identical to normal arousal by sensory stimuli. The sites at which stimulation led to arousal consisted of a series of points extending from the nonspecific medial thalamic nuclei down through the caudal midbrain. These loci were situated along the loosely organized core of neurons that anatomists refer to as the reticular system or formation.

The anatomic studies of the Scheibels have described widespread innervation of the reticular formation by multiple bifurcating and collateral axons of the ascending sensory systems, implying that this area is maintained in a tonically active state by ascending sensory stimulation. Because this region, especially the medial thalamus, projects widely to the cerebral hemispheres, the concept arose of a reticular activating system (RAS) that maintained the alert state and the inactivation or destruction of which led to an unarousable state. In this way, despite a number of experimental inconsistencies (see Steriade), the paramedian upper brainstem tegmentum and lower diencephalon came to be conceived as the locus of the arousal system of the brain.

The anatomic boundaries of the upper brainstem RAS are somewhat indistinct. The neurons of this system are interspersed throughout the paramedian regions of the upper (rostral) pontine and midbrain tegmentum; at the thalamic level, the RAS includes the functionally related posterior paramedian, parafascicular, and medial portions of the centromedian and adjacent intralaminar nuclei. In the brainstem, nuclei of the reticular formation receive collaterals from the spinothalamic and trigeminal-thalamic pathways and project not just to the sensory cortex of the parietal lobe, as do the thalamic relay nuclei for somatic sensation, but to the whole of the cerebral cortex. Thus, it would seem that sensory stimulation has a double effect—it conveys information to the brain from somatic structures and the environment and also activates those parts of the nervous system on which the maintenance of consciousness depends. The cerebral cortex not only receives impulses from the ascending RAS but also modulates this incoming information via corticofugal projections to the reticular formation. Although the physiology of the RAS is far more complicated than this simple formulation would suggest, it nevertheless, as a working idea, retains a great deal of clinical credibility, and makes comprehensible some of the neuropathologic observations noted further on, as well as the effects of deep brain stimulation to improve function in minimally conscious patients (see further on).

The presence of alpha rhythm with the eyes closed is a marker for wakefulness, but its representation at the cortical surface is not required for wakefulness as it is obliterated in cases of bilateral occipital infarction. It is, of course, possible that deep nuclei are still projecting the rhythm to other parts of the cerebrum to maintain wakefulness. Although for many years it has been taught that arousal causes a desynchronization of brain-wave activity (in distinction to the synchronized activity of sleep), it has become apparent that during wakefulness, there is a widespread low-voltage fast rhythm (a gamma rhythm that has a frequency of 30 to 60 Hz).

This activity, coordinated by the thalamus, has been theorized to synchronize cortical activity and to account perhaps for the unification of modular aspects of experience (color, shape, motion) that are processed in different cortical regions. In this way, the rhythm is said to “bind” various aspects of a sensory experience or memory. This fast and widespread electrographic activity is not appreciated with the usual EEG surface recordings but it can be extracted by sophisticated mathematical transformations. Using such electrophysiologic methods, Meador and colleagues have shown that the gamma rhythm can be detected over the primary somatosensory cortex after an electrical stimulus on the contralateral hand is perceived, but not if the patient fails to perceive it. The clinical relevance of the rhythm is uncertain but it has elicited interest because it may give insight into several intriguing questions about conscious experience.

METABOLIC MECHANISMS THAT DISTURB CONSCIOUSNESS

In a number of diseases that disturb consciousness, there is direct interference with the metabolic activities of the nerve cells in the cerebral cortex and the central nuclei of the brain. Hypoxia, global ischemia, hypoglycemia, hyper- and hyposmolar states, acidosis, alkalosis, hypokalemia, hyperammonemia, hypercalcemia, hypercarbia, drug intoxication, and severe vitamin deficiencies are well-known examples (see Chap. 40 and Table 40-1). In general, the loss of consciousness in these conditions parallels the reduction in cerebral metabolism. For example, in the case of global ischemia, in which oxygen and glucose are removed from the brain, an acute drop in cerebral blood flow (CBF) to 25 mL/min/100 g brain tissue from its normal 55 mL/min/100 g causes slowing of the EEG and syncope or impaired consciousness; a drop in CBF below 12 to 15 mL/min/100 g causes electrocerebral silence, coma, and cessation of most neuronal metabolic and synaptic functions. Lower levels of ischemia are tolerated if acquired more slowly, but neurons cannot survive when flow is reduced below 8 to 10 mL/min/100 g. Oxygen consumption of 2 mg/min/100 g (approximately half of normal) is incompatible with an alert state. In other types of metabolic encephalopathy, or with widespread anatomic damage to the hemispheres, blood flow may stay near normal while metabolism is greatly reduced. An exception to these statements is the coma that arises from seizures, in which metabolism and blood flow are greatly increased. Extremes of body temperature (above 41°C [105.8°F] or below 30°C [86°F]) also induce coma through a nonspecific effect on the metabolic activity of neurons. Some of these metabolic changes are probably epiphenomena, reflecting in each particular encephalopathy a specific type of dysfunction in neurons and their supporting cells. Again, for most metabolic alterations, the rate of change is equivalently important to the absolute level in causing a change in consciousness.

The endogenous metabolic toxin(s) that are responsible for coma cannot always be identified. In diabetes,

acetone bodies (acetoacetic acid, β -hydroxybutyric acid, and acetone) are present in high concentration; in uremia, there is probably an accumulation of dialyzable small molecular toxins, notably phenolic derivatives of the aromatic amino acids. In hepatic coma, elevation of blood NH_3 (ammonia) to 5 to 6 times normal levels corresponds roughly to the level of coma. Lactic acidosis may affect the brain by lowering arterial blood pH to less than 7.0. The impairment of consciousness that accompanies pulmonary insufficiency is related mainly to hypercapnia. This is not to say that the toxic effects of these molecules has been confirmed or is well understood, as noted below. In acute hyponatremia ($\text{Na} < 120 \text{ mEq/L}$) of whatever cause, neuronal dysfunction is probably a result of the intracellular movement of water, leading to neuronal swelling and loss of potassium chloride from the cells. The mode of action of bacterial toxins is not fully understood.

Drugs such as general anesthetics, which are addressed more fully in a later section, alcohol, opiates, barbiturates, phenytoin, antidepressants, and benzodiazepines induce coma by their direct effects on neuronal membranes in the cerebrum and RAS or on neurotransmitters and their receptors. Others, such as methyl alcohol and ethylene glycol, both act directly and by producing a metabolic acidosis. Although the coma of toxic and metabolic diseases usually evolves through stages of drowsiness, confusion, and stupor (and the reverse sequence occurs during emergence from coma), each disease imparts its own characteristic clinical features.

The sudden and excessive neuronal discharge that characterizes an epileptic seizure is another common mechanism of coma. Focal seizure activity has little effect on consciousness until it spreads from one side of the brain (and the body if there is a convulsion) to the other. Coma then ensues, presumably because the extension of the seizure discharge to deep central neuronal structures paralyzes their function. In other types of seizures, in which consciousness is interrupted from the very beginning, a diencephalic origin has been postulated (centrencephalic seizures of Penfield, as discussed in Chap. 16), but this idea has been contentious for decades.

Concussion exemplifies yet another special pathophysiologic mechanism of coma. In closed head injury, it has been shown that at the moment of the concussive injury there is an enormous increase in intracranial pressure, on the order of 200 to 700 lb/in^2 , lasting a few thousandths of a second. The vibration set up in the skull and transmitted to the brain was for many years thought to be the basis of the abrupt paralysis of nervous function that characterizes concussive head injury (commotio cerebri). While not excluding this mechanism, it is more likely that the sudden swirling motion of the brain induced by the acceleration or deceleration from blow to the head produces a rotation (torque) of the cerebral hemispheres around the axis of the upper brainstem. Disruption of the function of neurons in some unknown way from the mechanical deformation is the proximate cause of loss of consciousness. These same physical forces, when extreme, cause multiple shearing lesions or hemorrhages in the diencephalon and upper brainstem. Chapter 35 fully discusses the subject of concussion.

Yet another unique form of coma is that produced by inhalation anesthetics. The effects of general anesthesia had for many years been attributed to changes in the physical chemistry of neuronal membranes. More recently, it has been recognized that interactions with ligand-gated ion channels, particularly gamma-aminobutyric acid (GABA)-A receptors and alterations in neurotransmitter function are a more likely mechanism of anesthesia-induced unconsciousness. An extensive summary of what is known about the metabolic neurochemistry of anesthetics has been given by Campagna and colleagues and by Brown and coworkers; it emphasizes the changes in neurotransmitter function rather than alterations in membrane fluidity but still cannot give a unified theory of the effects of these agents, partly because different classes of drug act at different sites. Inhalation anesthetics are unusual among coma-producing drugs in respect to the sequence of inhibitory and excitatory effects that they produce at different concentrations. During anesthesia, sufficient inhibition of brainstem activity can be attained to eliminate the pupillary responses and the corneal reflex. Both return to normal by the time the patient is able to speak. Sustained clonus, exaggerated tendon reflexes, and Babinski signs are common during the process of arousal. Rosenberg and associates systematically studied these findings. Preexisting focal cerebral deficits from strokes often worsen transiently with the administration of anesthetics, as is true to a lesser extent with other sedatives, metabolic encephalopathies, and hyperthermia.

RECURRING STUPOR AND COMA

Aside from repeated drug overdose, recurring episodes of stupor are usually a result of the recurrence of an underlying biochemical derangement, hepatic failure being the most common. A similar condition of periodic hyperammonemic coma in children and adults can come about from urea cycle enzyme defects, such as ornithine transcarbamylase deficiency. These are discussed in Chap. 37.

Under the title of *idiopathic recurring stupor*, a rare condition has been described in adult men who displayed a prolonged state of deep sleepiness lasting from hours to days intermittently over a period of many years. Despite the impression of a sleep disorder related to narcolepsy, the EEG showed widespread fast (beta) activity, and both the stupor and EEG changes were promptly reversed by flumazenil, a benzodiazepine receptor antagonist. During the bouts, a 100 fold increase of circulating endozepine-4, an ostensibly naturally occurring diazepam agonist, was present in the serum and spinal fluid. Subsequently, the authors of the original reports (Lugaresi et al) found, by the use of more advanced techniques, that intoxication with lorazepam may have accounted for at least some of the cases. Although such cases in which diazepam antagonists reverse episodes of recurrent coma continue to be reported (Huberfeld et al), the status of this entity

is ambiguous. The vigilance-producing drug, modafinil, has also been effective in one report (Scott and Ahmed).

A peculiar form of transient unresponsiveness in elderly individuals has been pointed out by Haimovic and Beresford. It accounted for 2 percent of hospitalized patients referred to them for coma. The EEG and other evaluations gave no explanation but their 5 patients had various systemic illnesses. It may recur but appears to be benign. Our patients had no systemic illness with this disorder and were men in their eighth decade who lacked Babinski signs, pupillary abnormalities and, for the most part, eye movement limitations (one had disproportionately better horizontal than vertical gaze with oculocephalic testing). Patients with advanced Parkinson disease will occasionally display episodic unresponsiveness with eyes open.

It is unclear to us whether migraine can cause a similar syndrome, as suggested in the study of familial hemiplegic migraine by Fitzsimmons and Wolfenden. Basilar migraine may exceptionally cause transient stupor and coma. Catatonic stupor and Kleine-Levin syndrome of periodic hypersomnolence and behavioral changes (Chap. 19) also need to be considered.

PATHOLOGIC ANATOMY OF COMA

Coma is produced by 1 of 2 broad problems: The first is clearly morphologic, consisting either of a discrete structural lesion in the upper brainstem and lower diencephalon (which may be primary or secondary to compression) or of more widespread destructive changes throughout the hemispheres. The second is metabolic or submicroscopic, resulting in suppression of neuronal activity in the cerebrum and reticular activating system. The clinical examination in coma is designed to separate these mechanisms and to gauge the depth of brain dysfunction.

With regard to visible lesions, the study of a large number of human cases in which coma preceded death by several days has disclosed 3 types of lesions, each of which directly or indirectly damage the function of the RAS or its projections to the cortices. In the *first type*, a large mass in the cerebral hemisphere—chiefly a tumor; abscess; massive edematous infarct; intracerebral, subarachnoid, subdural, or epidural hemorrhage, or obstructive hydrocephalus—is demonstrable. The mass in or surrounding the hemisphere usually involves only a portion of the cortex and white matter, leaving much of the cerebrum intact. These mass lesions cause coma by secondary compression of the midbrain and subthalamic region of the RAS. Either lateral displacement or compression of these structures by herniation of the temporal lobe into the tentorial opening may be the proximate cause of compression (see below and also Chap. 31). Likewise, a cerebellar lesion may compress the adjacent upper brainstem reticular region by displacing it forward and upward. A detailed clinical record will show the coma to have coincided with these displacements and herniations as discussed further on.

In the *second configuration*, which occurs less frequently than the first, a destructive lesion is located within the thalamus or midbrain, in which case the neurons of the RAS are damaged directly. This pathoanatomic pattern characterizes brainstem stroke from basilar artery occlusion, thalamic and upper brainstem hemorrhages, as well as some forms of traumatic damage.

In the *third type of structural damage*, there is widespread bilateral damage to the cortex and cerebral white matter, the result of traumatic damage (contusions, diffuse axonal injury), bilateral infarcts or hemorrhages, encephalitis, meningitis, hypoxia, or global ischemia. The coma in these cases results from interruption of thalamocortical impulses or from generalized destruction of cortical neurons. It is only if the cerebral lesions are bilateral and extensive that the consciousness is impaired. Many of the diseases in this category also cause severe thalamic damage of the type mentioned earlier; the thalamic damage may contribute to the coma.

Thus, the pathologic changes found in cases of coma are compatible with physiologic deductions—namely that the state of coma correlates with lesions of the diencephalic cortical-activating system of neurons. Small and discrete lesions restricted to the upper dorsal brainstem and lower midline thalami are sufficient to produce coma. A study by Parvizi and Damasio, on the basis of 9 cases of restricted dorsal bilateral pontine lesions, has suggested that damage at a site caudal to the midbrain lesion may cause coma. This view may expand our conceptions of the areas of the reticular system that are necessary for arousal, but further study is justified. One conceptual explanation for this configuration would be the disruption of noradrenergic input from the locus coeruleus to the reticular system.

In the largest group of cases of coma, no structural lesion is revealed by any technique of conventional pathology. Instead, a metabolic or toxic abnormality or generalized electrical discharge (seizure) causes neuronal failure at a subcellular or molecular level.

PATHOANATOMY OF BRAIN DISPLACEMENT AND HERNIATIONS (See Also Chap. 31)

As pointed out above, large, destructive, and space-consuming lesions of the cerebrum, such as hemorrhage, tumor, abscess, or infarction with brain swelling, impair consciousness mostly indirectly by lateral and downward displacement of the subthalamic-upper brainstem structures and herniation of the medial part of the temporal lobe (uncus, hippocampus) into the opening in the tentorium. One consequence of lateral displacement is that the upper midbrain, particularly the cerebral peduncle, is pushed against the opposite free edge of the tentorium (the resulting creasing of the lateral edge of the peduncle is called the *Kernohan notch* or, more properly, the *Kernohan-Woltman phenomenon*). This causes weakness and a Babinski sign ipsilateral to the hemispherical lesion and later, extensor posturing on

that side. The ipsilateral posterior cerebral artery and rarely the cisternal segment of the ipsilateral oculomotor nerve may also be compressed at the edge of the tentorium, leading to infarction of the ipsilateral occipital lobe in the former, and ophthalmoparesis with pupillary enlargement in the latter.

It follows from the foregoing discussion that unilateral destructive lesions of the hemispheres, such as infarcts or hemorrhages, do not usually cause coma unless they create some degree of mass effect, which secondarily compresses the upper brainstem. There are exceptions in which patients with massive strokes affecting the territory of the internal carotid artery are drowsy and inattentive from the onset, even before brain swelling occurs. More often they are simply apathetic with a tendency to keep their eyes closed, a state that may be misinterpreted as stupor.

The term *herniation* refers to the dislocation of a portion of the cerebral or cerebellar hemisphere from its normal position to an adjacent compartment that is bounded by dural folds, a phenomenon that is evident both at the autopsy table and by imaging of the brain. Thus, herniations are termed *transfalcine* (across the falx) or *transtentorial* (through the tentorial aperture) or are named by the structure that is displaced—*cerebellar*, *uncal*, etc. Figure 17-1 and Table 17-2 illustrate these displacements between dural compartments. Plum and Posner, following from earlier observations by McNealy and Plum, divided the transtentorial brainstem displacements into two groups: one a central herniation syndrome with downward displacement and midline compression of the upper brainstem, and the other a unilateral insinuation of the medial temporal lobe,

Figure 17-1. Schematic depiction of brain herniations between dural compartments. Transfalcine (1), transtentorial uncal-parahippocampal (2), cerebellar tonsillar (3), and horizontal (4), causing Kernohan-Woltman notch phenomenon. Herniations are shown in pink. M = mass.

including the uncal gyrus, into the tentorial opening and compression of the midbrain from the sides.

According to these authors, the *central syndrome* takes the form of a rostral-caudal deterioration of brainstem function: there is first confusion, apathy, and drowsiness,

Table 17-2

CLINICOPATHOLOGIC FEATURES OF TEMPORAL LOBE–TRANSTENTORIAL HERNIATION

PATHOLOGIC CHANGE	MECHANISM	CLINICAL DISORDERS
Injury to outer fibers of ipsilateral oculomotor nerve	Strangulation of nerve between herniating tissue and medial petroclinoid ligament; stretching of nerve over clivus from lateral displacement of midbrain; entrapment of nerve between posterior cerebral and superior cerebellar arteries from downward displacement of midbrain	Pupillary dilatation (Hutchinson pupil), ophthalmoplegia later
Creasing of contralateral cerebral peduncle (Kernohan notch)	Pressure of laterally displaced midbrain against sharp edge of tentorium	Hemiplegia ipsilateral to herniation (<i>false localizing sign</i>) and bilateral corticospinal tract signs
Lateral flattening of midbrain, and zones of necrosis and secondary hemorrhages in tegmentum and base of subthalamus, midbrain, and upper pons (Duret hemorrhages)	Crushing of midbrain between herniating temporal lobe and opposite leaf of tentorium and vascular occlusion (hemorrhages around arterioles and veins)	Cheyne-Stokes respirations; stupor; coma; bipyramidal signs; decerebration; dilated, fixed pupils and alterations of gaze (facilitated oculocephalic reflex movement giving way to loss of all response to head movement and labyrinthine stimulation)
Unilateral or bilateral infarction (hemorrhagic) of occipital lobes	Compression of posterior cerebral artery against the tentorium by herniating temporal lobe	Usually none detectable during coma; hemianopia (unilateral or bilateral) with recovery
Rising intracranial pressure and hydrocephalus	Lateral flattening of aqueduct and third ventricle and blockage of perimesencephalic subarachnoid space	Increasing coma, rising blood pressure, bradycardia (Cushing response)

and, often, the periodic Cheyne-Stokes pattern of respiration; following this, the pupils become small and react very little to light; “doll’s-head” (“doll’s-eyes,” oculocephalic) eye movements are still elicitable, as are deviations of the eyes in response to cold-water caloric testing. Bilateral Babinski signs can be detected early; later, grasp reflexes and decorticate postures appear. These signs give way to a downward gradient of brainstem signs: coma; medium-sized fixed pupils that are referable to midbrain damage; bilateral decerebrate postures; loss of vestibuloocular (caloric, oculovestibular) responses all of which are the result of pontine damage; irregular breathing patterns that implicate medullary destruction; and death.

The *uncal syndrome*, the result of herniation of the medial temporal lobe into the tentorial opening, differs in that drowsiness in the early stages is accompanied or preceded by unilateral pupillary dilatation, most often on the side of the mass, as a result of compression of the third nerve by the advancing uncal gyrus.

Our own experience does not fully accord with this distinction between the two syndromes, and seldom have we been able to follow such an orderly sequence of neural dysfunction from the diencephalic to the medullary level but we do not promote this as a contrary view to the herniation syndromes. With lateral shift and uncal herniation, one sometimes observes smallness of the pupils, rather than ipsilateral pupillary dilatation, as drowsiness develops. Or, infrequently, the contralateral pupil may dilate before the ipsilateral one. Nor is it clear that the dilatation of one pupil is always due to compression of the oculomotor nerve by the herniated uncal. As often in pathologic material, the third nerve is stretched and angulated over the clivus or compressed under the descended posterior cerebral artery. Involvement of the third nerve nucleus or its fibers of exit within the midbrain may be responsible for the dilatation of the opposite pupil, the usual occurrence after the pupil on the side of the mass has become fixed (Ropper, 1990).

In our serial study of 12 patients with brain swelling and lateral diencephalic–mesencephalic shifts caused by hemispherical infarcts, 4 initially had no ipsilateral pupillary enlargement; in 1 patient, the pupillary enlargement was contralateral; in 3 patients, the pupils were symmetrical when drowsiness gave way to stupor or coma (Ropper and Shafran). Cyclic Cheyne-Stokes breathing was an early sign of deterioration. In one patient, the first motor sign was an ipsilateral decerebrate rigidity rather than decorticate posturing; most of the patients had bilateral Babinski signs by the time they became stuporous. The appearance of a Babinski sign on the nonhemiparetic side has been a dependable sentinel of secondary brain tissue shift at the tentorial opening.

The important elements of secondary compression of the upper brainstem may occur in some cases entirely above the plane of the tentorium. With acute masses, a 3- to 5-mm horizontal displacement of the pineal calcification is associated with drowsiness; 5 to 8 mm, with stupor; and greater than 8 or 9 mm, with coma (Ropper, 1986). Shift of the septum pellucidum less dependably predicts the level of consciousness. The degree of vertical tissue distortion differs between cases. Pleasure and

colleagues described a syndrome of low cerebrospinal fluid (CSF) pressure causing a purely downward herniation and stupor that was corrected by the infusion of fluid into the spinal canal. Others, notably Reich and colleagues, have found evidence for vertical shift to be more compelling than for horizontal displacement.

In any case, the location as well as the size of a mass determines the degree of brain distortion and displacement of crucial structures in the diencephalon and upper midbrain. Andrews and colleagues have pointed out that frontal and occipital hemorrhages are less likely to displace deep structures and to cause coma than are clots of equivalent size in the parietal or temporal lobes. Nor is it surprising that slowly enlarging masses, such as brain tumors, cause massive shifts of brain tissue, yet result in few clinical changes. In other words, all of the above comments must take into consideration the rate of evolution of a mass and its location and relationship to vital structures that maintain arousal.

The resulting neural dysfunction of deep structures resulting from compression is probably due to ischemia but this issue has not been well studied and it is possible that mechanical distortion of neurons or glia may contribute.

CLINICAL APPROACH TO THE COMATOSE PATIENT

Many times the primary disorder underlying coma is perfectly obvious, as with severe cranial trauma. All too often, however, the comatose patient is brought to the hospital and little pertinent medical information is available. The need for efficiency in reaching a diagnosis and providing appropriate acute care demands that the physician have a methodical approach that addresses the common and treatable causes of coma. When the comatose patient is first seen, the patient’s airway is cleared and blood pressure is restored; if trauma has occurred, one must check for bleeding from a wound or ruptured organ (e.g., spleen or liver). With hypotension, placement of a central venous line and administration of fluids and pressor agents, oxygen, blood, or glucose solutions (preferably after blood is drawn for glucose determinations and thiamine is administered) take precedence over diagnostic procedures. If respirations are shallow or labored, or if there is emesis with a threat of aspiration, tracheal intubation and mechanical ventilation are instituted. An oropharyngeal airway is usually adequate in a comatose patient who is breathing normally. Deeply comatose patients with shallow respirations require endotracheal intubation. The patient with a head injury may also have suffered a fracture of the cervical vertebrae, in which case caution must be exercised in moving the head and neck as well as in intubation lest the spinal cord be inadvertently damaged. These matters are discussed in detail further on, under “Management of the Acutely Comatose Patient.”

An inquiry is then made as to how the patient was found and their previous health, whether there was a history of diabetes, a head injury, a convulsion, alcohol

or drug use, or a prior episode of coma or attempted suicide, and the circumstances in which the person was found. Persons who accompany the comatose patient to the hospital should be encouraged to remain until they have been questioned.

In assessing confusion, stupor, or coma in an already hospitalized patient, it is most instructive to review the patient's medications carefully. A large number of compounds may reduce alertness to the point of profound somnolence or stupor, particularly if there are underlying medical problems (e.g., a liver failure). Prominent in lists of iatrogenic drug intoxications are anesthetics, sedatives, antiepileptic drugs, opiates, certain antibiotics, antidepressants, and antipsychosis compounds. Chronic administration of nitroprusside for hypertension can induce stupor from cyanide toxicity. From an initial survey, many of the common causes of coma, such as severe head injury, alcoholism or other forms of drug intoxication, and hypertensive brain hemorrhage, are readily recognized.

General Examination

Alterations in vital signs (temperature, heart rate, respiratory rate, and blood pressure) are important aids in diagnosis. *Fever* is most often the result of a systemic infection such as pneumonia or bacterial meningitis or viral encephalitis. An excessively high body temperature (42°C [107.6°F] or 43°C [109.4°F]) associated with dry skin should arouse suspicion of heat stroke or intoxication by a drug with anticholinergic activity. Fever should not be too easily ascribed to a brain lesion that has disturbed the temperature-regulating center, so-called central fever, which is a rare occurrence. Hypothermia is observed in patients with alcohol or barbiturate intoxication, drowning, exposure to cold, peripheral circulatory failure, advanced tuberculous meningitis, and myxedema.

Slow breathing points to opiate or barbiturate intoxication and occasionally to hypothyroidism, whereas deep, rapid breathing (Kussmaul respiration) should suggest the presence of pneumonia, diabetic or uremic acidosis, pulmonary edema, or the less-common occurrence of an intracranial disease that causes central neurogenic hyperventilation. Diseases that elevate intracranial pressure or damage the brain often cause slow, irregular, or cyclic Cheyne-Stokes respiration. The various disordered patterns of breathing and their clinical significance are described further on. *Vomiting* at the outset of sudden coma, particularly if combined with pronounced hypertension, is characteristic of cerebral hemorrhage within the hemispheres, brainstem, cerebellum, or subarachnoid spaces. Marked *hypertension* is observed in patients with cerebral hemorrhage and in hypertensive encephalopathy and in children with markedly elevated intracranial pressure. *Hypotension* is the usual finding in states of depressed consciousness because of diabetes, alcohol or barbiturate intoxication, internal hemorrhage, myocardial infarction, dissecting aortic aneurysm, septicemia, Addison disease, or massive brain trauma. The *heart rate*, if exceptionally slow, suggests heart block from medications such as tricyclic antidepressants or anticonvulsants, or if combined with periodic breathing and hypertension, an increase in intracranial pressure.

Inspection of the skin may yield valuable information. Cyanosis of the lips and nail beds signifies inadequate oxygenation. Cherry-red coloration is typical of carbon monoxide poisoning. Multiple bruises (particularly a bruise or boggy area in the scalp), bleeding, CSF leakage from an ear or the nose, or periorbital hemorrhage greatly raises the likelihood of cranial fracture and intracranial trauma or of a severe coagulopathy causing intracranial bleeding. Telangiectases and hyperemia of the face and conjunctivae are the common stigmata of alcoholism; myxedema imparts a characteristic puffiness of the face, and hypopituitarism an equally characteristic sallow complexion. Marked pallor suggests internal hemorrhage. A macular-hemorrhagic rash indicates the possibility of meningococcal infection, staphylococcal endocarditis, typhus, or Rocky Mountain spotted fever. Excessive sweating suggests hypoglycemia or shock, and excessively dry skin, diabetic acidosis, or uremia. Large blisters, sometimes bloody, may form over pressure points such as the buttocks if the patient has been motionless for a time; this sign is particularly characteristic of the deeply unresponsive and prolonged motionless state of acute sedation, alcohol and opiate intoxication. Thrombotic thrombocytopenic purpura (TTP), disseminated intravascular coagulation, and fat embolism may cause diffuse petechiae or purpura; the last of these are often aggregated in the anterior axillary folds.

The *odor of the breath* may provide a clue to the etiology of coma. Alcohol is easily recognized. The spoiled-fruit odor of diabetic ketoacidotic coma, the urinous odor of uremia, the musky and slightly fecal fetor of hepatic coma, and the burnt almond odor of cyanide poisoning are distinctive enough to be identified by physicians who possess a keen sense of smell. The distinctive odor of melena is a sign of rapid gastrointestinal bleeding.

Neurologic Examination of the Stuporous or Comatose Patient

Although limited in some ways in comparison to the examination of the alert patient, the neurologic examination of the comatose patient is relatively simple. Watching the patient for a few moments often yields considerable information. The predominant postures of the limbs and body; the presence or absence of spontaneous movements on one side; the position of the head and eyes; and the rate, depth, and rhythm of respiration each give substantial information. The state of responsiveness is then estimated by noting the patient's reaction to calling his name, to simple commands, or to noxious stimuli such as tickling the nares, supraorbital or sternal pressure, pinching the side of the neck or inner parts of the arms or thighs, or applying pressure to the knuckles. By gradually increasing the strength of these stimuli, one can roughly estimate both the degree of unresponsiveness and changes from hour to hour. Vocalization may persist in stupor and is the first response to be lost as coma appears. Grimacing and deft avoidance movements of stimulated parts of the body are preserved in stupor; their presence substantiates the integrity of corticobulbar and corticospinal tracts. Yawning and spontaneous shifting of body positions

indicate a minimal degree of unresponsiveness. These signs have been elegantly summarized by Fisher based on his own observations. The widely adopted Glasgow Coma Scale, constructed originally as a quick and simple means of quantitating the responsiveness of patients with cerebral trauma, can be used in the grading of other acute coma-producing diseases as mentioned earlier in this chapter (see also Chap. 35). Several other scales such as the "FOUR Score" (Wijdicks et al 2005) have been devised and are used in various units.

It is usually possible to determine whether coma is associated with meningeal irritation. In all but the deepest stages of coma, meningeal irritation from either bacterial meningitis or subarachnoid hemorrhage will cause resistance to the initial excursion of passive flexion of the neck but not to extension, turning, or tilting of the head. Meningismus is a fairly specific but somewhat insensitive sign of meningeal irritation as commented in Chap. 1. Resistance to movement of the neck in all directions may be part of generalized muscular rigidity or dystonia (as in phenothiazine intoxication) or indicate disease of the cervical spine. In the infant, bulging of the anterior fontanel is at times a more reliable sign of meningitis than is a stiff neck. A temporal lobe or cerebellar herniation or decerebrate rigidity may also create resistance to passive flexion of the neck and be confused with meningeal irritation.

A coma-causing lesion in a cerebral hemisphere can be detected by careful observation of spontaneous movements, responses to stimulation, prevailing postures, and by examination of the cranial nerves. *Hemiplegia* is revealed by a lack of restless movements of the limbs on one side and by inadequate protective movements in response to painful stimuli. The weakened limbs are usually slack and, if lifted from the bed, they "fall flail." The hemiplegic leg lies in a position of external rotation (this may also be caused by a fractured femur), and the affected thigh appears wider and flatter than the nonhemiplegic one. In expiration, the cheek and lips puff out on the paralyzed side of the face. A lesion in one cerebral hemisphere causes the eyes to be turned away from the paralyzed side (toward the lesion, as described below); the opposite occurs with brainstem lesions. In most cases, a hemiplegia and an accompanying Babinski sign are indicative of a contralateral hemispherical lesion; but with lateral mass effect and compression of the opposite cerebral peduncle against the tentorium, extensor posturing, a Babinski sign, and weakness of arm and leg may appear ipsilateral to the lesion (the earlier-mentioned Kernohan-Woltman sign). A moan or grimace may be provoked by painful stimuli applied to one side but not to the other, reflecting hemianesthesia. During grimacing in response to stimuli, facial weakness may be noted.

Of the various indicators of brainstem function, the most useful are pupillary size and reactivity, ocular movements, oculovestibular reflexes and, to a lesser extent, the pattern of breathing. These functions, like consciousness itself, are dependent on the integrity of structures in the midbrain and rostral pons.

Pupillary Reactions

These are of great diagnostic importance in the comatose patient. A unilaterally enlarged pupil is an early indicator

of stretching or compression of the third nerve and reflects the presence of an overlying ipsilateral hemispherical mass as described earlier in the section on herniations. A loss of light reaction usually precedes enlargement of the pupil. As a transitional phenomenon, the pupil may become oval or pear-shaped or appear to be off center (*corectopia*) because of a differential loss of innervation of a portion of the pupillary sphincter. The light-unreactive pupil continues to enlarge to a size of 6 to 9 mm diameter and is soon joined by a slight outward deviation of the eye. In unusual instances, the pupil contralateral to the mass may enlarge first; this has reportedly been the case in 10 percent of subdural hematomas but has been far less frequent in our experience. As midbrain displacement continues, both pupils dilate and become unreactive to light, probably as a result of compression of the oculomotor nuclei in the rostral midbrain (Ropper, 1990). The last step in the evolution of brainstem compression tends to be a slight reduction in pupillary size on both sides, to 5 mm or smaller. Normal pupillary size, shape, and light reflexes indicate integrity of midbrain structures and direct attention to a cause of coma other than a mass.

Pontine tegmental lesions cause extremely miotic pupils (<1 mm in diameter) with barely perceptible reaction to strong light; this is characteristic of the early phase of pontine hemorrhage. The ipsilateral pupillary dilatation from pinching the side of the neck (the ciliospinal reflex) is usually lost in brainstem lesions. The Horner syndrome (miosis, ptosis, and reduced facial sweating) may be observed ipsilateral to a lesion of the brainstem or hypothalamus or as a sign of dissection of the internal carotid artery.

With coma caused by drug intoxications and intrinsic metabolic disorders, pupillary reactions are usually spared, but there are notable exceptions. Serum concentrations of opiates that are high enough to cause coma have as a consistent sign pinpoint pupils, with constriction to light that may be so slight that it is detectable only with a magnifying glass. High-dose barbiturates may act similarly, but the pupillary diameter tends to be 1 mm or more. Systemic poisoning with atropine or with drugs that have atropinic qualities, especially the tricyclic antidepressants, is characterized by wide dilatation and fixity of the pupils. Hippus, or fluctuating pupillary size, is occasionally characteristic of metabolic encephalopathy.

Movements of Eyes and Eyelids and Corneal Responses

These are altered in a variety of ways in coma. In light coma of metabolic origin, the eyes rove conjugately from side to side in seemingly random fashion, sometimes resting briefly in an eccentric position. These movements disappear as coma deepens, and the eyes then remain motionless and slightly exotropic.

A lateral and slight downward deviation of one eye suggests the presence of a third-nerve palsy, and a medial deviation, a sixth-nerve palsy. There is persistent conjugate deviation of the eyes to one side—away from the side of the paralysis with a large cerebral lesion (looking toward the lesion) and toward the side of the paralysis with a unilateral pontine lesion (looking away from

the lesion). “Wrong-way eyes” a paradoxical conjugate deviation to the side opposite the lesion may sometimes occur with thalamic and upper brainstem lesions. During a focal seizure the eyes turn or jerk toward the convulsing side (opposite to the irritative focus). The globes turn down and inward (looking at the nose) with hematomas or ischemic lesions of the thalamus and upper midbrain (a variant of Parinaud syndrome). Retraction and convergence nystagmus and “ocular bobbing,” described in Chap. 14, occur with lesions in the tegmentum of the mid-brain and pons, respectively. “Ocular dipping,” in which the eyes move down slowly and return rapidly to the meridian, is observed with coma caused by anoxia and drug intoxications; horizontal eye movements are preserved with ocular dipping but obliterated in cases of ocular bobbing as a result of destruction of pontine gaze centers. Coma-producing structural lesions of the brainstem abolish most if not all conjugate ocular movements, whereas metabolic disorders generally do not (except for instances of deep hepatic coma and antiepileptic drug overdose).

Oculocephalic reflexes (doll’s-eye movements) are elicited by turning or tilting the head. The response in coma of metabolic origin or that caused by bihemispheric structural lesions consists of conjugate movement of the eyes in the opposite direction. Elicitation of these ocular reflexes in a comatose patient provides two pieces of information: (1) evidence of unimpeded function of the midbrain and pontine tegmental structures that integrate ocular movements and of the oculomotor nerves, and (2) loss of the cortical inhibition that normally holds these movements in check. In other words, the presence of unimpaired reflex eye movements implies that coma is not caused by compression or destruction of the upper midbrain. There must instead be widespread cerebral dysfunction, such as occurs after anoxia or with metabolic-toxic suppression of cortical neuronal activity. It must be conceded, however, that sedative or anticonvulsant intoxication profound enough to cause coma may obliterate the brainstem mechanisms for oculocephalic reactions and, in extreme cases, even the vestibular-ocular (caloric) responses as noted below.

Asymmetry of the elicited eye movements remains a dependable sign of focal brainstem disease. In instances of coma caused by a large mass in one cerebral hemisphere that secondarily compresses the upper brainstem, the oculocephalic reflexes are usually present, but the movement of the eye on the side of the mass may be impeded in adduction as a result of a compressive third-nerve paresis.

Irrigation of one ear with 10 mL of cold water (or room-temperature water if the patient is arousable) causes slow conjugate deviation of the eyes toward the irrigated ear, followed in a few seconds by compensatory nystagmus (fast component away from the stimulated side). This is the *oculovestibular*, or *caloric* test. The ears are irrigated separately several minutes apart. In comatose patients, the fast “corrective” phase of nystagmus is lost and the eyes are tonically deflected to the side irrigated with cold water or away from the side irrigated with warm water; this position may be held for 2 to 3 min. Brainstem lesions disrupt these vestibuloocular reflexes; if one eye abducts and the other fails to adduct, one can conclude that the medial longitudinal fasciculus

has been interrupted (an internuclear ophthalmoplegia on the side of adductor paralysis). Abducens palsy is indicated by an esotropic resting position and a lack of outward deviation of one eye with the reflex maneuvers. The complete absence of ocular movement in response to oculovestibular testing indicates a severe disruption of brainstem tegmental systems in the pons or midbrain or, as already mentioned, a profound overdose of sedative, anesthetic, or anticonvulsant drugs.

A reduction in the frequency and eventual loss of spontaneous blinking, then a loss of response to touching the eyelashes, and, finally, a lack of response to corneal touch (the corneal reflex afferent limb travels in the trigeminal nerve and efferent limb, facial nerve) are among the most dependable signs of deepening coma. A marked asymmetry in corneal responses indicates either an acute lesion of the opposite hemisphere or, less often, an ipsilateral lesion in the brainstem.

Spontaneous Limb Movements

Restless movements of both arms and both legs and grasping and picking movements signify that the corticospinal tracts are more or less intact. Oppositional resistance to passive movement (paratonic rigidity), complex avoidance movements, and discrete protective movements have the same meaning; especially if they are bilateral and they suggest the coma is not deep. Abduction movements (away from the midline) to escape a noxious stimulus have the same significance and differentiate a motor response from posturing, described below. Focal motor epilepsy indicates that the corticospinal pathway to the convulsing side is intact. With massive destruction of a cerebral hemisphere, as occurs in hypertensive hemorrhage or internal carotid–middle cerebral artery occlusion, seizure activity may be manifest solely in the ipsilateral limbs, the contralateral limbs being prevented from participating by the hemiplegia. Elaborate forms of semivoluntary movement may be manifest on the non-hemiparetic side in patients with extensive disease in one hemisphere; they probably represent some type of disinhibition of cortical and subcortical movement patterns. Choreic, athetotic, or hemiballistic movements indicate a disorder of the basal ganglionic and subthalamic structures, just as they do in the alert patient, but are not helpful in localizing the cause of coma.

Posturing in the Comatose Patient

An abnormal posture of some consequence is *decerebrate rigidity*, which in its fully developed form consists of opisthotonos, clenching of the jaws, and stiff extension of the limbs, with internal rotation of the arms and plantar flexion of the feet (see Chap. 3). It is most often manifest as brief tonic extension of the limbs. This postural pattern was first described by Sherrington, who produced it in cats and monkeys by transecting the brainstem at the intercollicular level. Decerebrate posture was noted in animals to be ipsilateral to a one-sided lesion, hence not a result of involvement of the corticospinal tracts; the opposite is true in humans. A precise anatomic correlation between posturing and the level of the lesion is rarely possible in patients who develop stereotyped extensor

posturing as it arises in a variety of settings—with mid-brain compression caused by a hemispherical mass; with cerebellar or other posterior fossa lesions; in certain metabolic disorders such as anoxia and hypoglycemia; and, rarely, with hepatic coma and profound drug or alcohol intoxication. Patients with an acute lesion of one cerebral hemisphere may show a similar type of extensor posturing of the contralateral and sometimes ipsilateral limbs, and this may coexist with the ability to make purposeful movements of the same limb. Extensor postures, unilateral or bilateral, occur spontaneously, but more often they are in response to manipulation of the limbs or a tactile or noxious stimulus. Another related pattern consists of extensor posturing of an arm and leg on one side, and flexion and abduction of the opposite arm.

In some patients with the extensor postural changes the lesion is clearly in the cerebral white matter or basal ganglia, which is difficult to reconcile with the classic physiologic explanation for decerebrate posturing. Decerebrate posturing, either in experimental preparations or in humans, is usually not a persistent state. Hence the term *decerebrate state*, as suggested by Feldman, is preferable to *decerebrate rigidity*, which implies a fixed, tonic extensor attitude.

Decorticate posturing, usually, with arm or arms in flexion and adduction and leg(s) extended, signifies lesions at a more rostral level of the nervous system—in the cerebral white matter or internal capsule and thalamus. Bilateral decorticate rigidity is essentially a bilateral spastic hemiplegia. Diagonal postures, e.g., flexion of one arm and extension of the opposite arm and leg, usually indicate a supratentorial lesion. Forceful extensor postures of the arms and weak flexor responses of the legs are usually seen with lesions at about the level of the vestibular nuclei. Lesions below this level lead to flaccidity and abolition of all postures and movements. If preceded by decorticate or decerebrate postures, the coma is profound and usually progresses to brain death.

Only in the most advanced forms of intoxication and metabolic coma, as might occur with anoxic necrosis of neurons throughout the entire brain, are coughing, swallowing, hiccupping, and spontaneous respiration all abolished. Further, the tendon and plantar reflexes may give little indication of what is happening. Tendon reflexes are preserved until the late stages of coma that is due to metabolic disturbances and intoxications. In coma caused by a large cerebral infarct or hemorrhage, the tendon reflexes may be normal or only reduced on the hemiplegic side and the plantar reflexes may initially be absent before becoming extensor. Plantar flexor responses, succeeding extensor responses, signify either a return to normalcy or, in the context of deepening coma, a transition to brain death.

Patterns of Breathing

Massive supratentorial lesions, bilateral deep-seated cerebral lesions, and mild metabolic disturbances give rise to altered patterns of breathing, particularly periods of waxing and waning hyperpnea alternating with a shorter period of apnea (*Cheyne-Stokes respiration*). This phenomenon has been attributed, on uncertain grounds,

to isolation of the brainstem respiratory centers from the cerebrum, rendering them more sensitive than usual to carbon dioxide (hyperventilation drive). It is postulated that as a result of overbreathing, the blood carbon dioxide drops below the concentration required to stimulate the centers, and breathing gradually stops. Carbon dioxide then reaccumulates until it exceeds the respiratory threshold, and the cycle then repeats itself. Alternatively, the periodicity has been attributed to the stimulating effect of a low arterial PO_2 on a depressed respiratory center. In either case, the presence of Cheyne-Stokes breathing signifies bilateral dysfunction of cerebral structures, usually deep in the hemispheres or diencephalon, usually from intoxication or a metabolic derangement or occasionally, from bilateral structural lesions such as subdural hematomas. In itself, Cheyne-Stokes breathing is not a grave sign. It may occur during sleep in elderly individuals and can be a manifestation of a variety of cardio-pulmonary disorders in awake patients. Only when it gives way to more irregular respiratory patterns that reflect structural damage of the brainstem is the patient in imminent danger, as discussed below.

A number of other aberrant breathing rhythms occur from brainstem lesions (these are reviewed in Chap. 26), but few are specifically localizing. The more conspicuous respiratory arrhythmias are associated with lesions below the level of the reticular-activating system and are therefore found in the late stages of brainstem compression or with destructive brainstem lesions such as infarction, hemorrhage, or infiltrating tumor.

Lesions of the lower midbrain-upper pontine tegmentum, either primary or secondary to transtentorial herniation, may give rise to *central neurogenic hyperventilation* (CNH). This disorder is characterized by an increase in the rate and depth of respiration to an extent that produces advanced respiratory alkalosis. The pattern must be distinguished from compensatory overbreathing caused by systemic acidosis, particularly diabetic ketoacidosis (Kussmaul breathing). In addition, mild degrees of hyperventilation are common after a number of acute neurologic events, notably head injury. The neurologic basis of central neurogenic hyperventilation is uncertain. It is theorized to represent a release of the reflex mechanisms for respiratory control in the lower brainstem. It has been observed with tumors of the medulla, lower pons, and midbrain. However, North and Jennett, in a study of respiratory abnormalities in neurosurgical patients, found no consistent correlation between tachypnea and the site of the lesion. As noteworthy, primary brain lymphoma without brainstem involvement has emerged as a curious cause of central hyperventilation, of which we have seen several examples (Pauzner et al).

Low pontine lesions, usually caused by basilar artery occlusion, sometimes cause *apneustic breathing* (a pause of 2 to 3 s in full inspiration) or so-called short-cycle Cheyne-Stokes respiration, in which a few rapid deep breaths alternate with apneic cycles. With lesions of the dorsomedial part of the medulla, the rhythm of breathing is chaotic, being irregularly interrupted and each breath varying in rate and depth (*Biot breathing*; also called "ataxia of breathing"). This pattern progresses to one of intermittent

prolonged inspiratory gasps that are recognized by all physicians as agonal in nature, and finally to apnea. In fact, respiratory arrest is the mode of death of most patients with serious central nervous system (CNS) disease.

Probably all of these erratic patterns of breathing are interrelated in some manner. Webber and Speck have shown that apnea, Biot breathing, and gasping could be produced in the same animal with lesions in the dorso-lateral pontine tegmentum by altering the depth of anesthesia. As pointed out by Fisher and by Plum and Posner, when certain supratentorial lesions progress to the point of temporal lobe and cerebellar herniation, one may observe a succession of respiratory patterns (Cheyne-Stokes, then hyperventilation, then Biot breathing), indicating an extension of the functional disorder from upper to lower brainstem; but again, such a sequence is not always observed. Rapidly evolving lesions of the posterior fossa, mainly masses in the cerebellum, more often cause sudden respiratory arrest without any of the aforementioned abnormalities of breathing as intermediaries; presumably apnea results from fulminant medullary compression by the cerebellar tonsils.

Clinical Signs of Increased Intracranial Pressure

A history of headache before the onset of coma, vomiting, severe hypertension beyond the patient's static level, unexplained bradycardia, and subhyaloid retinal hemorrhages (Terson syndrome) are immediate clues to the presence of increased intracranial pressure, usually from one of the types of intracranial hemorrhage. Papilledema develops within 12 to 24 h in cases of brain trauma and hemorrhage, and if it is apparent when coma supervenes, it usually signifies brain tumor or abscess, i.e., a lesion of longer duration. Increased intracranial pressure produces coma by impeding global cerebral blood flow; but this occurs only at extremely high levels of pressure. Increased pressure within one compartment displaces central structures and produces a series of "false localizing" signs because of lateral distortion of deep brain tissue and herniations, as noted in the earlier discussion of this type. However, the absence of papilledema does not exclude the presence of increased intracranial pressure, particularly in the elderly.

Acute Hydrocephalus

The syndrome of acute hydrocephalus, most often from subarachnoid hemorrhage or from obstruction of the ventricular system by a tumor in the posterior fossa, induces a state of abulia (slowed responsiveness), followed by stupor, and then coma with bilateral Babinski signs. The pupils are small and the tone in the legs is increased or there may be extensor posturing. The signs of hydrocephalus may be accompanied by headache and systemic hypertension, mediated through raised intracranial pressure. Chapter 30 discusses this subject further.

Laboratory Procedures for the Diagnosis of Coma

Unless the cause of coma is established at once by history and physical examination, it becomes necessary to

carry out a number of laboratory procedures. In patients with signs of raised intracranial pressure or indications of brain displacements, CT scan or MRI should be obtained as the primary procedure. As discussed in Chap. 2, lumbar puncture, although carrying a small risk of promoting further herniation, is nevertheless necessary in some instances to exclude bacterial meningitis or encephalitis. If poisoning or drug overdosage is suspected, aspiration and analysis of the gastric contents are sometimes helpful, but greater reliance should be placed on chromatographic analysis of the blood and urine ("toxic screen"). Accurate means are available for measuring the blood concentrations of most antiepileptic drugs, opiates, diazepam, barbiturates, alcohol, and a wide range of other toxic substances. These screening procedures vary widely between hospitals and certain toxins must be specifically sought. A specimen of urine is obtained by catheter for determination of specific gravity and for glucose, acetone, and protein content. Proteinuria may also be found for 2 or 3 days after a subarachnoid hemorrhage or with high fever. Urine of high specific gravity, glycosuria, and acetonuria occurs almost invariably in diabetic coma; but transient glycosuria and hyperglycemia may be precipitated solely by a massive cerebral lesion. Blood counts should be obtained and in malarial districts, a blood smear should be examined for parasites. Neutrophilic leukocytosis occurs in bacterial infections and mild elevations of the white blood cell counts also with brain hemorrhage and infarction, although rarely exceeding 12,000/mm³. Venous blood should be examined for the concentrations of glucose, urea, carbon dioxide, bicarbonate, ammonia, sodium, potassium, chloride, calcium, and AST (aspartate serum transaminase); analysis of blood gases and carboxyhemoglobin should be obtained in appropriate cases of anoxia or exposure to carbon monoxide by smoke inhalation or faulty heating systems.

It should be kept in mind that disorders of water and sodium balance, reflected in hyper- or hyponatremia, may be the result of cerebral disease (excess antidiuretic hormone [ADH] secretion, diabetes insipidus, atrial natriuretic factor release), as well as being the proximate cause of coma.

An EEG may be highly informative if no adequate explanation for coma is forthcoming from the initial examinations. At times, this is the only way to reveal nonconvulsive status epilepticus as the cause of stupor.

Classification of Coma and Differential Diagnosis (See also Table 17-3)

The demonstration of focal brain disease by hemiparesis, and meningeal irritation with abnormalities of the CSF serve to divide the diseases that cause coma into three classes, as follows:

- I. Diseases that cause no focal or lateralizing neurologic signs, usually with normal brainstem functions. CT scan and cellular content of the CSF are normal.
 - A. Exogenous intoxications: alcohols, barbiturates and other sedative drugs, opiates (Chaps. 42 and 43)

Table 17-3

IMPORTANT POINTS IN THE DIFFERENTIAL DIAGNOSIS OF THE COMMON CAUSES OF COMA

GENERAL GROUP	SPECIFIC DISORDER	IMPORTANT CLINICAL FINDINGS	IMPORTANT LABORATORY FINDINGS	REMARKS
Coma <i>with</i> focal or lateralizing signs	Cerebral hemorrhage	Hemiplegia, hypertension, cyclic breathing, specific ocular signs (See Chaps. 14 and 33)	Hyperdense blood on CT	Sudden onset, often with headache, vomiting; history of chronic hypertension; late pupillary enlargement
	Basilar artery occlusion (thrombotic or embolic)	Extensor posturing and bilateral Babinski signs; early loss of oculocephalic responses; ocular bobbing	Hyperdense basilar artery (acute thrombosis) on CT; reduced diffusivity and T2 hyperintensity (on MRI) in brainstem and PCA territory; normal cerebrospinal fluid (CSF)	Onset subacute (thrombosis), or sudden (rostral basilar embolism)
	Territorial infarction in internal carotid territory	Hemiplegia, unilateral unresponsive, or enlarged pupil	Extensive edema, loss of gray-white matter differentiation, sulcal and ventricular effacement, subfalcine and uncal herniation	Coma preceded by drowsiness for several days after stroke
	Subdural hematoma	Slow or cyclic respiration, rising blood pressure, hemiparesis, unilateral enlarged pupil	Hyperdense blood on CT; CSF xanthochromic with relatively low protein	Signs or history of trauma, headache, confusion, progressive drowsiness
	Trauma	Signs of cranial and facial injury	CT and MRI show contusions, hemorrhages, and other injuries; CSF may be bloody	Unstable blood pressure, associated systemic injuries
	Brain abscess	Neurologic signs depending on location	Rim-enhancing mass with surrounding edema	Systemic infection or neurosurgical procedure, fever
	Hypertensive encephalopathy; eclampsia	Blood pressure >210/110 mm Hg (lower in eclampsia and in children), headache, seizures, hypertensive retinal changes	Posterior predominant hypodensity on CT and T2 hyperintensity on MRI affecting gray matter and subcortical white matter; CSF pressure elevated	Acute or subacute evolution, use of aminophylline or catecholamine medications
	Thrombotic thrombocytopenic purpura (TTP)	Petechiae, seizures shifting focal signs	Multiple small cortical infarctions and/or microhemorrhages; thrombocytopenia	Similar to fat embolism; multifocal microvasculopathy
Coma <i>without</i> focal or lateralizing signs, <i>with</i> signs of meningeal irritation	Meningitis and encephalitis	Stiff neck, Kernig sign, fever, headache	Possible cerebral edema; meningeal enhancement; pleocytosis, increased protein, low glucose in CSF	Subacute or acute onset
	Subarachnoid hemorrhage	Stertorous breathing, hypertension, stiff neck, Kernig sign	Cisternal and sulcal blood; bloody or xanthochromic CSF under increased pressure	Sudden onset with severe headache
Coma <i>without</i> focal neurologic signs or meningeal irritation; CT scan and CSF normal	Alcohol intoxication	Hypothermia, hypotension, flushed skin, alcohol breath	Elevated blood alcohol	May be combined with head injury, infection, or hepatic failure
	Sedative intoxication	Hypothermia, hypotension	Drug in urine and blood; electroencephalogram (EEG) often shows fast activity	History of intake of drug; suicide attempt
	Opioid intoxication	Slow respiration, cyanosis, constricted pupils		Administration of naloxone causes awakening and withdrawal signs
	Carbon monoxide intoxication	Cherry-red skin	Reduced diffusivity in globus pallidi; Carboxyhemoglobin	Pallidal necrosis

Global ischemia–anoxia	Rigidity, decerebrate postures, fever, seizures, myoclonus	Reduced diffusivity and edema in cerebral and cerebellar cortex and deep nuclei; CSF normal; EEG may be isoelectric or show high-voltage delta	Abrupt onset following cardiopulmonary arrest; damage permanent if anoxia exceeds 3–5 min
Hypoglycemia	Same as in anoxia	Low blood and CSF glucose	Characteristic slow evolution through stages of nervousness, hunger, sweating, flushed face; then pallor, shallow respirations, and seizures
Diabetic coma	Signs of extracellular fluid deficit, hyperventilation with Kussmaul respiration, “fruity” breath	Glycosuria, hyperglycemia, acidosis; reduced serum bicarbonate; ketonemia and ketonuria, or hyperosmolarity	History of polyuria, polydipsia, weight loss, or diabetes
Uremia	Hypertension; sallow, dry skin, uriferous breath, twitch-convulsive syndrome	Protein and casts in urine; elevated blood urea nitrogen and serum creatinine; anemia, acidosis, hypocalcemia	Progressive apathy, confusion, and asterix precede coma
Hepatic coma	Jaundice, ascites, and other signs of portal hypertension; asterix	T1 hyperintensity from manganese deposition in globus pallidi and other structures; Elevated blood NH ₃ levels; CSF yellow (bilirubin) with normal or slightly elevated protein	Onset over a few days or after paracentesis or hemorrhage from varices; confusion, stupor, asterix, and characteristic EEG changes precede coma
Hypercapnia	Papilledema, diffuse myoclonus, asterix	Increased CSF pressure; Pco ₂ may exceed 75 mm Hg; EEG theta and delta activity	Advanced pulmonary disease; profound coma and brain damage uncommon
Severe infections (septic shock); heat stroke	Extreme hyperthermia, rapid respiration	Vary according to cause	Evidence of a specific infection or exposure to extreme heat
Seizures	Episodic disturbance of behavior or convulsive movements	In status epilepticus, reduced diffusivity on MRI in the involved cortex; characteristic EEG changes	History of previous attacks

- B. Endogenous metabolic disturbances: anoxia, diabetic acidosis, uremia, hepatic failure, nonketotic hyperosmolar hyperglycemia, hypo- and hypernatremia, hypoglycemia, Addisonian crisis, profound nutritional deficiency, carbon monoxide poisoning, thyroid states, hypercalcemia (Chaps. 40 and 41)
- C. Severe systemic infections: pneumonia, peritonitis, typhoid fever, malaria, septicemia, Waterhouse-Friderichsen syndrome
- D. Circulatory collapse (shock) from any cause
- E. Postseizure states and convulsive and nonconvulsive status epilepticus (Chap. 16)
- F. Hypertensive encephalopathy and eclampsia (Chap. 34)
- G. Hyperthermia and hypothermia (Chap. 40)
- H. Concussion (Chap. 35)
 - I. Acute hydrocephalus (Chap. 30)
 - J. Late stages of certain degenerative diseases and Creutzfeldt-Jakob disease
- II. Diseases that cause meningeal irritation and an excess of white blood cells (WBCs) or red blood cells (RBCs) in the CSF, usually without focal or lateralizing cerebral or brainstem signs. CT scanning or MRI (which preferably should precede lumbar puncture) may be normal or abnormal.
 - A. Subarachnoid hemorrhage from ruptured aneurysm, arteriovenous malformation, and cerebral trauma (Chaps. 34 and 35)
 - B. Acute bacterial meningitis (Chap. 32)
 - C. Viral meningoenzephalitis (Chap. 33)
 - D. Neoplastic meningeal infiltration (Chap. 31)
 - E. Parasitic meningitis (Chap. 32)
 - F. Pituitary apoplexy (Chap. 31)
- III. Diseases that cause focal brainstem or lateralizing cerebral signs, with or without changes in the CSF. CT scan and MRI are abnormal.
 - A. Hemispherical hemorrhage or massive cerebral infarction (Chap. 34)
 - B. Brainstem infarction caused by basilar artery thrombosis or embolism (Chap. 34)
 - C. Brain abscess, subdural empyema, herpes encephalitis (Chap. 32)
 - D. Epidural and subdural hemorrhage and brain contusion (Chap. 35)
 - E. Brain tumor (Chap. 31)
 - F. Cerebellar and pontine hemorrhage (Chap. 34)
 - G. Miscellaneous: cortical vein thrombosis, focal embolic infarction caused by bacterial endocarditis, acute disseminated (postinfectious) encephalomyelitis, intravascular lymphoma, TTP, diffuse fat embolism, and others

Problems in Differential Diagnosis of Coma (Table 17-3)

Using the clinical criteria outlined above, one can usually ascertain whether a given case of coma falls into one of these three categories. Concerning the group without focal or lateralizing or meningeal signs (which includes most of the metabolic encephalopathies, intoxications,

concussion, and postseizure states), it must be kept in mind that residua from previous neurologic disease may confuse the clinical picture. Thus, an earlier hemiparesis from vascular disease or trauma may reassert itself in the course of uremic or hepatic coma with hypotension, hypoglycemia, diabetic acidosis, or following a seizure. In hypertensive encephalopathy, focal signs may also be present. Occasionally, for no understandable reason, one leg may seem to move less, one plantar reflex may be extensor, or seizures may be predominantly or entirely unilateral in a metabolic coma, particularly in the hyperglycemic-hyperosmolar states. Babinski signs and extensor rigidity, conventionally considered to be indicators of structural disease, do sometimes occur in profound intoxications with a number of agents or with hepatic encephalopathy.

The diagnosis of concussion or of postictal coma depends on observation of the precipitating event or indirect evidence, as discussed in Chap. 35. Usually, a convulsive seizure is marked by a bitten tongue, urinary incontinence, and an elevated creatine kinase-skeletal muscle fraction; it may be followed by another seizure or burst of seizures. The presence of small clonic or myoclonic convulsive movements of a hand or foot or fluttering of the eyelids or eyes requires that an EEG be performed to determine whether status epilepticus is the cause of coma. This state, nonconvulsive status epilepticus, described in Chap. 16, must be considered in the diagnosis of unexplained coma, especially in known epileptics (Table 17-3).

With respect to the second group in the above classification with signs primarily of meningeal irritation (head retraction, stiffness of neck on forward bending, Kernig and Brudzinski signs), bacterial meningitis and subarachnoid hemorrhage are the usual causes. However, if the coma is profound, stiff neck may be absent in both infants and adults. In such cases the spinal fluid must be examined in order to establish the diagnosis. In most cases of bacterial meningitis, the CSF pressure is elevated but is not exceptionally high (usually < 400 mm H₂O). However, in cases associated with brain swelling, the CSF pressure is greatly elevated; the pupils become fixed and dilated, and there may be signs of compression of the brainstem with arrest of respiration. Patients in coma from ruptured aneurysms also have high CSF pressure; the CSF is overtly bloody and the blood is invariably visible in the CT scan throughout the basal cisterns and ventricles if the bleeding has been severe enough to cause coma.

In the third group of patients, it is the focality of sensorimotor signs and the abnormal pupillary and ocular reflexes, postural states, and breathing patterns that provide the clues to serious structural lesions in the cerebral hemispheres and their pressure effects upon segmental brainstem functions. As the brainstem features become more prominent, they may obscure earlier signs of cerebral disease.

It is worth emphasizing once more that profound hepatic, hypoglycemic, hyperglycemic, and hypoxic states may resemble the coma due to a brainstem lesion in that asymmetrical motor signs, focal seizures, and decerebrate postures arise and deep coma from
