Several synthetic preparations of anticholinergic drugs are available, the most widely used ones being trihexyphenidyl (beginning with 1 to 2 mg/d and increased up to 6 to 8 mg over several weeks) and benztropine mesylate (1 to 4 mg/d in divided doses). When it has been available, we have also had success with the related agent ethopropazine (50 to 200 mg daily in divided doses; but it has become difficult to obtain). The effects on tremor are cumulative and may not be evident for several days. To obtain maximum benefit from the use of these drugs, they should be given in gradually increasing dosage to the point where toxic effects appear: dryness of the mouth (which can be beneficial when drooling of saliva is a problem), blurring of vision from pupillary mydriasis, constipation, and urinary retention as mentioned (especially with prostatism). The presence of angle closure glaucoma is a contraindication to its use. Tremor abates in several days and most of our patients have become tolerant to the dry mouth after several weeks. Pyridostigmine, propantheline, or glycopyrrolate can be given to reduce the oral dryness.

With higher dose ranges, mental slowing, confusional states, hallucinations, and impairment of memory in elderly patients—specifically if there is already some degree of forgetfulness—are side effects that limit usefulness. Occasionally, further benefit may accrue from the addition of another antihistaminic drug, such as diphenhydramine or phenindamine.

The antiviral agent amantadine (100 mg bid) has mild or moderate benefit for tremor, hypokinesia, and postural symptoms. In some patients, it reduces L-dopa-induced dyskinesias (see further on). Its mechanism of action is unknown but antagonism of NMDA or release of stored dopamine has been proposed. It should be noted that amantadine commonly causes leg swelling, may worsen congestive heart failure, and can have an adverse effect on glaucoma, as well as exaggerate the cognitive changes associated with anticholinergic medications. The use of the centrally acting anticholinesterase, donepezil, is being explored for a possible effect on improving gait stability but requires further study. Finally, the monoamine oxidase inhibitors, described just below as putative neuroprotective agents, have a beneficial effect on motor fluctuations induced by L-dopa and may have a slight beneficial effect on the main Parkinson symptoms as described in several trials, such as the one reported by Rascol and colleagues.

Neuroprotective Agents An additional approach, still somewhat controversial, has been to initiate treatment early in the course of the disease with a monoamine oxidase-B inhibitor (MAO-B inhibitor), with the aim of reducing oxidative stress in dopaminergic neurons. The DTAATOP trial conducted by The Parkinson Study Group (1989) reported a slowing of disease progression but later followup showed little difference between treated and untreated groups. Other agents in this class, notably rasagiline, have given similar mixed results in brief studies including the ADAGIO trial reported by Olanow and coworker. The difficulty in assessing the benefit of these agents has to do with their mild but definite symptomatic benefit on motor function. A credible long-term study has reported that early initiation of treatment with bromocriptine (now little used) did not reduce mortality or motor disability over 14 years and that any reduction in motor complications was unsustainable (Katzenschlager et al). Nonetheless, we institute one of these MAO-B inhibitors in many patients.

Following this same line of reasoning, several studies, most still disputed or unconfirmed, have suggested that ropinirole, pramipexole, and even L-dopa have "neuroprotective" effects in Parkinson disease. However, slowing of the progression of symptoms, as measured by a variety of scales, has not been corroborated. Technical problems in interpreting these results are discussed at length in the reviews by Wooten and by Clarke and Guttman. The uncertainties have to do with clinical grading systems, functional imaging techniques, and points of comparison to treatment with L-dopa.

The notion that the administration of L-dopa early in the disease might reduce the period over which it remains effective has been largely dispelled, but some neurologists continue to adhere to this idea. Cedarbaum and colleagues, who reviewed the course of the illness in 307 patients over a 7-year period, found no evidence that the early initiation of L-dopa treatment predisposed to the development of fluctuations in motor response or to dyskinesia and dementia. In fact, the findings of the "Elldopa" trial by The Parkinson Study Group (2004) were that functional and other measures were better in patients who had taken L-dopa for 40 weeks and then stopped the medications than in those who received no medication. Neuropathologic study of the substantia nigra in the brains of Parkinson patients and their medication histories also failed to corroborate a reduction in the number of pigmented neurons (Parkkinen et al). Also, the large multicenter study reported by Diamond and colleagues indicated that patients who were given L-dopa early in the disease actually survived longer and with less disability than those who began the medication late in the course; that is, L-dopa may have itself been neuroprotective. However, there have been many alternative interpretations of these data.

Finally, attempts to slow the disease by vitamin antioxidants such as vitamin E have met with mixed, but generally negative, results. A possible exception was the trial of coenzyme Q10 by Shults and colleagues. Massive doses of this agent, 1,200 mg/d, were found to offer marginal advantages on the progression over 6 to 18 months

as measured by certain scores of overall daily function but not on most neurologic scales. Further study of this approach is advised.

Side Effects of Dopamine Treatment and Their Management The side effects of L-dopa are at times significant to the degree that its continuation cannot be tolerated. Some patients are at first troubled by nausea, although this can be mitigated by taking the medication with meals. Nausea usually disappears after several weeks of continued use or can be allayed by the specific dopaminergic chemoreceptor antagonist domperidone. A few have mild orthostatic hypotensive episodes.

The most troublesome effects of L-dopa as the disease advances, usually after several years of treatment, are end-of-dose reduction in efficacy and the induction of involuntary “dyskinetic” movements—restlessness, head wagging, grimacing, lingual-labial dyskinesia, blepharospasm, and especially, choreoathetosis and dystonia of the limbs, neck, and trunk. A decline in efficacy at the end of the dose interval, typically 2 to 4 h, may be treated by more frequent dosing, the addition of dopaminergic agonist, or a COMT inhibitor.

The *on-off* or *off phenomenon* is a rapid and sometimes unpredictable change—in a matter of minutes or from 1 h to the next—from a state of relative freedom from symptoms to one of nearly complete immobility. Both dyskinesias and severe “off” periods appear in approximately 75 percent of patients within 5 years. Few patients escape these opposing effects, forcing an increased frequency of administration and usually a reduction in dosage.

If involuntary dyskinetic movements are induced by relatively small doses of L-dopa, the problem may be suppressed to some extent by the addition of direct-acting dopaminergic agents or by the concurrent administration of amantadine, or by the use of an oral suspension of L-dopa as mentioned earlier. The use of lower doses of long-acting preparations of L-dopa may be helpful in reducing dyskinesias and the atypical antipsychotic medications have been said to be useful for this purpose but carry their own risks.

The onset of psychiatric symptoms coincident with the use of L-dopa or dopamine agonists may also present problems and is to be expected eventually in 15 to 25 percent of patients, particularly in the elderly. Confusion and outright *psychosis* (hallucinations and delusions) are seen in advanced cases of Parkinson disease when high doses of L-dopa are required and the disease has been present for many years. This may first be treated by reducing the dose of the drug. If this is not tolerated, the atypical neuroleptics olanzapine, clozapine, risperidone, or quetiapine may be given in low doses. The side effects of these drugs include sleepiness, orthostatic hypotension, and sialorrhea. As noted above, clozapine has been said to provide an additional benefit of suppressing dyskinesias in advanced Parkinson disease, but its hematologic risks have led to limited use. Although useful in the treatment of frankly psychotic patients, these drugs tend to be far less effective once dementia has supervened. The antiepileptic drug, valproate is also said to be useful in this circumstance, but it has not been as effective as clozapine and related drugs. Despite its lesser tendency

to produce rigidity, olanzapine, and probably the other similar agents, in high doses may slightly worsen motor disability.

Depression, although frequent, is only occasionally a serious problem, even to the point of suicide. Delusional thinking may also occur in these circumstances. This combination of movement and psychiatric disorders is difficult to treat, and one is faced with instituting an antidepressant regimen or perhaps using one of the newer classes of antipsychotic medications that have the least extrapyramidal side effects (see below). While the selective serotonin reuptake inhibitors have been useful in cases of apathetic depression, they may cause slight worsening of parkinsonian symptoms. Trazodone has been helpful in treating depression and insomnia, the latter also being a major problem in some patients. Excitement and aggressiveness appear in a few. A return of libido may lead to sexual assertiveness. Other curious effects of excessive drive from L-dopa and dopamine agonists have been *pathologic gambling* (the same has been seen in treatment of restless legs syndrome) and *cross-dressing* (Quinn et al, 1983).

Anticholinergic agents or L-dopa should not be discontinued abruptly in advanced Parkinson disease. If abruptly discontinued, the patient may become totally immobilized by a sudden and severe increase of tremor and rigidity; rarely, a neuroleptic syndrome, sometimes fatal, has been induced by such withdrawal. Reducing the medication dose over a week or so is usually adequate.

With progressive loss of nigral cells, there is an increasing inability to store L-dopa and periods of drug effectiveness become shorter. In some instances, the patient becomes so sensitive to L-dopa that 50 to 100 mg will precipitate dyskinesias; if the dose is lowered by the same amount, the patient may develop disabling rigidity. With the end-of-dose loss of effectiveness and the on-off phenomenon, which with time become increasingly frequent and unpredictable, the patient may experience pain, respiratory distress, akathisia, depression, anxiety, and even hallucinations. Some patients function quite well in the morning and much less well in the afternoon, or vice versa. In such cases, and for end-of-dose and on-off phenomena, one must titrate the dose of L-dopa and use more frequent dosing during the 24-h day; combining it with a dopamine agonist or a long-acting preparation may be helpful. Sometimes temporarily withdrawing L-dopa and at the same time substituting other medications may reduce the on-off phenomenon.

Based on the principle that alimentary-derived amino acids compete for absorption of L-dopa, the use of a low-protein diet has been advocated as a means of controlling the motor fluctuations (Pincus and Barry). Symptoms can sometimes be reduced by the simple expedient of eliminating dietary protein from breakfast and lunch. Moreover, this dietary regimen may permit the patient to reduce slightly the total daily dose of L-dopa. Such dietary manipulation is worth trying in appropriate patients; it is not harmful, and most of our patients with advanced disease who have persisted with this diet have reported improvement in their symptoms or an enhanced effect of L-dopa. A novel observation by Pierantozzi and

colleagues has been that the absorption of L-dopa may be influenced by the presence of gastric *Helicobacter pylori* infection and that eradication of the organism was associated with longer "on" time.

Surgical Measures

Until recently, success with L-dopa had replaced the use of the ablative surgical therapy pioneered by Cooper 50 years ago. The surgical approaches involved the placement of lesions in the globus pallidus, ventrolateral thalamus, or subthalamic nucleus, contralateral to the side of the body chiefly affected. The best results were obtained in relatively young patients, in whom unilateral tremor or rigidity rather than akinesia were predominant. The symptoms that responded least well to surgical therapy in Cooper's patients were postural imbalance and instability, paroxysmal akinesia, bladder and bowel disturbances, dystonia, and speech difficulties.

More recently, through the work of Laitinen, Leksell, and others, this mode of therapy has been revived as a stereotactically guided procedure and advanced by the newer technique of implanted electrodes (deep brain stimulation, DBS). For the treatment of Parkinson disease, the electrodes are placed in the posterior and ventral (medial) parts of the subthalamic nucleus or in the internal segment of the globus pallidus. Most patients who have DBS experience enhanced responsiveness to L-dopa and a reduction of drug-induced dyskinesias. Bilateral stimulation of the subthalamic nucleus has produced improvement in all features of the disease, including in bradykinesia, that is lost after several years, but there is generally little benefit for impaired gait and balance (Limousin et al; Weaver et al, who conducted a more extensive study but for only 6 months). A study by the Deep-Brain Stimulation for Parkinson's Disease Group demonstrated at least short-term benefit in motor fluctuations after the bilateral implantation of stimulating electrodes in the subthalamic nuclei and the durability of this effect with continued DBS in subsequent studies ranged from 2 to 7 years.

The ideal candidates for DBS are considered to be those in whom, after several years, there is a failure of medications to relieve symptoms but especially because of unmanageable dyskinesias that result from L-dopa. A randomized, blinded trial by Deuschl and colleagues confirmed this effect and demonstrated an overall improvement in the quality of life at 6 months. The benefit with bilateral stimulation of the globus pallidus has been essentially equivalent to results from subthalamic stimulation (Follett et al). Dystonia, when present as part of the native disease or as a result of medication, may also benefit from this treatment, perhaps more so with pallidal stimulation. Several groups have pointed out that cognitive function may decline slightly with DBS, but deterioration is not as prominent in some spheres of performance, such as speed of processing, with stimulation of the globus pallidus. Hemorrhage into the basal ganglia and local infection near the stimulator has occurred in a small number of patients so treated. Depression and suicides also appear as adverse events in some stimulation trials.

The typical patient who will derive benefit from deep-brain stimulation is considered to be one who, to maintain mobility, requires a dose of L-dopa that produces unacceptable dyskinesias and who is constantly cycling between on and off periods. More recently, DBS has been introduced earlier in the course of illness, when the patient is still largely responsive to L-dopa and before severe motor complications such as dyskinesias arise. These patients are, of course, younger and have had a shorter duration of disease. In a trial conducted by Schuepbach and coworkers, in patients with mean durations of illness of 7.5 years and 52 years of age, there was a significant and sustained benefit in quality of life measures, motor complications and on time, for subthalamic DBS.

The stimulator is inserted in a pouch that is created near the rostral pectoral muscle and inferior to the clavicle. An external controller allows the stimulator to be adjusted for which 4 electrodes on either side are activated and their polarity, voltage applied, frequency of pulses, and pulse duration are manipulated. All patients with implanted electrodes require frequent initial contact with a physician experienced in programming the stimulator. Some patients can make minor adjustments or even turn off the stimulator on their own with a small control device that has preset limits. The battery must be exchanged periodically, the duration of service depending on the voltage used over time and other parameters of use. A comprehensive review of the subject has been given by Okun, including comments on the controversies regarding the differences in cognitive disturbance and the reduction in L-dopa doses comparing stimulation of the globus pallidus with the subthalamic nucleus.

Presumably, the high-frequency electrical impulses cause a disruption of local neuronal activity that is the functional equivalent of an ablative lesion, but the effects of deep brain stimulation may be more complex by way of stimulating neurotransmitter release.

The cerebral implantation of fetal dopaminergic tissue provided a modest improvement in motor function for a limited period of time (Spencer et al; Freed et al). The study by Freed and colleagues found a small improvement on a global scale that measured functional, psychological, and neurologic aspects only in younger patients but the effect waned by 1 year. These procedures are hampered by many difficulties, mainly in obtaining tissue and the failure of grafts to survive but also the problem of uncontrollable dyskinesias in some patients. Another provocative approach has been the delivery of neural trophic factors directly or in a viral vector through a small catheter; at least 2 trials have failed to show benefit. Similarly, the implantation of stem cells is being explored but has several obstacles.

Techniques of focused ultrasound energy to produce ablative lesions in deep nuclei are being developed. So far, they have found use for the treatment of essential tremor, such as in the trial conducted by Elias with thalamic lesions (ventral intermediate nucleus).

Ancillary Treatments In the management of the patient with Parkinson disease, one must not neglect the maintenance of general health and neuromuscular efficiency by a program of exercise, activity, and rest; physical

therapy and exercises such as those performed in yoga may be of help in achieving these ends. Sleep may be aided by soporific antidepressants. Postural imbalance and falls can be greatly mitigated by the use of a cane or walking frame. A number of excellent exercise programs have been devised specifically for patients with Parkinson disease, and measures such as massage and yoga have their advocates. Among these mechanical therapies that have been studied systematically, tai chi has been found to improve balance and reduce falls as measured by objective criteria (Li et al), indicating that these approaches are of substantial value. Several of our patients have taken up dancing and report that their balance in daily circumstances is improved. Our position has been that any activity that keeps the patient moving and committed is of great value. Speech exercises help the motivated patient.

Hypotensive episodes respond to fludrocortisone or midodrine given each morning. Focal dystonias of the foot are partially treatable with local injections of botulinum toxin. In addition, the patient often needs emotional support in dealing with the stress of the illness, with the anxiety that seems to be an integral part of the disease in some patients, in comprehending the future, and in carrying on courageously in spite of it.

Multiple System Atrophy (Striatonigral Degeneration, Shy-Drager Syndrome, Olivopontocerebellar Degeneration)

As the name *multiple system atrophy* indicates, this depicts a group of disorders characterized by neuronal degeneration mainly in the substantia nigra, striatum, autonomic nervous system, and cerebellum. Following a report in 1964 by Adams and colleagues of what was then called *striatonigral degeneration*, many patients were recognized in whom the changes of striatonigral and olivopontocerebellar degeneration were combined and who had symptoms and signs of cerebellar ataxia and parkinsonian manifestations. The pathologic changes were found by chance in 4 middle-aged patients, in 3 of whom a parkinsonian syndrome had been described clinically, none with a family history of similar disease. Rigidity, stiffness, and akinesia had begun on one side of the body, then spread to the other, and progressed over a 5-year period but with minimal characteristic tremor of idiopathic Parkinson disease. A flexed posture of the trunk and limbs, slowness of all movements, poor balance, mumbling speech, and a tendency to faint when standing were other elements. There was an early-onset cerebellar ataxia in the fourth patient that was later obscured by a Parkinson syndrome.

The postmortem examinations disclosed extensive loss of neurons in the zona compacta of the substantia nigra, but notably, there were no Lewy bodies or neurofibrillary tangles in the remaining cells. Even more striking were the degenerative changes in the putamina and to a lesser extent in the caudate nuclei. Secondary pallidal atrophy (mainly a loss of striatopallidal fibers) was present. In the patient with ataxia there was, in addition, advanced degeneration of the pons, olives, and cerebellum (see below in the discussion of olivopontocerebellar degeneration).

Recognizing that the clinical and pathologic features of striatonigral degeneration, with or without autonomic failure, can coexist with olivopontocerebellar atrophy, Graham and Oppenheimer proposed the term *multiple system atrophy* (MSA), which has gained wide acceptance. Several large series of cases of this complex syndrome have been published, providing a perspective on the frequency and nature of its component syndromes. Either parkinsonism or cerebellar ataxia may predominate. In many writings they are categorized as MSA-P and MSA-C, respectively, depending on whether they display predominantly parkinsonism or cerebellar ataxia. More than half of the patients with striatonigral degeneration have *orthostatic hypotension*, which proves at autopsy to be associated with loss of intermedialateral horn cells and pigmented nuclei of the brainstem. This combined parkinsonian and autonomic disorder, formerly referred to as the Shy-Drager syndrome, was alluded to in Chaps. 18 and 26 and is now termed MSA-A, for multiple system atrophy with autonomic changes. In addition to orthostatic hypotension, other features of autonomic failure include erectile dysfunction, loss of sweating, dry mouth, miosis, and urinary retention or incontinence. Vocal cord palsy is an important and sometimes initial manifestation of the disorder; it may cause dysphonia or stridor and airway obstruction requiring tracheostomy. A dusky discoloration of the hands as a sign of this disorder was ascribed to poor control of cutaneous blood flow by Klein and colleagues. A diagnostic problem arises in that orthostatic hypotension is also observed in up to 15 percent of patients with Parkinson disease, a feature that may be exaggerated by medications, but the degree of drop in blood pressure is far greater and more frequent in patients with this form of multiple system atrophy.

In the Brain Tissue Bank of the Parkinson Disease Society of Great Britain, MSA accounted for 13 percent of patients who had been identified during life as having idiopathic Parkinson disease. All the patients with MSA had one or more symptoms of autonomic failure (postural hypotension, urinary urgency or retention, urinary or fecal incontinence, erectile dysfunction) and dysphonia or stridor. Babinski signs were present in half the patients and cerebellar ataxia in one-third. Tremor was rare. Males were affected more often than females. In a comparable series of 100 patients (67 men and 33 women) studied by Wenning and coworkers (1994), the disease began with a striatonigral-parkinsonian syndrome in approximately half; often it was asymmetrical at the onset. Mild tremor was detected in some but in only a few was it of the "resting" Parkinson type. In nearly half, the illness began with autonomic manifestations; orthostatic hypotension occurred eventually in almost all patients, but it was disabling in only a few. Cerebellar features dominated the initial stages of the disease in only 5 percent, but ataxia was eventually obvious in half the larger group. This ataxic clinical presentation of multiple system atrophy will be elaborated further in the section on the degenerative cerebellar ataxias.

The extrapyramidal illness, on the whole, is more severe than in Parkinson disease, as more than 40 percent of patients are confined to a wheelchair or otherwise

severely disabled within 5 years. These observations generally match the findings in the group described by Quinn and colleagues (1986), but they emphasized that pyramidal signs were present in 60 percent.

Colosimo and colleagues reviewed the clinical findings in 16 pathologically verified cases of MSA and found that several signs, namely, relative symmetry of the signs and rapid course, the lack of response to L-dopa, absence or minimal amount of tremor, and the early presence of autonomic disorders, reliably distinguished this syndrome from Parkinson disease. These observations are in keeping with our own and we would add that abnormalities of eye movement are not prominent in MSA. Additional features occurring occasionally in MSA are remarked upon in other series; anterocollis or dystonia of the lower facial muscles, for example, is striking in a few cases. It is noteworthy that levodopa has had little or no effect or has made these patients worse early in the disease but we have seen exceptions. The lack of L-dopa effect is probably attributable to the loss of striatal dopamine receptors.

The diagnosis of MSA, especially the form with ataxia, has been aided by imaging techniques. Both MRI and CT scanning frequently show atrophy of the cerebellum and pons in those with cerebellar features. The putamina are hypointense on T2-weighted MRI and may show an increased deposition of iron in the parkinsonian form. In the cerebellar form, a “hot cross bun” sign has been emphasized on MRI; it reflects atrophy of the pontocerebellar fibers that manifest high T2 signal intensity in an atrophic pons. Studies with PET have disclosed impairment of glucose metabolism in the striatum and to a lesser extent in the frontal cortex, a reflection, no doubt, of the loss of functioning neuronal elements in these parts.

Finally, despite the concurrence of striatonigral degeneration, olivopontocerebellar degeneration, and the Shy-Drager syndrome, *each of these disorders can occur in almost isolated clinical form*; we therefore retain their original designations.

Although the cause of this process is not known, and the majority of cases are sporadic, The Multiple System Atrophy Research Collaboration identified a mutation in the *COQ2* gene, coding for a protein involved in the synthesis of coenzyme Q₁₀, in both familial cases and a very small proportion of sporadic ones.

Pathology In recent years, attention has been drawn to the presence of abnormal staining material in the cytoplasm of astroglia and oligodendrocytes and in some neurons as well. These cytoplasmic aggregates have been referred to as *glial cytoplasmic inclusions* (Papp et al). Although they bear little resemblance morphologically to other discrete inclusions that have come to be accepted as characteristic of certain degenerative CNS diseases (e.g., Lewy bodies), they nonetheless contain α -synuclein (the main component of Lewy bodies). It is not clear to us whether these glial cytoplasmic accumulations represent a histopathologic hallmark of MSA as suggested by Chin and Goldman and by Lantos, as their presence is not specific; they have been identified in practically every degenerative disease that has been subjected to sensitive silver impregnation stains. Many types of inclusions are, of

course, nonspecific, as, for example, α -synuclein-positive inclusions have been detected in several neurodegenerative syndromes. Appropriate control studies to determine whether the glial inclusions are found in *nondegenerative* lesions in brain (at the edge of an infarct, for example) are needed. Also lacking is information about the frequency of these cytoplasmic inclusions in relation to the aging brain.

Progressive Supranuclear Palsy

In 1963, Richardson, Steele, and Olszewski crystallized medical thought about a clinicopathologic entity—progressive supranuclear palsy (PSP)—to which there had been only ambiguous reference in the past. The condition is not rare. By 1972, when Steele reviewed the subject, 73 cases (22 with postmortem examinations) had been described in the medical literature. Rare familial clusters have been described in which the pattern of inheritance is compatible with autosomal dominant transmission (Brown et al; de Yébenes et al). Rojo and coworkers described 12 pathologically confirmed pedigrees and made note of the variable phenotypical expression of the disease even within a single pedigree. No toxic, encephalitic, racial, or geographic factor has been incriminated.

Clinical Features

The disease has its onset typically in the sixth decade (range: 45 to 75 years), with some combination of difficulty in balance, abrupt falls, visual and ocular disturbances (giving the syndrome its name), slurred speech, dysphagia, and sometimes vague changes in personality, including apprehensiveness and fretfulness suggestive of an agitated depression. The most common early complaint is unsteadiness of gait and unexplained falling without loss of consciousness. The patient has difficulty in describing his imbalance, using terms such as “dizziness,” “toppling,” or an ambiguous problem with walking. At first, the neurologic and ophthalmologic examinations may be unrevealing, and it may take a year or longer for the characteristic syndrome comprising supranuclear ophthalmoplegia, pseudobulbar palsy, and axial dystonia to develop fully.

Difficulty in voluntary vertical movement of the eyes, often downward but sometimes only upward, and later impairment of voluntary saccades in all directions are characteristic. A related but more subtle sign has been the finding of hypometric saccades in response to an optokinetic drum or striped cloth moving vertically in one direction (usually best seen with stripes moving downward). Later, both ocular pursuit and refixation movements are delayed and diminished in amplitude and eventually all voluntary eye movements are lost, first the vertical ones and then the horizontal ones as well. However, if the eyes are fixated on a target and the head is turned slowly, full movements can be obtained, demonstrating the supranuclear, nonparalytic character of paralysis of ocular pursuit. Other prominent oculomotor signs are sudden jerks of the eyes during fixation, “cogwheel” or saccadic choppiness of pursuit movements, and hypometric saccades of long duration (Troost and Daroff). The Bell phenomenon (reflexive upturning

of eyes upon forced closure of the eyelids) and the ability to converge are also lost eventually, and the pupils become small but remain round and reactive to both light and to accommodative stimuli. The upper eyelids may be retracted, and the wide-eyed, unblinking stare imparts an expression of perpetual surprise. Blepharospasm and involuntary eye closure are prominent in some cases. In the late stages, the eyes may be fixed centrally and all oculocephalic and vestibular reflexes are lost. It should be emphasized, however, that a proportion of patients do not demonstrate these eye signs for a year or more after the onset of the illness. We have also followed several patients who had no disorder of eye movement during life but in whom the typical pathologic changes of PSP were nonetheless found. In one such patient, there was a subcortical type of dementia; in another, focal limb dystonia and parkinsonism. Furthermore, other degenerative conditions can manifest a supranuclear vertical gaze disorder, although never to the extent seen in PSP; these include corticobasal-ganglionic degeneration, Lewy-body disease, Parkinson disease, and Whipple disease.

The *gait disturbance* and *repeated falling* have proved difficult to analyze, as discussed in Chap. 7. Walking becomes increasingly awkward and tentative; the patient has a tendency to totter and fall repeatedly, but has no ataxia of gait or of the limbs and does not manifest a Romberg sign or orthostatic tremor. Some patients tend to lean and fall backward (retropulsion). One of our patients, a large man, fell repeatedly, wrecking household furniture as he went down, yet careful examination provided no clue as to the basic defect in this “toppling” phenomenon. Along with the oculomotor and balance disorders, there is a gradual stiffening and extension of the neck (in one of our patients it was sharply flexed in a manner consistent with camptocormia) but this is not an invariable finding. The face acquires a staring, “worried” expression with a furrowed brow (a result of the tonic contraction of the procerus muscle), made more striking by the paucity of eye movements. A number of our patients have displayed mild dystonic postures of a hand or foot, especially as the illness advanced but occasionally early on. The limbs may be slightly stiff and there are Babinski signs in a few cases.

The stiffness, slowness of movement, difficulty in turning and sitting down, and hypomimia may suggest a diagnosis of Parkinson disease. However, the facial expression of the PSP patient is more a matter of tonic grimace than of lack of movement, and the lack of tremor, the erect rather than stooped posture, and prominence of oculomotor abnormalities serve to distinguish the 2 disorders. The signs of pseudobulbar palsy are eventually prominent, and this feature, along with the eye movements, distinguishes the process most conspicuously from other degenerative conditions. The face becomes less expressive (“masked”), speech is slurred in a slowed spastic fashion, the mouth tends to be held open, and swallowing is difficult. Forced laughing and crying, said to be infrequent, have been present in about half of our cases late in the course. Many patients complain of sleep disturbances. The total sleep time and REM sleep are reduced, and spontaneous awakenings during the night are more

frequent and longer than in normal individuals of the same age. Complaints of urinary frequency and urgency have also been frequent in advanced cases under our care.

The diagnosis often proves difficult to make if the main features are not outstanding. Other features, such as tremor, palilalia, myoclonus, chorea, orofacial dyskinesias, and disturbances of vestibular function, are observed in some cases. Finally the patient becomes anarthric, immobile, and quite helpless. Dementia of some degree is probably present in many cases, but is mild in most. Some patients do become forgetful and appear apathetic and slow in thinking; many others are irritable or at times euphoric. Dubois and colleagues proposed an “applause sign” as distinctive to this disease; the patient fails to stop clapping after being asked to do so only 3 times, but we are unable to corroborate this.

By MRI one can, in advanced cases, appreciate atrophy of the dorsal mesencephalon (superior colliculi, red nuclei) giving rise to a “mouse ears” configuration (Fig. 39-7), but these changes may not be evident early in the illness when diagnosis is most difficult. Several measurements of midbrain atrophy have been proposed as aiding diagnosis; for example, there is little overlap between PSP, multiple system atrophy, and Parkinson disease in the ratio of midbrain-to-pons cross-sagittal area, according to Oba and colleagues. The CSF remains normal. Nonetheless, the diagnosis continues to rest on the clinical features, mainly affecting eye movements.

Pathology *Postmortem examinations* have disclosed a bilateral loss of neurons and gliosis in the periaqueductal gray matter, superior colliculus, subthalamic nucleus,

Figure 39-7. Progressive supranuclear palsy. T2-weighted axial MRI showing the atrophic dorsal midbrain that gives rise to the “mouse ears” (also “Mickey mouse”) appearance.

red nucleus, pallidum, dentate nucleus, and pretectal and vestibular nuclei, and to some extent in the oculomotor nucleus. The expected loss of the myelinated fiber bundles arising from these nuclear structures has also been commented upon. The remarkable finding has been the neurofibrillary degeneration of many of the residual neurons. The neurofibrillary tangles are thick and often composed of single strands, either twisted or in parallel arrangement. The neurons of the cerebral cortex have been involved in some cases (shown by staining of tau protein), but these changes do not correlate with dementia. The cerebellar cortex is usually spared.

The cause and nature of this disease remain obscure. Though some clinical and pathologic heterogeneity is seen, the majority of cases of PSP conform to the typical pattern as we have just described. These interesting diagnostic and clinicopathologic aspects are summarized by Williams and Lees. Studies with PET demonstrate a decrease in blood flow, most marked in the frontal lobes, and a lesser extent of oxygen utilization in central structures (Leenders et al). Striatal dopamine formation and storage are significantly decreased when compared with control values. Much current interest has been directed to the neurofibrillary tangles and tau deposition in PSP and a potential link to the tau pathology displayed in frontotemporal dementia and in corticobasal ganglionic degeneration (see below). As summarized by Golbe, certain tau gene haplotypes on chromosome 17p (the same site implicated in familial frontotemporal dementia) are more often associated with PSP than in unaffected individuals, but other factors, environmental or genetic, must also be involved. It is intriguing that the tau-gene haplotype of frontotemporal dementia is not found in PSP. A recent investigation into the mechanism of postural instability using functional imaging, showed a correlation between gait instability and decreased thalamic glucose metabolism and activation (Zwergal).

PSP should be suspected whenever an older adult inexplicably develops a state of imbalance, frequent falls with preserved consciousness, and variable extrapyramidal symptoms, particularly dystonia of the neck, ocular palsies, or a picture resembling pseudobulbar palsy. If the typical abnormalities of eye movements are present, the diagnosis is not difficult. When only a parkinsonian syndrome without tremor is apparent the main diagnostic consideration is striatonigral degeneration or the corticobasal ganglionic syndrome, described below.

Treatment L-Dopa has been of slight and unsustainable benefit in some of our patients, and combinations of L-dopa and anticholinergic drugs have been entirely ineffective in others. A marked response to these drugs should, of course, suggest the diagnosis of Parkinson disease. Recently, the drug zolpidem, a gabenergic agonist of benzodiazepine receptors, has been reported to ameliorate the akinesia and rigidity of PSP (Daniele et al); however, these observations require corroboration. Benzotropine or trihexyphenidyl has been somewhat helpful in reducing dystonia but botulinum injections may be a better alternative if there are focal signs. Treatments of the sleep difficulties and urinary incontinence are of great assistance to the patient and family. A feeding tube becomes

necessary in advanced cases. Observing the decline of these patients and the limitations of treatment is a frustrating ordeal for all involved.

Corticobasal Degeneration

Most neurologists have observed elderly patients in whom the essential abnormality was a progressive asymmetrical extrapyramidal rigidity combined with signs of corticospinal disease. Sometimes a mild postural action tremor beginning unilaterally and suggestive in some respects of Parkinson disease has been added. The parkinsonism is generally unresponsive to L-dopa. These cases have come to be known by the names *corticobasal-ganglionic* or *cortical-basal degeneration* and like sounding terms. The clinical relation of such cases is indeterminate to corticostriatal degeneration described earlier, and based on the finding of tau inclusions, to frontotemporal lobar degeneration and to progressive supranuclear palsy.

Wenning and colleagues (1998) described a series of such patients in whom the diagnosis was confirmed at postmortem examination. The most common early symptom was an asymmetrical clumsiness of the limbs, in half of the patients, with rigidity and, in one-fifth, with tremor; these features are now considered to be the most characteristic early features of the process. As the illness progressed, almost all the patients developed an asymmetric or unilateral akinetic-rigid syndrome, which may be considered the essential motor disorder of this disease and various forms of gait disorder and dysarthria. Stimulus-induced or spontaneous myoclonus and pyramidal signs, mentioned in other reports and frequent in our cases, were not prominent in their series; limitations of vertical gaze and frontal lobe release signs eventually became apparent in half.

Eventually, although able to exert considerable muscle power, these patients cannot effectively direct their voluntary actions. Attempts to move a limb to accomplish some purposeful act might result in a totally inappropriate movement, always with great enhancement of rigidity in the limb and in other affected parts, or the limb may drift off and assume an odd posture, such as a persistent elevation of the arm without the patient's awareness—a kind of catalepsy. The disorder of limb function has some of the attributes of a limb-kinetic or an ideomotor apraxia (see Chap. 3), but the hand postures, involuntary movements, and changes in tone are at times more of the type described as "alien hand." Some patients exhibit anosognosia, Babinski signs, impaired eyelid or ocular motion (upgaze paresis or abnormal saccadic movements), lingual dyskinesias, frontal release signs, myoclonus, or dysarthria.

Another distinct group has dementia as an early feature, as described by Grimes and colleagues, but mental deterioration is more often late and may not occur in all patients. There are also rare patients who present with behavioral disturbance or nonfluent aphasia as early features, which are difficult to distinguish from subtypes of frontotemporal dementia (Lee and colleagues, 2011). Occasionally, there is some involvement of lower

motor neurons with resulting amyotrophy. Several of our patients had myoclonus as an early feature, one displaying it only on one side of the face, the other in an arm. The condition progresses for 5 years or more before some medical complication overtakes the patient.

Postmortem examination of patients, originally reported by Rebeiz and colleagues, disclosed a combination of findings that differentiated the disease process from other neurodegenerative conditions. Cortical atrophy (mainly in the frontal motor-premotor and anterior parietal lobes) was associated with degeneration of the substantia nigra and, in one instance, of the dentatorubrothalamic fibers. The loss of nerve cells was fairly marked, but there was no gross lobar atrophy, as occurs in Pick disease. The neuronal degeneration was more on one side of the brain than the other. There was moderate gliosis in the cortex and underlying white matter. The disease is now clearly considered to be related to tau deposition in specific brain structures; however, the original authors were more impressed with ballooned and chromatolytic neurons with eccentric nuclei, a state that was called *neuronal achromasia*. The presence of these achromatic cells in posterior frontal and parietal neurons continues to be considered an essential feature of the disease, although the rounded areas within neurons stain for tau and resemble globose tangles that are found occasionally in Alzheimer disease (corticobasal bodies); in this way, CBD is connected to the other tau-related neurodegenerative diseases, “*tauopathies*.” In addition, adjacent glia are filled with various configurations of tau protein, thereby linking the disease to frontotemporal lobar degeneration and PSP. Our colleague Feany, with Dickson, has identified one type of these as “plaques” in the cortex that are composed of tau aggregates within the distal processes of astrocytes.

Both CT and MRI have demonstrated asymmetrical cerebral and pontine atrophy, and PET studies have revealed thalamoparietal metabolic asymmetries—a greater reduction of glucose metabolism on the side of the most extensive lesion (Riley et al).

There are no clues as to the pathogenesis of this disease. There are rare familial types but no definite genetic cause has been identified. No organ other than the CNS is affected. The progression is relentless. None of the drugs in common use for spasticity, rigidity, and tremor has been helpful.

Dystonic Disorders

Dystonia Musculorum Deformans (Torsion Dystonia)

Dystonia as a symptom was discussed in Chaps. 4 and 6. Here we are concerned with a disease or diseases of which dystonia is the major manifestation. Schwalbe's account, in 1908, of 3 sibilings of a Jewish family who were afflicted with progressive involuntary movements of trunk and limbs probably represents the first description of a disease in which severe and progressive dystonia was the sole manifestation. In 1911, Oppenheim contributed other cases and coined the term *dystonia musculorum*

deformans in the mistaken belief that the disorder was primarily one of muscle and always associated with deformity. Flatau and Sterling, in the same year, first suggested that the disease might have a hereditary basis and gave it the more accurate name *torsion dystonia of childhood*. At first the condition was considered by some to be a manifestation of hysteria; only later was it recognized as a neurologic entity with a predilection for individuals of Eastern European Jewish origin. Soon thereafter, a second hereditary form of torsion dystonia, affecting non-Jews, was observed. The recessive form begins in early childhood, is progressive over a few years, and is restricted to Jewish patients. The dominant form begins later, usually in late childhood and adolescence, progresses more slowly, and is not limited to any ethnic group.

As indicated in Chap. 6, most instances of idiopathic (primary) dystonias that come to our attention, particularly the segmental or restricted types, do not conform to the classic hereditary disorders as defined above, although some may represent limited variants of the disease. In general, these more restricted types have a later onset and a relatively milder, more slowly progressive course, with a tendency to involve an axial or a distal region alone. Only the paravertebral, cervical, or cranial muscles may be involved (focal dystonia including torticollis and writer's cramp), with little change from year to year. The clinical classification of the predominantly adult-onset dystonias is made more complex by the fact that both the restricted and generalized forms may be sporadic or genetic. Molecular genetic studies, although still incomplete, hold the promise of clarifying the classification of the heritable dystonias. More than 10 types have been distinguished by genetic mapping, as summarized by Németh. The most important of these is an abnormal gene (*DYT1*, also known as *TOR1A*) on chromosome 9q, which codes for the protein, torsin A in both Jewish and non-Jewish families. The most common *DYT1* mutation, causing deletion of a single glutamate from the torsin A peptide, is found in most cases of dystonia musculorum deformans. This disease is inherited in an autosomal dominant pattern. Although the penetrance of the clinical trait in these families is low, PET demonstrates hypermetabolism in the cerebellum, lenticular nuclei, and supplementary motor cortex in all carriers of the mutated gene.

The function of torsin A is not fully defined. It is present in neurons throughout the brain and has adenosine triphosphate (ATP) binding and nuclear localization. It may function as a chaperone protein that shuttles other proteins in and out of cells. A current speculation, shared with other degenerative disease, is that the absence of torsin A renders neurons unduly sensitive to oxidative stress (Walker and Shashidharan).

Although *DYT1* mutations account for the majority of inherited cases of generalized dystonia, they are also implicated in a small proportion of the more restricted dystonias, particularly blepharospasm (see further on). Some individuals in families affected with generalized dystonia will demonstrate only localized forms (e.g., writer's cramp or torticollis). The general rule stated above still holds, namely, that the inherited variety (dystonia musculorum deformans) related to *DYT1* manifests

early in life and begins in one limb and then spreads to most muscles of the body, while in the common dystonias (mostly sporadic but some heritable) the disease remains confined to the craniocervical or another region, does not generalize, and has an adult onset.

Clinical Features The first manifestations of the generalized disease may be rather subtle. Intermittently, and usually after activity (late in the day), the patient (usually a child between 6 and 14 years of age, less often an adolescent) begins to invert one foot, to extend one leg and foot in an unnatural way, or to hunch one shoulder, raising the question of a nervous tic. As time passes, the motor disturbance becomes more persistent and interferes increasingly with the patient's activities. Soon the muscles of the spine and shoulder or pelvic girdle become implicated in involuntary spasmodic twisting movements. The cardinal feature of these severe dystonic muscle contractions is the simultaneous contraction of both agonists and antagonists at a joint. These cocontraction spasms are intermittent at first; in intervals that are free of the dystonia, muscular tone and volitional movements are normal. In some instances, the muscles are hypotonic. Gradually, the spasms become more frequent; finally, they are continuous and the body may become grotesquely contorted, as shown in Fig. 4-5A. Lateral and rotatory scoliosis uniformly results as secondary deformities. For a time, recumbency relieves the spasms, but later on position has no influence. The hands are seldom involved, although at times they may be held in a fistful posture. Cranial muscles do not escape, and in a few instances a slurring, staccato-type speech was the initial manifestation. Uncontrollable blepharospasm was the initial disorder in one of our patients; in two others, severe dysarthria and dysphagia were the first signs, caused by dystonia of the tongue, pharyngeal, and laryngeal muscles.

Other manifestations include torticollis, tortipelvis, dromedary gait, propulsive gait, action tremor, myoclonic jerks during voluntary movement, and mild choreoathetosis of the limbs. Excitement worsens the dystonia and sleep abolishes it. As the years pass the postural distortion may become fixed to the point where it does not disappear even in sleep. Tendon reflexes are normal, corticospinal signs are absent, and there is no ataxia, sensory abnormality, convulsive disorder, or dementia.

Pathology No agreement has been reached concerning the pathologic substrate of the disease. None of the features of symptomatic dystonia are found, such as the ferrocalsinosis of PKAN, the lesions of Wilson disease, kernicterus, *état marbré* of neonatal hypoxia, or the cavitation of familial striatal necrosis, lesions have been observed in the basal ganglia. However, in the hereditary forms of dystonia, which are the subject of this section, one cannot be certain of any specific lesions that would account for the clinical manifestations. The brain is grossly normal and ventricular size is not increased. According to Zeman, who reviewed all the reported autopsy studies up to 1970, there were no significant changes in the striatum, pallidum, or elsewhere. This means only that the techniques being used (qualitative analysis of random sections by light microscopy) are inadequate or the problem

is subcellular. The report by McNaught and colleagues of perinuclear inclusions in periaqueductal neurons by the use of special immunostaining methods is provocative. There had been tentative interest in elevations of dopamine β -hydroxylase in patients with the autosomal dominant form of the disease, but the meaning of these findings is not clear.

Treatment Early in the course of the illness, several drugs including L-dopa, bromocriptine, carbamazepine, diazepam, and tetrabenazine seem to be helpful, but only in a few patients, and the benefit is not lasting. Intrathecal baclofen has been somewhat more successful in children. The rare hereditary form of dystonia-parkinsonism (described below) responds well to small doses of L-dopa and dopamine agonists and is exceptional in this respect. Burke and coworkers advocate the use of very high doses (up to 30 mg daily or more) of trihexyphenidyl (Artane). Apparently, dystonic children can tolerate these high doses if the medication is raised gradually, by 5-mg increments weekly. In adults, high-dose anticholinergic treatment is less successful but worthy of a trial. Clonazepam is beneficial in some patients with segmental myoclonus.

Impressive results were obtained in the past by the use of stereotactic techniques that made lesions in the ventrolateral nuclei of the thalamus or in the pallidum-ansa lenticularis region. Some frightfully disabled children, unable to sit or stand, were restored to near normalcy for a time. Approximately 70 percent of the patients in Cooper's series in the 1950s were moderately to markedly improved by unilateral or bilateral operations and, based on a 20-year followup study, the improvement was usually sustained. More recent studies report a somewhat less favorable but nonetheless clear improvement (see Tasker et al; Andrew et al). The main risk of the operation was a corticospinal tract lesion, produced inadvertently by damaging the internal capsule. Bilateral lesions have sometimes been disastrous, causing pseudobulbar palsy. The production of lesions has been supplanted, with success over long periods, by bilateral stimulation of the internal segments of the globus pallidus (Vidailhet and colleagues).

Hereditary Dystonia-Parkinsonism (Segawa Syndrome, Juvenile Dopa-Responsive Dystonia)

This process is discussed here because its main characteristic is a dystonia that is responsive to L-dopa, but most cases also have features of parkinsonism, which is why it was also mentioned in the earlier discussion of hereditary forms of Parkinson disease, especially in young patients. Following the description of the syndrome by Segawa and colleagues in 1976, others drew attention to this unique form of hereditary dystonia (Allen and Knopp; Deonna; Nygaard and Duvoisin). The pattern of inheritance is autosomal dominant and there is no ethnic predilection. Nygaard and colleagues found a linkage to the gene on chromosome 14q for the protein GTP cyclohydroxylase 1 (*GCH1* gene) that is implicated in the synthesis of tetrahydrobiopterin, a cofactor for tyrosine hydroxylase. It is likely that the mutation impairs the generation of dopamine, a prediction that accords with responsiveness

of the parkinsonian and dystonic features to L-dopa. In one autopsied case (an accidental death), there was a reduction in the amount of tyrosine hydroxylase in the striatum and depigmentation but no cell loss in the substantia nigra (Rajput et al). The affected enzyme was reduced in the striatum, as was the level of dopamine.

The dystonic manifestations usually become evident in childhood, usually between 4 and 8 years of age; females outnumber males in a ratio of 3:2. Often the legs are first affected by intermittent stiffening, with frequent falls and peculiar posturing, sometimes the feet assuming an equinovarus position. The arms become involved as well as the truncal muscles; retrocollis or torticollis may appear. Within 4 to 5 years, all parts of the body, including the bulbar muscles, are involved. Mild parkinsonian features (rigidity, bradykinesia, postural instability) can usually be detected early in the course of the illness, but more characteristically they are added to the clinical picture several years later. In our own patients, and in several of those of Deonna, there was rigidity of the limbs as well as slowness of movement and a tremor at rest, all aspects more parkinsonian than dystonic. In still others, the clinical picture has been one of cerebral spastic diplegia.

A remarkable feature is the disappearance or marked subsidence of the symptoms after a period of sleep and worsening as the day progresses. This diurnal variation is shared with many of the inherited forms of Parkinson disease listed in Table 39-3. Fluctuations of symptoms with exercise and menses and in the first month of pregnancy have been observed in some cases.

The special feature of this *juvenile dystonia-parkinsonism syndrome* is the dramatic response of both the dystonic and parkinsonian symptoms to treatment with L-dopa. As little as 10 mg/kg/d may eliminate the movement disorder and permit normal functioning. Unlike idiopathic Parkinson disease, the medication can be continued indefinitely without the development of tolerance, wearing-off effects, or dyskinesias. Segawa disease accounts for some cases that had in the past been reported as juvenile Parkinson disease.

Torticollis and Other Restricted Dyskinesias and Dystonias (See Chap. 6)

With advancing age, a large variety of focal or regional movement disorders come to light. Various neurophysiologic abnormalities, summarized in Chap. 6, have been implicated. In the common restricted dystonias, localized groups of adjacent muscles manifest arrhythmic cocontracting spasms (i.e., agonist and antagonist muscles are activated simultaneously). The patient's inability to suppress the dystonia and the recognition that it is for the most part beyond voluntary control distinguishes it from tics, habit spasms, and mannerisms described in Chap. 6. If the muscle contraction is frequent and prolonged, it is accompanied by an aching pain that may mistakenly be blamed for the spasm and the involved muscles may gradually undergo hypertrophy. Worsening under conditions of excitement and stress and improvement during quiet and relaxation are typical of this group of disorders and contributed in the past to the mistaken notion that the spasms had a psychogenic origin.

The most frequent and familiar type is *torticollis*, wherein an adult, more often a woman, becomes aware of a turning of the head to one side while walking. Usually this condition worsens gradually to a point where it may be more or less continuous, but in some patients it remains mild or intermittent for years on end. When followed over the years, the condition is observed to remain limited to the same muscles (mainly the scalene, sternocleidomastoid, and upper trapezius). Rarely, the torticollis is combined with dystonia of the shoulder, arm, and trunk; tremor; facial spasms; or dystonic writer's cramp.

Other restricted dyskinesias involve the neck in combination with facial muscles, the orbicularis oculi (*blepharospasm* and *blepharoclonus*), the throat and respiratory muscles (*spastic dysphonia*, *orofacial dyskinesia*, and *respiratory and phonatory spasms*), the hand in writer's cramp (*graphospasm*) or musician and other performing artist's dystonia, and proximal leg and pelvic-girdle muscles, where dyskinesia is elicited by walking. All these conditions and their treatments are discussed fully in Chap. 6.

Other Forms of Hereditary Dystonia

Several familial movement-induced (kinesogenic) dystonic syndromes and a type that is not kinesogenic and arises suddenly in adolescence, at times with parkinsonian features, have been described. There are other degenerative diseases that combine hereditary dystonia with neural deafness and intellectual impairment (Scribanu and Kennedy) and with amyotrophy in a paraplegic distribution (Gilman and Romanul). These are discussed in greater detail in Chap. 6.

Other important symptomatic dystonias that fall into the category of hereditary dystonia were described in Chap. 37. These are PKAN and calcification of the basal ganglia; of course, Wilson disease may have dystonia as a central feature. Many extrapyramidal diseases, including idiopathic Parkinson disease and progressive supranuclear palsy, may include fragmentary dystonias of the hand, foot, face, or periorbital muscles.

SYNDROME OF PROGRESSIVE ATAXIA

Wilson wrote that "the group of degenerative conditions strung together by the common feature of ataxia is one for which no very suitable classification has yet been devised," a statement that is not as appropriate today as when it was written 75 years ago. This topic was introduced in Chap. 5 and some of the congenital and acute acquired varieties are mentioned there. Here we consider the *chronic, progressive forms of cerebellar disease*. Although most of these are familial and are more or less confined to this part of the nervous system, a number of other systems may be involved to varying degrees. Most of the chronic progressive cerebellar diseases are subsumed under the "system atrophies," but no one classification designed to bring order to this category of diseases has proved satisfactory and a preferable genetic classification is emerging.

Setting aside those of congenital type and those caused by a metabolic disorder, Harding (1993) grouped

the ataxias by age of onset, pattern of heredity, and associated features. A modification of the classifications of Greenfield and of Harding, which is included in the introductory listing of this chapter, still has clinical value. It divides the progressive cerebellar syndromes into 3 main groups: (1) the spinocerebellar ataxias, with unmistakable involvement of the spinal cord (Romberg sign, sensory loss, diminished tendon reflexes, Babinski signs); (2) the pure cerebellar ataxias, with no other associated neurologic disorders; and (3) the complicated cerebellar ataxias, with a variety of pyramidal, extrapyramidal, retinal, optic nerve, oculomotor, auditory, peripheral nerve, and cerebrocortical accompaniments including what is now referred to as multiple system atrophy.

Without doubt, the advances in molecular genetics of recent years have greatly altered our understanding of the inherited ataxias and have already disclosed a large number of unexpected relationships between mutations and other neural and nonneural disorders. These data are incorporated at appropriate points in the following discussion in Table 39-5, later in this section. Inherited ataxias of early onset (before the age of 20 years) are usually of recessive type; those of later onset are more likely to have a dominant pattern but may be autosomal recessive. Table 39-5 lists several types of ataxias that have a genetic basis. At the time of this writing, 29 types have been listed in the literature, many of limited clinical consequence and low incidence. We have included the main varieties that may be of interest to clinicians because they appear regularly or offer an insight into this class of disorders. At the same time, it should be emphasized that many patients with chronic progressive ataxia have no family history of an ataxia and may have had a spontaneous mutation; even then, the genetic aspects of many cases have not been elucidated.

Early-Onset Spinocerebellar Ataxias (Predominantly Spinal)

Friedreich Ataxia

This is the prototype of all forms of progressive spinocerebellar ataxias and accounts for about half of all cases of hereditary ataxias in most large case series (86 of 171 patients collected by Sjögren); its incidence among Europeans and North Americans is 1.5 cases per 100,000 per year. Friedreich, of Heidelberg, began in 1861 to report on a form of familial progressive ataxia that he had observed among nearby villagers. It was already known through the writings of Duchenne that locomotor ataxia was the prominent feature of spinal cord syphilis, that is *tabes dorsalis*, but it was Friedreich who demonstrated a nonsyphilitic hereditary type. This concept was greeted with skepticism, but soon Duchenne himself affirmed the existence of the new disease and other case reports appeared in England, France, and the United States. In 1882, in a thesis on this subject by Brousse of Montpellier, Friedreich's name was attached to the entity.

The pattern of inheritance is autosomal recessive. Genetic linkage studies led to the assignment of the gene mutation to chromosome 9q13-2 and subsequently, it

was shown that in virtually all cases the mutation is an expansion of a GAA trinucleotide repeat within a gene that codes for the protein *frataxin*. (It is of interest that this mutation is within an intron). In a small proportion of cases, the mutation is a missense mutation rather than an expansion. In either case, the consequence of the mutation is a reduction in levels of frataxin and loss of its function. Cases in which the mutation allows the presence of some residual protein have a milder course. A current hypothesis is that frataxin is a mitochondrial matrix protein whose function is to prevent intramitochondrial iron overloading.

Clinical Features Ataxia of gait is nearly always the initial symptom. Difficulties in standing steadily and in running are early symptoms. The hands usually become clumsy months or years after the gait disorder, and dysarthric speech appears after the arms are involved (this is rarely an early symptom). Exceptionally the ataxia begins rather abruptly after a febrile illness, and one leg may become clumsy before the other. In some patients, pes cavus and kyphoscoliosis (scoliosis) are evident well before the neurologic symptoms; in others, they follow by several years. The characteristic foot deformity takes the form of a high plantar arch with retraction of the toes at the metatarsophalangeal joints and flexion at the interphalangeal joints (hammertoes).

A notable feature in more than half of patients is a cardiomyopathy. The myocardial fibers are hypertrophic and may contain iron-reactive granules (Koeppen). Many of the patients die as a result of cardiac arrhythmia or congestive heart failure. For this reason, it is essential that affected individuals have a cardiologic assessment including electrocardiography and echocardiography. The cardiomyopathy of Friedreich disease can develop insidiously but with fulminant consequences. Kyphoscoliosis and restricted respiratory function are additional important contributory causes of death. Harding observed that approximately 10 percent of these patients have diabetes mellitus and a higher proportion have impaired glucose tolerance; there is both insulin deficiency and peripheral insulin resistance.

In the fully developed syndrome, the abnormality of gait is of mixed sensory and cerebellar type, aptly called *tabetocerebellar* by Charcot. According to Mollaret, the author of an authoritative monograph on the disease, the cerebellar component predominates, but in our relatively small series we have been as impressed almost as much with the sensory (tabetic) aspect. The patient stands with feet wide apart, constantly shifting position to maintain balance. Friedreich referred to the constant teetering and swaying on standing as *static ataxia*. In walking, as with all sensory ataxias, the movements of the legs tend to be brusque, the feet resounding unevenly and irregularly as they strike the floor, and closure of the eyes causes the patient to fall (Romberg sign). This is one component of the spinal aspect (posterior columns) of the disease. Attempts to correct the imbalance may result in abrupt, wild movements. Often there is a rhythmic tremor of the head. Eventually, the arms are grossly ataxic, and both action and intention tremors are manifest. Speech is slow, slurred, explosive, and, finally, almost incomprehensible.

Table 39-5

GENETIC DEFECTS ASSOCIATED WITH SPINOCEREBELLAR ATAXIAS (SCA)

NOTATION	GENE (PROTEIN)	INHERITANCE	AGE OF ONSET	CLINICAL FEATURES IN ADDITION TO ATAXIA
Progressive				
Dentatorubropallidolulsian atrophy (DRPLA)	<i>ATN1</i> (atrophin1)	AD ^a	Childhood	Chorea, dystonia, seizures, dementia
SCA1	<i>ATXN1</i> (ataxin-1)	AD ^a	Variable	10–25% of dominant ataxias; spasticity, polyneuropathy, ophthalmoparesis, dementia
SCA2	<i>ATXN2</i> (ataxin-2)	AD ^a	Teens	Neuropathy, ophthalmoparesis, extrapyramidal features
SCA3 (Machado-Joseph)	<i>ATXN3</i> (ataxin-3)	AD ^a	Teens	25% of dominant ataxias, spasticity, neuropathy, extrapyramidal features
SCA6	<i>CACNA1A</i> (alpha _{1A} calcium channel)	AD ^a	Adult	20% of dominant ataxias; dysarthria, nystagmus, posterior column signs (see episodic ataxia below; gene implicated in familial hemiplegic migraine)
SCA7	<i>ATXN7</i> (ataxin-7)	AD ^a	Late teens	Olivopontocerebellar atrophy and syndrome of retinal degeneration, hearing loss, ophthalmoplegia, spasticity; generational anticipation
SCA8	<i>ATXN8</i> (ataxin-8; CTG repeat (noncoding))	AD, AR, sporadic	Adult	Fulminant, with large CAG expansion Slowly progressive sensory neuropathy, spasticity; known rapid infantile variant
SCA10	<i>ATTCT</i> repeat (ataxin-10)	AD	Teens–adult	Seizures, personality change
SCA11	<i>TTBK2</i> (serine/threonine kinase)	AD	Adult	Mild phenotype, nystagmus, cerebellar ataxia, neuropathy, dystonia
SCA12	<i>PPP2R2B</i> (protein phosphatase 2A), CAG repeat, noncoding	AD	Adult	Head and hand tremor
SCA13	<i>KCNC3</i> (Kv3.3 channel)	AD	Childhood	Developmental delay
SCA14	<i>PRKCG</i> (protein kinase C gamma)	AD	Teens–adult	Myoclonus, tremor
SCA15 & 16	<i>ITPR1</i> (ITPR1)	AD	Varies	Head and hand tremor, gaze palsy
SCA17	<i>TATA</i> (TATA box binding protein, TBP)	AD ^a	Variable	Cognitive decline, seizures, extrapyramidal features
SCA with tremor	Fibroblast growth factor 14	AD	Childhood	Tremor, cognitive defects, facial dyskinesia
Friedreich ataxia	<i>FXN</i> (frataxin)	AR	Teens	Spinocerebellar ataxia, neuropathy, cardiomyopathy, arrhythmia
Vitamin E deficiency	<i>TPPA</i> (vitamin E transfer protein)	AR	Childhood	Spinocerebellar ataxia, neuropathy, cardiomyopathy, arrhythmia
Episodic				
Episodic ataxia with myokymia (EA1, EAM1)	<i>KCNA1</i> (Kv1.1)	AD	Teens	Limb stiffness, dizziness, visual blurring
Paroxysmal episodic ataxia (EA2)	<i>CACNA1A</i> (Cav2.1)	AD	Teens	Nystagmus, vertigo, weakness
Episodic ataxia (EA5)	<i>CACNB4</i> (calcium channel beta-subunit)	AD	Teens	Seizures, myoclonus, nystagmus

^aCAG expansion. AD denotes autosomal dominant, AR autosomal recessive

Breathing, speaking, swallowing, and laughing may be so incoordinated that the patient nearly chokes while speaking. Holmes (1907a) remarked on an ataxia of respiration that causes “curious short inspiratory whoops.” Facial, buccal, and arm muscles may display tremulous and sometimes choreiform movements.

Although mentation is generally preserved, emotional lability has been sufficiently prominent to provoke comment. Torsional and vertical nystagmus is rare but “square wave jerks” are seen in the early stages of disease. Horizontal nystagmus may be present late in the course of the illness, but not early, but it is slight in amplitude. Ocular movements usually remain full, and pupillary reflexes are normal. The facial muscles may seem slightly weak, and deglutition may become impaired. Amyotrophy occurs late in the illness and is usually mild, but it may be extreme in patients with an associated neuropathy (see below). The tendon reflexes are abolished in nearly every case; rarely, they may be obtainable when the patient is examined early in the illness (see below). Plantar reflexes are extensor and flexor spasms may occur even with complete absence of tendon reflexes (another manifestation of the spinal component). The abdominal reflexes are usually retained until late in the illness. Loss of vibratory and position sense is invariable from the beginning; later, there may be some diminution of tactile, pain, and temperature sensation as well. Sphincter control is usually preserved.

Variants of Friedreich Ataxia In one important variant of Friedreich ataxia the tendon reflexes are preserved or even hyperactive and the limbs may be spastic. It is the finding of the aberrant frataxin gene that links these unusual cases to Friedreich ataxia; some are associated with hypogonadism. Harding (1981) found 20 such cases among her 200 familial ataxias at the National Hospital, London. Nevertheless, the distinction between classic Friedreich ataxia and ataxia with retained tendon reflexes is an important one clinically, insofar as kyphoscoliosis and heart disease do not occur in the latter group and the prognosis is better. Two of our Friedreich patients had occasional seizures. There are many additional forms of spinocerebellar ataxia, most displaying mainly a cerebellar atrophy, that may simulate Friedreich disease, but due to different mutations. These are taken up below.

Laboratory Testing Laboratory tests of diagnostic value are the measurement of sensory nerve conduction velocities and amplitudes, which for the most part are normal because peripheral neuropathy is not a component of the process. Electrocardiography and echocardiography may demonstrate the heart block and ventricular hypertrophy. The CT and MRI seldom reveal a significant degree of cerebellar atrophy but the spinal cord is small. There is no consistent abnormality of blood or CSF and no biochemical abnormalities have been demonstrated. Genetic testing for the length of the GAA trinucleotide repeat segment is available.

Pathology The spinal cord is thin. The posterior columns and the corticospinal and spinocerebellar tracts are all depleted of myelinated fibers, and there is a mild gliosis that does not replace the bulk of the lost fibers. The nerve cells in the Clarke column and the large neurons

of the dorsal root ganglia, especially lumbosacral ones, are reduced in number—but perhaps not to a degree that would fully explain the posterior column degeneration. The posterior roots are thin. Betz cells are also diminished in some cases, but the corticospinal tracts are relatively intact down to the medullary–cervical junction. Beyond this point, they are degenerated, but to a lesser degree than the posterior columns. The nuclei of cranial nerves VIII, X, and XII all exhibit a reduction of cells. Slight to moderate neuronal loss is seen also in the dentate nuclei, and the middle and superior cerebellar peduncles are reduced in size. Some depletion of Purkinje cells in the superior vermis and neurons in corresponding parts of the inferior olivary nuclei can be seen. Many of the myocardial muscle fibers degenerate and are replaced by fibrous connective tissue.

By way of exploring the anatomic basis of the clinical findings, pes cavus is not different from that seen in other neuromuscular diseases of early onset with mild hypertonus of the long extensors and flexors of the feet. There is also cause of amyotrophy of intrinsic foot muscles and foreshortening of the foot when the bones are still malleable. The kyphoscoliosis is probably a result of imbalance of the paravertebral muscles during development. The tabetic aspects of the disease are explained by the degeneration of large cells in the dorsal root ganglia and the large sensory fibers in nerves, dorsal roots, and the columns of Goll and Burdach. The loss of neurons in the sensory ganglia also causes abolition of tendon reflexes. Cerebellar ataxia is attributable to a combined degeneration of the superior vermis and the dentatorubral pathways but also the spinocerebellar tracts, in various combinations. Corticospinal lesions account for the weakness and Babinski signs and contribute to the pes cavus.

Diagnosis Friedreich disease and its variants must be distinguished from familial cerebellar cortical atrophy described next, and from familial spastic paraparesis with ataxia, as well as from peroneal muscular atrophy and the Levy-Roussy syndrome, which are discussed also with the hereditary neuropathies in Chap. 46. It is advisable to assay serum vitamin E levels, as a rare (except in North Africa) but treatable inherited deficiency of a vitamin E transport protein causes a spinocerebellar syndrome with areflexia in children that resembles Friedreich disease (see Chap. 41). The absence of dysarthria and of skeletal or cardiac abnormalities in the vitamin-deficiency illness may be helpful. Exceptionally, a cardiac disturbance has been seen in the vitamin deficiency. A form of chronic inflammatory demyelinating polyneuropathy has long since overtaken tabes dorsalis as the most frequent type of areflexic ataxia. It bears a superficial resemblance to Friedreich ataxia when the onset is in early life, but lacks dysarthria and Babinski signs. A form of spinocerebellar degeneration related to human T-cell lymphotropic virus type I (HTLV-I), causing so-called tropical spastic paraparesis, as well as the vacuolar myelopathy of AIDS multiple sclerosis, syringomyelia, neuroacanthocytosis, and cervical spondylosis, must be included in the differential diagnosis of late-onset cases. Genetic testing settles the matter.

Treatment Not much can be said on this subject because there is little effective therapy. A double-blind crossover study by Trouillas and associates found that the administration of oral 5-hydroxytryptophan modified the cerebellar symptoms. This has not been tested in another study. Apart from this form of treatment, with which we have had no experience, no therapeutic measures are known to alter the course of the disease. In several small trials, idebenone, an antioxidant (the short-chain analogue of coenzyme Q10), reduced the progression of left ventricular hypertrophy, a risk factor for arrhythmias and sudden death in these patients, but this could not be confirmed in subsequent trials. These results are summarized in an article by Filla and Moss. Heart failure, arrhythmias, and diabetes mellitus are treated by the usual medical measures and it bears repetition that careful evaluation of the cardiac disorder may prevent premature death. Surgery for scoliosis and foot deformities may be helpful in selected cases.

Predominantly Cerebellar (Cortical, Holmes Type) Hereditary and Sporadic Ataxia

Soon after the publication of Friedreich's descriptions of a spinal type of hereditary ataxia, reports began to appear of somewhat different diseases in which the ataxia was related to degenerative changes in the cerebellum and brainstem rather than in the spinal cord. Claims of their independence from the spinal type were based largely on a later age of onset, a more definite hereditary transmission (usually of autosomal dominant type), the persistence or hyperactivity of tendon reflexes, and associations with ophthalmoplegia, retinal degeneration, and optic atrophy. Several of these clinical features, particularly briskness of tendon reflexes, are alien to the classic form of Friedreich ataxia.

By 1893, Pierre Marie thought it desirable to create a new category of hereditary ataxia that would embrace all of the non-Friedreich cases. He collated the familial cases of progressive ataxia that had been described by Fraser, Nonne, Sanger Brown, and Klippel and Durante (see both Greenfield and Harding [1993] for references) and proposed that all of them were examples of an entity to which he applied the name *hérédo-ataxie cérébelleuse*. Marie's proposition was based almost entirely on clinical observations not his own but those made by the aforementioned authors. Later, as members of these families died, post-mortem examinations disclosed that Marie's hereditary cerebellar ataxia included not one but several disease entities. Indeed, as pointed out by Holmes (1907b) and later by Greenfield, in 3 of the 4 families the cerebellum showed no significant lesions at all. Yet there was by then no doubt of the existence of a separate class of predominantly cerebellar atrophies, some purely cortical and others associated with a variety of noncerebellar disorders.

Clinical Features

Holmes (1907a) described a family of 8 siblings, of whom 3 brothers and 1 sister were affected by a progressive ataxia, beginning with a reeling gait and followed by clumsiness of the hands, dysarthria, tremor of the head,

and a variable nystagmus, but without additional features to implicate disease of the spinal cord or brainstem. It may be taken as the prototype of pure cerebellar cortical degeneration.

The ataxia begins insidiously, usually in the fourth decade but with wide variability in age of onset, and progresses slowly over many years. Ataxia of gait, instability of the trunk, tremor of the hands and head, and slightly slowed, hesitant speech is the usual clinical picture. Nystagmus is rare and intelligence is usually preserved. The patellar reflexes may be slightly increased but this may be apparent based on the pendular character of reflexes in cerebellar disease; the plantar reflexes are flexor and the ankle jerks are present but there are exceptions and probably mark the process as one of the other genetic ataxias.

This clinical syndrome probably can result from several genetically determined processes, some of which declare themselves as the illness progresses by displaying characteristic signs other than ataxia. The differential diagnosis in the nonfamilial cases is even broader, including many acquired types of ataxias discussed in Chap. 5 (see Table 5-1) and at the end of this section.

Pathology Postmortem examination of the Holmes-type cases discloses symmetrical atrophy of the cerebellum involving mainly the anterior lobe and vermis, the latter being more affected. Purkinje cells are absent in the lingula, centralis, and pyramis of the superior vermis and reduced in number in the quadrangularis, flocculus, biventral, and pyramidal lobes. The other cerebellar cortical neurons and granule cells and dorsal and medial parts of the inferior olivary nuclei are diminished less so. The white matter is slightly pale in myelin stains. The vermian atrophy and that of adjacent parts of the cerebellum can be visualized with clarity in MRIs (Fig. 39-8).

Figure 39-8. Familial cortical cerebellar atrophy. T1-weighted MRI in the sagittal plane showing marked atrophy of vermis and enlargement of fourth ventricle. The brainstem is only mildly atrophic and the posterior fossa is normal in size. Compare with Fig. 39-9 in which the cerebellum and pons are atrophic.

The vague similarity of the pathologic (and clinical) changes to those of *alcoholic cerebellar degeneration* is at once apparent and should raise the question of an alcoholic-nutritional cause in sporadic cases (see Chap. 41); in serious alcohol-nutritional disease, there usually is an accompanying polyneuropathy and reduced ankle reflexes.

Fragile X Tremor–Ataxic Premutation Syndrome

This type of developmental delay, caused by an unstable extended trinucleotide repeat sequence and breakage of the X-chromosome, is discussed in Chap. 38. Here we refer to an unusual variant of the degenerative process with onset in mid- or late adulthood, mainly but not exclusively in men, and consisting of gait or limb ataxia and mild tremor. The process affects carriers of a “premutation” who have 50 to 200 CGG repeat sequences in the *FMRI* gene. In contradistinction to the full mutation of over 200 repeats, there is apparently a buildup of messenger ribonucleic acid (mRNA) in the adult form that interferes in some way with cellular function. Aggregating several studies, the frequency of this genetic abnormality among otherwise unassignable adult ataxia cases is less than 10 percent.

The entire clinical spectrum has yet to be defined but our experience with 2 patients featured mild progressive gait ataxia in the sixth decade that was misattributed to normal-pressure hydrocephalus and an intermittent hand tremor that was probably ataxic in nature. Some reports have included a parkinsonian syndrome and more consistently, a mild frontal dementia, making the distinction from frontotemporal dementia difficult. Many cases have been confused with multiple system atrophy.

T2 hyperintensity in the cerebellar peduncles are characteristic of some cases, but this was not found in our patients, which showed only midline cerebellar atrophy. A family history of developmental delay or autistic spectrum disorder may be a hint to diagnosis and some proportion of individuals with the premutation also have a nonprogressive cognitive deficiency.

A study of the neuropathology by Greco and colleagues showed cerebral and cerebellar spongiform white matter changes and both intranuclear and astrocytic inclusions. Their report demonstrated a correspondence between the quantity of trinucleotide repeats and the number of inclusion bodies.

Familial and Sporadic Forms of Combined Cerebellar Atrophy With Brainstem and Extrapyramidal Features

A sporadically occurring disorder closely resembling the Holmes type of cortical cerebellar degeneration but with additional features of brainstem atrophy was described in 1900 by Déjérine and André-Thomas, who named it *olivopontocerebellar atrophy* (OPCA). As more cases of this type were collected, an autosomal dominant *hereditary pattern* was evident in some, and one or more long tracts in the spinal cord were found to have degenerated. About half the cases later developed the parkinsonism with degeneration

of nigral cells and, in a few, of striatal cells, thereby marking the disease as a form of striatonigral degeneration that is essentially a type of *multiple system atrophy* (MSA-C) as discussed in detail in an earlier section and also below.

Notable findings in both the sporadic and the familial forms of many of the variants of cerebellar atrophy are extensive degeneration of the middle cerebellar peduncles, cerebellar white matter, and pontine, olivary, and arcuate nuclei; loss of Purkinje cells has been variable. Most likely this degeneration represents a “dying back” of axons of the cerebellar, pontine, and olivary nuclei with secondary myelin degeneration. Extreme atrophy of the medullary olivary nuclei, evident on MRIs (Fig. 39-9), identifies a special process that represents the aforementioned OPCA.

Although the associated features in each of the inherited cerebellar degenerations do not conform to newer genetic classifications, certain clinical constellations are nonetheless recognizable and clinically useful. Many texts use a genetic system exclusively to categorize these diseases. In the past, Königsmark and Weiner subdivided them into several types, including a dominantly inherited OPCA (of Menzel); a recessive type (of Fickler-Winkler); a dominant type with retinal degeneration; one with spastic paraplegia and areflexia; and with dementia, ophthalmoplegia, and extrapyramidal signs. To these had been added cases of OPCA with neuropathy and slowed eye movements (Wadia type), of which we have seen 2 cases, and cases with dystonia and a variety of other clinical findings, most in single families (hemiballismus, athetosis, contractures of the legs, fixed pupils, ophthalmoplegia, ptosis, gaze palsy, deafness, retinal degeneration, mental retardation and epilepsy, claw foot and scoliosis, incontinence, parkinsonian symptoms and signs, plethora of presentations including a neonatal type). Some of these are detailed below.

Figure 39-9. Olivopontocerebellar atrophy. MRI in the sagittal plane demonstrating both vermian atrophy (*black arrow*) and smallness of the pons (*white arrow*). (Reproduced by permission from Bisese JH: *Cranial MRI*. New York, McGraw-Hill, 1991.)

Cases of *sporadic olivopontocerebellar atrophy* are more common than the familial variety and tend to occur at an older age; nystagmus, optic atrophy, retinal degeneration, ophthalmoplegia, and urinary incontinence are generally not observed. However, there are numerous cases that include mild extrapyramidal and neuropathic signs, slow eye movements, dystonia, impairment of vertical saccadic eye movements (thus simulating progressive supranuclear palsy), vocal cord paralysis, all of which probably mark the process as multiple system atrophy (MSA-C) or Machado-Joseph-Azorean disease (SCA3, discussed below), and some cases with deafness. The relationship of olivopontocerebellar atrophy to MSA was discussed in under "Multiple System Atrophy," but we emphasize that OPCA occurs as often independently of extrapyramidal degeneration for which reason we retain a separate designation.

Cerebellar Atrophy With Prominent Basal Ganglionic Features

Machado-Joseph-Azorean Disease (SCA3)

A special form of hereditary ataxia with brainstem and extrapyramidal signs has been described in patients mainly, but not exclusively, of Portuguese-Azorean origin. The disorder is characterized by an autosomal dominant pattern of inheritance and by a slowly progressive ataxia beginning in adolescence or early adult life in association with hyperreflexia, extrapyramidal features, dystonia, bulbar signs, distal motor weakness, and ophthalmoplegia. There is usually no impairment of intellect and in the examples the authors have seen, the extrapyramidal symptoms were mainly rigidity and slowness of movement. Early Machado-Joseph disease characteristically demonstrates the finding of dysmetric horizontal and vertical saccades, even before the ataxia is obvious (Hotson et al). This conjunction of a parkinsonian syndrome with cerebellar ataxia is suggestive of MSA except for an earlier age of onset and the prominence in some cases of dystonia, amyotrophy, and ophthalmoplegia in Machado-Joseph. Postmortem examination discloses a degeneration of the dentate nuclei and spinocerebellar tracts and a loss of anterior horn cells and neurons of the pons, substantia nigra, and oculomotor nuclei. Cancel and colleagues found an unstable number of CAG repeating sequences in a gene, ataxin-3, and named the disorder spinocerebellar ataxia type 3 (SCA3).

An affected Azorean family named Joseph was described in 1976 by Rosenberg and colleagues under the name of *autosomal dominant striatonigral degeneration*. Using the term *Azorean disease of the nervous system* (now better known as *Machado-Joseph disease*), Romanul and colleagues described yet another family of Portuguese-Azorean descent, many members of which were affected by a syndrome comprising a progressive ataxia of gait, parkinsonian features, limitation of conjugate gaze, fasciculations, areflexia, nystagmus, ataxic tremor, and extensor plantar responses; the pathologic changes closely resembled those described by Woods and Schaumburg. Romanul and coworkers compared the genetic, clinical, and pathologic features of their

cases with those described in other Portuguese-Azorean families and concluded that all of them represent a single genetic entity with variable expression. This concept of the disease has been corroborated by the further observations of Rosenberg and of Fowler who studied 20 patients with the Machado-Joseph-Azorean disease over a 10-year period and more recently by genetic testing.

The disease is not limited to Azoreans. Cases conforming to the above descriptions have now been observed among African American, Indian, and Japanese families (Sakai et al; Yuasa et al; Bharucha et al). There are no signs of polyneuropathy, which is the main feature of another disease in Portuguese emigrants caused by amyloid deposition, described by Nakano and colleagues as "Machado disease," this being the name of the progenitor of the afflicted family.

In fully developed cases, the MRI findings are of reduced width of the superior and middle cerebellar peduncles, atrophy of the frontal and temporal lobes, and smallness of the pons and globus pallidus (Murata et al). There is no treatment of proven value.

Multiple System Atrophy With Predominant Ataxia (See Section Multiple System Atrophy)

This entity has been discussed with the degenerative disorders of the basal ganglia earlier in the chapter. Here it is pointed out that a number of cases of sporadic progressive ataxia in mid- and late life are attributable to this process and have been termed MSA-C to signify the predominant cerebellar feature. The extrapyramidal, corticospinal, or autonomic aspects of the illness may or may not become evident only with continued observation or by pathologic examination. Some guidance as to the frequency of MSA as the cause of otherwise undifferentiated sporadic ataxia is given in the study by Abele and colleagues who found that it accounts for almost one-third of cases, but the precise number is open to question as pathologic examinations were not made.

Dentatorubropallidolusian Atrophy (DRPLA)

This is a rare familial disorder, described mostly in Japan and in small European pockets, in which symptoms of cerebellar ataxia are coupled with those of choreoathetosis and dystonia and, in a few instances, parkinsonism, myoclonus, epilepsy, or dementia. Pathologically there is degeneration of the dentatorubral and pallidolusian systems. The main consideration when chorea is a prominent feature is the separation of this disorder from Huntington disease. The gene defect in DRPLA is an unstable CAG trinucleotide repeat in the gene that codes for the protein atrophin. This same mutation has been defined in affected families from throughout the world (e.g., Warner et al). As with Huntington chorea (where the expanded polyglutamine tract is in the protein huntingtin), this disease is inherited as an autosomal dominant trait and shows an inverse correlation between the age of onset and the size of the gene expansion (anticipation). When chorea predominates early in the illness, there may be difficulty distinguishing DRPLA from Huntington disease. The diagnosis is confirmed by sequencing of the affected gene.

Dentatorubral Degeneration

This is a rare and still nebulous entity but it is probably distinct from the condition described above. There are several instructive features. In 1921, Ramsay Hunt published an account of 6 patients (2 of whom were twin brothers) in whom myoclonus was combined with progressive cerebellar ataxia. The age of onset in the 4 nonfamilial cases was between 7 and 17 years, and the cerebellar ataxia followed the myoclonus by an interval of 1 to 20 years. Hunt named the disorder *dyssynergia cerebellaris myoclonica*. There were signs of Friedreich ataxia in the twin brothers; postmortem examination of one showed cerebellar atrophy, degeneration of the posterior columns and spinocerebellar tracts but not of the corticospinal tracts. In 1947, Louis-Bar and van Bogaert reported a similar case and noted, in addition to the above findings, degeneration of the corticospinal tracts and loss of fibers in the posterior roots. Thus the pathology was identical to that of Friedreich ataxia except for the more severe atrophy of the dentate nuclei.

Earlier (1914), under the title *dyssynergia cerebellaris progressiva*, Hunt had drawn attention to a progressive disease in young individuals manifest by what he considered to be a pure cerebellar syndrome but one of his cases was revealed at autopsy to be Wilson disease. Hunt's reports emphasize the hazard of classifying cerebellar ataxias on the basis of clinical findings alone, a point made effectively by Holmes.

Paroxysmal Ataxias (See Chap. 5)

Two adult forms of hereditary cerebellar ataxia are paroxysmal in nature. In one (EA-2 for "episodic ataxia, type 2"), the episodes occur without explanation and last several hours; vertigo is the prominent feature of the attacks. Between attacks the patient is normal or has only minimal ataxia and nystagmus (Griggs et al). These ataxic episodes are prevented strikingly by the administration of oral acetazolamide. The disorder has been found to be a mutation of the calcium channel gene on chromosome 19 as listed in Table 39-5.

A similar but physiologically and genetically unrelated paroxysmal ataxia (EA-1) is characterized by episodes that may be precipitated by exercise and by the presence of muscle myokymia (rippling) between attacks. Vertigo does not occur and acetazolamide is less effective or not effective at all. The disorder is caused by an abnormality of the potassium channel gene on chromosome 12 (see Table 39-5). Both of these episodic ataxias are therefore "channelopathies" (see Chap. 50). Also of interest is spinocerebellar atrophy type 6, a progressive condition in which a mutation has been traced to same gene implicated in the EA-2 acetazolamide-responsive paroxysmal ataxia, but this disorder is not paroxysmal and results in progressive ataxia, dysarthria, and loss of proprioception.

Genetics of the Heredodegenerative Ataxias

(See Table 39-5)

The many familial degenerative ataxic disorders described in the preceding pages are genetically distinct. As indicated, the *autosomal recessive* type of Friedreich ataxia is the result of an expanded GAA repeat in the frataxin gene

(Campuzano et al), quite different from the large number of dominant forms of inherited ataxia. The direct molecular test for the GAA expansion is useful for diagnosis, particularly for atypical cases with late onset (Dürr et al). The rarer recessive spinocerebellar ataxia associated with vitamin E deficiency arises from mutations in the gene that encodes an alpha tocopherol (vitamin E) transport protein, as mentioned above.

Among the common *autosomal dominant* cerebellar ataxias of later onset, molecular and gene studies have identified numerous mutations. Of these autosomal dominant ataxias, many are known to be caused by expanded CAG-trinucleotide repeats (including SCA types 1, 3, 6, and 7, 12, 17, as well as DRPLA). Undoubtedly others will be discovered. However, the mechanisms by which the expanded polyglutamine molecule leads to neuronal cell death or dysfunction remain uncertain. It is likely that differences in the clinical manifestations of these disorders will reflect differences in the patterns of expression of the affected proteins; that is each is expressed in different populations of neurons and at different stages in development. This raises the possibility that the cascade of events that triggers neuronal degeneration is similar in each of the diseases with a CAG expansion and that a therapy might be discovered that is effective in all of them.

The special case of fragile X premutation that may cause ataxia and tremor in adults is addressed in Chap. 38. Table 39-5 summarizes the genes, terminology, related neural abnormalities, and clinical features of the cerebellar atrophies.

Differential Diagnosis of the Degenerative Ataxias in Adults (See also Table 5-1)

Sporadic forms of cerebellar ataxia in adults are in some instances traceable to strokes involving cerebellar pathways (Safe et al). These are, of course, of acute onset. Some cases of ataxia are alcoholic-nutritional in origin, and a few are related to excessive use of drugs or therapeutic medications, especially antiepileptic drugs, which may in a few cases cause a slowly progressive and permanent ataxia. Organic mercury induces subacute cerebellar degeneration, and adulterated heroin causes a more abrupt and severe ataxic syndrome. The paraneoplastic variety of cerebellar degeneration often enters into the differential diagnosis; it occurs mostly in women with breast or ovarian cancers and evolves much more rapidly than any of the heredodegenerative forms. The more rapid onset of ataxia and the presence of anti-Purkinje cell antibodies (anti-Yo; see "Paraneoplastic Cerebellar Degeneration" in Chap. 31) are central to identifying the nature of this disease. From time to time one observes a similar idiopathic variety of subacute cerebellar degeneration, particularly in women who have no neoplasm and lack the specific antibodies of the paraneoplastic disease (Ropper). Rare cases of ataxia have been associated with celiac disease and Whipple disease, and metronidazole as noted in Chap. 5. Ataxia may also be an early and prominent manifestation of Creutzfeldt-Jakob disease caused by a prion (see Chap. 33) or of an inherited metabolic disease (see Chap. 37). Of the latter, late-onset G_{M2} gangliosidosis may simulate cerebellar degeneration in

adults (see Chap. 37). Rare cases of aminoacidopathy manifesting for the first time in adult life have also provoked a cerebellar syndrome (see Chap. 37).

Hereditary Polymyoclonus

The syndrome of quick, arrhythmic, involuntary single or repetitive twitches of a muscle or group of muscles was described in Chap. 6, where it was pointed out that the condition has many causes. Chapter 37 discusses those caused by hereditary metabolic diseases. Familial forms are known, one of which, associated with cerebellar ataxia, was discussed earlier (dyssynergia cerebellaris myoclonica of Ramsay Hunt). But there is another disease, known as *hereditary essential benign myoclonus*, that occurs in relatively pure form unaccompanied by ataxia (termed essential, or familial, myoclonus; see Chap. 6). In this condition, it is difficult to evaluate coordination because willed movement is interrupted by myoclonus that may be mistaken for intention tremor. Only by slowing the voluntary movement can the myoclonus be reduced or eliminated. This myoclonic disease is inherited as an autosomal dominant trait. It becomes manifest early in life; once established, it persists with little or no change in severity throughout life, often with rather little disability. It can, by its natural course, be differentiated from some of the hereditary metabolic diseases such as the Unverricht and Lafora types of myoclonic epilepsy, the lipidoses, tuberous sclerosis, and myoclonic disorders that follow certain viral infections and anoxic encephalopathy. Of interest is the response of this form of movement disorder to certain pharmacologic agents, notably clonazepam, valproic acid, and 5-hydroxytryptophan, the amino acid precursor of serotonin, particularly when these agents are used in combination (postanoxic myoclonus responds to the same medications).

Another form of nonprogressive myoclonus, dominantly inherited, is associated with dystonia, which is due to a mutation in a sarcoglycan gene, *SGCE*.

The main clinical distinctions are from juvenile myoclonic epilepsy (see Chap. 16), drug-induced myoclonus, particularly lithium and opiates; renal failure and other acquired metabolic disorders; asterixis; and from the startle responses and some of the diseases that have this sign as their main characteristic (see Chap. 6). Creutzfeldt-Jakob subacute spongiform encephalopathy may cause difficulty in diagnosis initially but the course of illness clarifies the situation rapidly. Myoclonus is also one component of the complex movement disorder in corticobasal-ganglionic degeneration that was described in an earlier section.

SYNDROME OF MUSCULAR WEAKNESS AND WASTING WITHOUT SENSORY CHANGES

Motor Neuron Disease

This general term designates a group of progressive degenerative disorders of motor neurons in the spinal cord, brainstem, and motor cortex, manifest clinically by

muscular weakness, atrophy, and corticospinal tract signs in varying combinations. It is for the most part a disease of middle life and progresses to death in a matter of 2 to 5 years or longer in exceptional cases.

Customarily, motor system disease is subdivided into several subtypes on the basis of the grouping of symptoms and signs. The most frequent form, in which amyotrophy and hyperreflexia are combined, is *ALS* (*amyotrophy* is the term applied to denervation atrophy and weakness of muscles). Less frequent are cases in which weakness and atrophy occur alone, without evidence of corticospinal tract dysfunction; for these the term *progressive spinal muscular atrophy* is used. When the weakness and wasting predominate in muscles innervated by the motor nuclei of the lower brainstem (i.e., muscles of the jaw, face, tongue, pharynx, and larynx), it is customary to speak of *progressive bulbar palsy*. In a small proportion of patients, the clinical state is dominated by spastic weakness, hyperreflexia, and Babinski signs, with lower motor neuron aspects becoming apparent only at a later stage of the illness, or not at all. This is designated *primary lateral sclerosis*, an infrequent form of motor system disease in which the degenerative process remains confined to the corticospinal pathways (Pringle et al). The pure spastic paraplegias without amyotrophy may represent a special class of disease hence they are described separately. There are also relatively common familial forms of spastic paraplegia in which the disease is confined to the corticospinal tracts or, in some cases, combined with posterior column or other neurologic signs.

Furthermore, an important group of special spinal muscular atrophies occurs in infancy and childhood and are the leading cause of heritable infant mortality and, after cystic fibrosis, the most frequent form of serious childhood autosomal recessive disease (Pearn). The best known is the Werdnig-Hoffmann type of *infantile spinal muscular atrophy* (SMA type I); but there are other forms beginning in later childhood, adolescence, or early adult life (SMA types II and III, or the Wohlfart-Kugelberg-Welander type). Despite the clinical heterogeneity of the heritable childhood spinal muscular atrophies, they all derive from mutations in the *SMN* gene (see below; see Gilliam et al; Brzustowicz et al). This group of early-onset spinal muscular atrophies is separate genetically from a familial form of ALS.

Amyotrophic Lateral Sclerosis

History Credit for the original delineation of amyotrophic lateral sclerosis is appropriately given to Charcot. With Joffroy in 1869 and Gombault in 1871, he studied the pathologic aspects of the disease. In a series of lectures given from 1872 to 1874, he provided a lucid account of the clinical and pathologic findings. Although called Charcot disease in France, *amyotrophic lateral sclerosis* (the term recommended by Charcot) has been preferred in the English-speaking world. Duchenne had earlier (1858) described *labioglossolaryngeal paralysis*, a term that Wachsmuth in 1864 changed to *progressive bulbar palsy*. In 1869, Charcot called attention to the nuclear origin of progressive bulbar palsy, and in 1882 Déjérine established its relationship to ALS. Most authors credit Aran

and Duchenne with the earliest descriptions of progressive spinal muscular atrophy, which they believed to be of myogenic origin. This interpretation was, of course, incorrect; Cruveilhier, a few years later, noted the slender anterior roots, and soon thereafter the disease was brought into line with ALS as a spinal muscular atrophy. The singular genetic discovery in relation to this disease has been of the mutation in the superoxide dismutase (SOD1) gene in familial cases of motor neuron disease.

Epidemiology This is a disease commonly encountered by neurologists, with an annual incidence rate of 0.4 to 1.76 per 100,000 population. Men are affected nearly twice as often as women. Most patients are older than age 45 years at the onset of symptoms, and the incidence increases with each decade of life (Mulder). The disease occurs in a random pattern throughout the world except for a dramatic clustering of patients among inhabitants of the Kii peninsula in Japan and in Guam, where ALS is often combined with dementia and parkinsonism. In approximately 10 percent of cases the disease is familial, being inherited as an autosomal dominant trait with age-dependent penetrance. The familial cases do not differ fundamentally in their symptoms and clinical course from nonfamilial ones, although as a group the former have an earlier age of onset, an equal distribution in men and women, and a slightly shorter survival. Unusual environmental associations are reported from time to time, for example, an increased incidence among Italian professional football players (Chio et al, 2005) and among soldiers who had served in various regions. All of these are questionable on methodologic grounds (they are retrospective case control epidemiologic studies) but further exploration is warranted.

Clinical Features In the most typical forms of disease, the onset is perceived by the patient as weakness in a distal part of one limb. This is noted first as an unexplained tripping from slight foot-drop, or by awkwardness in tasks requiring fine finger movements (handling buttons and automobile ignition keys), stiffness of the fingers, and slight weakness or wasting of the hand muscles on one side. In other words, features related to upper and to lower motor neuron degeneration (or both) may appear insidiously in one limb. Cramping beyond what seems natural and fasciculations of the muscles of the forearm, upper arm, and shoulder girdle may also arise. The earliest manifestation of the lower motor neuron component of this disease is sometimes volitional cramping—for example, leg cramps as the patient turns in bed during the early morning hours.

As the weeks and months pass, the other hand and arm become similarly affected with weakness, stiffness, slowness, atrophy or cramps. Before long, the triad of atrophic weakness of the hands and forearms, fasciculations, slight spasticity of the arms or legs, and generalized hyperreflexia—all in the absence of sensory change—leaves little doubt as to the diagnosis. Muscle strength and bulk diminish in parallel or there is a relative preservation of power early in the illness. Despite the amyotrophy, the tendon reflexes are notable for their liveliness. Babinski and Hoffmann signs are variably present; surprisingly, they may not appear even as the illness progresses.

Abductors, adductors, and extensors of fingers and thumb tend to become weak before the long flexors, on which the handgrip depends, and the dorsal interosseous spaces become hollowed, giving rise to the “cadaveric” or “skelletal” hand. The muscles of the upper arm and shoulder girdles are typically involved later. There is a general tendency for adjacent areas to be involved before more distant ones. When an arm is the first limb affected, all this occurs while the thigh and leg muscles seem relatively normal, and there may come a time in some cases when the patient walks about with useless, dangling arms. Later the atrophic weakness spreads to the neck, tongue, pharyngeal, and laryngeal muscles, and eventually those in the trunk and lower extremities yield to the onslaught of the disease.

The affected parts may ache and feel cold, but true paresthesias, except from poor positioning and pressure on nerves, do not occur or are minor. Sphincteric control is well maintained even after both legs have become weak and spastic, but many patients acquire urinary and sometimes fecal urgency in the advanced stages of the disease. The abdominal reflexes may be elicitable even when the plantar reflexes are extensor. Extreme spasticity is rarely seen.

Coarse fasciculations are usually evident in the weakened muscles but may not be noticed by the patient until the physician calls attention to them. Fasciculations are almost never the sole presenting feature of ALS—a clinical truism with which one can reassure physicians and medical students who fear, on the basis of persistent focal muscle twitching in the thumb, face, foot, or forearm, that they are developing the disease.

The course of this illness, irrespective of its particular mode of onset and pattern of evolution, is progressive. There may be periods lasting weeks or months during which the patient observes no advance in symptoms but clinical changes can nonetheless be detected. Half the patients succumb within 3 years of onset and 90 percent within 6 years (Mulder et al). Several clinical variations that occur with regularity and have distinguishing clinical features are described below.

Other Patterns of Clinical Evolution In addition to the special configurations discussed further on, there are many patterns of neuromuscular involvement other than the one just described. A leg may be affected before the hands. A foot-drop with weakness and wasting of the peroneal muscles may be incorrectly attributed to peroneal nerve compression until weakness of the gastrocnemius and other muscles betray more widespread involvement of lumbosacral neurons. In our experience, this crural amyotrophy has been less frequent than the brachial-manual type. Another variant is early involvement of thoracic, abdominal, or posterior neck muscles, the last being one of the causes of head lolling and camptocormia (forward bending of the neck and trunk) in older individuals. Yet another pattern is of early diaphragmatic weakness; such cases come to attention because of respiratory failure. A symmetrical proximal limb or shoulder-girdle amyotrophy with onset at an early age is also known and simulates muscular dystrophy (Wohlfart-Kugelberg-Welander disease, discussed later in this chapter). On several occasions we have observed a pattern involving

the arm and leg on the same side, first with spasticity and then with some degree of amyotrophy; this has been called the *hemiplegic* or *Mills variant*. However, this clinical pattern more often turns out to be a result of multiple sclerosis of compression of the spinal cord from laterally, as occurs with a neurofibroma.

The first and dominant manifestations of motor neuron disease may be a spastic weakness of the legs, in which case a diagnosis of primary lateral sclerosis is tentatively made (discussed further on); only after a year or two do the hand and arm muscles weaken, waste, and fasciculate, making it obvious that both upper and lower motor neurons are diseased. Early on, a spastic bulbar palsy with dysarthria and dysphagia, hyperactive jaw jerk and facial reflexes, but without muscle atrophy, may be the initial phase of disease.

As the disease advances, very mild distal sensory loss may be observed in the feet without explanation, but, if the sensory loss is a definite and early feature, the diagnosis must remain in doubt. Approximately 5 percent of cases of ALS are observed in conjunction with a frontotemporal dementia; less commonly, there is an association with a Parkinson syndrome.

Progressive Muscular Atrophy

This purely lower motor neuron syndrome is more common in men than in women, reportedly in a ratio of 4:1. It probably encompasses several diseases of the lower motor neuron, but most of which are manifestations of ALS.

These purely lower motor neuron amyotrophies tend to progress at a slower pace than the usual case of ALS, some patients surviving for 15 years or longer. Chio and colleagues (1985), who analyzed the factors affecting life expectancy in 155 patients with progressive muscular atrophy (PMA), found that younger patients had a more benign course: The 5-year survival was 72 percent in patients with an onset before age 50 years and 40 percent in patients with onset after age 50 years. Some of the most chronic varieties of PMA are familial. It has been revealed that the original report of a familial variety of this illness by William Osler described a family now known to have had a mutation in the *SOD1* gene, as discussed below. In about half the patients, the illness takes the form of a symmetrical (sometimes asymmetrical) wasting of intrinsic hand muscles, slowly advancing to the more proximal parts of the arms; less often, the legs and thighs are the sites of the initial atrophic weakness; or the proximal parts of the limbs are affected before the distal ones. Fascicular twitchings and cramping are variably present. Otherwise they differ from ALS only in that the tendon reflexes are diminished or absent, and signs of corticospinal tract disease cannot be detected. Nonetheless, many cases of ostensible PMA are found to have indications of corticospinal tract degeneration at autopsy (Ince et al).

The main disease to be distinguished from PMA is an immune-mediated motor neuropathy that occurs with or without multifocal block of electrical conduction (see Chap. 46), and various muscle diseases that produce a similar pattern of weakness, notably, inclusion body myopathy and polymyositis. The presence of a paraproteinemia, specifically immunoglobulin (Ig) M with

antibodies against G_{MI} ganglioside, or the finding of focal conduction block or sensory nerve abnormalities on the EMG implies the presence of an autoimmune neuropathy disease rather than of a degenerative motor neuron type.

Progressive Bulbar Palsy

Here reference is made to a condition in which the first and dominant symptoms relate to weakness and laxity of muscles innervated by the motor nuclei of the lower brainstem, that is muscles of the jaw, face, tongue, pharynx, and larynx. This weakness gives rise to an early defect in articulation, in which there is difficulty in the pronunciation of lingual (*r, n, l*), labial (*b, m, p, f*), dental (*d, t*), and palatal (*k, g*) consonants. As the condition worsens, syllables lose their clarity and run together, until, finally, the patient's speech becomes unintelligible. In other patients, slurring is a result of spasticity of the tongue, pharyngeal, and laryngeal muscles; the speech sounds as if the patient were eating food that is too hot. Usually the voice is modified by a combination of atrophic and spastic weakness. Defective modulation with variable degrees of rasping and nasality is another characteristic. The pharyngeal reflex is lost, and the palate and vocal cords move imperfectly or not at all during attempted phonation. Mastication and deglutition become impaired; the bolus of food cannot be manipulated and may lodge between the cheek and teeth and the pharyngeal muscles do not force it properly into the esophagus. Liquids and small particles of food find their way into the trachea or nose. The facial muscles, particularly of the lower face, weaken and sag. Fasciculations and focal loss of tissue of the tongue are usually early manifestations; eventually the tongue becomes shriveled and lies useless on the floor of the mouth. The chin may also quiver from fascicular twitchings, but the diagnosis should not be made on the basis of fasciculations alone, in the absence of weakness and atrophy.

The jaw jerk may be present or exaggerated at a time when the muscles of mastication are markedly weak. In fact, spasticity of the jaw muscles may be so pronounced that the slightest tap on the chin will evoke clonus and blinking; rarely, attempts to open the mouth elicit a "bulldog" reflex (jaw snaps shut involuntarily). Spastic weakness of the oropharyngeal muscles may be the initial manifestation of bulbar palsy and may at times surpass signs of atrophic weakness; pseudobulbar signs (pathologic laughing and crying) may reach extreme degrees. This is the only common clinical situation in which spastic and atrophic bulbar palsy coexist. Strangely, the ocular muscles always escape.

As with other forms of motor system disease, the course of bulbar palsy is inexorably progressive. Eventually the weakness spreads to the respiratory muscles and deglutition fails entirely; the patient dies of inanition and aspiration pneumonia, usually within 2 to 3 years of onset. Approximately 25 percent of cases of motor system disease begin with bulbar symptoms, but rarely, if ever, does the sporadic form of progressive bulbar palsy run its course as an independent syndrome (pure hereditary forms of progressive bulbar palsy in the adult are known, e.g., Kennedy disease, discussed

further on). In general, the earlier the onset of the bulbar involvement, the shorter the course of the disease.

Primary Lateral Sclerosis

This entity, like ALS, can be a form of motor neuron disease, although most cases appear to be examples of a unique degenerative process. Many patients in whom the signs of corticospinal tract degeneration suggest the presence of ALS will develop indications of lower motor neuron disease within 1 year, usually earlier. Approximately 20 percent, however, have a slowly progressive corticospinal tract disorder that begins with a pure spastic paraparesis; later, the arms and oropharyngeal muscles become involved and the disease remains one solely of the upper neurons. These cases have distinctive neuropathologic features and are designated as *primary lateral sclerosis* (PLS), a term originally suggested by Erb in 1875. A historical review of the subject appears in the article by Pringle and colleagues.

The typical case begins insidiously in the fifth or sixth decade with a stiffness in one leg, then in the other; there is a slowing of gait, with spasticity predominating over weakness as the years go on. Walking is still possible with the help of a cane for many years after the onset, but eventually this condition acquires the characteristic features of a severe spastic paraparesis. Over the years, finger movements become slower, the arms become spastic, and, if the illness persists for decades, speech takes on a pseudobulbar lilt. There are no sensory symptoms or signs. The legs are often found to be surprisingly strong, the difficulty in locomotion being attributable to rigid spasticity. About half the patients eventually acquire spasticity of the bladder. Pringle and associates suggest that a diagnostic criterion of the disease is progression for 3 years without evidence of lower motor neuron dysfunction.

Pathologic studies in a limited number of cases have disclosed a relatively stereotyped pattern of reduced numbers of Betz cells in the frontal and prefrontal motor cortex, degeneration of the corticospinal tracts, and preservation of motor neurons in the spinal cord and brainstem (Beal and Richardson; Fisher; Pringle et al). The corticospinal tract lesions are identical to those in typical ALS. Whether some of these cases are examples of late-onset familial spastic paraplegia (see further on) has not been extensively explored with molecular techniques.

Some patients who have only restricted bilateral signs of upper motor neuron disease prove to have multiple sclerosis, a slow compression of the spinal cord by spondylosis or meningioma, spinal dural arteriovenous fistula, or the myelopathic form of adrenoleukodystrophy (affected males or female carriers). In a few cases, tropical spastic paraplegia, HIV myelopathy, copper deficiency myelopathy, or a familial type of spastic paraplegia (described further on) will be uncovered. Exceptionally, progressive spastic paraparesis has been linked to an adult onset of phenylketonuria or other aminoacidopathies to vitamin B₁₂ deficiency or to the fragile X premutation syndrome.

Laboratory Features of Motor Neuron Disease

Investigation provides useful confirmatory evidence even in the typical clinical syndrome. The EMG, as expected,

displays widespread fibrillations (evidence of active denervation) and fasciculations and enlarged motor units (denoting reinnervation), and motor nerve conduction studies reveal only slight slowing, without focal motor conduction block. If the atrophic paresis is restricted to an arm or hand, raising the question of cervical spondylosis, evidence of denervation in many widely separated somatic segments favors the diagnosis of ALS. In questionable cases, it is good practice to insist that denervation be demonstrated in at least 3 limbs before concluding that the process is ALS. (The currently favored "El-Escorial" criteria that are used for the purposes of clinical research mandate that this finding be present.) Widespread denervation of the paraspinal muscles and of the genioglossus or facial muscles is also strongly suggestive of the disease but electromyographic testing of these muscles demands considerable experience and is uncomfortable for patients. A muscle biopsy is sometimes helpful in corroborating neurogenic denervation. Sensory nerve action potentials should be normal; tests of motor nerve conduction have a normal velocity, but the amplitudes become progressively lower as the disease progresses—in the earliest stages, they too may be normal. When in a typical case the amplitudes of sensory nerve action potentials are reduced, there is usually an underlying entrapment neuropathy, diabetes, or other late-life neuropathy. Sensory evoked potentials are mildly abnormal in a proportion of patients, but the explanation for this finding is unclear. (Sensory complaints and minimal sensory loss have been commented on above.)

The CSF protein is usually normal or marginally elevated. Serum creatine kinase is moderately elevated in patients with rapidly progressive atrophy and weakness, but it is just as often normal. Motor evoked potentials elicited from the cortex are also prolonged in patients with prominent corticospinal signs. In this group, the MRI may show slight atrophy of the motor cortices and wallerian degeneration of the motor tracts (Fig. 39-10). These changes may be diagnostically useful and appear as increased FLAIR and T2 signal intensity in the posterior limb of the internal capsule, descending motor tracts of the brainstem, and spinal cord, all of which are subtle and may be missed. All these laboratory findings, particularly the degeneration of the lateral columns of the cord and changes in the internal capsules, pertain also to primary lateral sclerosis with the notable exception of EMG findings of denervation and of elevations of creatine kinase (CK).

Pathology

The principal finding in ALS is a loss of nerve cells in the anterior horns of the spinal cord and motor nuclei of the lower brainstem. Large alpha motor neurons tend to be affected before small ones. In addition to neuronal loss, there is evidence of slight gliosis and proliferation of microglia cells. Many of the surviving nerve cells are small, shrunken, and filled with lipofuscin. It is not uncommon to detect ubiquitin inclusions in threads, skeins, or dense aggregates within the affected neurons by special stains. Occasionally, there is another ill-defined cytoplasmic inclusion that is present in neurons

Figure 39-10. Axial T2-weighted MRI showing abnormal hyperintensity reflecting wallerian change in the corticospinal tracts at the level of the internal capsule (*top, arrow*) and the pons (*bottom*) in a patient with ALS.

and glia. Most studies indicate that these are made up of TDP-43 and ubiquitin as discussed in the alter section on “Pathogenesis”. According to some reports, swelling of the proximal axon is an early finding, presumably antedating visible changes in the cell body itself. The anterior roots are thin, and there is a disproportionate loss of large myelinated fibers in motor nerves (Bradley et al). The muscles show typical denervation atrophy of different ages. Whitehouse and coworkers found a depletion of muscarinic, cholinergic, glycinergic, and benzodiazepine receptors in regions of the spinal cord where motor neurons had disappeared.

The corticospinal tract degeneration is most evident in the lower parts of the spinal cord, but it can be traced up through the brainstem to the posterior limb of the internal capsule and corona radiata by means of fat stains, which show the macrophages that accumulate in response to chronic myelin degeneration. There is a loss of Betz cells in the motor cortex; this is manifest as a slight frontal lobe atrophy on the MRI, but it is not a prominent finding in most cases of ALS (Kiernan and Hudson). Other fibers in the ventral and lateral funiculi are depleted, imparting a characteristic pallor in myelin stains. Some pathologists

have interpreted this as evidence of involvement of non-motor neurons and hence object to the term *motor system disease*. However, this condition of more diffuse pallor may be a result of a loss of collaterals of motor neurons that contribute to the lamina propria. One observes the same effect in long-standing poliomyelitis. In cases of familial ALS resulting from mutations in the *SOD1* gene, the non-motor systems seem to be more affected (Cudkovic et al).

Neuropathologic studies of cases of ALS with dementia are few in number. In addition to the usual loss of motor neurons, these cases have shown an extensive neuronal loss, gliosis, and vacuolation involving the frontal premotor area, particularly the superior frontal gyri and the inferolateral cortex of the temporal lobes. The histologic changes of Alzheimer or Pick disease have not been seen in our cases; neurofibrillary degeneration has been observed, but is inconsequential in comparison to that seen in the Guamanian Parkinson-dementia-ALS complex (Finlayson et al; Mitsuyama). Attempts to transmit this ALS-dementia syndrome to subhuman primates have been unsuccessful.

Diagnosis of ALS

The early clinical picture of motor system disease is closely simulated by a centrally placed cervical spondylotic bar or ruptured cervical disc, but with these conditions there is usually pain in the neck and shoulders, limitation of neck movements, and sensory changes, and the lower motor neuron changes are restricted to 1 or 2 spinal segments. The EMG is helpful if not decisive in differentiating these disorders. A mild hemiparesis or monoparesis because of multiple sclerosis may be, for a time, difficult to distinguish from early ALS and primary lateral sclerosis. Progressive spinal muscular atrophy may be differentiated from peroneal muscular atrophy (Charcot-Marie-Tooth neuropathy) by the lack of family history, the complete lack of sensory change, and different EMG patterns, as described in Chap. 46. Motor system disease beginning in the proximal limb muscles may be misdiagnosed as an inflammatory myopathy or a limb-girdle type of muscular dystrophy.

The main considerations in relation to progressive bulbar palsy are myasthenia gravis and, less often, inflammatory myopathy, muscular dystrophy, and especially the inherited (Kennedy) type of bulbospinal atrophy, which is discussed further on. The spastic form of bulbar palsy may suggest the pseudobulbar palsy of lacunar disease and can be a prominent part of the progressive supranuclear palsy described earlier in the chapter. A crural form of PMA may be confused with diabetic polyradiculopathy or polymyositis.

A major consideration is the differentiation of PMA from a chronic motor polyneuropathy, particularly the form that displays multifocal conduction block. Extensive nerve conduction studies and EMG examinations are necessary to distinguish the two; these neuropathic processes are discussed with the peripheral neuropathies in Chap. 46. The presence of an IgM monoclonal paraproteinemia or of specific antibodies directed against the G_{M1} ganglioside are usually indicative of the immune motor neuropathy, but in half of the cases these laboratory

tests are negative. There is also a rare form of subacute poliomyelitis (possibly viral) in patients with lymphoma or carcinoma; it leads to an amyotrophy that progresses to death over a period of several months. Chapter 31 discusses this paraneoplastic variety of motor system disease in greater detail.

Because it may produce a motor-predominant radiculopathy, chronic Lyme infection is sometimes considered in the differential diagnosis of ALS. Some clinics screen for Lyme antibodies using both an enzyme-linked immunosorbent assay (ELISA) and the more sensitive and specific Western immunoblot, but we have never detected such a case and doubt there is much similarity. Infrequently, we have seen myelopathic motor findings and motor radiculopathy with vitamin B₁₂ deficiency, and there are exceptional reports of myeloradiculopathy with lead poisoning; we sometimes include tests for these conditions. Another entity that may simulate ALS is inclusion body myositis (IBM), an atypical myopathy that begins asymmetrically and involves distal muscles, usually without much elevation of serum CPK levels. In a recent series of 70 patients with this condition, 13 percent were initially diagnosed as having ALS (Dabby et al). Features distinguishing the IBM cases included normal corticospinal function, preservation of deep tendon reflexes in weak muscles, and finger flexor weakness. One concludes from this series that a detailed, quantitative EMG and possibly a muscle biopsy are indicated in cases that display predominantly lower motor features. Fully developed ALS is difficult to confuse with these conditions. Acid maltase deficiency may also simulate ALS in causing fatigability and early respiratory failure.

Over the years, the authors have encountered young men with localized and asymmetrical amyotrophy of the leg or forearm that became arrested and did not advance over a decade or two. Several reports of such a partial cervical spinal amyotrophy have appeared in recent years (Hirayama et al; Moreno Martinez et al). In the type described by Hirayama and associates, young men are affected with progressive and asymmetrical amyotrophy of the forearm and hand that has been traced to ligamentous

hypertrophy and buckling in the ventral spinal canal. This causes a compression of the cervical spinal cord gray matter, presumably by a chronic ischemic effect as discussed in detail in Chap. 44. In a familial variety of pure restricted amyotrophy, only the vocal cords became paralyzed over a period of years in adult life; only later were the hands affected.

Some patients who have recovered from paralytic poliomyelitis may develop progressive muscular weakness 30 or 40 years later; the nature of this relationship is obscure. We favor the explanation that atrophy of anterior horn cells with aging brings to light a critically depleted motor neuron population (see further on). It appears to progress little if at all.

An observation of interest is the finding of a form of progressive spinal muscular atrophy in patients with G_{M2} gangliosidosis, the storage disease that presents in infancy as Tay-Sachs disease (Kolodny and Raghavan). The onset is in late adolescence and early adult life and the atrophic paralysis is progressive, so that this condition is often mistaken for Wohlfart-Kugelberg-Welander disease or ALS. A number of cases of this type have been discovered in Ashkenazi Jews by the use of lysosomal enzyme analysis. The rare and incompletely characterized entity of polyglucosan disease, discussed in other sections of the book, has simulated ALS.

The differential diagnosis of the purely spastic state of primary lateral sclerosis is broad and has been listed earlier. An estimate of the frequency of all the aforementioned alternative diagnoses may be appreciated from a study of cases by Visser and colleagues that were initially presumed to be PMA but turned out to represent another process. In 17 of 89 patients the diagnosis proved to be anti-G_{M1} motor conduction block, chronic inflammatory demyelinating polyneuropathy, and various myopathies. This notwithstanding, ALS or the more discrete forms of motor system disease rarely offer any difficulty in diagnosis.

Pathogenesis

Insight into the sporadic form of the disease has been afforded by analyses of the approximately 10 percent of

Table 39-6

GENETIC DEFECTS ASSOCIATED WITH ALS

GENE	PROTEIN	INHERITANCE	AGE OF ONSET	CLINICAL FEATURES
SOD1	Superoxide dismutase 1	AD	Adult	Clinically and pathologically similar to sporadic ALS
FUS	Fused sarcoma	AD	Adult	ALS with frontotemporal dementia
TARDP5P		AD, rare recessive		
DCTN	Dynactin	AD	Adult	Slowly progressive with predominant bulbar features
CytoC	Cytochrome-c oxidase	Mitochondrial	Adult	Prominent spasticity
ALS2	GEF/alsin	AR	Juvenile	Very slowly progressive, predominantly corticospinal
SETX	Senataxin	AD	Juvenile	Very slowly progressive
VAPB	Vesicle-associated membrane protein	AD	Adult	Similar to sporadic ALS

AD autosomal dominant; AR autosomal recessive

ALS cases that are familial and caused by identifiable mutations. They are inherited mainly in an autosomal dominant pattern (Table 39-6). Of these inherited forms, approximately 40 percent are associated with a hexanucleotide expansion in the *C9orf72* gene, and provocatively, 4 to 8 percent of ostensibly sporadic cases have mutations in the gene. The mechanism of motor neuron death that results from this mutation is not known but may be associated with mishandling of RNA-binding proteins. Of similar interest are the *TARDBP* and *FUS* genes that each has an association with approximately 5 percent of familial cases and 2 percent of sporadic ones. These genetic and molecular influences are summarized by Andersen and Al-Chalabi. All 3 of the aforementioned genes have also been implicated in degenerative frontotemporal dementia and in the combination of this dementia with ALS. The *SOD1* mutation, the first to be found in familial ALS, codes for the cytosolic enzyme Cu-Zn superoxide dismutase (*SOD1*; Rosen et al); it has also been implicated in a small proportion of sporadic cases. There are yet other mutations in this group that have associations, not necessarily causal, with small numbers of both sporadic and inherited cases (Table 39-7).

What has emerged from these genetic studies is the common feature of the accumulation of the TDP-43 and *FUS* proteins in neurons. The mechanisms that lead to cell death as a result of any of these mutations or the protein deposition are being sought.

A rare and recessively inherited childhood form of motor neuron disease (affecting corticospinal more than spinal motor neurons) has been attributed to mutations in a gene whose protein (alsin) is a component of the neuronal cell-signaling pathways. Yet another rare childhood-onset form of disease arises from mutations in the senataxin gene, a DNA helicase that probably assists in chromatin folding and unfolding. (It is of interest that a recessively inherited mutation in the same gene transmits a recessive form of ataxia with oculomotor disorder.) In several families, a mutation has been detected in a protein that is involved in the transport of vesicles in neurons. Table 39-6 summarizes these various genetic forms of motor neuron disease.

Trauma, particularly traction injury of an arm, but also repetitive head and spine injury has been reported occasionally as an antecedent event in patients with ALS, but a causative relationship has not been established. Younger and coworkers have found a higher incidence of paraproteinemia in patients with motor system disease than can be accounted for by chance. Many other examples of disordered immune function have been described but a coherent explanation of ALS as an autoimmune disease has not emerged. It has never been proved that intoxication with heavy metals (lead, mercury, aluminum) can cause motor system disease, although there are reports of concurrent myelopathic and radicular motor signs in patients with lead intoxication. There is little evidence that such cases represent a reactivation of a virus or the presence of some other infectious agent. The progressive weakness that occurs some 30 to 40 years after recovery from polio should not be confused with PMA, as already indicated. Finally, we have had occasion to see patients who, many years after a severe electrical injury that passed through

the region of the cord, developed a progressive and severe amyotrophy of the arms; other such extraordinary cases are known but the concordance is considered coincidental by most authorities (see Chap. 44).

Treatment

With the exception of riluzole, discussed below, there is no specific treatment for any of the motor neuron diseases. Supportive measures, however, are exceedingly important. In initial office visits, it has been our practice to give the patient some idea of the seriousness of the condition; but in early discussions we avoid the devastating statement that ALS is invariably fatal. Typically, patients and family members will ask explicitly about these matters in subsequent visits; such data as are appropriate to the patient's circumstances and character can be conveyed at that time, usually with the caveat that any individual may outlive the standard survival statistics.

The antiglutamate agent riluzole was shown by Bensimon and colleagues to slow the progression of ALS and improve survival in patients with disease of bulbar onset. However, it added only 3 months of life at best. This claim has been confirmed in several followup studies, although again the benefit has been marginal. Several additional agents are reported to have been effective in genetic models of ALS. These are presently undergoing study in ALS patients. Guanidine hydrochloride and injections of cobra venom, gangliosides, interferons, high-dose intravenous cyclophosphamide, and thyrotropin-releasing hormone are but some of a long list of agents that were said to arrest the disease process, but these claims have been discredited.

An attempt can be made to reduce the spasticity with medications, such as baclofen or tizanidine, or by subarachnoid infusions of baclofen via an implanted lumbar pump. Initial intrathecal test doses are given to predict a response to the pump infusions of baclofen, but this test may fail; consequently, in severe cases it may be advisable to proceed with a constant infusion for several days. Some degree of improved comfort from a reduction in the extreme rigidity is usually the most that can be expected. Partial relief from spasticity may also be afforded by the use of benzodiazepines or sometimes dantrolene. These approaches are most suitable for cases of primary lateral sclerosis, which can be expected to progress slowly and for a long period.

At all stages of ALS, physical therapy is useful in maintaining mobility, but overwork of the muscles leading to fatigue and cramps should be avoided. Physical therapy is invaluable, for example, for avoiding contractures of the fingers and shoulders. Occupational therapy is likewise helpful, particularly assessments of the patient's function in the home.

Important in the management of ALS is periodic monitoring of respiratory function. We typically perform pulmonary function tests every few months after the first year or so of illness. Our experience has been that the vital capacity in cubic centimeters can be estimated by multiplying the highest number to which a patient can count with one deep breath by 100. Thus, the ability to count to 25 with a full effort in a single breath corresponds to a vital capacity of approximately 2.5 L. Significant practical advances have been made in the respiratory management of ALS. The

Table 39-7

CLASSIFICATION OF THE SPINAL MUSCULAR ATROPHIES (SMA)				
TYPE	INHERITANCE	AGE OF ONSET	CLINICAL FEATURES	PROGNOSIS
SMA I (infantile, Werdnig-Hoffmann)	Autosomal recessive Two copies of SMN 2	Preterm to 6 months	Neonatal hypotonia (floppy baby), weakness of sucking and swallowing, may have arthrogryposis, unable to sit	Few survive 1 year
SMA II (intermediate type; Dubowitz disease)	Autosomal recessive At least 3 copies of SMN 2	6 to 15 months	Proximal weakness, fasciculation, fine hand tremor, unable to stand	Variable; death from respiratory complications
SMA III (Wohlfart-Kugelberg-Welander)	Autosomal recessive or dominant At least 3 copies of SMN 2	1 year to adolescence	Delayed motor development, proximal leg weakness	Slowly progressive, variable outcome
SMA IV	Autosomal recessive At least 4 copies of SMN 2	After age 30	Proximal limb weakness and diaphragm	Slowly progressive; eventually wheelchair-bound but normal life expectancy
Kennedy syndrome (bulbosplinal atrophy)	X-linked (CAG repeat expansion in the AR gene), less often autosomal dominant	Early adulthood	Scapulo-peroneal or distal atrophy, oropharyngeal weakness, gynecomastia, oligospermia	Slowly progressive
Fazio-Londe disease	Autosomal recessive, rarely dominant, <i>SLC52A3</i> gene	Childhood to early adolescence	Progressive bulbar and respiratory failure	Survival for years, respiratory failure

introduction of bilevel positive airway pressure (BiPAP) has allowed patients to sleep better and reduce daytime somnolence. Many patients do not initially tolerate the device, usually because of maladjusted face masks or excessive applied airway pressures. Almost always, a seasoned pulmonary technologist can find solutions to these problems. It is appropriate to begin BiPAP at (or before) the earliest sign of carbon dioxide retention, a state that is heralded by disruption of sleep, nightmares, early morning headaches, and daytime drowsiness. With noninvasive respiratory assistance, it may be possible to defer tracheostomy for months or years. Ultimately, as the diaphragm fails, BiPAP is needed not only at night but also during the day. As BiPAP use approaches 20 to 24 h per day, patients must usually address the difficult question of tracheostomy and mechanical ventilation. We broach this subject early enough in the course of the disease to allow ample time for discussion and reflection. In practice, most patients elect not to undergo tracheostomy and full ventilation.

Another important issue regards nutrition. As oropharyngeal palsy progresses, food should be cut into small pieces and dry foods, such as toast should be avoided; milk shakes and preparations of the same consistency are ideal at this stage. Speech therapists are capable of teaching patients methods to adapt to declining bulbar function and at the same time minimizing aspiration. Ultimately, in our experience, most ALS patients will need a feeding tube to maintain normal hydration and caloric intake. Although we adopt a neutral position in discussions with patients regarding mechanical ventilation, we tend to urge patients to undergo placement of a feeding tube at the appropriate time. This presumably increases survival and improves quality of life by preventing dehydration and recurrent aspiration. Laparoscopic and

radiologic technologies for the placement of a gastrostomy tube render the procedure swift and nearly painless. Some patients have tubes inserted as outpatients and then start gastric feeding within a day or two.

Other devices, often guided by the physical and occupational therapist, may be of great assistance to the patient and family as the disease progresses. These include a mechanized bed and structural accommodations in the home that facilitate entry of a wheelchair and the safe use of the bath or shower as well as thick-handled utensils. Ambulation aids, beginning with simple canes (first one, then two) followed by a walker (preferably with basket and seat) and then a wheelchair (manual or electric) are of value in maintaining a sense of independence and assuring safety.

The American Academy of Neurology has published explicit guidelines for management that have been of great aid to patients and physicians; they emphasize the complex and multidisciplinary needs of ALS patients (see Miller et al 2009a and 2009b).

Hereditary Forms of Progressive Muscular Atrophy

These diverse diseases are the concern mainly of child neurology. They are presented here because they fall within the category of system degenerations and are usually inherited.

Spinal Muscular Atrophy (Werdnig-Hoffman Disease)

The classic form of spinal muscular atrophy was described by Werdnig in 1891 and 1894, by Hoffmann in 1893 and, at about the same time, by Thomsen and Bruce. The cases

described by these authors were all in infants. Further clinical analyses, however, indicated the inadequacy of this narrow grouping for the large group of spinal muscular atrophies. Brandt, in his study of 112 Danish patients, found that in about one-third the weakness was present at birth, and in 97 the onset was in the first year of life; in 9 patients, the disease was not recognized until after the first year of life. In 1956, Walton, and later Wohlfart and colleagues and Kugelberg and Welander (see below), identified milder forms of spinal muscular atrophy in which the onset was between 2 and 17 years and walking was still possible in adult life. Byers and Banker, in a study of 52 patients, subdivided them into 3 groups on the basis of age of onset; in one group the disease was recognized at birth or in the first month or two of life; in a second, between 6 and 12 months; and in a third, after the first year. In their last group, it was not unusual for the patient to survive into adolescence and adult life. In a few of the late-onset types, signs of corticospinal tract involvement are conjoined, and Bonduelle has also included some patients with areflexia, pes cavus, Babinski signs, choreiform movements, and developmental delay in this group. More recently, the designations SMA I, II, and III have been introduced, based largely on the age of onset (see Table 39-7).

Genetic Aspects of Spinal Muscular Atrophies Familial spinal muscular atrophy that begins in infancy and childhood is inherited mainly as an autosomal recessive trait. All the SMA phenotypes in children have been mapped to the same chromosome, 5q11.2-13.3 (Brzustowicz et al; Gilliam et al; Munsat et al). The mutations affect the gene at the "survival of motor neuron" (SMN) site. The SMN protein participates in forming protein-RNA complexes (small nuclear ribonucleoproteins and RNA) that are essential for gene splicing. Within the SMN locus there are 2 alleles: *SMN1*, which generates a full-length, fully functional form of SMN, and *SMN2*, which makes a truncated, partially functional SMN. The latter can partially compensate for the loss of *SMN1*. Making matters more complex, individuals vary in the number copies of *SMN2*. As a result, disease due to loss of both copies of *SMN1* causes very severe SMA in individuals who carry only one copy of *SMN2*, while those with multiple copies of *SMN2* have milder disease. Thus, the amount of SMN2 protein determines the severity and time of onset of disease.

Although affected siblings demonstrate very similar clinical patterns of disease, the same mutation may give rise to very different phenotypes in different families, so that additional modifying posttranscriptional or nongenetic attributes must be playing a role. Less often, autosomal dominant and X-linked patterns of inheritance have been found, resulting from mutations in *UBA1*, usually in adults. A rare autosomal dominant adult form is the result of mutations in *VABP* and a form that affects only the legs is associated with mutations in *DYNC1H1*.

Clinical Manifestations of Werdnig-Hoffmann Disease (SMA I) The most frequent form of these spinal muscular atrophies, the severe infantile type, is a common disease, occurring once in every 20,000 live births. After cystic fibrosis, it is also the most frequent cause of death from a recessively inherited disease.

Characteristically the infant, usually born normally, is noted from birth to be unnaturally weak and limp ("floppy"). Some mothers report that fetal movement in utero had been less than expected or lacking altogether. In severe cases, arthrogryposis at the ankles and wrists or dislocation of the hips is noted at birth (arthrogryposis and its differential diagnosis is discussed in Chap. 48 in the section on the congenital neuromuscular disorders). The muscle weakness in these children is generalized from the beginning, and death comes early, usually within the first year. Other infants seem to develop normally for several months before the weakness becomes apparent. In these, the trunk, pelvic, and shoulder-girdle muscles are at first disproportionately affected, while the fingers and hands, toes and feet, and cranial muscles retain mobility. *Hypotonia* accompanies the weakness, and because passive displacement of articulated parts in testing muscle tone is easier to judge than power of contraction at this early age, it may be singled out as the dominant clinical characteristic. As a rule, the tendon reflexes are unobtainable. Volume of muscle is diminished but is difficult to evaluate in the infant because of the coverings of adipose tissue. Fasciculations are seldom visible except sometimes in the tongue. Perception of tactile and painful stimuli is undiminished, and emotional and social development measures up to age.

As the months pass, the weakness and hypotonia progress gradually and spread to all the skeletal muscles except the ocular ones. Intercostal paralysis with a degree of collapse of the chest is the rule. Respiratory movements become paradoxical (abdominal protrusion with chest retraction). The cry becomes feeble, and sucking and swallowing are less efficient. Such infants are unable to sit unless propped, and they cannot hold up their heads without support and cannot roll over or support their weight when placed on their feet. Their posture is characteristic: arms abducted and flexed at the elbow, legs in the "frog position" with external rotation and abduction at hips and flexion at hips and knees. If the effects of gravity are removed, all muscles continue to contract; that is there is paresis, not paralysis. Until late in the illness, these children appear bright-eyed, alert, and responsive.

Infants in whom the disease becomes apparent only after several months of life have a less-rapid decline than those affected in utero or at birth. Some of the former become able to sit and creep and even to walk with support; those with later onset may survive for several years and even into adolescence or early adult life, as already mentioned.

Laboratory data of confirmatory value are few. Muscle enzymes in the serum are usually normal or rarely elevated. The EMG, if performed at a late enough stage of development, displays fibrillations, proving the denervative basis of the weakness. Motor unit potentials are diminished in number and, in the more slowly evolving cases, some are larger than normal (giant or polyphasic potentials reflecting reinnervation). Motor nerve conduction velocities are normal or fall in the low-normal range (these are normally slower in infants than in adults). Electrophysiologic studies performed in the first few months of life may give ambiguous results.

Pathologic Findings Muscle biopsy after 1 month of age reveals a typical picture of group atrophy; shortly after birth this change is difficult to discern. Aside from denervative atrophy, the essential abnormalities are in the anterior horn cells in the spinal cord and the motor nuclei in the lower brainstem. Nerve cells are greatly reduced in number, and many of the remaining ones are in varying stages of degeneration; a few are chromatolytic and contain cytoplasmic inclusions. It is not unusual to see figures of neuronophagia. There is replacement gliosis and secondary degeneration in roots and nerves. Other systems of neurons, including the corticospinal and corticobulbar systems, are entirely unaffected.

Differential Diagnosis The major problem in diagnosis is to distinguish Werdnig-Hoffmann disease from an array of other diseases that cause hypotonia and delayed motor development in the neonate and infant. The list of disorders that imitates spinal muscular atrophy constitutes a large part of the differential diagnosis of the so-called *floppy infant*. The congenital myopathies (as described in Chap. 48), the glycogenoses, neonatal myasthenia gravis, Prader-Willi syndrome, and disorders of fatty acid metabolism frequently present in this way. The preservation of tendon reflexes and relative lack of progression of muscle weakness distinguish the latter disorders. Because of the gravity of the diagnosis, muscle biopsy should be performed if there is any suspicion of spinal muscular atrophy. If studied properly, the biopsy usually yields the correct diagnosis.

Clinical disorders more or less similar to the spinal muscular atrophies may be identified occasionally in certain hereditary metabolic diseases. For example, Johnson and coworkers have described a patient who began experiencing weakness of the legs, cramping, and fasciculations during adolescence in what proved to be a variant of hexosaminidase A (G_{M2}) deficiency, and biopsy of rectal mucosa showed nerve cells with the typical membranous cytoplasmic bodies of Tay-Sachs disease. Others have reported similar cases. A progressive motor neuron or motor nerve disorder has also been observed in glycogen storage disease affecting anterior horn cells. Motor nerve fibers also suffer damage in metachromatic and globoid body leukoencephalopathies.

Certain forms of muscular dystrophy, notably myotonic dystrophy, which is about twice as frequent as Werdnig-Hoffmann disease, may become manifest in the neonatal period and interfere with sucking and motor development (see Chap. 48). As a rule, the weakness is not as severe or diffuse as that in Werdnig-Hoffmann disease. The mother, but not the child, may display myotonia, either elicitable clinically or, if more subtle, with EMG recording. Also, a number of polyneuropathies may cause a serious degree of weakness in early childhood. Unfortunately, in respect to the latter, adequate sensory testing is not possible because of the patient's age, but the CSF protein is often elevated. Again, diagnosis is greatly facilitated by nerve-muscle biopsy and measurement of nerve conduction velocities. These velocities are reduced but must be interpreted with caution because of incomplete development of axons and of myelination in the first months of life. The needle EMG examination

shows subtle signs of denervation that cannot be easily distinguished from the finding in the spinal muscular atrophies. Examination of parents and siblings may disclose a clinically inapparent neuropathy. Polymyositis of childhood may also simulate both muscular dystrophy and motor neuron disease. Finally nemaline and central core myopathy can manifest in infancy and early childhood and cause a floppy child syndrome.

Developmental delay with a flaccid rather than spastic weakness of the limbs is another major category of disease that must be distinguished. These include Down syndrome, cretinism, Prader-Willi syndrome, and achondrodysplasia. It should be commented that very sick children with celiac disease, cystic fibrosis, and other chronic diseases may be hypotonic to the point of simulating neuromuscular disease. Usually speech is not delayed and tendon reflexes are preserved in these purely medical states, and strength returns as the medical problem is corrected. Also, certain of the polioencephalopathies and leukodystrophies may weaken muscles and abolish tendon reflexes, but usually there is evidence of cerebral involvement.

There remains, after the assiduous study of the "floppy infant," a group of cases of hypotonia and motor underdevelopment that cannot be classified. The term *amyotonia congenita* (Oppenheim) was once applied to this entire group but is now obsolete. Walto proposed the term *benign congenital hypotonia* to designate patients who manifest limp and flabby limbs in infancy and a delay in sitting up and walking but who improve gradually, some completely and others incompletely. It is likely that among this group there are examples of congenital myopathy that await differentiation by application of modern histochemical, ultrastructural, and genetic techniques.

Chronic Childhood and Juvenile Proximal Spinal Muscular Atrophy (Wohlfart-Kugelberg-Welander Syndrome; SMA III) This is a somewhat different form of hereditary familial spinal muscular atrophy, which, as the name indicates, involves the proximal muscles of the limbs predominantly and is only slowly progressive. It was first separated from other forms of motor system disease and from muscular dystrophy by Wohlfart and by Kugelberg and Welander in the mid-1950s. In about one-third of the cases the onset is before 2 years of age, and in half, between 3 and 18 years. Males predominate, especially among patients with juvenile and adult onset. The usual form of transmission is by an autosomal recessive pattern; most cases result from mutations in the *SMN* gene; as mentioned, multiple copies of the *SMN2* gene partly rescue the loss of *SMN1* and lead to this milder form of disease. Families with dominant and sex-linked inheritance have also been described.

The disease begins insidiously, with weakness and atrophy of the pelvic girdle and proximal leg muscles, followed by involvement of the shoulder girdle and upper arm muscles. Unlike the sporadic form of spinal muscular atrophy, the Wohlfart-Kugelberg-Welander variety (also listed in other books and monographs as Kugelberg-Welander disease) is bilaterally symmetrical from the beginning, and fasciculations are observed in only half the cases. Ultimately the distal limb muscles are involved and tendon reflexes are lost. Bulbar musculature and

corticospinal tracts are spared, although Babinski signs and an associated ophthalmoplegia (presumably neural) have been reported in rare instances.

The presence of fasciculations and the EMG and muscle biopsy findings—all of which show the characteristic abnormalities of neural atrophy—permit distinction from muscular dystrophy. Cases that have been examined postmortem have shown loss and degeneration of the anterior horn cells.

The disease progresses very slowly, and some patients survive to old age without serious disability. In general, the earlier the onset, the less favorable the prognosis; however, even the most severely affected patients retain the ability to walk for at least 10 years after the onset. Admittedly, it is difficult to make a sharp distinction between these cases of Wohlfart-Kugelberg-Welander disease and certain milder instances of Werdnig-Hoffmann disease with onset in late infancy and early childhood and prolonged survival (Byers and Banker).

A form that is intermediate between the severe Werdnig-Hoffmann type and the milder Wohlfart-Kugelberg-Welander is termed Dubowitz syndrome and designated SMA II.

Kennedy Syndrome (X-Linked Bulbospinal Muscular Atrophy)

An unusual pattern of *distal muscular atrophy with prominent bulbar signs* and, less often, ocular palsies was described by Kennedy and coworkers. The onset has varied from childhood to adult age, but symptoms typically begin in the third decade. Most cases have shown an X-linked pattern of inheritance and a lesser number, an autosomal dominant pattern. The proximal shoulder and hip musculature are involved first by weakness and atrophy, followed in about half of patients by dysarthria and dysphagia. Muscle cramps or twitching often precedes weakness. Facial fasciculations and mild weakness are characteristic and may be striking. The tendon reflexes become depressed and may be absent; a mild sensory neuropathy is almost universal. In the family described by Kaeser, in which 12 members in 5 generations were affected, the pattern of weakness was shoulder-shank, that is scapuloperoneal; it may therefore be mistaken for muscular dystrophy. Two-thirds of patients have gynecomastia, a feature that may first identify affected men in a kindred; oligospermia and diabetes are additional associations; therefore, the presence of genuine progeny virtually excludes the disease in a male. The CK level is elevated, sometimes tenfold, and physiologic studies reveal denervation and reinnervation as well as indications of a mild sensory neuropathy.

As in Huntington disease and certain of the spinocerebellar atrophies, the genetic defect is a CAG expansion, in this case in the gene (AR) that codes for the androgen receptor on the short arm of the X-chromosome (La Spada et al; see Table 39-7). Indeed, the first reported polyglutamine disease was Kennedy syndrome. Lengthened sequences correlate with an earlier age of onset (anticipation, as in Huntington disease) but have no relation to the severity of disease. Androgen receptors have been found on motor neurons of the spinal cord; the subpopulation

of motor neurons that is susceptible to both Kennedy syndrome and ALS express abundant surface androgen receptors, but it is not clear whether this finding has direct pathogenic significance. Neuronal inclusions have been described, composed of aggregations of the abnormally long polyglutamine protein sequences that correspond to the CAG expansion. A family with the bulbospinal phenotype but without the CAG expansion has also been reported (Paradiso et al). Other features, such as optic atrophy and sensory neuronopathy, were present in some members of this kindred but are not features of typical cases. The diagnosis can be confirmed by genetic testing for the lengthened trinucleotide sequence. Prenatal diagnosis and identification of female carriers are also possible by this method.

Progressive Bulbar Palsy of Childhood (Fazio-Londe Syndrome)

Fazio in 1892, and Londe in 1893, described the development of a progressive bulbar palsy in children, adolescents, and young adults. There is progressive paralysis of the facial, lingual, pharyngeal, laryngeal, and sometimes ocular muscles. The illness usually presents with stridor and respiratory symptoms, followed by facial diplegia, dysarthria, dysphagia, and dysphonia. These features become increasingly pronounced until the time of death some years later. In a few patients there is a late development of corticospinal signs and sometimes ocular palsies. Occasionally, jaw and oculomotor paresis appears, and in one case, there was progressive deafness. The disease is rare, only several dozen well-described examples had been recorded in the medical literature by 1992 (McShane et al). Inheritance may be autosomal dominant, as in Fazio's original case, and rarely X-linked, but it is more likely to be autosomal recessive. Pathologic examination has shown a loss of motor neurons in the hypoglossal, ambiguous, facial, and trigeminal motor nuclei. In a few cases, the nerve cells in the ocular motor nuclei also were diminished. This disease, the 2 times we have encountered it, had to be differentiated from myasthenia gravis, a pontomedullary glioma, and brainstem multiple sclerosis.

The cause of the disease is interesting in that it results from mutations in SLC52A3, a riboflavin transporter, and some beneficial effect is derived from the administration of riboflavin (vitamin B₂). The disease is allelic with *Brown-Vialetto-Van Laere syndrome*, another motor neuron degeneration, which includes deafness.

Hereditary Forms of Spastic Paraplegia

Hereditary Spastic Paraplegia (Strümpell-Lorrain Disease)

This disease was described by Seeligmuller in 1874 and later by Strümpell in Germany and Lorrain in France; it has now been identified in nearly every part of the world. The pattern of inheritance is usually autosomal dominant, less often recessive (one family has shown X-linked inheritance), and the onset may be at any age from childhood to the senium. Harding (1993) divided the disease

Table 39-8

GENETIC DEFECTS ASSOCIATED WITH HEREDITARY SPASTIC PARAPLEGIA (HSP)

HSP TYPE	GENE (PROTEIN)	GENETICS	AGE OF ONSET	CLINICAL AND MISCELLANEOUS FEATURES
3A	<i>ATL1</i> (atlastin)	AD	Childhood	Guanylate-binding protein
4	Spastin	AD	20's	40–50% of HSP; binds to microtubules
6	<i>NIPA1</i>	AD	Teens	Golgi membrane protein
10	<i>KIF5A</i> (kinesin-1)	AD	Childhood	Kinesin heavy chain–motor protein
13	HSP (heat shock protein)	AD	Adult	Located in mitochondrial matrix
17	<i>BSC2L2</i> (seipin)	AD	Variable	Silver syndrome: HSP with wasting of hands, feet
7	<i>SPG7</i> (paraplegin)	AR	Adult	Mitochondrial chaperone and metalloprotease; optic atrophy, neuropathy, myopathy
	Spartin	AR		HSP with wasting of distal limbs, hands, feet
21	<i>SPG21</i> (maspardin)	AR	Late teens	Endosomal protein involved in protein transport
1	<i>L1CAM</i> (L1 cell adhesion molecule)	XR	Infancy	Developmental delay, hydrocephalus, callosal hypoplasia, spasticity
2	<i>PLP</i> (proteolipid protein)	XR	Infancy	Cognitive impairment, spasticity, ataxia

AD autosomal dominant; AR autosomal recessive; XR X-linked recessive

into 2 groups, the more common one beginning before age 35 with a very protracted course and the other with a late onset (40 to 60 years). The latter type often shows sensory loss, urinary symptoms, and action tremor.

The clinical picture is that of a gradual development of spastic weakness of the legs with increasing difficulty in walking. The tendon reflexes are hyperactive and the plantar reflexes extensor. In the pure form of the disease, sensory and other nervous functions are entirely intact. If the onset is in childhood, as many cases are, the foot arches become exaggerated, the feet are shortened, and there is a tightening (pseudocontracture) of calf muscles, forcing the child or adolescent to “toe-walk.” This is a common orthopedic problem and may require surgical correction. In children, the legs appear to be underdeveloped, and in both children and adults they may become quite thin. Sometimes the knees are slightly flexed; at other times the legs are fully extended or hyperextended (*genu recurvatum*) and adducted. Weakness is variable and difficult to estimate. Sphincteric function is usually retained. Subtle sensory loss in the feet has been reported. The arms are variably involved. In some patients, the arms appear to be spared even though the tendon reflexes are lively. In others, the hands are stiff, movements are clumsy, and speech is mildly dysarthric. Conjoined findings such as nystagmus, ocular palsies, optic atrophy, pigmentary macular degeneration, ataxia (both cerebellar and sensory), sensorimotor polyneuropathy, ichthyosis, patchy skin pigmentation, epilepsy, and dementia have all been described in isolated families (see further on).

The few available pathologic studies have shown that, in addition to degeneration of the corticospinal tracts throughout the spinal cord, there is thinning of the columns of Goll, mainly in the lumbosacral regions, and of the spinocerebellar tracts, even when no sensory abnormalities had been detected during life. These were

the pathologic findings described by Strümpell in his original (1880) report of 2 brothers with spastic paraplegia; one of them, in addition, had a cerebellar syndrome, but again, there were no sensory abnormalities. A reduction in the number of Betz and anterior horn cells has also been reported.

Genetic Aspects of Hereditary Spastic Paraplegia

Numerous genetic mutations have given rise to this disease. As of this writing, there were 52 hereditary spastic paraplegia (HSP) loci many of which are shown in Table 39-8. The disease types have been renamed under the designation “SPG” (for spastic paraplegia) and numbered in order of discovery of the associated gene. The common uncomplicated autosomal dominant form of disease has been linked to mutations in many proteins, the most common being (proteins in parentheses) SPAST (spastin) and ALT1 (atlastin); and the common recessive varieties, are in SPG7 (paraplegin); and X-linked in L1CAM and PLP1 (proteolipid protein). The common spastin variety, associated with a mutation on chromosome 2p, results in great variability of clinical presentation within and among families (see Nielsen et al). A high frequency of partial deletions of the *SPAST* gene has been found. The possible subcellular mechanisms by which these mutations cause degeneration of the corticospinal tracts have been reviewed by Blackstone.

Differential Diagnosis In the diagnosis of this disorder, one should consider an indolent spinal cord or foramen magnum tumor, cervical spondylosis, a spinal form of multiple sclerosis (this was the clinical diagnosis in Strümpell's original cases), Chiari malformation, compression of the cord by a variety of congenital bony malformations at the craniocervical junction, and a number of chronic myelitides, among them, lupus erythematosus, sarcoidosis, AIDS, adrenomyeloneuropathy, primary lateral sclerosis (described earlier in this chapter), hypocupric

myelopathy, spinal arteriovenous dural fistula, and especially, tropical spastic paraparesis (caused by the HTLV-1 virus as discussed in Chap. 33).

Variants of Familial Spastic Paraplegia

The literature contains a large number of descriptions of familial spastic paraplegia combined with other neurologic abnormalities. Some of the syndromes had developed early in life in conjunction with moderate degrees of mental retardation. In these, the rest of the neurologic picture appeared many years after birth and was progressive. Some idea of the number of these “hereditary paraplegia-plus” syndromes and the diverse combinations in which they may be present is conveyed in the review by Gout and colleagues. Again, it is hardly possible to describe each of these symptoms in any degree of detail. The list below includes the best-known entities but all are rare. But if the term *hereditary spastic paraplegia* is to have any neurologic significance, it should be applied only to the pure form of the progressive syndrome. The more common “atypical” or “syndromic” cases—with amyotrophy, cerebellar ataxia, tremors, dystonia, athetosis, optic atrophy, retinal degeneration, amentia, and dementia—should be put in separate categories and their identity retained for nosologic purposes until such time as additional biochemical and genetic data related to pathogenesis are forthcoming. The gene mutations found in some of the variant types have been summarized by Fink, but—as with all types of uncomplicated hereditary spastic paraplegia—the mechanisms of neuronal loss are not known. To be separated from these cases are all the congenital nonprogressive types of spastic diplegia and athetosis. The following list includes the best-known entities:

1. *Hereditary spastic paraplegia with ataxia (Ferguson-Critchley syndrome)* This syndrome is one of a collection of leg spasticity and generalized ataxia syndrome that may also be characterized by a disorder of gaze, or optic atrophy. Most impressive are the manifestations of spinocerebellar ataxia beginning during the fourth and fifth decades of life, accompanied by weakness of the legs, alterations of mood, pathologic crying and laughing, dysarthria and diplopia, dysesthesias of limbs, and poor bladder control. The tendon reflexes are lively, with bilateral Babinski signs. Sensation is diminished distally in the limbs. The whole picture resembles a chronic progressive form of multiple sclerosis. In other cases, running through several generations of a family, the extrapyramidal features were more striking; such cases overlap with the following syndromes. A dominant form of the disease is due to a mutation in *SAX1*.
2. *Hereditary spastic paraplegia with extrapyramidal signs* Action and static tremors, parkinsonian rigidity, dystonic tongue movement, and athetosis of the limbs have all been conjoined with spastic paraplegia. Gilman and Romanul have reviewed the literature on this subject. In the authors’ experience, the picture of parkinsonism with spastic weakness and other corticospinal signs has been the most frequent combination.
3. *Hereditary spastic paraplegia with optic atrophy* This is known as *Behr syndrome* or *optic atrophy-ataxia syndrome*, since cerebellar signs are usually con-
4. *Hereditary spastic paraplegia with macular degeneration (Kjellin syndrome)* Spastic paraplegia with amyotrophy, oligophrenia, and central retinal degeneration constitutes the syndrome described in 1959 by Kjellin. Although the developmental delay is stationary, the spastic weakness and retinal changes are of late onset and progressive. Mutations have been found in *SPG11* and *SPG15*.
5. *Hereditary spastic paraplegia with developmental delay or dementia* Many of the children with progressive spastic paraplegia either have been developmentally delayed since early life or have appeared to regress mentally as other neurologic symptoms developed. Examples of this syndrome and its variants are too numerous to be considered here but are contained in the review by Gilman and Romanul. The autosomal recessive syndrome of *Sjögren-Larsson*, with the onset in infancy of spastic weakness of the legs in association with developmental delay, stands somewhat apart from the others in this large group because of the associated ichthyosis. The mutation for the latter is in *ALDH3A2* that codes for fatty aldehyde dehydrogenase. This relates to both dry skin, itchy and discolored skin, and the myelinopathy that characterize *Sjögren-Larsson* syndrome.
6. *Hereditary spastic paraplegia with polyneuropathy* Our colleagues had observed several patients in whom a sensorimotor polyneuropathy was combined with unmistakable signs of corticospinal disease. The age of onset was in childhood or adolescence, and the disability progressed to the point where the patient was chairbound by early adult life. In two of the cases, a sural nerve biopsy revealed a typical hypertrophic polyneuropathy; in a third case there was only a depletion of large myelinated fibers. The syndrome resembles the myeloneuropathy of adrenoleukodystrophy.
7. *Spastic paraparesis with distal muscle wasting (Troyer syndrome)* This disorder is transmitted as an autosomal recessive trait in the Amish population. Onset is in childhood with amyotrophy of the hands, followed by spasticity and contractures of the lower limbs. Cerebellar signs (mild), athetosis, and deafness may be added. The mutation is in *SPG20*.

SYNDROME OF PROGRESSIVE BLINDNESS (See Chap. 13)

There are 2 main classes of progressive blindness in children, adolescents, and adults: progressive optic neuropathy and retinal degenerations (retinitis pigmentosa and tapetoretinal macular degeneration). Of course, there are many congenital anomalies and retinal diseases beginning

in infancy that result in blindness and microphthalmia. Some of those of neurologic interest were described briefly in connection with the hereditary spastic paraplegias and in Chap. 13.

Leber Hereditary Optic Atrophy

Although familial amaurosis was known in the early eighteenth century, it was Leber, in 1871, who gave the definitive description of this disease and traced it through many genealogies. The family studies of Nikoskelainen and coworkers indicate that all daughters of carrier mothers become carriers themselves, a type of transmission that is determined by inheritance of defective mitochondrial DNA from the mother (Wallace et al). Common to all cases is the presence of a pathogenic mitochondrial DNA abnormality (Riordan-Eva et al), but the defect may occur at one of several sites as discussed in Chap. 37. Thus, Leber optic atrophy has been added to the growing list of mitochondrial diseases. Mutations in approximately 20 genes have been detected, together accounting for about half of cases.

In most patients, the visual loss begins between 18 and 25 years of age, but the range of age of onset is much broader. Usually the visual loss has an insidious onset and a subacute evolution, but it may evolve rapidly, suggesting a retrobulbar neuritis; moreover, in these latter instances, aching in the eye or brow may accompany the visual loss, just as it does in the demyelinating variety. Subjective visual phenomena are reported by some. Usually both eyes are affected simultaneously, although in some one eye is affected first, followed by the other after an interval of several weeks or months. In practically all cases, the second eye is affected within a year of the first. In the unimpaired eye, abnormalities of visual evoked potentials may antedate impairment of visual acuity (Carroll and Mastaglia).

Once started, the visual loss progresses over a period of weeks to months. Characteristically, central vision is lost before peripheral, and there is a stage at which bilateral central scotomata are readily demonstrated. Early on, perception of blue-yellow is deficient, while that of red and green is relatively preserved. In the more advanced stages, however, the patients are totally color-blind. Constriction of the fields may be added later. At first there may be swelling and hyperemia of the discs, but soon they become atrophic. Peripapillary vasculopathy, consisting of tortuosity and arteriovenous shunting, is the primary structural change; this has been present also in asymptomatic offspring of carrier females.

As visual symptoms develop, fluorescein angiography shows shunting in the abnormal vascular bed, with reduced filling of the capillaries of the papillomacular bundle. Although patients are left with dense central scotomata, it is of some importance that the visual impairment is seldom complete; in some patients, relative stabilization of visual function occurs. In a few, there may be a surprising improvement.

Examination of the optic nerve lesion shows the central parts of the nerves to be degenerated from papillae to the lateral geniculate bodies, that is the papillomacular

bundles are particularly affected. Presumably axis cylinders and myelin degenerate together, as would be expected from the loss of nerve cells in the superficial layer of the retina. Both astrocytic glial and endoneurial fibroblastic connective tissue are increased. Tests for the 3 main mitochondrial mutations that give rise to the disorder are now available.

Congenital optic atrophy (of which recessive and dominant forms are known), retrobulbar neuritis, and nutritional optic neuropathy are the main considerations in differential diagnosis.

Retinitis Pigmentosa (See Chap. 13)

This remarkable retinal abiotrophy, known to Helmholtz in 1851, soon after he invented the ophthalmoscope, usually begins in childhood and adolescence. Unlike the optic atrophy of Leber, which affects only the third neuron of the visual neuronal chain, retinitis pigmentosa affects all the retinal layers, both the neuroepithelium and pigment epithelium (see Fig. 13-2). The incidence of this disorder is 2 or 3 times greater in males than in females. Inheritance is more often autosomal recessive than dominant; in the former, consanguinity plays an important part, increasing the likelihood of the disease by approximately 20 times. Sex-linked types are also known. It is estimated that 100,000 Americans are afflicted with this disease. Mutations in approximately 60 genes have been associated with the disorder but the most commonly affected in autosomal dominant cases is RHO; in recessive cases, USH2A, and in X-linked cases, RPGR and RP2.

The first symptom is usually an impairment of twilight vision (nyctalopia). Under dim light, the visual fields tend to constrict; but slowly, as the disease progresses, there is permanent visual impairment in all degrees of illumination. The perimacular zones tend to be the first and most severely involved, giving rise to partial or complete ring scotomata. Peripheral loss sets in later. Usually both eyes are affected simultaneously, but cases are on record where one eye was affected first and more severely. Ophthalmoscopic examination shows the characteristic triad of pigmentary deposits that assume the configuration of bone corpuscles, attenuated vessels, and pallor of the optic discs. The pigment is caused by clumping of epithelial cells that migrate from the pigment layer to the superficial parts of the retina as the rod cells degenerate. The pigmentary change spares only the fovea, so that eventually the world is perceived by the patient as though he were looking through narrow tubes.

The many and diverse syndromes to which retinitis pigmentosa may be linked include oligophrenia, obesity, syndactyly, and hypogonadism (Bardet-Biedl syndrome); hypogonadism, obesity, and mental deficiency (Laurence-Moon syndrome); Friedreich and other types of spinocerebellar and cerebellar ataxia; spastic paraplegia and quadriplegia with Laurence-Moon syndrome; neurogenic amyotrophy, myopia, and color-blindness; polyneuropathy and deafness (Refsum disease); deaf mutism; Cockayne syndrome and Bassen-Kornzweig

disease; and several mitochondrial diseases, particularly progressive external ophthalmoplegia and Kearns-Sayre syndromes.

Stargardt Disease

This is a bilaterally symmetrical, slowly progressive macular degeneration, differentiated from retinitis pigmentosa by Stargardt in 1909. In essence, it is a hereditary (usually autosomal recessive) tapetoretinal degeneration or dystrophy (the latter term being preferred by Waardenburg), with onset between 6 and 20 years of age, rarely later, and leading to a loss of central vision. The macular region becomes gray or yellow-brown with pigmentary spots, and the visual fields show central scotomata. Later the periphery of the retina may become dystrophic. The lesion is well visualized by fluorescein angiography, which discloses a virtually pathognomonic “dark choroid” pattern. Activity in the electroretinogram is diminished or abolished. Both recessively inherited Stargardt disease and the closely related cone-rod dystrophy have been linked to mutations of *ABCA4* or *ELOVL4* the former codes for a transporter protein (termed ABCR) of the photoreceptor.

This disease, with its selective loss of cone function, is in a sense the inverse of retinitis pigmentosa. According to Cohan and associates, it may be associated with epilepsy, Refsum syndrome, Kearns-Sayre syndrome, Bassen-Kornzweig syndrome, or Sjögren-Larsson syndrome, or with spinocerebellar and other forms of cerebellar degeneration and familial paraplegia.

SYNDROME OF CONGENITAL OR PROGRESSIVE DEAFNESS (See Chap. 15)

There is an impressive group of hereditary, progressive cochleovestibular atrophies that are linked to degenerations of the nervous system. These are the subject of an informative review by Konigsmark and are summarized below. Such neurotologic syndromes must be set alongside a group of 5 diseases that affect the auditory and vestibular nerves exclusively: dominant progressive nerve deafness; dominant low-frequency hearing loss; dominant midfrequency hearing loss; sex-linked, early-onset neural deafness; and hereditary episodic vertigo and hearing loss. The last of these is of special interest to neurologists because both balance and hearing are affected.

It should be pointed out that in 70 percent of cases of hereditary deafness, there are no other somatic or neurologic abnormalities. To date, 3 separate autosomal mutations have been identified that are associated with this pure “nonsyndromic” type of hereditary deafness, the most common of which is in the connexin gene, as discussed in Chap. 15. A number of mitochondrial disorders have been associated with deafness alone as well as with a number of the better-characterized mitochondrial syndromes (see Chap. 37). The age of onset of hearing loss in the pure forms has been variable, extending well into adulthood.

Hereditary Hearing Loss With Retinal Diseases

Konigsmark has separated this overall category into 3 subgroups: patients with typical retinitis pigmentosa, those with Leber optic atrophy, and those with other retinal changes. With respect to retinitis pigmentosa, 4 syndromes are recognized in which retinitis pigmentosa appears in combination: with congenital hearing loss (Usher syndrome); with polyneuropathy (Refsum syndrome); with hypogonadism and obesity (Alstrom syndrome); and with dwarfism, mental retardation, premature senility, and photosensitive dermatitis (Cockayne syndrome).

Hereditary hearing loss with optic atrophy forms the core of 4 special syndromes: dominant optic atrophy, ataxia, muscle wasting, and progressive hearing loss (Sylvester disease); recessive optic atrophy, polyneuropathy, and neural hearing loss (Rosenberg-Chutorian syndrome); optic atrophy, hearing loss, and juvenile diabetes mellitus (Tun-bridge-Paley syndrome); and optico-cochleodentate degeneration with optic atrophy, hearing loss, quadriparesis, and developmental delay (Nyssen-van Bogaert syndrome).

Hearing loss has also been observed with other retinal changes, two of which are Norrie disease, with retinal malformation, hearing loss, and mental retardation (oculoacousticocerebral degeneration), and Small disease, with recessive hearing loss, mental retardation, narrowing of retinal vessels, and muscle atrophy. In the former, the infant is born blind, with a white vascularized retinal mass behind a clear lens; later the lens and cornea become opaque. The eyes are small, and the iris is atrophied. In the latter, the optic fundi shows tortuosity of vessels, telangiectases, and retinal detachment. The nature of the progressive generalized muscular weakness has not been ascertained.

In this group should be included Susac syndrome, ostensibly a microvasculopathy that causes characteristic changes in the white matter of the cerebral hemispheres, retinal vasculopathy, and progressive deafness as discussed in Chap. 34. The later onset and progressive nature of deafness in this and several other syndromes are distinguished from forms of congenital deafness that are typical of the group discussed below.

Hereditary Hearing Loss with Diseases of the Nervous System (See Table 15-1)

There are numerous conditions, mostly of childhood and including developmental abnormalities, in which congenital deafness accompanies disease of the peripheral or central nervous system. Those associated with mitochondrial encephalopathies have already been mentioned. The other main types with autosomal inheritance include the following:

1. *Hereditary hearing loss with epilepsy* The seizure disorder is mainly one of myoclonus. In one dominantly inherited form, photomyoclonus is associated with mental deterioration, hearing loss, and nephropathy (Hermann disease). In May-White disease, also inherited as an autosomal dominant trait, myoclonus and

ataxia accompany hearing loss. Congenital deafness and mild chronic epilepsy of recessive type have also been observed (Latham-Monro disease).

2. *Hereditary hearing loss and ataxia* Here Konigsmark was able to delineate 5 syndromes, the first 2 of which show a dominant pattern of heredity, the last 3 a recessive pattern: piebaldism, ataxia, and neural hearing loss (Telfer-Sugar-Jaeger syndrome); hearing loss, hyperuricemia, and ataxia (Rosenberg-Bergstrom syndrome); ataxia and progressive hearing loss (Lichtenstein-Knorr syndrome); ataxia, hypogonadism, mental deficiency, and hearing loss (Richards-Rundle syndrome); ataxia, mental retardation, hearing loss, and pigmentary changes in the skin (Jeune-Tommasi syndrome).
3. *Hereditary hearing loss and other neurologic syndromes* These include dominantly inherited sensory radicular neuropathy (Denny-Brown); progressive polyneuropathy, kyphoscoliosis, skin atrophy, eye defects (myopia, cataracts, atypical retinitis pigmentosa), bone cysts, and osteoporosis (Flynn-Aird syndrome); chronic polyneuropathy and nephritis (Lemieux-Neemeh

syndrome); congenital pain asymbolia and auditory imperception (Osuntokun syndrome); and bulbo-pontine paralysis (facial weakness, dysarthria, dysphagia, and atrophy of the tongue with fasciculations) with progressive neural hearing loss. The onset of the last syndrome occurs at 10 to 35 years of age; the pattern of inheritance is autosomal recessive. The disease progresses to death. It resembles the progressive hereditary bulbar paralysis of Fazio-Londe except for the progressive deafness and loss of vestibular responses. Regrettably, in most of these syndromes, there are no data regarding labyrinthine function.

The details of these many syndromes are contained in Konigsmark's review, of course, in the era before the genetic underpinnings of these diseases were accessible. The main syndromes are listed in Table 15-1 and are summarized above so as to increase awareness of the large number of hereditary-degenerative neurologic diseases for which the clue is provided by the detection of impaired hearing and labyrinthine functions.

The Acquired Metabolic Disorders of the Nervous System

An important segment of neurologic medicine, and one that is seen with great frequency in general hospitals, are disorders in which a global disturbance of cerebral function (encephalopathy) results from failure of some other organ system—heart and circulation, lungs and respiration, kidneys, liver, pancreas, and the endocrine glands. Unlike the diseases considered in Chap. 37, in which a genetic abnormality affects the metabolic functions of many organs and tissues including the brain, the cerebral disorders discussed in this chapter are strictly secondary to derangements of the visceral organs themselves. They stand at the interface of internal medicine and neurology.

Relationships of this type, between an acquired disease of some thoracic, abdominal, or endocrine organ and the brain, have rather interesting implications. In the first place, recognition of the neurologic syndrome may be a guide to the diagnosis of the systemic disease; indeed, the neurologic symptoms may be more informative and significant than the symptoms referable to the organ primarily involved. Moreover, these encephalopathies are often reversible if the systemic dysfunction is brought under control. Neurologists must therefore have an understanding of the underlying medical disorder, for this may provide the means of controlling the neurologic part of the disease. In other words, the therapy for what appears to be a nervous system disease lies squarely in the field of internal medicine—a clear reason why every neurologist should be well trained in internal medicine. Of more theoretical importance, the investigation of the acquired metabolic diseases provides new insights into the chemistry and pathology of the brain. Each visceral disease affects the brain in a somewhat different way and, because the pathogenic mechanism is not completely understood in any of them, the study of these metabolic diseases promises rich rewards to the scientist.

Table 40-1 lists the main acquired metabolic diseases of the nervous system according to their most common modes of clinical expression. Not included are the diseases caused by nutritional deficiencies and those caused by exogenous drugs and toxins, which can be considered metabolic in the broad sense; these are discussed in the following chapters.

DISEASES PRESENTING AS CONFUSION, STUPOR, OR COMA (METABOLIC ENCEPHALOPATHY)

The syndrome of impaired consciousness, its general features, the terms used to describe it, and the mechanisms involved are discussed in Chap. 17. There it was pointed out that metabolic disturbances are frequent causes of impaired consciousness and that their presence must always be considered when there are no focal signs of cerebral disease and both the imaging studies and the cerebrospinal fluid (CSF) are normal.

Intoxication with alcohol and other drugs figures prominently in the differential diagnosis. *The main features of the reversible metabolic encephalopathies are confusion, typified by disorientation and inattentiveness and accompanied in certain special instances by asterixis, tremor, and myoclonus, usually without signs of focal cerebral disease.* This state may progress in stages to one of stupor and coma. Slowing of the background rhythms in the electroencephalogram (EEG) reflects the severity of the metabolic disturbance. With few exceptions, usually pertaining to cerebral edema and certain cases of hepatic encephalopathy, imaging studies are normal. Seizures may or may not occur, most being associated with particular underlying causes of encephalopathy such as hyponatremia and hyperosmolality.

Laboratory examinations are highly informative in the investigation of the acquired metabolic diseases. In patients with symptoms suggestive of a metabolic encephalopathy the following determinations are usually made: serum Na, K, Cl, Ca, Mg, glucose, HCO_3^- , renal function tests (blood urea nitrogen [BUN] and creatinine), liver function tests (aspartate aminotransferase [AST], alanine aminotransferase [ALT], bilirubin, NH_3), thyroid function tests (T_4 and thyroid-stimulating hormone [TSH]), and osmolality and, in certain cases, oxygen saturation and blood gas determinations. These are almost always supplemented by toxicology tests and measurement of the serum concentrations of relevant medications as discussed in the next chapter. Serum osmolality can be measured directly or calculated from

Table 40-1

CLASSIFICATION OF THE ACQUIRED METABOLIC DISORDERS OF THE NERVOUS SYSTEM IN ADULTS

- I. Metabolic diseases presenting as a syndrome of confusion, stupor, or coma
 - A. Ischemia-hypoxia
 - B. Hypercapnia
 - C. Hypoglycemia
 - D. Hyperglycemia
 - E. Hepatic failure
 - F. Reye syndrome
 - G. Azotemia
 - H. Disturbances of sodium, water balance, and osmolality
 - I. Hypercalcemia
 - J. Other metabolic encephalopathies: acidosis due to diabetes mellitus or renal failure (see also inherited forms of acidosis, in Chap. 37); Addison disease
 - K. Hashimoto disease steroid-responsive encephalopathy
 - L. Myxedema
- II. Metabolic diseases presenting as a progressive extrapyramidal syndrome
 - A. Acquired hepatocerebral degeneration
 - B. Hyperbilirubinemia and kernicterus
 - C. Hypoparathyroidism
- III. Metabolic diseases presenting as cerebellar ataxia
 - A. Hypothyroidism
 - B. Hyperthermia
 - C. Celiac sprue disease
- IV. Metabolic diseases causing psychosis, or dementia
 - A. Cushing disease and steroid encephalopathy
 - B. Hyperthyroid psychosis and hypothyroidism (myxedema)
 - C. Hyperparathyroidism
 - D. Pancreatic encephalopathy

the values of Na, glucose, and BUN (in mg/dL), using the following formula:

$$\text{OSM} = 2 \times \text{Na} + \text{glucose}/18 + \text{BUN}/3$$

Normal serum osmolality is 270 to 290 mOsm/L. When there is a discrepancy of greater than 10 mOsm/L between the calculated and the directly measured values (osmolal, or osmolar gap), it can be assumed that additional circulating ions are present. Most often they are derived from an exogenous toxin or drug such as mannitol, but renal failure, ketonemia, or an increase of serum lactate may result in the accumulation of small molecules that contribute to the measured serum osmolality.

A point to be remembered is that the brain may be damaged, even to an irreparable degree, by a disturbance of blood chemistry (e.g., hypoglycemia, hypoxia) that has vanished by the time the patient is examined.

Ischemic-Hypoxic Encephalopathy

Here the basic disorder is a lack of oxygen and of blood flow to the brain, the result of failure of the heart and circulation or of the lungs and respiration. Often, both are responsible and one cannot say which predominates; hence the dually ambiguous allusions in medical records to “ischemic-hypoxic” encephalopathy. This combined

encephalopathy in various forms and degrees of severity is one of the most frequent and disastrous cerebral disorders encountered in every general hospital.

Reduced to the simplest formulation, a deficient supply of oxygen to the brain is either the result of a failure of cerebral perfusion (ischemia) or of a reduced amount of circulating arterial oxygen, of diminished oxygen saturation, or of insufficiency of hemoglobin (hypoxia). Although they are often combined, the neurologic effects of ischemia and hypoxia are subtly different. The medical conditions that most often lead to it are as follows:

1. A global reduction in cerebral blood flow (myocardial infarction, ventricular arrhythmia, aortic dissection, external or internal blood loss, and septic or traumatic shock)
2. Hypoxia from suffocation (drowning, strangulation, or aspiration of vomitus, food, or blood; from compression of the trachea by a mass or hemorrhage; tracheal obstruction by a foreign body, or a general anesthesia accident)
3. As a subset of the above, diseases that paralyze the respiratory muscles (Guillain-Barré syndrome, amyotrophic lateral sclerosis, myasthenia, and, in the past, poliomyelitis) or damages the medulla and leads to failure of breathing
4. The special case of carbon monoxide (CO) poisoning (nonischemic hypoxia)

The product of blood oxygen content and the cardiac output is the ultimate determinant of the adequacy of oxygen supply to the organs. When blood flow is stable, the most important element in the delivery of oxygen is the oxygen content of the blood. This is the product of hemoglobin concentration and the percentage of oxygen saturation of the hemoglobin molecule. At normal temperature and pH, hemoglobin is 90 percent saturated at an oxygen partial pressure of 60 mm Hg and still 75 percent saturated at 40 mm Hg; i.e., as is well known, the oxygen saturation curve is not linear.

Physiology of Ischemic and Hypoxic Damage

A number of physiologic mechanisms of a homeostatic nature protect the brain under conditions of both ischemia and hypoxia. Through a mechanism termed *autoregulation*, there is a compensatory dilatation of resistance vessels in response to a reduction in cerebral perfusion, which maintains blood flow at a constant rate, as noted in Chap. 34. When the cerebral blood pressure falls below 60 to 70 mm Hg, an additional compensation in the form of increased oxygen extraction allows normal energy metabolism to continue. In total cerebral ischemia, the tissue is depleted of its sources of energy in about 5 min, although longer periods are tolerated under conditions of hypothermia. Also, energy failure because of hypoxia is counteracted by an autoregulatory increase in cerebral blood flow; at a P_{O_2} of 25 mm Hg, the increase in blood flow is approximately 400 percent. A similar increase in

flow occurs with a decrease in hemoglobin to 20 percent of normal.

In most clinical situations in which the brain is deprived of adequate oxygen, as already commented, there is a combination of ischemia and hypoxia, with one or the other predominating. The pathologic effects of ischemic brain injury from systemic hypotension differ from those caused by pure anoxia. Under conditions of transient ischemia, one pattern of damage takes the form of incomplete infarctions in the border zones between major cerebral arteries (Chap. 34). With predominant anoxia, neurons in portions of the hippocampus and the deep folia of the cerebellum are particularly vulnerable. More severe degrees of either ischemia or hypoxia, or the combination, lead to selective damage to certain layers of cortical neurons, and if more profound, to generalized damage of all the cerebral cortex, deep nuclei, and cerebellum. The nuclear structures of the brainstem and spinal cord are relatively resistant to anoxia and hypotension and stop functioning only after the cortex has been badly damaged.

The cellular pathophysiology of neuronal damage under conditions of ischemia is discussed in Chap. 34. One mechanism of injury is an arrest of the aerobic metabolic processes necessary to sustain the Krebs (tricarboxylic acid) cycle and the electron transport system. Neurons, if completely deprived of their source of energy, are unable to maintain their integrity and undergo necrosis. However, neuronal cell death occurs through more than one mechanism. The most acute forms of cell death are characterized by massive swelling and necrosis of neuronal and nonneuronal cells (cytotoxic edema). Short of immediate ischemic necrosis, a series of internally programmed cellular events may also propel the cell toward death in a delayed fashion, a process for which the term *apoptosis* has been borrowed from embryology. There is experimental evidence that certain excitatory neurotransmitters, particularly glutamate, contribute to the rapid destruction of neurons under conditions of anoxia and ischemia (Choi and Rothman); the pertinence of these effects to clinical situations is uncertain. Ultimately, this process may be affected by massive calcium influx through a number of different membrane channels, which activates various kinases that participate in the process of gradual cellular destruction. Free radical generation appears to play a role in membrane dissolution as a result of these processes. As shown in experimental models, one of the reasons for the irreversibility of ischemic lesions may be swelling of the endothelium and blockage of circulation into the ischemic cerebral tissues, the "no-reflow" phenomenon described by Ames and colleagues. There is also a poorly understood phenomenon of delayed neurologic deterioration after anoxia; this may be a result of the blockage or exhaustion of some enzymatic process during the period when brain metabolism is restored.

Clinical Features of Anoxic Encephalopathy

Mild degrees of hypoxia without loss of consciousness induce only inattentiveness, poor judgment, and incoordination; in our experience, there have been no lasting clinical effects in such cases, although Hornbein and colleagues

found a slight decline in visual and verbal long-term memory and mild aphasic errors in Himalayan mountaineers who had earlier ascended to altitudes of 18,000 to 29,000 ft. These observations make the point that profound anoxia may be well tolerated if arrived at gradually. For example, we have seen several patients with advanced pulmonary disease who were fully awake when their arterial oxygen pressure was in the range of 30 mm Hg. This level, if it occurs abruptly, causes coma. *An important derivative observation is that degrees of hypoxia that at no time abolish consciousness rarely, if ever, cause permanent damage to the nervous system.*

In the circumstances of *severe global ischemia with prolonged loss of consciousness*, the clinical effects can be quite variable. Following cardiac arrest, for example, consciousness is lost within seconds but recovery can be complete if breathing, oxygenation, and cardiac action are restored within 3 to 5 min. Beyond 5 min there is usually permanent injury. Clinically, however, it is often difficult to judge the precise degree and duration of ischemia, because slight heart action or an imperceptible blood pressure may have served to maintain the circulation to some extent. Hence some individuals have made an excellent recovery after cerebral ischemia that apparently lasted 8 to 10 min or longer. Subnormal body temperatures, as might occur when the body is immersed in ice-cold water, greatly prolong the tolerable period of hypoxia. This has led to the successful application of moderate cooling after cardiac arrest as a technique to limit cerebral damage (see further on in Treatment of Hypoxic-Ischemic Encephalopathy section).

Generally speaking, anoxic patients who demonstrate intact brainstem function as indicated by normal pupillary light and ciliospinal responses, induced by passive head turning (doll's eye movements), and other vestibulo-ocular reflexes have a more favorable outlook for recovery of consciousness and perhaps of all mental faculties. Conversely, the absence of these brainstem reflexes even after circulation and oxygenation have been restored, particularly pupils that fail to react to light, implies a grave outlook as elaborated further on. If the damage is almost total, coma persists, decerebrate postures may be present spontaneously or in response to painful stimuli, and bilateral Babinski signs can be evoked. In the first 24 to 48 h, death may terminate this state in a setting of rising temperature, deepening coma, and circulatory collapse, or the syndrome of brain death intervenes, as discussed below.

Most patients who have suffered *severe but lesser degrees of hypoxia* will have stabilized their breathing and cardiac activity by the time they are first examined; yet they are comatose, with the eyes slightly divergent and motionless but with reactive pupils, the limbs inert and flaccid or intensely rigid, and the tendon reflexes diminished. Within a few minutes after cardiac action and breathing have been restored, generalized convulsions and isolated or grouped myoclonic twitches may occur. Either of these phenomena are poor prognostic signs. With severe degrees of injury, the cerebral and cerebellar cortices and parts of the thalami are partly or completely

destroyed but the brainstem-spinal structures survive. Tragically, the individual may survive for an indefinite period in a state that is variously referred to as cortical death, irreversible coma, or *persistent vegetative state* (see discussion of these subjects in Chap. 17). Some patients remain mute, unresponsive, and unaware of their environment for weeks, months, or years. Long survival is usually attended by some degree of improvement but the patient appears to know nothing of his present situation and to have lost all past memories, cognitive function, and capacity for meaningful social interaction and independent existence (a *minimally conscious state*, actually a severe dementia; see Chap. 17). One has only to observe such patients and their families to appreciate the gravity of the problem, the family's anguish, and the tremendous expense of medical care. The only person who does not appear to suffer is the patient.

With *lesser degrees of anoxic-ischemic injury*, the patient improves after a period of coma lasting hours or less. Some of these patients quickly pass through this acute post-hypoxic phase and proceed to make a full recovery; others are left with varying degrees of permanent disability.

The findings on imaging studies vary. The most common early change in cases of severe injury is a loss of the distinction between the cerebral gray and white matter (Fig. 40-1); patients with this finding are invariably comatose and few awaken with a good neurologic outcome. With less severe and predominantly hypotensive-ischemic events such as cardiac arrest, watershed infarctions become evident in the border zones between the anterior, middle, and posterior cerebral arteries (Fig. 40-2). The clinical syndromes associated with watershed infarction are discussed below. Yet another pattern of brain destruction, seen at times also in CO poisoning, consists of striatal damage that is evident more by imaging than by clinical features (Fig. 40-3).

Brain Death Syndrome

(See Chap. 17 for a full discussion)

This represents the most severe degree of hypoxia, usually caused by circulatory arrest; it is manifest by a state of complete unawareness and unresponsiveness with abolition of all brainstem reflexes. Natural respiration cannot be sustained; only cardiac action and blood pressure are maintained. No electrical activity is seen in the EEG (it is isoelectric). At autopsy one finds that most, if not all, the gray matter of cerebral, cerebellar, and brainstem structures—and in some instances, even the upper cervical spinal cord—has been severely damaged.

One must always exercise caution in concluding that a patient has this form of irreversible brain damage, because anesthesia, intoxication with certain drugs, and hypothermia may also cause deep coma and an isoelectric EEG but permit recovery. Therefore it is often advisable to repeat the clinical and laboratory tests after an interval of a day or so, during which

Figure 40-1. CT without contrast infusion after 1 day cardiac arrest demonstrating the loss of distinction between gray and white matter throughout the cerebral hemispheres. The patient remained comatose and became vegetative.

Figure 40-2. Watershed infarction between the middle and posterior cerebral arteries after brief cardiac arrest. The patient had Balint syndrome.

Figure 40-3. T2-weighted MRI of striatal damage after anoxia from hanging. The pallidum is spared, in contrast to typical cases of carbon monoxide poisoning (see Fig. 40-5).

time the results of toxic screening also become available. The authors' experience corroborates the general notion that the vital functions of patients with the brain death syndrome usually cannot be sustained for more than several days; in other words, the problem settles itself. In exceptional cases, however, the provision of adequate fluid, vasopressors, and respiratory support allows preservation of the body in a comatose state for longer periods.

Posthypoxic Neurologic Syndromes

The permanent neurologic sequelae or *posthypoxic syndromes* observed most frequently are as follows:

1. *Persistent coma or stupor*, described above
2. With lesser degrees of cerebral injury, *dementia* with or without extrapyramidal signs
3. *Extrapyramidal (parkinsonian) syndrome with cognitive impairment* (discussed in relation to CO poisoning)
4. *Choreoathetosis*
5. *Cerebellar ataxia*
6. *Intention or action myoclonus (Lance-Adams syndrome)*
7. *An amnesic state*

If *hypoperfusion* dominates, the patient may also display the manifestations of watershed infarctions that are situated between the end territories of the major

cerebral vessels. The main syndromes that become evident soon after the patient awakens are:

1. *Visual agnosias including Balint syndrome and cortical blindness (Anton Syndrome)* (see Chap. 22), representing infarctions of the watershed between the middle and posterior cerebral arteries (see Fig. 40-2)
2. *Proximal arm and shoulder weakness*, sometimes accompanied by hip weakness (referred to as a "man-in-the-barrel" syndrome), reflecting infarction in the territory between the middle and anterior cerebral arteries. These patients are able to walk, but their arms dangle and their hips may be weak.

The two watershed syndromes may rarely coexist. The interested reader may consult the appropriate chapter in the text on neurologic intensive care by Ropper and colleagues for further details. There are also watershed areas in the spinal cord (Chap. 44).

Seizures may or may not be a problem, and they are often resistant to treatment. Well-formed motor convulsions are infrequent. Myoclonus is more common and may be intermixed with fragmentary convulsions. Myoclonus is a grave sign in most cases but it generally recedes after several hours or a few days. These movements are also difficult to suppress, as noted further on.

Delayed Postanoxic Encephalopathy and Leukoencephalopathy

This is a relatively uncommon and unexplained phenomenon. Initial improvement, which appears to be complete, is followed after a variable period of time (1 to 4 weeks in most instances) by a relapse, characterized by apathy, confusion, irritability, and occasionally agitation or mania. Most patients survive this second episode, but some are left with serious mental and motor disturbances (Choi; Plum et al). In still other cases, there appears to be progression of the initial neurologic syndrome with additional weakness, shuffling gait, diffuse rigidity and spasticity, sphincteric incontinence, coma, and death after 1 to 2 weeks. Exceptionally, there is yet another syndrome in which an episode of hypoxia is followed by slow deterioration, which progresses for weeks to months until the patient is mute, rigid, and helpless. In such cases, the basal ganglia are affected more than the cerebral cortex and white matter as in the case studied by our colleagues Dooling and Richardson. Instances have followed cardiac arrest, drowning, asphyxiation, and carbon monoxide poisoning.

The imaging features of the white matter disorder can be quite striking (Fig. 40-4). A mitochondrial disorder has been suggested, on uncertain grounds, as the underlying mechanism.

Prognosis of Hypoxic-Ischemic Brain Injury

(See also "Prognosis in Coma" in Chap. 17)

Several validated models have been developed to predict the outcome of anoxic-ischemic coma. All of them incorporate simple clinical features involving loss of motor, verbal, and pupillary functions in various combinations. The most often cited study of the prognostic aspects of coma following cardiac arrest is the one by Levy and colleagues

Figure 40-4. MRI fluid-attenuated inversion recovery (FLAIR) sequence of delayed postanoxic leukoencephalopathy in a patient who had recovered after drowning and deteriorated 2 weeks later.

of 210 patients, which provided the following guidelines: 13 percent of patients attained a state of independent function within 1 year; at the time of the initial evaluation, approximately 25 percent of patients had absent pupillary light reflexes, none of whom regained independent function; by contrast, the presence on admission of reactive pupils, eye movements, and any motor response, a configuration displayed in approximately 10 percent, was associated with a better prognosis in almost 50 percent of cases. The absence of neurologic function in any of these spheres at 1 day after cardiac arrest, unsurprisingly, was associated with an even poorer outcome. Similarly, Booth and colleagues analyzed previously published studies and determined that 5 clinical signs at 1 day after cardiac arrest predicted a poor neurologic outcome or death: (1) absent corneal responses, (2) absent pupillary reactivity, (3) no withdrawal to pain, and (4) the absence of any motor response. The use of somatosensory evoked potentials in the prognostication of coma is discussed in Chaps. 2 and 17.

Most workers in the field of coma studies have been unable to establish signs that confidently predict a good outcome. The role of somatosensory evoked potentials in prognosis of coma has been addressed in Chap. 17.

In any such case, concurrent intoxication must, of course, be excluded.

The question of what to do with patients in such states of protracted coma is a societal as much as a medical

problem. The neurologist can be expected to state the level and degree of brain damage, its cause, and the prognosis based on his own and published experience. One prudently avoids heroic, lifesaving therapeutic measures once the nature of this state has been determined with certainty.

Treatment of Hypoxic-Ischemic Encephalopathy

Treatment is directed initially to the prevention of further hypoxic injury. A clear airway is secured, cardiopulmonary resuscitation is initiated, and every second counts in their prompt utilization. Oxygen may be of value during the first hours but is probably of little use after the blood becomes well oxygenated. Once cardiac and pulmonary function are restored, there is experimental and clinical evidence that reducing cerebral metabolic requirements by inducing hypothermia may have a slight beneficial effect on outcome and may prevent the delayed worsening referred to above, though a recent clinical trial brings this into question (see further on). The use of high-dose barbiturates has not met with the same success.

Much attention was drawn to the randomized trials conducted by Bernard and colleagues and by the Hypothermia After Cardiac Arrest Study Group, of mild hypothermia applied to unconscious patients immediately after cardiac arrest. They reduced the core temperature to 33°C (91°F) within 2 h of the arrest and sustained this level for 12 h in the first trial, and between 32°C and 34°C for 24 h in the second study. Both trials demonstrated improved survival and better cognitive outcome in survivors, compared to leaving the patient in a normothermic state and this led to the development of guidelines and a change in clinical practice in the U.S. and elsewhere after 2002. The outcomes were evaluated by coarse measures of neurologic function. Implementing and sustaining hypothermia, either by external cooling, infusion of cooled normal saline, or intravenous cooling devices is difficult, and the iatrogenic problems of hypotension, bleeding, ventricular ectopy and infection have sometimes arisen, although this mild degree of temperature reduction is usually well tolerated. A third larger trial conducted by Nielsen and colleagues compared temperature maintenance after cardiac arrest at 33°C to maintenance of 36°C and found no difference in the rate of death or in neurological outcome. The results of this third study are still being discussed and it is not clear if it should be interpreted as demonstrating that hypothermic treatment is ineffective or if the avoidance of even mild hyperthermia, observed in the control groups of previous trials, was the important factor in improving outcome. At the time of this writing, it seems to us that induced hypothermia is not obligatory after cardiac arrest but that attempts should be made to keep the body temperature from rising above normal.

Vasodilator drugs, glutamate blockers, opiate antagonists, and calcium channel blockers have been of no proven benefit despite their theoretical appeal and some experimental successes. Corticosteroids ostensibly help to allay brain (possibly cellular) swelling, but, again, their therapeutic benefit has not been evident in clinical trials.

Seizures should be controlled by the methods indicated in Chap. 16. If convulsions are severe, continuous, and unresponsive to the usual medications, continuous infusion of a drug such as midazolam or propofol, and eventually the suppression of convulsions with neuromuscular blocking agents may be required. Often the seizures cease after a few hours and are replaced by polymyoclonus. For the latter, clonazepam, 8 to 12 mg daily in divided doses may be useful but the commonly used antiepileptic drugs have little effect. A state of spontaneous and stimulus-sensitive myoclonus as well as persistent limb posturing usually presages a poor outcome. The striking disorder of delayed movement-induced myoclonus and ataxic tremor that appear after the patient awakens from an anoxic episode (Lance-Adams myoclonus) is a special issue, which is discussed in Chap. 6. Its treatment usually requires the use of multiple medications. Fever is treated with antipyretics or a cooling blanket combined with neuromuscular paralyzing agents.

Carbon Monoxide Poisoning

Strictly speaking, CO is an exogenous toxin, but it is considered here because it produces a characteristic cerebral injury and is frequently associated with delayed neurologic deterioration. The extreme affinity of CO for hemoglobin (more than 200 times that of oxygen) drastically reduces the oxygen content of blood and subjects the brain to prolonged hypoxia and acidosis. Cardiac toxicity and hypotension generally follow. Whether CO also has a direct toxic action on neuronal components is not settled. The effects on the brain for the most part simulate those caused by cardiac arrest. Neurologists are likely to encounter instances of CO poisoning in burn units and in patients who have attempted suicide or have been exposed accidentally to a faulty furnace or to car exhaust in a closed garage. A contemporary review of the subject has been given by Weaver.

Early symptoms include headache, nausea, dyspnea, confusion, dizziness, and clumsiness. These occur when the carboxyhemoglobin level reaches 20 to 30 percent of total hemoglobin. Exposure to relatively low levels of CO from faulty furnaces and gasoline engines should be suspected as the cause of recurrent headaches and confusion that clear upon hospitalization or other change of venue. A cherry-red color of the skin may appear, but is actually an infrequent finding; cyanosis is more common. At slightly higher levels of carboxyhemoglobin, blindness, visual field defects, and papilledema develop, and levels of 50 to 60 percent are associated with coma, decerebrate or decorticate posturing, seizures in a few patients, and generalized slowing of the EEG rhythms. The initial CT scanning is normal or shows mild cerebral edema; later scans may show a characteristic lesion in the pallidum, as described below. Only if there has been associated hypotension does one see the same types of vascular borderzone infarctions that appear after cardiac arrest.

Delayed neurologic deterioration 1 to 3 weeks (sometimes much longer) after CO exposure occurs more frequently than with other forms of cerebral hypoxia. In Choi's survey, this feature was observed in 3 percent of

2,360 cases of CO poisoning and in 12 percent of those ill enough to be admitted to a hospital. Extrapyramidal features (parkinsonian gait and bradykinesia) predominated. Three-quarters of such patients were said to recover within a year. Discrete lesions centered in the globus pallidus bilaterally and sometimes the inner portion of the putamina are characteristic of CO poisoning that had produced coma (Fig. 40-5), but similar focal destruction may be seen after drowning, strangulation, and other forms of anoxia. The common feature among the delayed-relapse patients is a prolonged period of pure anoxia (before the occurrence of ischemia). Basal ganglia lesions may be quite prominent on CT scans even when delayed neurologic sequelae do not occur but they are invariably present between 1 and 4 weeks in patients who develop the delayed extrapyramidal syndrome. In less-severely affected patients we have seen such lesions resolve entirely on CT and MRI and there is no resultant movement disorder.

The initial treatment for carbon monoxide exposure is with inspired oxygen. Because the half-life of CO (normally 5 h) is greatly reduced by the administration of hyperbaric oxygen at 2 or 3 atmospheres, this additional treatment is recommended when the carboxyhemoglobin concentration is greater than 40 percent or in the presence of coma or seizures (Myers et al). According to a trial conducted by Weaver and colleagues, this treatment reduces

Figure 40-5. Unenhanced CT of the brain of a 30-year-old woman who attempted suicide by carbon monoxide inhalation. The only neurologic residua were a mild defect in retentive memory and areas of decreased attenuation in the pallidum bilaterally (arrows).

the incidence of cognitive sequelae from 46 to 25 percent. They administered 3 hyperbaric sessions in the first 24 h after exposure to CO.

High-Altitude (Mountain) Sickness

Acute mountain sickness is another special form of cerebral hypoxia. It occurs when a sea-level inhabitant abruptly ascends to a high altitude. Headache, anorexia, nausea and vomiting, weakness, and insomnia appear at altitudes above 8,000 ft; on reaching higher altitudes, there may be ataxia, tremor, drowsiness, mild confusion, and hallucinations. At 16,000 ft, according to Griggs and Sutton, 50 percent of individuals develop asymptomatic retinal hemorrhages, and it has been suggested that such hemorrhages also occur in the cerebral white matter. Extreme altitude sickness may result in fatal cerebral edema. The overexpression of vascular endothelial growth factor (VEGF), a protein originally noted for its effects on vascular permeability, has been implicated as the cause of cerebral edema in the experiments of Schoch and colleagues. With more prolonged exposure at these altitudes or with further ascent, affected individuals suffer mental impairment that may progress to coma. Hypoxemia at high altitudes is intensified during sleep, as ventilation normally diminishes and also by pulmonary edema, another manifestation of mountain sickness. Reference was made earlier to the observation of Hombein and colleagues of a mild, but possibly lasting, memory impairment even in acclimated mountaineers who had been exposed to extremely high altitudes for several days. Hackett and Roach have reviewed the treatments for altitude illness.

Chronic mountain sickness, also called Monge disease (after the physician who described the condition in Andean Indians of Peru), is observed in long-term inhabitants of high-altitude mountainous regions. Pulmonary hypertension, cor pulmonale, and secondary polycythemia are the main features. There is usually hypercarbia as well, with the expected degree of mild mental dullness, slowness, fatigue, nocturnal headache, and, sometimes, papilledema (see below). Thomas and colleagues have called attention to a syndrome of burning hands and feet in Peruvians at high altitude, apparently a maladaptive response to chronic hypoxia.

Sedatives, alcohol, and a slightly elevated P_{CO_2} in the blood all reduce tolerance to high altitude. Dexamethasone and acetazolamide prevent and counteract mountain sickness to some extent. The most effective preventive measure is acclimatization by a 2- to 4-day stay at intermediate altitudes.

Hypercapnic Pulmonary Disease

Chronic obstructive pulmonary disease such as emphysema, fibrosing lung disease, neuromuscular weakness, and, in some instances, inadequacy of the medullary respiratory centers each may lead to persistent respiratory acidosis, with elevated P_{CO_2} and reduced in arterial P_{O_2} . The complete clinical syndrome of chronic hypercapnia described by Austen, Carmichael, and

Adams comprises *headache, papilledema, mental dullness, drowsiness, confusion, stupor and coma, and asterixis*. More typically, only some of these features are found. Some patients have a fast-frequency tremor. The headache tends to be generalized, frontal, or occipital and can be quite intense, persistent, steady, and aching in type; nocturnal occurrence is a feature of some cases. The papilledema is bilateral but may be slightly greater in one eye than in the other, and hemorrhages may encircle the choked disc (a later finding). The tendon reflexes are lively and plantar reflexes may be extensor. Intermittent drowsiness, inattentiveness, reduction of psychomotor activity, inability to perceive all the items in a sequence of events, and forgetfulness constitute the more subtle manifestations of this syndrome and may prompt the family to seek medical help. Such symptoms may last only a few minutes or hours, and one cannot count on their presence at the time of a particular examination. In fully developed cases, the CSF is under increased pressure; P_{CO_2} may exceed 75 mm Hg, and the O_2 saturation of arterial blood ranges from 85 percent to as low as 40 percent. The EEG shows slow activity in the delta or theta range, which is sometimes bilaterally synchronous.

The mechanism of the cerebral disorder is from a direct CO_2 narcosis, but the biochemical details are not known. Normally the CSF is slightly acidotic in comparison to the blood and the P_{CO_2} of the CSF is about 10 mm Hg higher than that of the blood. With respiratory acidosis, the pH of the CSF falls (into the range of 7.15 to 7.25) and cerebral blood flow increases as a result of cerebral vasodilatation. However, the brain rapidly adapts to respiratory acidosis through the generation and secretion of bicarbonate by the choroid plexuses. Brain water content also increases, mainly in the white matter. In animal models of hypercarbia, blood and brain NH_3 is elevated, which may explain the similarity of the syndrome to that of hyperammonemic liver failure (Herrera and Kazemi).

The most effective therapeutic measures are positive-pressure ventilation, using oxygen if there is also hypoxia. Oxygen supplementation is, of course, used cautiously in these patients in order to avoid suppressing respiratory drive; marginally compensated patients treated with excessive oxygen have lapsed into coma. Treatment of heart failure, phlebotomy to reduce the viscosity of the blood, and antibiotics to suppress pulmonary infection may be necessary. Often these measures result in a surprising degree of improvement, which may be maintained for months or years.

Unlike pure hypoxic encephalopathy, prolonged coma because of hypercapnia is relatively rare and in our experience has not led to irreversible brain damage. Papilledema, myoclonus, and especially asterixis are important diagnostic features. If aminophylline is administered for the treatment of the underlying pulmonary airway disease, it may produce high blood levels and a tendency for it to produce seizures.

Hypoglycemic Encephalopathy

This condition is now relatively infrequent but is an important cause of confusion, convulsions, stupor, and coma; as

such, it merits separate consideration as a metabolic disorder of the brain. The essential biochemical abnormality is a critical lowering of the blood glucose. At a level of about 30 mg/dL, the cerebral disorder takes the form of a confusional state and one or more seizures may occur; at a level of 10 mg/dL, there is coma that may result in irreparable injury to the brain if not corrected immediately by the administration of glucose. As with most other metabolic encephalopathies, the rate of decline of blood glucose is a factor in both the depression of consciousness and residual dementia.

The normal brain has a glucose reserve of 1 to 2 g (30 mmol/100 g of tissue), mostly in the form of glycogen. Because glucose is utilized by the brain at a rate of 60 to 80 mg/min, the glucose reserve may sustain cerebral activity for 30 min or less once blood glucose is no longer available. Glucose is transported from the blood to the brain by an active carrier system. Glucose entering the brain either undergoes glycolysis or is stored as glycogen. During normal oxygenation (aerobic metabolism), glucose is converted to pyruvate, which enters the Krebs cycle; with anaerobic metabolism, lactate is formed. The oxidation of 1 mole of glucose requires 6 mole of O_2 . Of the glucose taken up by the brain, 85 to 90 percent is oxidized; the remainder is used in the formation of proteins and other substances, notably neurotransmitters and particularly gamma-aminobutyric acid (GABA).

When blood glucose falls, the central nervous system (CNS) can utilize nonglucose substrates to a variable extent for its metabolic needs, especially keto acids and intermediates of glucose metabolism, such as lactate, pyruvate, fructose, and other hexoses. In the neonatal brain, which has a higher glycogen reserve, keto acids provide a considerable proportion of cerebral energy requirements; this also happens after prolonged starvation. However, in the face of severe and sustained hypoglycemia, these alternative substrates are inadequate to preserve the structural integrity of neurons, and eventually adenosine triphosphate (ATP) is depleted as well. If convulsions occur, they usually do so during a period of confusion; the convulsions have been attributed to an altered integrity of neuronal membranes and to elevated NH_3 and depressed GABA and lactate levels (Wilkinson and Prockop).

The brain is the only organ besides the heart that suffers severe functional and structural impairment under conditions of severe hypoglycemia. Beyond what is described above, the pathophysiology of the cerebral disorder has not been fully elucidated. It is known that hypoglycemia reduces O_2 uptake and increases cerebral blood flow. As with anoxia and ischemia, there is experimental evidence that the excitatory amino acid glutamate is involved in the process. The levels of several brain phospholipid fractions decrease when animals are given large doses of insulin. However, the suggestion that hypoglycemia results in a rapid depletion and inadequate production of high-energy phosphate compounds has not been corroborated; some other glucose-dependent biochemical processes must be implicated.

Etiology

The most common causes of hypoglycemic encephalopathy are: (1) accidental or deliberate overdose of insulin or an oral diabetic agent; (2) islet cell insulin-secreting tumor of the pancreas; (3) depletion of liver glycogen, which occasionally follows a prolonged alcoholic binge, starvation, or any form of severe liver failure; (4) glycogen storage disease of infancy; and (5) an idiopathic hypoglycemia in the neonatal period and infancy; (6) subacute and chronic hypoglycemia from islet cell hypertrophy and islet cell tumors of the pancreas, carcinoma of the stomach, fibrous mesothelioma, carcinoma of the cecum, and hepatoma. Purportedly, an insulin-like substance is elaborated by these nonpancreatic tumors. In the past, hypoglycemic encephalopathy was a not infrequent complication of "insulin shock" therapy for schizophrenia. In functional hyperinsulinism, as occurs in anorexia nervosa and dietary faddism, the hypoglycemia is rarely of sufficient severity or duration to damage the CNS.

Clinical Features

The initial symptoms appear when the blood glucose has descended to about 30 mg/dL, nervousness, hunger, flushed facies, sweating, headache, palpitation, trembling, and anxiety. These gradually give way to confusion and drowsiness or occasionally, to excitement, overactivity, and bizarre or combative behavior. Many of the early symptoms relate to adrenal and sympathetic overactivity and some of the manifestations may be muted in diabetic patients with neuropathy. In the next stage, forced sucking, grasping, motor restlessness, muscular spasms, and decerebrate rigidity occur, in that sequence. Myoclonic twitching and convulsions develop in some patients. Rarely, there are focal cerebral deficits, the pathogenesis of which remains unexplained; according to Malouf and Brust, hemiplegia, corrected by intravenous glucose, was observed in 3 of 125 patients who presented with symptomatic hypoglycemia.

Blood glucose levels of approximately 10 mg/dL are associated with deep coma, dilatation of pupils, pale skin, shallow respiration, slow pulse and hypotonia, what had in the past been termed the "medullary phase" of hypoglycemia. If glucose is administered before this level has been attained, the patient can be restored to normal, retracing the aforementioned steps in reverse order. However, once this state is reached, and particularly if it persists for more than a few minutes, recovery is delayed for a period of days or weeks and may be incomplete as noted below.

The EEG is altered as the blood glucose falls, but the correlations are imprecise. There is diffuse slowing in the theta or delta range. During recovery, sharp waves may appear and coincide in some cases with seizures.

The major clinical differences between hypoglycemic and hypoxic encephalopathy lie in the setting and the mode of evolution of the neurologic disorder. The effects of hypoglycemia usually unfold more slowly, over a period of 30 to 60 min, rather than in a few seconds or minutes. The recovery phase and sequelae of the 2 conditions are quite similar.

A large dose of insulin, which produces intense hypoglycemia, even of relatively brief duration (30 to 60 min), is more dangerous than a series of less-severe hypoglycemic episodes from smaller doses of insulin, possibly because the former impairs or exhausts essential enzymes, a condition that cannot then be overcome by large quantities of intravenous glucose. Reflecting the benignity of repeated minor occurrences, the Epidemiology of Diabetes Interventions and Complications Study Research Group have demonstrated that recurrent hypoglycemic episodes in the course of treatment of diabetes over many years are very well tolerated and do not lead to cognitive decline.

A severe and prolonged episode of hypoglycemia may result in permanent impairment of intellectual function as well as other neurologic residua, like those that follow severe anoxia. We also have observed states of protracted coma, as well as relatively pure Korsakoff amnesia. However, one should not be hasty in prognosis, for we have observed slow improvement to continue for 1 to 2 years.

Recurrent hypoglycemia from an islet cell tumor may masquerade for some time as an episodic confusional psychosis or convulsive illness; diagnosis then awaits the demonstration of low blood glucose or hyperinsulinism in association with the neurologic symptoms. We saw a man in the emergency department whose main complaint was episodic inability to dial a touchtone telephone and a mild mental foginess; he was found to have an insulinoma.

Functional or reactive hypoglycemia is the most ambiguous of all syndromes related to low blood glucose. This condition is usually idiopathic but may precede the onset of diabetes mellitus. The rise of insulin in response to a carbohydrate meal is delayed but then causes an excessive fall in blood glucose, to 30 to 40 mg/dL. The symptoms are malaise, fatigue, nervousness, headache and tremor, which may be difficult to distinguish from anxious depression. Not surprisingly, the term *functional hypoglycemia* has been much abused, being applied indiscriminately to a variety of complaints that would now be called chronic fatigue syndrome or an anxiety syndrome. In fact, a syndrome attributable to functional or reactive hypoglycemia is infrequent and its diagnosis requires the finding of an excessive reaction to insulin, low blood glucose during the symptomatic period, and a salutary response to oral glucose.

In all forms of hypoglycemic encephalopathy, the major damage is to the cerebral cortex. Cortical nerve cells degenerate and are replaced by microglia cells and astrocytes. The distribution of lesions is similar, although probably not identical to that in hypoxic encephalopathy. The cerebellar cortex is less vulnerable to hypoglycemia than to hypoxia. Auer has described the ultrastructural changes in neurons resulting from experimental hypoglycemia; with increasing duration of hypoglycemia and EEG silence, there are mitochondrial changes, first in dendrites and then in nerve cell soma, followed by nuclear membrane disruption leading to cell death.

Treatment of all forms of hypoglycemia obviously consists of correction of the hypoglycemia at the earliest

possible moment. It is not known whether hypothermia or other measures will increase the safety period in hypoglycemia or alter the outcome. Seizures and twitching may not stop with antiepileptic drugs until the hypoglycemia is corrected.

Hyperglycemia

Two syndromes have been defined, mainly in diabetics: (1) hyperglycemia with ketoacidosis and (2) hyperosmolar nonketotic hyperglycemia.

In *diabetic acidosis*, the familiar picture is one of dehydration, fatigue, weakness, headache, abdominal pain, dryness of the mouth, stupor or coma, and Kussmaul type of breathing. Usually the condition has developed over a period of days in a patient known or proven to be diabetic. Often, the patient had failed to take a regular insulin dose. The blood glucose level is found to be more than 400 mg/dL, the pH of the blood less than 7.20, and the bicarbonate less than 10 mEq/L. Ketone bodies and β -hydroxybutyric acid are elevated in the blood and urine, and there is marked glycosuria. The prompt administration of insulin and repletion of intravascular volume correct the clinical and chemical abnormalities over a period of hours.

A small group of patients with diabetic ketoacidosis, such as those reported by Young and Bradley, develop deepening coma and cerebral edema as the elevated glucose is corrected. Mild cerebral edema is commonly observed in children during treatment with fluids and insulin (Krane et al). Prockop attributed this condition to an accumulation of fructose and sorbitol in the brain. The latter substance, a polyol that is formed during hyperglycemia, crosses membranes slowly, but once it does so, is said to cause a shift of water into the brain and an intracellular edema. However, according to Fishman (1974), the increased polyols in the brain in hyperglycemia are not present in sufficient concentration to be important osmotically; though they may induce other metabolic effects related to the encephalopathy. These are matters of conjecture, as the increase of polyols has never been found. The brain edema in this condition is probably a result of reversal of the osmolality gradient from blood to brain, which occurs with rapid correction of hyperglycemia.

The pathophysiology of the cerebral disorder in diabetic ketoacidosis is not fully understood. No consistent cellular pathology of the brain has been identified in the cases we have examined. Factors such as ketosis, tissue acidosis, hypotension, hyperosmolality, and hypoxia have not been identified. Attempts at therapy by the administration of urea, mannitol, salt-poor albumin, and dexamethasone are usually unsuccessful, though recoveries are reported.

In *hyperosmolar nonketotic hyperglycemia*, the blood glucose is extremely high, more than 600 mg/dL, but ketoacidosis does not develop, or if it does develop, it is mild. Osmolality is usually in excess of 330 mOsm/L. There is also hemoconcentration and prerenal azotemia. Appreciation of the neurologic syndrome is generally credited to Wegierko, who published descriptions of it in

1956 and 1957. Most of the patients are elderly diabetics but some were not previously known to have been diabetic. An infection, enteritis, pancreatitis, dehydration, or a drug known to upset diabetic control (thiazides, corticosteroids, and phenytoin) leads to polyuria, fatigue, confusion, stupor, and coma. Often the syndrome arises in conjunction with the combined use of corticosteroids and phenytoin (which inhibits insulin release), for example, in elderly patients with brain tumors. The use of osmotic diuretics enhances the risk.

Seizures and focal signs such as a hemiparesis, a hemisensory defect, choreoathetosis, or a homonymous visual field defect are more common than in any other metabolic encephalopathy and may erroneously suggest the possibility of a stroke. Fluids should be replaced cautiously, using isotonic saline and potassium. Correction of the markedly elevated blood glucose requires relatively small amounts of insulin, since these patients often do not have a high degree of insulin resistance.

Hepatic Stupor and Coma (Hepatic, or Portal–Systemic Encephalopathy)

Chronic hepatic insufficiency with portosystemic shunting of blood is punctuated by episodes of stupor, coma, and other neurologic symptoms—a state referred to as *hepatic stupor, coma, or encephalopathy*. It was clearly delineated by Adams and Foley over 50 years ago. This state complicates all varieties of liver disease and is unrelated to jaundice or ascites. Any form of shunting, even without hepatic disease, such as surgical portal–systemic shunt (Eck fistula) is attended by the same clinical picture (see further on). There are also a number of hereditary hyperammonemic syndromes, usually first apparent in infancy or childhood (discussed extensively in Chap. 37) that lead to episodic coma with or without seizures. In all these states, it is common for an excess of protein derived from the diet or from gastrointestinal hemorrhage to induce or worsen the encephalopathy. Additional predisposing factors are hypoxia, hypokalemia, metabolic alkalosis, excessive diuresis, use of sedative hypnotic drugs, and constipation. A special form of the syndrome in epilepsy patients exposed to valproate; confusion and ataxia may occur acutely or subacutely in these patients (Gomcella et al). Reye syndrome following viral infections in children, now infrequent, was also associated with very high levels of ammonia in the blood and encephalopathy (see further on).

Clinical Features

The clinical picture of acute, subacute, or chronic hepatic encephalopathy consists of a derangement of consciousness, presenting first as mental slowing and confusion, occasionally with hyperactivity, followed by progressive drowsiness, stupor, and coma. The confusional state is combined with a characteristic intermittency of sustained muscle contraction; this phenomenon, which was originally described in patients with hepatic stupor by Adams and Foley and called *asterixis* (from the Greek *sterixis*, a “fixed position”). It is now recognized as a sign of various metabolic encephalopathies but is most prominent in this

disorder (see Chap. 6). It is conventionally demonstrated by having the patient hold his arms outstretched with the wrists extended, but the same tremor can be elicited by any sustained posture, including that of the protruded tongue. We have seen patients in whom asterixis of the large antigravity muscles (e.g., iliopsoas or quadriceps) causes falling. A variable, fluctuating rigidity of the trunk and limbs, grimacing, suck and grasp reflexes, exaggeration or asymmetry of tendon reflexes, Babinski signs, and focal or generalized seizures round out the clinical picture in a few patients.

The EEG is a sensitive and reliable indicator of impending coma, becoming abnormal during the earliest phases of the disordered mental state. Foley, Watson, and Adams noted an EEG abnormality consisting of paroxysms of bilaterally synchronous slow or triphasic waves in the delta range, which at first predominate frontally and are interspersed with alpha activity and later, as the coma deepens, displace all normal activity (see Fig. 2-5H). A few patients show only random high-voltage asynchronous slow waves.

This syndrome of hepatic encephalopathy is remarkably diverse in its course and evolution. It usually appears over a period of days to weeks and may terminate fatally; or, with appropriate treatment, the symptoms may regress and then fluctuate in severity for several weeks or months. Persistent hepatic coma of the latter type proves fatal in about half of patients (Levy et al). In many patients, the syndrome is relatively mild and does not evolve beyond the stage of mental dullness and confusion, with asterixis and EEG changes. In yet others, a subtle disorder of mood, personality, and intellect may be protracted over a period of many months or even years; this chronic but nevertheless reversible mental disturbance need not be associated with overt clinical signs of liver failure (jaundice and ascites) or other neurologic signs. Characteristically in these patients, an extensive portal–systemic collateral circulation can be demonstrated (hence the term *portal–systemic encephalopathy*) and an association established between the mental disturbance and an intolerance to dietary protein as well as raised blood ammonia levels (Summerskill et al).

The diversion of blood from the portal system into the vena cava after ligation of the portal veins was first performed in dogs by Eck in 1877. Probably the first and certainly most striking example in man was the case of pure “Eck” fistula reported by McDermott and Adams, in which a portacaval shunt was created during the removal of a pancreatic tumor. The liver was normal. Episodic coma occurred thereafter whenever dietary protein increased. Consciousness was restored on a protein-free diet, and coma could be induced again by ammonium chloride. Postmortem examination 2 years later confirmed the normal liver and showed cerebral changes of hepatic encephalopathy, as described below.

Finally, there is a group of patients (most of whom have experienced repeated attacks of hepatic coma) in whom an *irreversible* mild dementia and a disorder of posture and movement (grimacing, tremor, dysarthria, ataxia of gait, choreoathetosis) gradually appear. This condition of *chronic acquired hepatocerebral degeneration*

must be distinguished from other dementing and extrapyramidal syndromes (see further on). A few cases of isolated spastic paraplegia (so-called *hepatic myelopathy*, or more correctly *hepatic paraplegia*) have been described. Pant and Richardson attributed the syndrome to a loss of Betz cells in the frontal cortex; in other words, a restricted encephalopathy seen in some patients with portal-systemic encephalopathy. Indeed, the spasticity of the legs, increased tendon reflexes, and Babinski signs that are found with PSE, suggest that “hepatic paraparesis” is a common feature of the encephalopathy.

MRI in PSE often demonstrates high signal intensity in the globus pallidus, likely the result of manganese deposition.

The concentrations of blood NH_3 , particularly if measured repeatedly in arterial blood samples, usually are well in excess of 200 mg/dL, and the severity of the neurologic and EEG disorders roughly parallels to the ammonia levels. With treatment, a fall in the NH_3 levels precedes clinical improvement.

Neuropathologic Changes

The striking finding by Adams and Foley in patients who died in a state of hepatic coma was a diffuse increase in the number and size of the protoplasmic astrocytes in the deep layers of the cerebral cortex, lenticular nuclei, thalamus, substantia nigra, cerebellar cortex, and red, dentate, and pontine nuclei, with little or no visible alteration in the nerve cells or other parenchymal elements. With periodic acid-Schiff (PAS) staining, the astrocytes were seen to contain glycogen inclusions. These abnormal glia cells are generally referred to as Alzheimer type II astrocytes, having been described originally in 1912 by von Hosslin and Alzheimer in a patient with Westphal-Strümpell pseudosclerosis (or Wilson disease). These astrocytes have been studied by electron microscopy in rats with surgically created portacaval shunts (Cavanagh; Norenberg); the cells show a number of striking abnormalities—swelling of their terminal processes, cytoplasmic vacuolation (distended sacs of rough endoplasmic reticulum), formation of folds in the basement membrane around capillaries, and an increase in both the number of mitochondria and enzymes that catabolize ammonia. Also, some degeneration in myelinated nerve fibers in the neuropil and an increase in the cytoplasm of oligodendrocytes are seen. In chronic cases, neuronal loss in the deep layers of the cerebral and cerebellar cortex and lenticular nuclei is found, as well as vacuolization of tissue (possibly astrocytic) resembling the lesions of Wilson disease.

The ubiquitous astrocytic alterations occur to some degree in all patients who die of progressive liver failure and the degree of glial abnormality corresponds generally to the intensity and duration of the neurologic disorder. Possibly, the astrocytic changes affect the synaptic activities of the neurons. The clinical and EEG features of hepatic encephalopathy as well as the astrocytic hyperplasia are more or less specific features of this metabolic disorder. Nevertheless, taken together in a setting of liver failure, they constitute a distinctive clinicopathologic entity.

Pathogenesis of Hepatic Encephalopathy

The most plausible hypothesis relates hepatic coma to an abnormality of nitrogen metabolism, wherein ammonia, which is formed in the bowel by the action of urease-containing organisms on dietary protein, is carried to the liver in the portal circulation but fails to be converted into urea because of hepatocellular disease, portal–systemic shunting of blood, or both. As a result, excess NH_3 reaches the systemic circulation, where it interferes with cerebral metabolism in a way that is not fully understood. The ammonia theory best explains the basic neuropathologic change. Because the brain is lacking in urea cycle enzymes, Norenberg has proposed that the hypertrophy of the astrocytic cytoplasm and proliferation of mitochondria and endoplasmic reticulum, as well as the increase in the astroglial glutamic dehydrogenase activity, all reflect heightened metabolic activity of these systems within astrocytes associated with ammonia detoxification. Removal of brain ammonia depends on the formation of glutamine, a reaction that is catalyzed by the ATP-dependent enzyme glutamine synthetase, which is compartmentalized to astrocytes. It has been shown in experimental animals that hyperammonemia leads to a depletion of ATP in midbrain reticular nuclei. Whether this is the primary cause of cerebral dysfunction has not been resolved.

Numerous alternative theories have been suggested. One is that CNS function in cirrhotic patients is impaired by phenols or short-chain fatty acids derived from the diet or from bacterial metabolism of carbohydrate. Another theory holds that biogenic amines (e.g., octopamine), which arise in the gut and bypass the liver, act as false neurotransmitters, displacing norepinephrine and dopamine (Fischer and Baldessarini). Zieve has presented evidence that mercaptans (methanethiol, methionine), which are also generated in the gastrointestinal tract and removed by the liver, act in conjunction with NH_3 to produce hepatic encephalopathy. This theory and others have been largely discounted; they are the subject of reviews by Butterworth and coworkers, by Zieve, by Rothstein and Herlong, and by Jones and Basile, to which the reader is referred for detailed information.

Also, manganese has emerged as a potential neurotoxin in the pathogenesis of hepatic encephalopathy (Kreiger et al; Pomier-Layrargues et al). In patients with chronic liver disease and with spontaneous or surgically induced portal–systemic shunts, manganese accumulates in the serum and in the brain, more specifically in the pallidum. This accumulation is readily discernible as a pallidal signal hyperintensity on T1-weighted MRI. Following liver transplantation, there is normalization of the MRI changes and of the associated extrapyramidal symptoms. The effects of manganese chelation on such patients have not been well studied and the mechanisms of accumulated manganese in the pathogenesis of hepatic encephalopathy are not known. It is clear, therefore, that any theory of hepatic encephalopathy must incorporate the cerebral effects of hyperammonemia.

For some time, it has been known that hepatic encephalopathy is associated with increased activity of

the inhibitory transmitter GABA in the cerebral cortex. It has also been observed that increased gabanergic neurotransmission may result from substances that inhibit the binding of endogenous benzodiazepine-like compounds to their receptors (Basile et al). Furthermore, these antagonists are found to have some clinical effect—transient arousal in patients with hepatic encephalopathy. The actions of benzodiazepines are mediated by these receptors; hence the designation *GABA-benzodiazepine theory*. The practicality of using benzodiazepine receptor antagonists, which are short-acting and reversible (e.g., flumazenil) in the treatment of hepatic encephalopathy, remains to be determined (see Mullen), but they offer an interesting diagnostic test.

Until recently, the ammonia and the gabanergic-benzodiazepine hypotheses of the pathogenesis of hepatic encephalopathy had appeared to be unrelated. However, there is evidence, reviewed by Jones and Basile, that ammonia, even in the modestly elevated concentrations that occur in liver failure, inhibits metabolism of GABA by the astrocytes and enhances gabanergic neurotransmission—a concept that unifies hyperammonemia and the neurotransmitter change. Furthermore, the aforementioned glial abnormality may be the explanation for the disorder of the blood-brain barrier that leads to the brain swelling that is seen in some rapidly developing cases of PSE, the prototype for which is the now infrequent Reye syndrome. A parallel astrocytic dysfunction may lead to disruption of the blood-brain barrier and the brain swelling that is known to occur in cases of acute liver failure.

Treatment

Despite the incompleteness of our understanding of the role of disordered ammonia metabolism in the genesis of hepatic coma, an awareness of this relationship has provided the few effective means of treating this disorder: restriction of dietary protein; reduction of bowel flora by oral administration of neomycin or kanamycin, which suppresses the urease-producing organisms in the bowel; and the use of enemas. The mainstay of treatment has been oral lactulose, an inert sugar that is metabolized by colonic bacteria that produce hydrogen ions and shifts ammonia to ammonium, a nontoxic product that is eliminated in the stool. The past use of oral neomycin carried a risk of renal damage and ototoxicity and has therefore been replaced by rifaximin, a minimally absorbed antibiotic that has less risk. This antibiotic has also been shown by Bass and coworkers to be highly effective in preventing episodic hepatic encephalopathy in tenuously compensated patients. The salutary effect of these therapeutic measures, the common attribute of which is the lowering of the blood NH_3 , further supports the theory of ammonia intoxication. Ultimately, in cases of intractable liver failure, transplantation becomes a treatment of last resort.

Other treatments with lesser value include bromocriptine, the aforementioned diazepam antagonist flumazenil, and keto analogues of essential amino acids. Theoretically, the keto analogues should provide a nitrogen-free source of essential amino acids (Maddrey et al), a treatment that has been largely abandoned, and bromocriptine, a

dopamine agonist, should enhance dopaminergic transmission (Morgan et al) but its mechanism is not known. Administration of branched-chain amino acids may result in improvement in mental status but their effects have been variable and associated with an increased mortality (Naylor et al). The transient beneficial effect of the benzodiazepine antagonist flumazenil has already been mentioned; it is used as well as a diagnostic test.

Fulminant Hepatic Failure and Cerebral Edema

In *acute hepatitis*, confusional, delirious, and comatose states also occur but their mechanisms are still unknown. Blood NH_3 may be elevated but usually not to a degree that would be expected to cause encephalopathy. Severe acute hepatic failure may cause hypoglycemia, which contributes to the encephalopathy and often presages a fatal outcome but the levels of glucose typically detected do not provide an explanation for the encephalopathy.

Cerebral edema is a prominent finding in cases of fulminant hepatic failure and is the main cause of death in patients awaiting liver transplantation. The cerebral edema in these circumstances appears to be related to the rapidity of rise of blood ammonia, but it probably depends as well on additional metabolic derangements that complicate acute liver failure including glial cell failure with consequent incompetence of the blood-brain barrier. The combination of rapidly evolving hepatic failure and massive cerebral edema is similar to that observed in the Reye syndrome, described below.

CT and MRI are effective means of detecting cerebral edema in patients with fulminant hepatic failure, and according to Wijdicks and colleagues, the degree of cerebral swelling is roughly proportional to the severity of encephalopathy. Because patients with fulminant hepatic failure can survive liver transplantation with few or no neurologic deficits, it is important to recognize cerebral edema before the stage of stupor and increased intracranial pressure has been established. Short of transplantation, death in these cases may sometimes be prevented by monitoring the intracranial pressure (as outlined by Lidofsky et al) and administering osmotic diuretics and hyperventilation, as detailed in Chaps. 31 and 35 for the treatment of intracranial hypertension. Some survivors are nonetheless left with cerebral damage from raised intracranial pressure.

An additional issue that arises in assessing cerebral dysfunction in patients with liver disease is the possibility of adverse effects of medications. Individuals with hepatitis C who are treated with interferon-alpha may develop a spectrum of problems ranging from subtle cognitive impairment to a subacutely worsening headache, vomiting, altered consciousness, and focal neurologic findings. The milder syndromes are associated with no or few MRI-visible lesions but the severe ones are usually accompanied by signal changes in the white matter of the occipital lobes and elsewhere (posterior leukoencephalopathy; see Fig. 43-1).

Reye Syndrome (Reye-Johnson Syndrome)

This is a special type of nonicteric hepatic encephalopathy occurring in children and adolescents and characterized by acute brain swelling in association with fatty

infiltration of the viscera, particularly the liver. Although individual cases of this disorder had been described for many years, its recognition as a clinical-pathologic entity dates from 1963, when a large series was reported from Australia by Reye and colleagues and from the United States by Johnson and coworkers. The disorder tended to occur in outbreaks (286 cases were reported to the Centers for Disease Control during a 4-month period in 1974). Mainly, these outbreaks were observed in association with influenza B virus and varicella infections, but a variety of other viral infections were implicated (influenza A, echovirus, reovirus, rubella, rubeola, herpes simplex, Epstein-Barr virus). Later it became apparent that the toxic or adjuvant effects of aspirin given during these infections played an important role in producing the disease. Today, only occasional instances of Reye syndrome are observed now that the association with aspirin administration has become widely known and its use in children with viral infections has been interdicted.

Most patients are children, boys and girls being equally affected, but rare instances are known in infants (Huttenlocher and Trauner) and young adults. In most cases, the encephalopathy is preceded for several days to a week by fever, symptoms of upper respiratory infection, and protracted vomiting. These are followed by the rapid evolution of stupor and coma, associated in many cases with focal and generalized seizures, signs of sympathetic overactivity (tachypnea, tachycardia, mydriasis), decorticate and decerebrate rigidity, and loss of pupillary, corneal, and vestibuloocular reflexes. One or two such cases were included in the series of acute "toxic encephalopathy" reported by Lyon and colleagues (see "Acute Toxic Encephalopathy" in Chap. 32). In infants, respiratory distress, tachypnea, and apnea are the most prominent features.

The liver may be greatly enlarged, often extending to the pelvis and providing an important diagnostic clue as to the cause of the cerebral changes. Initially there is a metabolic acidosis, followed by a respiratory alkalosis (rising arterial pH and falling P_{CO_2}). The CSF is usually under increased pressure and is acellular; glucose values may be low, reflecting the hypoglycemia. The serum ALT, coagulation times, and blood ammonia are increased, sometimes to an extreme degree. The EEG is characterized by diffuse arrhythmic delta activity, progressing to electrocerebral silence in patients who fail to survive. CT and MRI show the cerebral swelling but are difficult to interpret in these young individuals, who lack any adult brain atrophy.

The major *pathologic findings* are cerebral edema, often with cerebellar herniation, and infiltration of hepatocytes with fine droplets of fat (mainly triglycerides); the renal tubules, myocardium, skeletal muscles, pancreas, and spleen are infiltrated to a lesser extent. There are no inflammatory lesions in the brain, liver, or other organs. There is not full agreement as to the pathogenesis of this disorder and the mechanism of aspirin toxicity but mitochondrial dysfunction has been implicated.

Prognosis and Treatment

In a series of children with blood ammonia levels greater than 500 mg/dL who were treated during the years 1967

to 1974, Shaywitz and colleagues reported a mortality of 60 percent. Once the child became comatose, death was almost inevitable. In more recent years, early diagnosis and initiation of treatment before the onset of coma have reduced the fatality rate to 5 to 10 percent. Treatment consists of the following measures: temperature control with a cooling blanket; nasotracheal intubation and controlled ventilation to maintain P_{CO_2} below 32 mm Hg; intravenous glucose covered by insulin to maintain blood glucose at 150 to 200 mg/dL; administration of lactulose, neomycin enemas, and hemodialysis to directly lower the NH_3 concentration; control of intracranial pressure by means of continual monitoring and the use of hypertonic solutions (see Chap. 30); and the maintenance of fluid and electrolyte balance (Trauner). Upon recovery, cerebral function returns to normal unless there had been deep and prolonged coma or protracted elevation of intracranial pressure.

Uremic Encephalopathy

Episodic confusion and stupor and other neurologic symptoms may accompany any form of severe renal disease—acute or chronic. The cerebral symptoms attributable to uremia (first described by Addison in 1832) are discerned in normotensive individuals in whom renal failure develops rapidly. Apathy, fatigue, inattentiveness, and irritability are usually the initial symptoms; later, there is confusion, dysarthria, tremor, and asterixis. Infrequently, this takes the form of a toxic psychosis, with hallucinations, delusions, insomnia, or catatonia (Marshall). These symptoms characteristically fluctuate from day to day, or even from hour to hour. In some patients, especially those who become anuric, symptoms may come on abruptly and progress rapidly to a state of stupor and coma. In others, in whom uremia develops more gradually, mild visual hallucinations and a disorder of attention may persist for several weeks in relatively pure form. The EEG becomes diffusely and irregularly slow and may remain so for several weeks after the institution of dialysis. The CSF pressure is normal and the protein is not elevated unless there is a uremic or diabetic neuropathy. In several reports, meningismus and a low-grade mononuclear pleocytosis have been mentioned (Merritt and Fremont-Smith), but we have not encountered this.

In acute renal failure, clouding of the sensorium is practically always associated with a variety of motor phenomena. These usually occur early in the course of the encephalopathy, sometimes when the patient is still mentally clear. The patient begins to twitch and jerk and may convulse. The myoclonic twitches involve parts of muscles, whole muscles, or entire limbs and are lightning-quick, arrhythmic, and asynchronous on the two sides of the body; they are incessant during both wakefulness and sleep. At times the movements resemble those of chorea or an arrhythmic tremor; asterixis is also readily evoked. The motor phenomena are often difficult to classify. Our predecessor authors described the condition as a *uremic twitch-convulsive syndrome*.

The resemblance of uremic encephalopathy to hepatic and other metabolic encephalopathies has been stressed

by Raskin and Fishman, yet we are more impressed with differences than with similarities. When the twitch-convulsive syndrome is observed in association with other diseases such as widespread neoplasia, delirium tremens, diabetic coma, and lupus erythematosus, the causative factor of renal failure is usually discovered.

As the uremia worsens, the patient lapses into a quiet coma. Unless the accompanying metabolic acidosis is corrected, Kussmaul breathing appears and gives way to Cheyne-Stokes breathing and death.

Encephalopathy and coma in the patient with renal failure may, of course, be a result of disorders other than uremia itself. Because of the similarity of this syndrome to tetany, measurement should be made of serum calcium and magnesium—and, of course, hypocalcemia and hypomagnesemia do occur in uremia. But often the values for these ions are normal or near normal, and the administration of calcium and magnesium salts has little effect. The altered excretion of drugs leads to their accumulation, sometimes evoking excessive sedation. Subdural and intracerebral hemorrhages may complicate uremia (and dialysis) because of clotting defects and hypertension; and uremic patients are prone to infections, including meningitis.

Because chronic uremia is so frequently associated with hypertension, a major problem also arises in distinguishing the cerebral effects of uremia from those of severe and accelerated hypertension. Volhard was the first to make this distinction; he introduced the term *pseudouremia* to designate the cerebral effects of malignant hypertension and to separate them from true uremia. The preferable term, *hypertensive encephalopathy*, was first used by Oppenheimer and Fishberg. However, the myoclonic-twitch syndrome is not a component of hypertensive encephalopathy. The clinical picture of the latter disorder and its pathophysiology are discussed in "Hypertensive Encephalopathy and Eclampsia" in Chap. 34.

Pathogenesis

Opinions vary widely as to the biochemical basis of uremic encephalopathy and the twitch-convulsive syndrome. Restoration of renal function completely corrects the neurologic syndrome, attesting to the absence of structural change and a functional disorder of subcellular type. Whether caused by the retention of organic acids, elevation of phosphate in the CSF (claimed by Harrison et al), or the action of urea or other toxins, among them parathyroid hormone, has never been settled. The data supporting the causative role of urea itself are also ambiguous, just as they are for other putative endogenous agents (see Bolton and Young and the review by Burn and Bates). However, it can be stated that urea itself is not the sole inductive agent, as its infusion does not produce the syndrome in humans or animals.

It would appear that every level of the CNS is affected in uremia, from spinal cord to cerebrum. Cellular changes in the brain or spinal cord are limited to mild hyperplasia of protoplasmic astrocytes in some cases, but never of the degree observed in hepatic encephalopathy. Cerebral edema is notably absent. In fact, CT scans and

MRI regularly show an element of cerebral shrinkage. A peripheral neuropathy is also a common complication of uremia and is considered in Chap. 46.

Treatment

Improvement of encephalopathic symptoms may not be evident for a day or two after institution of dialysis. Convulsions, which occur in about one-third of cases, often preterminally, may be resistant to treatment until the uremia is addressed. However, some seizures may be suppressed with relatively low plasma concentrations of antiepileptic drugs, the reason being that serum albumin is depressed in uremia, increasing the unbound, therapeutically active portion of a drug. If there are severe associated metabolic disturbances, such as hyponatremia, the seizures may be difficult to control. One must be cautious in prescribing any of a large number of drugs in the face of renal failure, for inordinately high, toxic blood levels may result. Examples that affect the nervous system are aminoglycoside antibiotics (vestibular damage); furosemide (cochlear damage); and nitrofurantoin, isoniazid, and hydralazine (peripheral nerve damage).

"Dialysis Disequilibrium" Syndrome

This term refers to a group of symptoms that may occur during and following hemodialysis or peritoneal dialysis as a byproduct of some degree of cerebral edema. The symptoms include headache, nausea, muscle cramps, nervous irritability, agitation, drowsiness, and convulsions. The headache, which may be bilateral and throbbing and resemble common migraine, develops in approximately 70 percent of patients, whereas the other symptoms are observed in 5 to 10 percent, usually in those undergoing rapid dialysis or in the early stages of a dialysis program. The symptoms tend to occur in the third or fourth hour of dialysis and last for several hours. Sometimes they appear 8 to 48 h after the completion of dialysis. Originally, these symptoms were attributed to the rapid lowering of serum urea, leaving the brain with a higher concentration of urea than the serum and resulting in a shift of water into the brain to equalize the osmotic gradient (*reverse urea syndrome*). Now it is believed that the shift of water into the brain is akin to water intoxication and is a result of the inappropriate secretion of antidiuretic hormone.

The symptoms of subdural hematoma, which in some series had in the past occurred in 3 to 4 percent of patients undergoing dialysis, now being less frequent, may be mistakenly attributed to the disequilibrium syndrome.

Dialysis Encephalopathy (Dialysis Dementia)

This is a subacutely progressive syndrome that in the past complicated chronic hemodialysis. Characteristically, the condition begins with a hesitant, stuttering dysarthria and aphasia, to which are added facial and then generalized myoclonus, focal and generalized seizures, personality and behavioral changes, and intellectual decline. The EEG is invariably abnormal, taking the form of paroxysmal and sometimes periodic sharp-wave or spike-and-wave activity (up to 500 mV and lasting 1 to 20 s),

intermixed with abundant theta and delta activity. The CSF is normal except occasionally for increased protein.

At first the myoclonus and speech disorders are intermittent, occurring during or immediately after dialysis and lasting for only a few hours, but gradually they become more persistent and eventually permanent. Once established, the syndrome is usually steadily progressive over a 1- to 15-month period (average survival of 6 months in the 42 cases analyzed by Lederman and Henry). A characteristic feature is a transient improvement in speech with the administration of intravenous diazepam.

The neuropathologic changes are said to be subtle and consist of a mild degree of microcavitation of the superficial layers of the cerebral cortex. Although the changes are diffuse, they have been found in one study to be more severe in the left (dominant) hemisphere than in the right and more severe in the left frontotemporal operculum than in the surrounding cortex (Winkelman and Ricanati). The disproportionate affection of the left frontotemporal opercular cortex putatively explains the distinctive disorder of speech and language. In the one case we have studied carefully, we could not be certain of any microscopic changes.

The most plausible view of the pathogenesis of dialysis encephalopathy is that it represented a form of aluminum intoxication (Alfrey et al), the aluminum being derived from the dialysate or from orally administered aluminum gels. In recent years, this disorder has disappeared, the result, in all likelihood, of the universal practice of purifying the water used in dialysis and thereby removing aluminum from the dialysate. This subject has been reviewed by Parkinson and coworkers.

Complications of Renal Transplantation

The risk in immunosuppressed persons of developing a primary lymphoma of the brain or progressive multifocal leukoencephalopathy is well known and has been mentioned in previous chapters. An entirely different encephalopathy that is marked by widespread visual symptoms and edema of the cerebral white matter, evident on the MRI, but mainly occipital, occurs after the administration of cyclosporine and other immunosuppressant drugs. These imaging features of reversible posterior leukoencephalopathy or posterior reversible encephalopathy syndrome (PRES; see Chaps. 34 and 43), are not specific, being seen also in patients with hypertensive encephalopathy, eclampsia, intrathecal methotrexate administration, and other conditions (see Table 43-1 and Fig. 43-1) all of which are probably linked by endothelial dysfunction of cerebral vessels. Systemic fungal infections had in the past been found at autopsy in approximately 45 percent of patients who had had renal transplants and long periods of immunosuppressive treatment; in about one-third of these patients, the CNS was involved. *Cryptococcus*, *Listeria*, *Aspergillus*, *Candida*, *Nocardia*, and *Histoplasma* were the usual organisms. Recent experience suggests a far lower rate of infection but it remains a threat. Other CNS infections that have complicated transplantation are toxoplasmosis and cytomegalovirus (CMV) inclusion disease.

We have found examples of Wernicke-Korsakoff disease and central pontine myelinolysis in uremic patients. A bleeding diathesis may result in subdural or cerebral hemorrhage, as already mentioned.

Encephalopathy Associated with Sepsis and Burns ("Septic Encephalopathy")

Bolton and Young have drawn attention to the frequent occurrence, in severely septic patients, of a drowsy or confusional state that is reversible and not explained by hepatic, pulmonary, or renal failure, electrolyte imbalance, hypotension, drug intoxication, or a primary lesion of the brain. They called the condition "septic encephalopathy." According to their surveys, 70 percent of patients become disoriented and confused within hours of the onset of severe systemic infection; in a few cases, this state may progress to stupor and coma. Notably there are no signs of asterixis, myoclonus, or focal cerebral disorder but paratonia is common, as is the later development of a polyneuropathy. Rapid changes in water balance may occur, leading to the type of osmotic demyelination discussed below.

The encephalopathic state that occurs with severe systemic infection may also develop independently of sepsis, as a component of a syndrome of multiple organ failure and, according to some authors, a complication of widespread cutaneous burns (Aikawa et al). Others have questioned the validity of this last category and have instead found explanatory electrolyte disorders (particularly hyponatremia), sepsis, or multiple brain abscesses.

It has been useful in clinical work to distinguish these encephalopathies of infection and multiorgan failure from those caused by isolated hepatic or renal disease. The lack of a biochemical marker and the confounding effects of hypotension during sepsis (septic shock) leave doubt as to pathogenesis. Altered phenylalanine metabolism and circulating cytokines have been proposed as causes, without firm evidence. Of interest in two of our fatal cases was the presence of *brain purpura*, but this has otherwise been an infrequent finding. Here, the white matter of the cerebrum and cerebellum was speckled with myriad pericapillary hemorrhages and zones of adjacent necrosis. This pathologic reaction is nonspecific, having also been seen in cases of viral pneumonia, heart failure with morphine overdose, thrombotic thrombocytopenic purpura and arsenic poisoning.

Disorders of Sodium, Potassium, and Water Balance

Drowsiness, confusion, stupor, and coma, in conjunction with seizures and sometimes with other neurologic deficits, may have as their basis a more or less pure abnormality of electrolyte or water balance. Only brief reference is made here to some of these, such as hypocalcemia, hypercalcemia, hypophosphatemia, and hypomagnesemia, as they are considered in other parts of the text.

Hyponatremia and Syndrome of Inappropriate Antidiuretic Hormone

Hyponatremia is defined as a serum sodium level below 135 mEq/L. The hyponatremic state may be isotonic, hypertonic, or hypotonic, depending on the mechanism of reduced sodium concentration. The hypotonic variety is most common in neurologic practice but one also encounters cases of pseudohyponatremia caused by hyperlipidemia or hyperproteinemia (isotonic), hyperglycemic or mannitol-induced hyponatremia (hypertonic), and also cases of water intoxication. The last of these may be associated with systemic hypovolemic (blood loss, salt wasting), hypervolemic (edematous states such as renal, hepatic or heart failure), or isovolemic states (retention of free water).

Hypotonic isovolemic hyponatremia is most often a result of the *syndrome of inappropriate antidiuretic hormone secretion (SIADH)*. This state is of special importance because it complicates neurologic diseases of many types: head trauma, bacterial meningitis and encephalitis, cerebral infarction, subarachnoid hemorrhage, cerebral and systemic neoplasm, Guillain-Barré syndrome and the effects of certain medications. SIADH is the result of excretion of urine that is hypertonic relative to the plasma.

As the hyponatremia develops, there is a decrease in alertness, which progresses through stages of confusion to coma, often with convulsions. *As with many other metabolic derangements, the severity of the clinical effect is related to the rapidity of decline in serum Na.* Lack of recognition of this state may allow the serum Na to fall to dangerously low levels, 100 mEq/L or lower.

Treatment Most instances of hyponatremia have developed slowly, allowing for maintenance of brain volume by the extrusion from cells of various osmotic substances. Rapid correction of sodium in these circumstances risks a reversal of osmotic gradient and a reduction in brain volume. This, in turn, is associated with a special type of central nervous system demyelination (“osmotic demyelination” and central pontine myelinolysis) discussed below. One’s first impulse is to administer NaCl intravenously, but this must be done cautiously to avoid these complications. Most cases of SIADH respond to the restriction of fluid intake—to 500 mL per 24 h if the serum Na is less than 120 mEq/L and to 1,000 mL per 24 h if less than 130 mEq/L. Even when the Na reaches 130 mEq/L, the fluid intake should not exceed 1,500 mL per 24 h. In extreme and rapidly developing (less than 48 h) hyponatremia with stupor or seizures, the mechanisms for maintaining cerebral cellular volume have not yet been engaged and therefore infusion of NaCl is necessary to prevent cerebral edema. The amount of NaCl to be infused can be calculated from the current and the target levels of serum Na by assuming that the infused sodium load is distributed throughout the total body water content ($0.6 \times \text{weight}$ in kilograms):

$$([\text{target Na} - \text{starting Na}] \times 0.6) \\ \times \text{weight (kg)} = \text{infused Na load (mEq)}$$

The desired volume of normal saline can then be determined by keeping in mind that its sodium concentration is 154 mEq/L and that of 3 percent (hypertonic) saline solution is 513 mEq/L. If hypertonic saline is administered, it is usually necessary to simultaneously reduce intravascular volume with furosemide, beginning with a dose of 0.5 mg/kg intravenously, and to increase the dosage until a diuresis is obtained. (As a rule of thumb, 300 to 500 mL of 3 percent saline, infused rapidly intravenously, will increase the serum sodium concentration by about 1 mEq/L/h for 4 h.) Guidelines to prevent an overly rapid correction of Na are elaborated further on in relation to central pontine myelinolysis (no more rapidly than 10 mmol/L in the first 24 h). Although the syndrome of SIADH is usually self-limiting, it may continue for weeks or months, depending on the type of associated brain disease.

Not all patients with neurologic disorders who manifest hyponatremia have SIADH. Diuretic excess, adrenal insufficiency, and salt wasting also produce hypovolemic hyponatremia as a result of natriuresis. When renal salt wasting is seen in the context of a central neurologic disorder, the process has been termed “cerebral salt wasting” (Nelson et al). Sodium loss in these circumstances is attributable to the production by the heart or brain of a potent polypeptide natriuretic factor. As discussed in Chap. 34, under “Subarachnoid Hemorrhage,” the distinction between SIADH and cerebral salt wasting is of more than theoretical importance, insofar as fluid restriction to correct hyponatremia may be dangerous in patients with salt wasting, particularly in those with vasospasm after ruptured intracranial aneurysms.

Arieff emphasized the hazards of *postoperative hyponatremia* in a series of 15 patients, all of them women, in whom *severe hyponatremia* followed elective surgery. About 48 h after these patients had recovered from anesthesia, their serum Na fell markedly, at which point generalized seizures occurred, followed by respiratory arrest. We are more familiar with acutely developing hyponatremia in the context of prostate surgery, where large amounts of hypotonic fluids are routinely administered both intravenously and intravascularly. A similar syndrome is known in instances of overly zealous fluid resuscitation in children with diabetic ketoacidosis. The mechanisms of neurologic deterioration in all of these cases is likely to be brain edema.

An important consideration in the management of severe hyponatremia, as mentioned earlier, is *the rapidity with which the abnormality is corrected and the danger of provoking central pontine myelinolysis* and related brainstem, cerebellar, and cerebral lesions (extrapontine myelinolysis; osmotic demyelination). These issues are considered below, in the section “Central Pontine Myelinolysis.”

Hypernatremia

Hypernatremia (Na >155 mEq/L) and dehydration are observed in diabetes insipidus, the neurologic causes of which include head trauma with damage to the pituitary stalk (Chap. 27), and in nonketotic diabetic coma, protracted diarrhea in infants, and the deprivation of fluid

intake in the stuporous patient. The last condition is usually associated with a brain lesion that impairs consciousness. Exceptionally, in patients with chronic hydrocephalus, the hypothalamic thirst center is rendered inactive and severe hypernatremia, stupor, and coma may follow a failure to drink. In hypernatremia from any cause, the brain volume is manifestly reduced. Retraction of the cerebral cortex from the dura has been known to rupture a bridging vein and cause a subdural hematoma.

As is true for hyponatremia, the degree of CNS disturbance in hypernatremia is generally related to the rate at which the serum Na rises. Slowly rising values, to levels as high as 170 mEq/L, may be surprisingly well tolerated. Rapid elevations of sodium shrink the brain, especially in infants. Extremely high levels cause impairment of consciousness with asterixis, myoclonus, seizures, and choreiform movements. In addition, muscular weakness, rhabdomyolysis, and myoglobinuria have been reported.

In hypernatremia with hyperosmolality, the brain retains its volume more effectively than do other organs by a compensatory mechanism that has been attributed to the presence of "idiogenic osmoles," possibly glucose, glucose metabolites, and amino acids. The impairment of neuronal function in this state is not understood. Theoretically one would expect neuronal shrinkage and possibly alteration of the synaptic surface of the cell.

Hypo- and Hyperkalemia

The main clinical effect of *hypokalemia* (≤ 2.0 mEq/L) is generalized muscular weakness (see Chap. 48). A mild confusional state had been alluded to in the literature but must be very infrequent. The electrolyte condition is readily corrected by adding K to intravenous fluid and infusing it at no more than 4 to 6 mEq/h. *Hyperkalemia* (>7 mEq/L) also may manifest itself by generalized muscle weakness, although the main effects are changes in the electrocardiogram (ECG), possibly leading to cardiac arrest.

Other Metabolic Encephalopathies

Limitation of space permits only brief reference to other metabolic disturbances that may present as episodic confusion, stupor, or coma. The most important members of this group are summarized below.

Hypercalcemia This is defined as an elevation of the serum calcium concentration greater than 10.5 mg/dL. If the serum protein content is normal, Ca levels greater than 12 mg/dL are required to produce neurologic symptoms. However, with low serum albumin levels, an increased proportion of the serum Ca is in the unbound or ionized form (upon which the clinical effects depend), and symptoms may occur with total serum Ca levels as low as 10 mg/dL.

In young persons, the most common cause of hypercalcemia is hyperparathyroidism (either primary or secondary); in older persons, osteolytic bone tumors, particularly meta-static carcinoma and multiple myeloma, are often causative. Less-common causes are vitamin D intoxication, prolonged immobilization, hyperthyroidism, sarcoidosis, and decreased calcium excretion (renal failure).

Anorexia, nausea and vomiting, fatigue, and headache are usually the *initial symptoms*, followed by confusion (rarely a delirium) and drowsiness, progressing to stupor or coma in untreated patients. A history of recent constipation is common. Diffuse myoclonus and rigidity occur occasionally, as do elevations of spinal fluid protein (up to 175 mg/100 mL). Convulsions are uncommon.

Hypocalcemia The usual manifestations are paresthesias, tetany, and seizures. With severe and persistent hypocalcemia, altered mental status in the form of depression, confusion, dementia, or personality change can occur. Anxiety to the point of panic attack is also known. Even coma may result, in which case there may be papilledema as a result of increased intracranial pressure. Aside from the raised pressure, the CSF shows no consistent abnormality. This increase in intracranial pressure may be manifest by headache and papilledema without altered mentation or with visual obscurations. Hypoparathyroidism is discussed again further on, under "Acquired Metabolic Diseases Presenting as Progressive Extraparamidal Syndromes."

Other Electrolyte and Acid-Base Disorders Severe *metabolic acidosis* from any cause produces a syndrome of drowsiness, stupor, and coma, with dry skin and Kussmaul breathing. The CNS depression does not correlate with the concentration of ketones. Possibly, there are associated effects on neurotransmitters. It is often not possible to separate the effects of acidosis from those caused by an underlying condition or toxic ingestion.

In infants and children, acidosis may occur in the course of hyperammonemia, isovaleric acidemia, maple syrup urine disease, lactic and glutaric acidemia, hyperglycinemia, and other disorders, which are described in detail in Chap. 37. High-voltage slow activity predominates in the EEG, and correction of the acidosis or elevated ammonia level restores CNS function to normal provided that coma was not prolonged or complicated by hypoxia or hypotension. In uncomplicated acidotic coma, no recognizable neuropathologic change has been observed by light microscopy.

Encephalopathy as a consequence of *Addison disease* (adrenal insufficiency) may be attended by episodic confusion, stupor, or coma without special identifying features; it is usually precipitated in the Addisonian patient by infection or surgical stress. Hemorrhagic destruction of the adrenals in meningococcal meningitis (Waterhouse-Friderichsen syndrome) is another cause. Hypotension and diminished cerebral circulation and hypoglycemia are the most readily recognized metabolic abnormalities; measures that correct these conditions reverse the adrenal crisis in some instances. Laurenco (1993) reviewed the various neurologic syndromes that result from electrolytic disorders.

Central Pontine Myelinolysis and Other Patterns of Osmotic Demyelination

Adams, Victor, and Mancall observed a rapidly evolving quadriplegia and pseudobulbar palsy in a young alcoholic man who had entered the hospital 10 days earlier with

symptoms of alcohol withdrawal. Postmortem examination several weeks later disclosed a large, symmetrical, essentially demyelinating lesion occupying the greater part of the base of the pons. Over the next 5 years, 3 additional cases (2 alcoholic patients and 1 with scleroderma) were studied clinically and pathologically, and in 1959 these 4 cases were reported by Adams and colleagues under the heading of *central pontine myelinolysis* (CPM). This term was chosen because it reflects both the main anatomic localization of the disease and its essential pathologic attribute: the remarkably dissolution of the sheaths of myelinated fibers and the sparing of neurons. Once attention was focused on this distinctive lesion, many other reports appeared and it became apparent that other areas of myelin in the brain could be similarly affected. The exact incidence of this disease is not known, but in a series of 3,548 consecutive autopsies in adults, the typical lesion was found in 9 cases, or 0.25 percent (Victor and Laurenco).

Pathologic Features

One is compelled to define this disease in terms of its pathologic anatomy because this stands as its most characteristic feature, but it has been appreciated in recent years that the pons is not the only structure that may be affected. Transverse sectioning of the fixed brainstem discloses a grayish discoloration and fine granularity in the center of the base of the pons. The lesion may be only a few millimeters in diameter, or it may occupy almost the entire ventral pons. There is always a rim of intact myelin between the lesion and the surface of the pons. Posteriorly, it may reach and involve the medial lemnisci and, in the most advanced cases, other tegmental structures as well. Very rarely, the lesion encroaches on the midbrain but inferiorly it does not extend as far as the medulla. Identical extrapontine myelinolytic foci in the internal capsule, deep cerebral white matter and corpus callosum may occur independently ("extrapontine myelinolysis"). Exceptionally, symmetrically distributed lesions are found in the thalamus, subthalamic nucleus, striatum, amygdaloid nuclei, lateral geniculate body, white matter of the cerebellar folia (Wright et al).

Microscopically, the fundamental abnormality consists of destruction of the myelinated sheaths throughout the lesion, with relative sparing of the axons and intactness of the nerve cells of the pontine nuclei. These changes always begin and are most severe in the geometric center of the pons, where they may proceed to frank necrosis of tissue. Reactive phagocytes and glia cells are in evidence throughout the demyelinating focus, but oligodendrocytes are depleted. Signs of inflammation are conspicuously absent.

This constellation of pathologic findings provides easy differentiation of the lesion from infarction and the inflammatory demyelination of multiple sclerosis and postinfectious encephalomyelitis. Microscopically, the lesion resembles that of Marchiafava-Bignami disease (Chap. 41), with which it is rarely associated. In the chronic alcoholic, Wernicke disease is often associated with osmotic demyelination, but the lesions bear no resemblance to one another in terms of topography and histology.

Clinical Features

The two sexes are affected equally, and the patients do not fall into any one age period. Whereas the cases first reported had occurred in adults, there are now many reports of the disease in children, particularly in those with severe burns (McKee et al). More than half the cases have appeared in the late stages of chronic alcoholism, often in association with Wernicke disease and polyneuropathy. Most cases occur in the context of other serious medical conditions, and diseases with which osmotic demyelination has been conjoined are chronic renal failure being treated with dialysis, hepatic failure, advanced lymphoma, cancer, cachexia from a variety of other causes, severe bacterial infections, dehydration and electrolyte disturbances, acute hemorrhagic pancreatitis, and pellagra. The changes in serum sodium concentration, with which the process is closely aligned, are discussed below.

In many patients there are no symptoms or signs that betray the pontine lesion, presumably because it is so small, extending only 2 to 3 mm on either side of the median raphe and involving only a small portion of the corticopontine or pontocerebellar fibers. In others, its presence is obscured by coma from a metabolic or other associated disease. Prior to the inception of MRI only a minority of cases, exemplified by the first patient observed by Adams, Victor, and Mancall, were recognized during life. In this patient, a serious alcoholic with delirium tremens and pneumonia, there evolved, over a period of several days, a flaccid paralysis of all 4 limbs and an inability to chew, swallow, or speak (thus simulating occlusion of the basilar artery). Pupillary reflexes, movements of the eyes and lids, corneal reflexes, and facial sensation were spared. In some instances, however, conjugate eye movements are limited, and there may be nystagmus. With survival for several days, the tendon reflexes become more active, followed by spasticity and extensor posturing of the limbs on painful stimulation. Some patients are left in a state of mutism and paralysis with relative intactness of sensation and comprehension (pseudocoma, or locked-in syndrome).

The capacity of CT and especially MRI to visualize the pontine lesion has greatly increased the frequency of premortem diagnoses. The MRI discloses a characteristic "batwing" lesion of the pons in typical cases (Fig. 40-6), although this change may become evident only several days after the onset of symptoms. Brainstem auditory evoked responses also disclose the lesions that encroach upon the pontine tegmentum.

Variants of this syndrome are being encountered with increasing frequency. Two of our elderly patients, with confusion and stupor but without signs of corticospinal or pseudobulbar palsy, recovered; however, they were left with a severe dysarthria and cerebellar ataxia lasting many months. After 6 months, these patients' nervous system function was essentially restored to normal. In reference to the pathogenesis of this lesion, originally both patients had serum Na levels of 99 mEq/L, but information about the rate of correction of serum Na was not available. Another of our patients developed a typical locked-in syndrome after the rapid correction of a serum

Figure 40-6. T2-weighted MRI showing the typical lesion of central pontine myelinolysis in an alcoholic patient.

sodium of 104 mEq/L. He showed large symmetrical lesions of the frontal cortex and underlying white matter but no pontine lesion (by MRI).

Brainstem infarction caused by basilar artery occlusion may be simulated by pontine myelinolysis. Sudden onset or step-like progression of the clinical state, asymmetry of long tract signs, and more extensive involvement of tegmental structures of the pons as well as the midbrain and thalamus are the distinguishing characteristics of vertebrobasilar thrombosis or embolism. On MRI studies, an evolving infarction shows signal changes on diffusion-weighted imaging, while the primary finding in osmotic demyelination is brightness of the T2-weighted images. Massive pontine demyelination in acute or chronic relapsing multiple sclerosis rarely produces a pure pontine syndrome. The clinical features and context provide the clues to correct diagnosis.

Etiology and Pathogenesis

As mentioned in the section on hyponatremia, a rapid rise in serum osmolality to normal or higher-than-normal levels is an almost obligate antecedent of this process. One encounters this most commonly in the rapid correction of hyponatremia. In cases related to the correction of hyponatremia, the initial serum sodium concentration is less than 130 mEq/L and usually much lower; this was the case in all the patients reported by Burcar and colleagues and by Karp and Lauren. Lauren (1983) demonstrated the importance of serum sodium in the pathogenesis of this disease experimentally. Dogs made severely hyponatremic (100 to 115 mEq/L) had the electrolyte disorder corrected rapidly by infusion of hypertonic (3 percent)

saline; this led to spastic quadriplegia and pontine and extrapontine lesions were found at autopsy, indistinguishable in their distribution and histologic features from those of the human disease. Hyponatremia alone or slowly corrected hyponatremia (<15 mEq/dL in the initial 24 h) did not produce the disease.

McKee and colleagues adduced that in burn patients, extreme serum hyperosmolality was the important factor in the pathogenesis of demyelination. They found the characteristic pontine and extrapontine lesions in 10 of 139 severely burned patients who were examined after death. Each of their patients with CPM had suffered a prolonged, nonterminal episode of severe serum hyperosmolality, which coincided temporally with the onset of the lesion, as judged by its histologic features. Hyponatremia was not prominent and no other independent features could explain the changes. These observations suggest that rapidly rising osmolality may be a cause of the osmotic demyelination syndromes.

At the present time all one can say is that specific myelinated regions of the brain, most often but not exclusively the center of the base of the pons, have a susceptibility to rapid increase in serum osmolality.

Karp and Lauren, on the basis of their experience and that of Sterns and colleagues, have suggested that the hyponatremia be corrected by no more than 10 mEq/L in the initial 24 h and by no more than about 21 mEq/L in the initial 48 h.

ACQUIRED METABOLIC DISEASES PRESENTING AS PROGRESSIVE EXTRAPYRAMIDAL SYNDROMES

These syndromes are usually of mixed type; i.e., they include a number of basal ganglionic and cerebellar symptoms in various combinations. They emerge as part of acquired chronic hepatocerebral degeneration or chronic hypoparathyroidism or as sequels to kernicterus, hypoxic, or hypoglycemic encephalopathy. The basal ganglionic–cerebellar symptoms that result from severe anoxia and hypoglycemia were described in the preceding section and in Chaps. 4 and 5. Kernicterus and calcification of the basal ganglia and cerebellum are considered in Chap. 37 and further on in this chapter. Acquired hypoparathyroidism may also lead to calcification of the basal ganglia and an extrapyramidal disorder. Choreiform movements are also observed in patients with hyperosmolar coma and with severe hyperthyroidism, ascribed by Weiner and Klawans to a disturbance of dopamine metabolism.

Chronic Acquired (Nonwilsonian) Hepatocerebral Degeneration

Patients who survive an episode or several episodes of hepatic coma are sometimes left with residual neurologic abnormalities such as tremor of the head or arms, asterixis, grimacing, choreic movements and twitching of the limbs, dysarthria, ataxia of gait, or impairment of

intellectual function. These symptoms may worsen with repeated attacks of stupor and coma. In few patients with chronic liver disease, permanent neurologic abnormalities become manifest in the absence of discrete episodes of hepatic coma. Patients deteriorate neurologically over a period of months or years. Examination of their brains discloses foci of destruction of nerve cells and other parenchymal elements in addition to a widespread transformation of astrocytes, changes very much similar to those of Wilson disease.

Probably the first to describe this acquired type of hepatocerebral degeneration was van Woerkom, whose report appeared only 2 years after Wilson's original description of the familial form. A full account of the cases reported since that time as well as the extensive experience of our colleagues with this disorder is contained in the article by Victor, Adams, and Cole.

Clinical Features

The first symptom may be a tremor of the outstretched arms, fleeting arrhythmic twitches of the face and limbs (resembling either myoclonus or chorea), or a mild unsteadiness of gait with action tremor. As the condition evolves over months or years, a characteristic dysarthria, ataxia, wide-based, unsteady gait, and choreoathetosis, mainly of the face, neck, and shoulders, are joined in a syndrome. Mental function is slowly altered, taking the form of a dementia with a seeming lack of concern about the illness. A coarse, rhythmic tremor of the arms appearing with certain sustained postures, corticospinal tract signs ("hepatic paraplegia"), and diffuse EEG abnormalities complete the clinical picture. Other less-frequent signs are rigidity, grasp reflexes, tremor in repose, nystagmus, asterixis, and action or intention myoclonus. In essence, each of the neurologic abnormalities observed in patients with acute hepatic encephalopathy are also part of chronic hepatocerebral degeneration, the only difference being that the abnormalities are evanescent in the former and irreversible and progressive in the latter.

As a rule, all measurable hepatic functions are altered but the chronic neurologic disorder correlates best with an elevation of serum ammonia (usually >200 mg/dL). Unlike Wilson disease, where the cirrhosis usually remains occult for a long time, there is no question about its presence in the acquired syndrome; jaundice, ascites, and esophageal varices are manifest in most of the acquired cases. Wilson disease, which enters into the differential diagnosis, is usually not difficult to differentiate on clinical grounds, although the distinction in some cases requires the critical evidence of familial occurrence, Kayser-Fleischer rings (never found in the acquired type), and certain biochemical abnormalities (diminished serum ceruloplasmin, elevated serum copper, and elevated urinary copper excretion, discussed in Chap. 41).

Pathology

The cerebral lesions are localized more regularly in the cortex than is the case in Wilson disease. In some specimens an irregular gray line of necrosis or gliosis can be observed throughout both hemispheres and the lenticular

nuclei may be shrunken and discolored. These lesions resemble hypoxic ones and may be concentrated in the vascular border zones but they tend to spare the hippocampus, globus pallidus, and deep folia of the cerebellar cortex, the sites of predilection in anoxic encephalopathy. Microscopically, a widespread hyperplasia of protoplasmic astrocytes is visible in the deep layers of the cerebral cortex and in the cerebellar cortex as well as in thalamic and lenticular nuclei and other nuclear structures of the brainstem. In the necrotic zones, the myelinated fibers and nerve cells are destroyed, with marginal fibrous gliosis; at the corticomedullary junction, in the striatum (particularly in the superior pole of the putamen) and in the cerebellar white matter, microcavitation may be prominent. Protoplasmic astrocytic nuclei contain PAS-positive glycogen granules. Some nerve cells appear swollen and chromatolyzed, taking the form of the Opalski cells usually associated with Wilson disease. The similarity of the lesions in the familial and acquired forms of hepatocerebral disease is striking.

Pathogenesis It is evident that a close relationship exists between the acute, transient form of hepatic encephalopathy and the chronic, largely irreversible hepatocerebral syndrome; frequently one blends imperceptibly into the other. The feature that ties these entities is the existence of portal-systemic shunting of blood. As noted above, this relationship is reflected in the pathologic findings as well. It appears that the parenchymal damage in the chronic disease simply represents the most severe degree of a pathologic process that in its mildest form is reflected in an astrocytic hyperplasia alone. Reducing the serum ammonia by the measures that are effective in acute hepatic encephalopathy will cause a recession of many of the chronic neurologic abnormalities—not completely, but to an extent that permits the patient to function better.

Hypoparathyroidism

This condition and pseudohypoparathyroidism were mentioned in relation to the hereditary metabolic disorders in Chap. 37. In the past, the usual cause was surgical removal of the parathyroid glands during subtotal thyroidectomy, although there continue to be idiopathic cases. With refinements in surgical technique and the use of radiation and drug therapy for thyroid disease, the number of surgically created cases has declined in proportion to nonsurgical ones. The condition in children may occur in pure form, presumably as an agenesis of the parathyroid glands, with unmeasurable levels of parathyroid hormone in the blood, or as part of the DiGeorge syndrome of agenesis of the thymus and parathyroid glands, organs that are embryologically derived from the third and fourth branchial clefts. Hypoparathyroidism is also part of a familial disorder in which a deficiency of thyroid, ovarian, and adrenal function, pernicious anemia, and other defects are combined, based presumably on autoimmune mechanisms. Other causes are intestinal malabsorption, pancreatic insufficiency, and vitamin D deficiency. In all instances the low levels of parathormone and normal responses to injected hormone permit the

recognition of a primary defect of the parathyroid glands and distinguish it from all other conditions in which there is hypocalcemia and hyperphosphatemia.

The clinical manifestations, mainly attributable to the effects of hypocalcemia, are tetany, paresthesias, muscle cramps, laryngeal spasm, and convulsions. Children with this disease may be irritable and show behavioral changes. In adults with chronic hypocalcemia, calcium deposits occur in the basal ganglia, dentate nuclei, and cerebellar cortex. In such patients we have observed unilateral tremor, a restless choreoathetotic hand, bilateral rigidity, slowness of movement and flexed posture resembling Parkinson disease, and ataxia of the limbs and gait—in various combinations. Interestingly, the multiple skeletal and developmental abnormalities that characterize both pseudohypoparathyroidism (a failure of sensitivity to the hormone) and pseudopseudohypoparathyroidism (short stature, round face, short neck, stocky body build, shortening of metacarpal and metatarsal bones and phalanges from premature epiphyseal closure) are rarely seen in pure hypoparathyroidism.

A similar deposition of iron and calcium in the walls of small blood vessels of the lenticular and dentate nuclei, and to a lesser extent in other parts of the brain, is a common finding in normal older individuals (Fahr disease). It also occurs in animals. Occasionally, it reaches a degree of severity that destroys striatal or dentate neurons. In such cases, films of the skull and particularly CT scans will reveal the deposits (see Fig. 37-8), but the cause of the deposits is unknown. Apparently some protein in the capillary walls has an avidity for both calcium and iron.

ACQUIRED METABOLIC DISEASES PRESENTING AS CEREBELLAR ATAXIA

Cerebellar Ataxia with Myxedema

The association of myxedema and cerebellar ataxia has been mentioned sporadically in medical writings since the latter part of the nineteenth century. Jellinek and Kelly described 6 such cases; all showed gait ataxia; in addition, some degree of ataxia of the arms and dysarthria were present in 4, and nystagmus in 2. Cremer and coworkers reported a similar clinical experience based on a study of 24 patients with either primary or secondary hypothyroidism.

There are only a few reports of the pathologic changes. The myxedematous patient described by Price and Netsky had also been an alcoholic, and the clinical signs (ataxia of gait and of the legs) and pathologic changes (loss of Purkinje cells and gliosis of the molecular layer, most pronounced in the vermis) could be distinguished from those caused by alcoholism and malnutrition. Scattered throughout the nervous system of their case were unusual glycogen-containing bodies, similar but not identical to corpora amylacea. These structures, designated myxedema bodies by Price and Netsky, were also observed in the cerebellar white matter of a second case of myxedema; there were no other neuropathologic

changes, however, and this patient had shown no ataxia during life. It is difficult to know whether these peculiar bodies have anything to do with myxedema. If they do, it should be possible to demonstrate them in more than 2 cases. Our colleagues did not see them in one carefully studied case of myxedema, nor have they been described by others. Serum creatine kinase (CK) is also slightly elevated in hypothyroidism, presumably because of its slowed metabolism. Thyroid medication corrects the defect in motor coordination and normalizes the CK, raising the possibility that this is the result of a subcellular mechanism.

Table 5-1 summarizes the various causes of cerebellar ataxia, including the metabolic ones. Notable metabolic disorders, some heritable, in which ataxia may be a leading manifestation include G_{M2} gangliosidosis, possibly sprue (discussed below), and a large number of neonatal and infantile aminoacidopathies.

Effects of Hyperthermia on the Cerebellum

The damaging effects of *hyperthermia*, like those of anoxia, involve the brain diffusely. In the case of hyperthermia, however, the changes are disproportionately severe in the cerebellum. The acute manifestations of profound hyperthermia are coma and convulsions, frequently complicated by shock and renal failure. Patients who survive the initial stage of the illness frequently show signs of widespread cerebral affection, such as confusion and pseudobulbar and spastic paralysis. These abnormalities tend to resolve gradually, leaving the patient with a more or less pure disorder of cerebellar function.

The most extensive account of the effects of hyperthermia is that of Malamud and colleagues. These authors studied 125 fatal cases of heat stroke but their observations are probably applicable to hyperthermia of other types. In patients who survived less than 24 h, the changes consisted mainly of a loss of some of the Purkinje cells and swelling, pyknosis, and disintegration of those that remained. In cases surviving beyond 24 h, there was almost complete degeneration of the Purkinje cells, with gliosis throughout the cerebellar cortex as well as degeneration of the dentate nuclei. The changes in the cerebellar cortex were equally pronounced in the hemispheres and vermis. The unanswered question is whether high temperature alone is an adequate cause or whether it must be combined with hypoxia and ischemia. It is of interest that this syndrome is not seen in patients with infective fevers, malignant hyperthermia, or the malignant neuroleptic syndrome—either the neuropathologic changes or the clinical cerebellar syndrome in survivors.

Cerebellar Syndromes Associated with Celiac Disease (Sprue, Gluten Sensitive Enteropathy)

Most often, the neurologic association with this disease has been a peripheral neuropathy, as described in Chap. 46. In addition, a progressive cerebellar ataxia of gait and limbs, sometimes with polymyoclonus in

association with a gluten-sensitive enteropathy, has been the subject of several reports. The underlying cause of the enteropathy is an intestinal allergy to gluten in wheat that produces a villous atrophy of the intestinal mucosa. Between 0.5 and 1 percent of the white population are affected with the intestinal disorder. The classic features are diarrhea and malabsorption but many individuals are asymptomatic (see also Chap. 41).

The neurologic disorder may appear several years after onset of the enteropathy and, in addition to ataxia, usually includes signs of peripheral neuropathy and rarely, myelopathy or encephalopathy (dementia) or psychiatric symptoms (Hallert and Astrom; Hallert and Deerefeldt). A rare spinocerebellar syndrome was described by Cooke and Smith. According to Finelli and colleagues, neurologic abnormalities occur in approximately 10 percent of cases of adult celiac sprue. This subject was reviewed by Bhatia and colleagues and extensively by Hadjivassiliou and colleagues (1998, 2002). The latter authors emphasize the frequent occurrence of ataxia in patients with gluten sensitivity and, more specifically, antibodies to transglutaminase and endomysium, but, curiously, often without overt signs of bowel disease. There is also an association of sprue in more than 90 percent of patients with the HLA DQ2 and DQ8 genotypes. The few cases that have come to autopsy have shown severe cerebellar atrophy, a finding that may also be disclosed by MRI. Hadjivassiliou and colleagues (1998) observed lymphocytic infiltration and perivascular cuffing in the cerebellar cortex and peripheral nerves in one autopsied case but not in another, changes that they took to represent immunologic injury to these parts.

Despite these associations, some authors have been skeptical of a "gluten ataxia" (see the editorial by Cross and Golumbek and the contrary case for a valid connection by Hadjivassiliou et al [2002]). Reports of improvement in the ataxia following the institution of a gluten-free diet are conflicting.

The situation is further complicated by the finding that anti gliadin antibodies (which are not autoantibodies but are directed against gluten, the offending agent), while not specific for celiac disease, do correspond to the presence of neurologic manifestations (ataxia and neuropathy); however, the more specific antiendomysium and antitransglutaminase autoantibody markers of sprue have little apparent relation to the presence of neurologic disease. Even more confusing is the claim that half of these patients will have one or another antibody but no clinical enteropathy, making it necessary to perform a small-bowel biopsy to detect villous atrophy.

A gluten-free diet is necessary, not only to reduce the enteropathy, if present, but also to reduce the chances of the later development of a bowel lymphoma. The medical issues relating to celiac disease and the use of antibody tests and bowel biopsy are reviewed by Farrell and Kelly.

We have sought evidence by antibody testing and bowel biopsy of sprue in numerous patients with an

ataxia of obscure origin and have only once found it. Nevertheless, the evidence presented in the writings of several authors, particularly Hadjivassiliou, suggest that sprue may underlie some cases of subacute ataxia in adults. Paraneoplastic cerebellar degeneration and Creutzfeldt-Jakob disease should always be considered in the differential diagnosis of a case of subacute cerebellar ataxia. Vitamin E deficiency may induce a similar syndrome with features of spinocerebellar dysfunction.

Jejunioileal bypass operations, in addition to causing a chronic arthropathy, neuropathy, and vasculitic skin lesions, may give rise to an episodic confusion and cerebellar ataxia associated with a lactic acidosis and abnormalities of pyruvate metabolism. Overfeeding and fasting are provocative factors (Dahlquist et al).

ACQUIRED METABOLIC DISEASE PRESENTING AS PSYCHOSIS AND DEMENTIA

The point has been made that milder forms of metabolic diseases that cause episodic stupor and coma, if persistent, may have a protracted course and are then difficult to distinguish from the dementias (Chap. 21). Examples are associated with chronic hepatic encephalopathy and the syndromes of episodic hypoglycemia, chronic hypercalcemia (in multiple myeloma, metastatic cancer, and sarcoidosis), hyponatremia, and hypernatremia. Unlike the common types of dementia described in Chap. 21, the acquired metabolic diseases are nearly always accompanied by a degree of drowsiness and inattentiveness—attributes that usually allow an encephalopathic confusional state to be distinguished from a dementia. The presence of asterixis is also an aid. If the onset of the illness is abrupt rather than gradual and of brief duration, and if therapy reverses the condition, restoring full mental clarity, the conclusion is justified that one is dealing with a confusional state, but at any one time in the active phase of the disease, the clinical state may resemble dementia.

In general hospitals, an episodic confusional state lasting days and weeks in the course of a medical illness or following an operation should always raise the suspicion of one of the aforementioned metabolic derangements (*or an adverse effect of a drug*). Usually, however, if these causes can be excluded, one falls back on a rather unsatisfactory interpretation—that a combination of drugs, fever, toxemia, and unrecognizable metabolic disorders is responsible. The "septic encephalopathy" described earlier in this chapter conforms to this ambiguous notion.

In the endocrine encephalopathies described below, the clinical phenomena may take the form of a delirium. Confusional states may be combined with agitation, hallucinations, delusions, anxiety, and depression, and the time span of the illness may be in terms of weeks and months rather than days. Certain aspects of the endocrine psychoses are discussed further on.

Cushing Syndrome and Corticosteroid Psychoses

Derangements of mental function that follow administration of adrenocorticotropic hormone (ACTH) and of corticosteroids have become the prototypes of iatrogenic psychoses. The same disturbances of mental function may accompany Cushing disease (see “Corticosteroid and Adrenocorticotropic Hormone Psychosis” in Chap. 53). Experience with this neuropsychiatric condition came originally from observations of patients receiving ACTH and later from those receiving prednisone for a variety of neurologic and medical diseases. With low doses there is usually no psychic effect other than a sense of well-being and decreased fatigability. At higher doses (equivalent to 60 to 100 mg/d of prednisone), approximately 10 to 15 percent of patients become overly active, emotionally labile, and unable to sleep. Unless the dose is promptly reduced, a progressive shift in mood follows, usually toward euphoria and hypomania, but sometimes toward depression and then inattentiveness, distractibility, and mild confusion. The EEG becomes less-well modulated and slower frequencies appear. A minority of patients experience frank hallucinations and delusions, giving the illness a truly psychotic stamp and raising the suspicion of schizophrenia or bipolar disease. In nearly all instances, there is mixture of confusion and mood change, distinguishing the state from other mundane metabolic encephalopathies. Withdrawal of medication relieves the symptoms but full recovery may take several days to a few weeks, at which time, as with all confusional states and deliria, the patient has only a fragmentary recollection of events that occurred during the illness.

The neurologic basis of this condition is poorly understood. Its attribution to premorbid personality traits or a disposition to psychiatric illness is unconvincing. Critical studies of cellular or subcellular metabolism and morphologic changes are lacking. “Cerebral atrophy” (ventricular enlargement and sulcal widening) has been shown radiologically in patients with Cushing disease and after a prolonged period of corticosteroid therapy, but the basis of this change also is unclear (Momose et al). In most cases of brain shrinkage, withdrawal of steroids has led to a reduction in ventricular size, as documented on sequential imaging studies.

In patients with Cushing disease because of adrenal or basophilic pituitary tumors, mental changes suggestive of dementia and enlarged ventricles are unusual, especially by comparison to the incidence of these changes with exogenous corticosteroids. Here again, there is a peculiar combination of mood changes and impaired cognitive function. A frank psychosis may occur. This condition is described more completely in Chap. 53 and the attendant proximal myopathy, in Chap. 48.

Thyroid Encephalopathies

Hyperthyroidism

Allusions to psychosis in thyrotoxic patients are frequent in the medical literature. Mental confusion, seizures, manic or depressive attacks, and delusions occur singly

or in combination. Action tremor is almost universal, and chorea occurs occasionally in various combinations with proximal muscular weakness. In descriptions of abnormal movements, it is often not clear whether it was chorea, tremor, myoclonus, or just fidgetiness that was observed. Treatment of the hyperthyroidism gradually restores the mental state to normal, leaving one with no explanation of what had happened to the CNS. The separate and special associations of hyperthyroidism with periodic paralysis and myasthenia are discussed in later chapters.

Thyroid crisis or “storm” refers to a fulminant increase in the symptoms and signs of thyrotoxicosis—extreme restlessness, tachycardia, fever, vomiting, and diarrhea—leading to delirium or coma. In the past, this was a not uncommon postoperative event in patients poorly prepared for thyroid surgery. Now it is seen mainly in patients with inadequately treated or untreated thyrotoxicosis complicated by serious medical or surgical illness.

Hashimoto Encephalopathy (Steroid-Responsive Encephalopathy Syndrome)

Brain and associates described an encephalopathy consisting of confusion, altered consciousness, and prominent myoclonus in patients with Hashimoto disease. The details were further elaborated by Shaw and colleagues and by Chong and associates. Some cases have had a relapsing course over months or years. It is important to note that most have had normal thyroid function. There are in these cases, however, high titers of several antithyroid antibodies, particularly antibodies against thyroid peroxidase and thyroglobulin; some affected individuals have more than one such antibody. Ferracci and colleagues found evidence of the production of these antibodies in the nervous system and of their presence in spinal fluid. One must be cautious, however, in interpreting the presence of antithyroid antibodies in the blood, as they are detected in many people without an encephalopathy, particularly older women, and in two-thirds of patients with Graves disease.

The most commonly observed syndrome is of confusion or stupor accompanied by multifocal myoclonus. Seizures—including myoclonic and rarely, nonconvulsive status epilepticus. Hemiparesis, ataxia, psychosis, and unusual tremors, including those of the palate, have been reported in individual cases as in the series reported by Castillo and colleagues; they found tremor, transient aphasia, myoclonus, ataxia and seizures to be present in that order of frequency. Many had liver function abnormalities and one-fifth showed inflammatory changes in the CSF. Some of the reports included children.

Often there are other members of the family with a different autoimmune disease. It has been the myoclonic aspect of the encephalopathy, a feature of all of the cases we have observed, which has usually led to consideration of this diagnosis. It is not uncommon for such cases to be mistaken for Creutzfeldt-Jakob disease (subacute spongiform encephalopathy). Early descriptions of the illness included a pleocytosis of the spinal fluid and white matter

lesions, but we have not noted these abnormalities. What limited pathology there is, in a case studied after 5 months of illness, has shown only nonspecific activation of microglia cells (Perrot et al).

Treatment The encephalopathic symptoms and high titers of antithyroid antibodies respond well to steroid therapy (see Chong et al). In the case reported by Newcomer and associates, a rapid reversal of thyrotoxic coma (and corticospinal signs) was effected by plasma exchange, in parallel with a reduction in T_4 and T_3 levels, and similar results were reported by Boers and Colebatch. The circulating antibodies and the response to corticosteroids and plasma exchange implicate an immune pathogenesis, perhaps similar to paraneoplastic "limbic encephalitis" (see "Encephalomyelitis Associated with Carcinoma and Limbic Encephalitis" in Chap. 31) and to lupus, as well as to the rare encephalitis that may accompany thymoma or ovarian teratoma.

Hypothyroidism

As a rule, in the myxedematous patient, cognitive activity is slowed; in exceptional cases, there is a significant confusional state or stupor. When such changes have been observed, we have noted drowsiness, inattentiveness, and apathy as early features. In 2 cases observed by our colleagues, the somnolence was so extreme that the patients could not stay awake long enough to be fed or examined. They were in a state of hypothermic stupor but exhibited no other neurologic abnormality. In extreme form, the state progresses to "myxedema coma." This state is often precipitated by stresses, particularly surgery and sepsis, mainly in the elderly. Hypothermia, hyponatremia and elevation of serum creatine kinase (CK) concentration, hypoventilation, and elevation of the CSF protein can be expected. The clinical state and laboratory abnormalities are reversed within a few days by thyroid medication. The treatment of myxedema coma has several refined aspects, including the need to administer thyroid hormone cautiously; details can be found in *Harrison's Principles of Internal Medicine*.

Hypothyroidism is associated with a number of distinctive myopathic disturbances, which are discussed in Chap. 51. The ataxia and peripheral neuropathy that are sometimes observed in patients with myxedema were described earlier and in Chap. 46.

Cretinism and Neonatal Myxedema

This form of severe intrauterine hypothyroidism (in mother and fetus) or postnatally as a hereditary or acquired thyroid disease, is probably the most frequent and potentially preventable and correctable metabolic mental defect in the world. Table 37-1 provides a perspective on its relative frequency among neonatal metabolic disorders. Although the condition is most common in goitrous regions where there is a lack of iodine, it may also be the result of any of several genetically determined defects in thyroxin synthesis that have come to light in recent years (Vassart et al). In areas of endemic cretinism, additional factors may be operative, such as the widespread

ingestion of cassava, which contains a toxic goitrogen that inhibits the uptake of iodine by the thyroid.

The symptoms and signs of congenital thyroid deficiency are not usually recognizable at birth but become apparent only after a few weeks; more often the diagnosis is first made between the sixth and twelfth months of life. Physiologic jaundice tends to have been severe and prolonged (up to 3 months), and this, along with widening of the posterior fontanelle and mottling of the skin, should raise suspicion of the disease.

Two types of early life hypothyroidism are recognized—sporadic and endemic. The sporadic type occurs occasionally in developed countries (less than once in 4,000 live births) and is a consequence of a congenital metabolic or anatomic disorder of the thyroid gland. At birth, the gland is either absent or represented by cysts, indicating a failure of development or a destructive lesion. In the sporadic form, in the latter part of the first year, stunting of growth and delay in psychomotor development become evident. Untreated, the child is severely retarded but placid and good natured; such children sleep contentedly for longer periods than normal children. Sitting, standing, and walking are delayed. Movements are slow, and if tendon reflexes can be obtained, their relaxation time is clearly delayed. The body temperature is low, and the extremities are cold and cyanotic. Although the head is small, the fontanelles may not close until the sixth or seventh year, and there is delayed ossification. This type of hypothyroidism is preventable by treatment with thyroid hormone.

Endemic cretinism is most common in developing countries, with an estimated incidence in some areas of 5 to 15 percent. DeLong and colleagues, on the basis of epidemiologic surveys mainly in western China, have distinguished two forms of endemic cretinism: neurologic and myxedematous. The occurrence of the two different types is governed by the timing, duration, and severity of the iodine deficiency (Thilly et al).

The *neurologic form of endemic cretinism* is characterized by varying degrees of deaf-mutism or lesser degrees of hearing loss, dysarthria, proximal limb and truncal rigid-spastic motor disorder involving mainly the lower extremities, and mental deficiency of a characteristic type. In the most severely affected, there is also strabismus, kyphoscoliosis, underdevelopment of leg muscles, and frontal lobe release signs. Bone age, head size, and height are normal and there are none of the coarse facial features of the myxedematous form. In the *myxedematous form of endemic cretinism*, short stature, microcephaly, coarse facial features, and retarded psychomotor development are the main features. There is no deafness or spastic rigidity of the limbs. In typical instances, the face is pale and puffy; the skin dry; the hair coarse, scanty, and dry; the eyelids thickened; the thickened lips parted by the enlarged tongue; the forehead low; and the base of the nose broad. There are fat pads above the clavicles and in the axillae. The abdomen is protuberant, often with an umbilical hernia, and the head is small.

DeLong and others attribute neurologic cretinism to a lack of available iodine in the mother and fetus during

the second and third trimesters of pregnancy; neither mother nor fetus produces thyroxine. It is during the latter part of the second trimester, when the cochleas and the neuronal population of the cerebral cortex and basal ganglia are forming, that these structures suffer irreparable damage from lack of thyroid hormone. The effects of this midfetal hypothyroidism and iodine deficiency cannot be corrected by giving thyroid hormone at birth and thereafter. It can be prevented only by providing iodine therapy to the mother before and during the first trimester of pregnancy (Cao et al). The myxedematous form of cretinism is more likely to occur from lack of thyroid hormone in the late second and the third trimesters.

The congenital mental defect ranges from apathy and absence of social interaction to an alert, cooperative state but slowness in higher-order thinking and verbal facility is always evident. The status of the thyroid gland varies; among neurologic cretins, about half have goiters or have palpable glands; in the rest, the glands are atrophied; practically all myxedematous cretins are athyrotic. Although typical examples of neurologic and myxedematous hypothyroidism are readily distinguished, both types may exist in the same endemic area, and the stigmata of both forms may be recognized in the same individual. The QRS complex of the ECG is of low voltage; the EEG is slower than normal, with less alpha activity; the CSF contains an excess of protein (50 to 150 mg/dL); and the serum T_3 and T_4 , protein-bound iodine, and radioactive iodine uptake are all subnormal. Serum cholesterol is increased (300 to 600 mg/dL).

At autopsy the brain of neurologic cretinism, although small, is normally formed, with all central and brainstem structures and cortical sulcation intact. A reduction in number of nerve cells was described by Marinesco, especially in the fifth cortical layer, but others have not confirmed this finding. The use of Golgi and other silver techniques has shown decreased interneuronal distances (packing density is increased, as in the immature cortex) where there is a deficiency of neuropil. The latter change is because of a poverty of dendritic branchings and crossings, and presumably there is a decrease of the synaptic surfaces of cells (Eayrs). Thyroid hormone appears to be essential, not for neuronal formation and migration but for dendritic-axonal development and organization.

There is substantial evidence that the administration of iodized salt or iodinated vegetable oil or iodide tablets to populations of women who are at risk of iodine deficiency, before and during the first trimester of pregnancy prevents sporadic and endemic cretinism.

Treatment begun during the second trimester protects the fetal brain to a varying degree. Treatment that is started after the beginning of the third trimester does not improve the neurologic status, although head growth and statural development may improve slightly (Cao et al). In sporadic cretinism, if the condition is recognized at birth and treated consistently with thyroid hormones, height and mental development can be stimulated to normal or near-normal levels. The extent of recovery depends on the severity and duration of intrauterine hypothyroidism, i.e., its duration before treatment was begun and the adequacy of therapy. In most patients, some degree of mental deficiency persists throughout life.

“Pancreatic Encephalopathy”

This term was introduced by Rothermich and von Haam in 1941 to describe what they considered to be a fairly uniform clinical state in patients with acute abdominal symptoms referable to pancreatic disease, mainly pancreatitis. The encephalopathy, as they described it, consisted of an agitated, confused state, sometimes with hallucinations and clouding of consciousness, dysarthria, and changing rigidity of the limbs—all of which fluctuated over a period of hours or days. Coma and quadriplegia have been reported. At autopsy, a variety of lesions have been described; two cases have had central pontine myelinolysis and others have had small foci of necrosis and edema, petechial hemorrhages, and “demyelination” scattered through the cerebrum, brainstem, and cerebellum. These have been uncritically attributed to the action of released lipases and proteases from the action of pancreatic enzymes (see review of this subject by Sharf and Levy).

The term *pancreatic encephalopathy* is now more often applied to a depressive illness that seems to occur with disproportionate frequency before the symptoms of a pancreatic cancer become apparent. More common in our experience are numerous cases of pancreatic cancer and sequential cerebral emboli from nonbacterial thrombotic (marantic) endocarditis.

The status of pancreatic encephalopathy, in the authors' opinion, is uncertain. Pallis and Lewis also express reservations and suggest that before such a diagnosis can be entertained in a patient with acute pancreatitis, one must exclude delirium tremens, shock, renal failure, hypoglycemia, diabetic acidosis, hyperosmolality, and hypocalcemia or hypercalcemia—any one of which may complicate the underlying disease. Other cases conform to the encephalopathy of multiorgan failure, discussed earlier.

Diseases of the Nervous System Caused by Nutritional Deficiency

Among nutritional disorders, those of the nervous system occupy a position of special interest and importance. The early studies of beriberi at the turn of the twentieth century were largely responsible for the discovery of thiamine and consequently for the modern concept of deficiency disease. A series of notable achievements in the science of nutrition followed the discovery of vitamins. Despite such progress, a number of diseases caused by nutritional deficiency, and particularly those of the nervous system, continue to represent a worldwide health problem of serious proportions. In some communities, where the diet consists mainly of highly milled rice, there is still a significant incidence of beriberi. In some developing countries, deficiency diseases are endemic, the result of chronic dietary deprivation. And the ultimate effects on the nervous system of intermittent mass starvation, involving large portions of the African continent, are alarming to contemplate.

It comes as a surprise to many physicians that deficiency diseases still occur in the United States and other parts of the developed world. To some extent this is attributable to the prevalence of alcoholism. Relatively less common causes are dietary faddism and impaired absorption of dietary nutrients, which occurs in patients with celiac sprue, pernicious anemia, or surgical exclusion of portions of the gastrointestinal tract for treatment of obesity, and the wasting syndromes of cancer and AIDS. Finally, there are iatrogenic deficiencies induced by the use of vitamin antagonists or certain drugs, such as isonicotinic acid hydrazide (INH), which is used in the treatment of tuberculosis and interferes with the enzymatic function of pyridoxine or methotrexate.

General Considerations

The term *deficiency* is used throughout this chapter in its strictest sense to designate disorders that result from *the lack of an essential nutrient or nutrients in the diet or from a conditioning factor that increases the need for these nutrients*. The most important of these are the vitamins, more specifically, members of the B group—thiamine, nicotinic acid, pyridoxine, pantothenic acid, riboflavin, folic acid, and cobalamin (vitamin B₁₂). However, some deficiency

diseases cannot be related to the lack of a single vitamin. Usually the effects of several vitamin deficiencies can be recognized (thiamine deficiency causing Wernicke disease and subacute combined degeneration [SCD] of the cord, as a result of vitamin B₁₂ deficiency, are notable exceptions that are due to single deficiencies).

Furthermore, nutritional diseases of the nervous system are not simply a matter of vitamin deprivation. The general signs of undernutrition, such as circulatory abnormalities and loss of subcutaneous fat and muscle bulk, are usually associated and conversely, a total lack of vitamins, as in starvation, is rarely associated with the classic deficiency syndromes of beriberi or pellagra. In other words, a certain amount of food is necessary to produce them. In a similar way, excessive intake of carbohydrates relative to the supply of thiamine favors the development of a thiamine-deficiency state. All deficiency diseases, including those of the nervous system, are influenced by factors such as exercise, growth, pregnancy, neoplasia, and systemic infection, which increase the need for essential nutrients, and by disorders of the liver and the gastrointestinal tract, which may interfere with the synthesis and absorption of these nutrients.

As already mentioned, alcoholism is an important factor in the causation of nutritional diseases of the nervous system. Alcohol acts mainly by displacing food in the diet but also by adding carbohydrate calories (alcohol is burned almost entirely as carbohydrates), thus increasing the need for thiamine. There is some evidence as well that alcohol impairs the absorption of thiamine and other vitamins from the gastrointestinal tract.

In infants and young children, a reduction in protein and caloric intake (so-called protein-calorie malnutrition [PCM]) has a devastating effect on body growth. Whether or not PCM also hinders the growth of the brain, with consequent effects on intellectual and behavioral development, cannot be answered as readily. The data bearing on this matter are discussed in the last part of this chapter.

Characteristic of the nutritional diseases is the potential for involvement of both the central and peripheral nervous systems, an attribute shared only with certain metabolic disorders. In addition, there are several distinctive neurologic disorders in which nutritional deficiency may play

a role, although this has not been proved. These include (1) "alcoholic" cerebellar degeneration, (2) Marchiafava-Bignami disease (degeneration of the corpus callosum), and (3) central pontine and extrapontine myelinolysis, which are more closely aligned with the rapid correction of hyponatremia, as discussed in Chap. 40.

Some comments will also be made in this chapter about PCM, the neurologic disorders consequent to intestinal malabsorption, and the rare hereditary vitamin-responsive diseases. Deficiencies of trace elements, because of their rarity, are not discussed; only iodine deficiency (cretinism) is of much importance in humans, and it was discussed in Chap. 40 on acquired metabolic diseases.

WERNICKE-KORSAKOFF SYNDROME (THIAMINE [B₁] DEFICIENCY)

Wernicke disease and the Korsakoff amnesic state are common neurologic disorders that have been recognized since the 1880s. *Wernicke disease* is characterized by nystagmus, abducens and conjugate gaze palsies, ataxia of gait, and mental confusion. These symptoms develop acutely or subacutely and may occur singly or, more often, in combination. Wernicke disease is specifically the result of a deficiency of thiamine and is observed mainly, although far from exclusively, in alcoholics.

The *Korsakoff amnesic state* (Korsakoff psychosis) is a mental disorder in which retentive memory is impaired out of proportion to all other cognitive functions in an otherwise alert and responsive patient. This amnesic disorder, like Wernicke disease, is most often associated with the thiamine deficiency of alcoholism and malnutrition, but it may be a symptom of various other non-nutritional diseases that have their basis in structural lesions of the medial thalami or the hippocampal portions of the temporal lobes, such as infarction in the territory of branches of the posterior cerebral arteries, hippocampal damage after cardiac arrest, third ventricular tumors, and herpes simplex encephalitis. An almost equivalent type of memory disturbance may also follow acute lesions of the basal septal nuclei of the frontal lobe. Transient impairments of retentive memory of the Korsakoff type may be the salient manifestations of temporal lobe epilepsy, concussive head injury, and a unique disorder known as transient global amnesia. The anatomic basis of the Korsakoff amnesic syndrome is described in Chap. 21.

In the nutritionally deficient patient, Korsakoff amnesia is usually associated with and immediately follows the occurrence of Wernicke disease. For this reason and others elaborated in the following text, the term *Wernicke disease* or *Wernicke encephalopathy* is applied to a symptom complex of ophthalmoparesis, nystagmus, ataxia, and an acute apathetic-confusional state. If an enduring defect in learning and memory results, as it often does, the symptom complex is designated as the *Wernicke-Korsakoff syndrome*.

It is perhaps in part due to the emphasis in previous editions of this book that alcoholism has been inordinately associated with this disease complex. The disease arises in many other clinical settings. One of Wernicke's

original cases, for example, occurred in a woman with hyperemesis gravidarum and such instances are still found. However, bariatric surgery, cancer chemotherapy, inanition in AIDS and from anorexia nervosa, and even in the frailty of older age, in nutritionally susceptible persons, starvation for economic and social reasons all may give rise to thiamine deficiency. Even the elderly and frail who subsist for years on "tea and toast" can acquire the disease. In addition, there are common medical circumstances in which a subclinical thiamine deficiency becomes manifest. Perhaps the most important of these is a carbohydrate load, particularly the administration of intravenous glucose to a malnourished individual; other precipitants are unbalanced intravenous hyperalimentation, refeeding syndrome, thyrotoxicosis, and hypomagnesemia.

The presence of this disease must be constantly emphasized. As summarized in the review by Sechi and Serra of published series from several countries, there is a discrepancy between the detection of the process in autopsy series, 0.5 to 3 percent, and the prevalence of the clinical diagnosis, 0.04 to 0.13 percent, indicating that *approximately three-quarters of cases are not recognized during life*.

Historical Note In 1881, Carl Wernicke first described an illness of sudden onset characterized by paralysis of eye movements, ataxia of gait, and mental confusion. His observations were made in 3 patients, of whom 2 were alcoholics and 1 was a young woman with persistent vomiting following the ingestion of sulfuric acid. In each of these patients there was progressive stupor and coma culminating in death. The pathologic changes described by Wernicke consisted of punctate hemorrhages affecting the gray matter around the third and fourth ventricles and aqueduct of Sylvius; he considered these changes to be inflammatory in nature and confined to the gray matter, hence his designation "polioencephalitis hemorrhagica superioris." In the belief that Gâyet had described an identical disorder in 1875, the term *Gâyet-Wernicke* is used frequently by French authors. Such a designation is hardly justified insofar as the clinical signs and pathologic changes in Gâyet's patients differed from those of Wernicke's patients in all essential details.

The first comprehensive account of this disorder was given by the Russian psychiatrist S.S. Korsakoff in a series of articles published between 1887 and 1891 (for English translation and commentary, see reference by Victor and Yakovlev). Korsakoff stressed the relationship between "neuritis" (a term used at that time for all types of peripheral nerve disease) and the characteristic alcoholic disorder of memory, which he believed to be "2 facets of the same disease" and which he called "psychosis polyneuritica." But he also made the points that neuritis need not accompany the amnesic syndrome and that both disorders could affect nonalcoholic as well as alcoholic patients. His clinical descriptions were remarkably complete and have not been surpassed to the present day. It is of interest that the relationship between Wernicke disease and Korsakoff polyneuritic psychosis was appreciated neither by Wernicke nor by Korsakoff. Murawieff, in 1897, first postulated that a single cause was responsible for both. The intimate clinical relationship was established by Bonhoeffer in 1904, who stated

that in all cases of Wernicke disease he found neuritis and an amnesic psychosis. Confirmation of this relationship on pathologic grounds came much later. For further details the reader is referred to the extensive monograph by Victor, Adams, and Collins.

Clinical Features

The incidence of the Wernicke-Korsakoff syndrome cannot be stated with precision, but it had been a common disorder as noted in the introductory comments. At the Cleveland Metropolitan General Hospital, for example, in a consecutive series of 3,548 autopsies in adults (for the period 1963 to 1976), our colleague M. Victor (1990) found the pathognomonic lesions in 77 cases (2.2 percent). The disease affects males slightly more often than females and the age of onset is fairly evenly distributed between 30 and 70 years. In the past few decades, the incidence of the Wernicke-Korsakoff syndrome has fallen in the alcoholic population, but it is being recognized with increasing frequency among nonalcoholic patients in a variety of clinical settings that are prone to include malnutrition, including iatrogenic ones.

The triad of clinical features described by Wernicke of ophthalmoplegia (with nystagmus), ataxia, and disturbances of mentation and consciousness is still clinically useful provided that the diagnosis is suspected and the signs are carefully sought. Often, the disease begins with ataxia, followed in a few days or weeks by mental confusion; or there may be confusion alone, or the more or less simultaneous onset of ataxia, nystagmus, and ophthalmoparesis with or without confusion. In approximately one-third of cases, one component of this triad may be the sole manifestation of the disease. Timely treatment with thiamine prevents the permanent Korsakoff-amnesic component of the disease. A schematic representation of the various features is shown in Fig. 41-1, adapted from the series of 131 autopsied proved cases described by Harper, Giles, and Finlay-Jones. The notable aspects are that all 3 of the typical signs were present in only 16 percent; 1 sign in 31 percent, usually confusion alone; 2 signs in 28 percent; and no signs reported or detected during life in 19 percent. A description of each of the major manifestations follows.

Oculomotor Abnormalities The diagnosis of Wernicke disease is made most readily on the basis of the ocular signs. These consist of (1) nystagmus that is both horizontal and vertical and mainly evoked by gaze; this is the most common feature, (2) weakness or paralysis of the lateral rectus muscles, and (3) weakness or paralysis of conjugate gaze. Usually there is some combination of these abnormalities (see Chap. 14).

Next to nystagmus, the most frequent ocular abnormality is lateral rectus weakness, which is bilateral but not necessarily symmetrical and is accompanied by diplopia and internal strabismus. With complete paralysis of the lateral rectus muscles, nystagmus is absent in the abducting eyes and it becomes evident as the weakness improves under treatment. The palsy of conjugate gaze varies from merely a paretic nystagmus on extreme gaze to a complete loss of ocular movement in horizontal or vertical movements, abnormalities of the former being more frequent. An isolated paralysis of downward gaze

Figure 41-1. Clinical features of Wernicke-Korsakoff disease in a series of 131 autopsy proved cases. (Reprinted with permission from Harper CG, Giles M, and Finlay-Jones R: *J Neurol Neurosurg Psychiatry* 49:341-345, 1986.)

does occur but is an unusual manifestation, and a pattern that simulates internuclear ophthalmoplegia has been seen. In advanced stages of the disease there may be a complete loss of ocular movements and the pupils, which are otherwise usually spared, may become miotic and nonreacting. Ptosis, small retinal hemorrhages, involvement of the near-far focusing mechanism, and evidence of optic neuropathy occur occasionally, but neither we nor our colleagues have observed papilledema that was included in Wernicke's original description. These ocular signs are highly characteristic of Wernicke disease and disappearance of nystagmus and an improvement in ophthalmoparesis within hours or a day of the administration of thiamine confirms the diagnosis.

Ataxia Essentially the ataxia is one of stance and gait; in the acute stage of the disease it may be so severe that the patient cannot stand or walk without support. Lesser degrees are characterized by a wide-based stance and a slow, uncertain, short-stepped gait; the mildest degrees are apparent only in tandem walking. In contrast to the gross disorder of locomotion is a relative infrequency of limb ataxia and of intention tremor; when present, they are more likely to be elicited by heel-to-knee than by finger-to-nose testing. Dysarthric, cerebellar-type scanning speech is present only rarely.

Disturbances of Consciousness and Mentation These occur in some form in all but 10 percent of patients who have clinical signs. From Fig. 41-1 it can also be appreciated that when there is only one sign of Wernicke disease, it is usually a confusional state. Several related types of disturbed mentation and consciousness are recognized. By far the most common disturbance is a *global confusional state*. The next following in frequency is memory loss discussed as follows. The patient is apathetic, inattentive, and indifferent to his surroundings. Spontaneous speech

is minimal and many questions are left unanswered, or the patient may suspend conversation and drift off to sleep, although he can be aroused without difficulty. Such questions as are answered betray disorientation in time and place, misidentification of those around him, and an inability to grasp the immediate situation. Many of the patient's remarks may be irrational and lack consistency from one moment to another. If the patient's interest and attention can be maintained long enough to ensure adequate testing, one finds that memory and learning ability are also impaired, in this way blending into the Korsakoff state. In response to the administration of thiamine, the patient rapidly becomes more alert and attentive and more capable of taking part in mental testing. If, however, the state is sustained, for some uncertain period, the most prominent abnormality becomes one of retentive memory (Korsakoff-amic state).

Drowsiness is a common feature of the Wernicke confusional state, but stupor and coma are rare as *initial* manifestations. If, however, the early signs of the disease are not recognized and the patient remains untreated, a progressive depression of the state of consciousness occurs with stupor, coma, and death in a matter of a week or two, just as occurred in Wernicke's original cases. Autopsy series of Wernicke disease are heavily weighted with cases of the latter type, often undiagnosed during life (Harper; Torvik et al).

Some patients are alert and responsive from the time they are first seen and already show the characteristic features of the Korsakoff amnesic state. In a small number of such patients, the amnesic state is the only manifestation of the syndrome, and no ocular or ataxic signs (other than possibly nystagmus) can be discerned.

The Amnesic State As indicated in Chap. 21, the core of the amnesic disorder is a defect in learning (*anterograde amnesia*) and a loss of past memories (*retrograde amnesia*). The defect in learning can be remarkably severe. The patient may be incapable, for example, of committing to memory the simplest of facts (such as the examiner's name, the date, and the time of day) despite countless attempts; the patient can repeat each fact as it is presented, indicating that he understands what is wanted of him and that "registration" is intact, but by the time the third fact is repeated, the first may have been forgotten. However, certain nonverbal learning may take place; for example, with repeated trials, the patient may learn complex tasks such as mirror writing or how to negotiate a maze, despite no recollection of ever having been confronted with these tasks.

Anterograde amnesia is always coupled with a disturbance of past or remote memory (retrograde amnesia). The latter disorder is usually severe in degree, although not complete, and covers a period that antedates the onset of the illness by up to several years. A few isolated events and information from the past are retained, but these are related without regard for the intervals that separated them or for their proper temporal sequence. Usually the patient "telescopes" events into a brief period of time; sometimes the opposite occurs. This aspect of the memory disorder becomes prominent as the initial confusional stage of the illness subsides.

It is probably true that memories of the recent past are more severely impaired than those of the remote past (the rule of Ribot); language, computation, knowledge acquired in school, and all habitual actions are preserved. This is not to say that all remote memories are intact. As discussed in Chap. 21, these are not as readily tested as more recent memories, making the two difficult to compare. It is our impression that there are gaps and inaccuracies in memories of the distant past in practically all cases of the Korsakoff amnesic state, and serious impairments in many.

The cognitive impairment of the Korsakoff patient is not exclusively one of memory loss. Psychologic testing discloses that certain cognitive and perceptual functions that depend little or not at all on retentive memory are also impaired. As a rule, the Korsakoff patient has no insight into his illness and is characteristically apathetic and inert, lacking in spontaneity and initiative, and indifferent to everything and everybody around him. However, the patient has a relatively normal capacity to reason with data immediately before him.

Confabulation has generally been considered to be a specific feature of Korsakoff psychosis, but the validity of this view depends largely on how one defines confabulation, and there is no uniformity of opinion on this point. The observations of our colleague Victor and his colleagues (1959) do not support the oft-repeated statement that the Korsakoff patient fills the gaps in his memory with confabulation. In the sense that gaps in memory exist and that whatever the patient supplies in place of the correct answers fills these gaps, the statement is incontrovertible. It is hardly explanatory, however. The implication that confabulation is a deliberate attempt to hide the memory defect, out of embarrassment or for other reasons, is incorrect. In fact, the opposite seems to pertain: As the patient improves and becomes more aware of a defect in memory, the tendency to confabulate diminishes. Furthermore, confabulation can be associated with both phases of the Wernicke-Korsakoff syndrome: The initial one in which profound general confusion dominates the disease, and the convalescent phase in which the patient recalls fragments of past experience in a distorted fashion. Events that were separated by long intervals are juxtaposed or related out of sequence, so that the narrative has an implausible or fictional aspect. In the chronic state of the disease, confabulation is usually absent. These and other aspects of confabulation are discussed fully in the monograph by Victor and colleagues (1959).

Other Clinical Abnormalities Approximately 15 percent of patients show signs of alcohol withdrawal, that is, hallucinations and other disorders of perception, confusion, agitation, tremor, and overactivity of autonomic nervous system function. These symptoms are evanescent in nature and usually mild.

Signs of *peripheral neuropathy* are found in more than 80 percent of patients with the Wernicke-Korsakoff syndrome. In most, the neuropathic disease is mild and does not account for the disorder of gait, but it may be so severe and particularly painful that stance and gait cannot be tested. In a small number, retrobulbar optic neuropathy is added. Despite the frequency of peripheral neuropathy, overt signs of beriberi heart disease are rare.

However, indications of disordered cardiovascular function such as tachycardia, exertional dyspnea, postural hypotension, and minor electrocardiographic abnormalities are frequent; occasionally, the patient dies suddenly following only slight exertion. These patients may show an elevation of cardiac output associated with low peripheral vascular resistance, abnormalities that revert to normal after the administration of thiamine. *Postural hypotension* and syncope are common findings in Wernicke disease and are probably a result of impaired function of the autonomic nervous system, more specifically to a defect in the sympathetic outflow (Birchfield). There may be mild *hypothermia*, loss of libido, and erectile dysfunction.

Patients with the Korsakoff amnesic state may have a demonstrably *impaired olfactory discrimination*. This deficit, like the notable apathy present in most Wernicke's patients, is probably attributable to a lesion of the mediodorsal nucleus of the thalamus and its connections, and not to a lesion of the peripheral olfactory system (Mair et al). Vestibular function, as measured by the response to standard ice-water caloric tests, is universally impaired in the acute stage of Wernicke disease (Ghez), but vertigo is not a complaint. This vestibular paresis probably accounts for the severe disequilibrium in the initial stage of the illness.

Laboratory Findings

The acute lesions of the Wernicke-Korsakoff syndrome in the mammillary bodies, and other medial thalamic and periaqueductal areas can be demonstrated in most cases by magnetic resonance imaging (MRI) (Donnal et al; Varnet et al). The changes are most apparent on the fluid-attenuated inversion recovery (FLAIR), T2, and diffusion-weighted sequences (if there is hemorrhage), but they may also enhance as shown in Fig. 41-2. It is not clear to what extent gradient-echo MRI images can be expected to consistently reveal the small hemorrhagic lesions of the diencephalon and periventricular areas. Imaging is particularly useful in patients in whom stupor or coma has supervened or in whom ocular and ataxic signs are otherwise invident (Victor, 1990), but in milder cases a normal MRI does not preclude the diagnosis. The typical MRI changes are observed in only 58 percent of cases according to Weidauer and colleagues. In the chronic state, the mammillary bodies may be shrunken if measured by volumetric techniques (Charness and DeLaPaz).

The cerebrospinal fluid (CSF) in uncomplicated cases of the Wernicke-Korsakoff syndrome is normal or shows only a modest elevation of the protein content. Protein values greater than 100 mg/dL or a pleocytosis indicates the presence of a complicating illness such as subdural hematoma, meningial infection, or encephalitis.

Measurements of serum thiamine and red blood cell transketolase have been explored as aids to diagnosis but are not sufficiently sensitive for clinical use and they are not readily available. Before treatment with thiamine, patients with Wernicke disease show a marked reduction in transketolase. Restoration of these values and of thiamine di- and triphosphate toward normal occurs within a few hours of the administration of thiamine, and completely normal values are usually attained within 24 h.

Figure 41-2. Axial T1-postgadolinium image of a 63-year-old woman with Wernicke encephalopathy showing abnormal enhancement of the mammillary bodies (arrow).

There are suggestions that there is a hereditary factor in the susceptibility of Wernicke-Korsakoff disease and possibly explains why only a small proportion of nutritionally deficient alcoholics develop this disease. Candidates for this variability have been proposed to be in transketolase activity or in the thiamine transporter gene, possibly on an epigenetic basis, but other genetic regions have been studied and to our reading, there is no clarity on this subject.

Approximately half of patients with Wernicke-Korsakoff disease show electroencephalographic (EEG) abnormalities, consisting of diffuse mild to moderate slow activity. Total cerebral blood flow and cerebral oxygen and glucose consumption may be reduced in the acute stages of the disease and may still be present after several weeks of treatment (Shimojyo et al). These observations indicate that significant reductions in brain metabolism need not be reflected in EEG abnormalities or in depression of the state of consciousness and that the latter is more a function of the location of the lesion than of the overall degree of metabolic defect.

Course of the Illness

The mortality rate in the acute phase of Wernicke disease was 17 percent in the series of patients collected by Victor, Adams, and Collins (1989) many decades ago.

The fatalities were attributable mainly to hepatic failure and infection (pneumonia, pulmonary tuberculosis, and septicemia being at that time the most common). Some deaths were undoubtedly a result of the cerebral or cardiac effects of thiamine deficiency that had reached an irreversible stage.

Most patients respond in a fairly predictable manner to the administration of thiamine, as detailed further on. The most dramatic improvement is in the ocular manifestations. Recovery often begins within hours or sooner after the administration of thiamine and practically always within several days. This effect is so constant that a failure of the nystagmus and ocular palsies to respond to thiamine should raise doubts about the diagnosis of Wernicke disease. Horizontal nystagmus sometimes disappears in minutes. Sixth-nerve palsies, ptosis, and vertical gaze palsies recover *completely* within a week or two in most cases, but vertical nystagmus may sometimes persist for several months. Horizontal gaze palsies recover completely as a rule, but in 60 percent of cases a fine horizontal nystagmus remains as a permanent sequela. In this respect, horizontal nystagmus is unique among the ocular signs.

In comparison with the ocular signs, improvement of ataxia is delayed. Approximately 40 percent of patients recover completely from ataxia. The remaining recover incompletely or not at all and are left with a slow, shuffling, wide-based gait and inability to walk tandem. The residual gait disturbances and horizontal nystagmus provide a means of identifying obscure and chronic cases of dementia as alcoholic-nutritional in origin. Vestibular function improves at about the same rate as the ataxia of gait, and recovery is usually but not always complete.

The early symptoms of apathy, drowsiness, and global confusion invariably recede, and as they do the defect in memory and learning stands out more clearly. However, the memory disorder, once established, recovers completely or almost completely in only 20 percent of patients. The remainder is left with varying degrees of permanent Korsakoff amnesia.

It is apparent from the foregoing account that Wernicke disease and Korsakoff amnesia are not separate diseases, but that *the ocular and ataxic signs and the transformation of the global confusional state into an amnesic syndrome are successive stages in a single disease process*. Of 186 patients in the series of Victor, Adams and Collins (1989) who survived the acute illness, 157 (84 percent) showed this sequence of clinical events. As a corollary, a survey of alcoholic patients with Korsakoff amnesia in a psychiatric hospital disclosed that in most patients the illness had begun with the symptoms of Wernicke disease and that approximately 60 percent of them still showed some ocular or cerebellar stigmata of Wernicke disease many years after the onset. The same continuum cannot be invoked to explain alcoholic-nutritional cerebellar degeneration that arises as an independent illness and is not as a residual of the ataxia of Wernicke disease (see further on).

Neuropathologic Findings

Patients who die in the acute stages of Wernicke disease show symmetrical lesions in the paraventricular regions of the thalamus and hypothalamus, mammillary bodies, periaqueductal region of the midbrain, floor of the fourth ventricle (particularly in the regions of the dorsal motor nuclei of the vagus and vestibular nuclei), and superior cerebellar vermis. Lesions are consistently found in the mammillary bodies and less consistently in other areas. The microscopic changes are characterized by varying degrees of necrosis of parenchymal structures. Within the area of necrosis, nerve cells are lost, but usually some remain; some of these are damaged but others are intact. Myelinated fibers are more affected than neurons. These changes are accompanied by a prominence of the blood vessels, although in some cases there appears to be a primary endothelial proliferation and evidence of recent or old petechial hemorrhage. In the areas of parenchymal damage there is astrocytic and microglial proliferation. Discrete hemorrhages were found in only 20 percent of Victor's (1989) cases, and many appeared to be agonal in nature. The cerebellar changes consist of degeneration of all layers of the cortex, particularly of the Purkinje cells; usually this lesion is confined to the superior parts of the vermis, but in advanced cases the cortex of the most anterior parts of the anterior lobes is involved as well. Of interest is the fact that the lesions of Leigh encephalomyelopathy, a mitochondrial disorder implicating pyruvate metabolism, bear a resemblance to those of Wernicke disease but have a slightly different distribution and histologic characteristics.

The ocular muscle and gaze palsies are attributable to lesions of the sixth- and third-nerve nuclei and adjacent tegmentum, and the nystagmus to lesions in the regions of the vestibular nuclei. The latter are also responsible for the loss of caloric responses and probably for the gross disturbance of equilibrium that characterizes the initial stage of the disease. The lack of significant destruction of nerve cells in these lesions accounts for the rapid improvement and the high degree of recovery of oculomotor and vestibular functions. The persistent ataxia of stance and gait is caused by the lesion of the superior vermis of the cerebellum; ataxia of individual movements of the legs is attributable to an extension of the lesion into the anterior parts of the anterior lobes. Hypothermia, which occurs sometimes as an early feature of Wernicke disease, is probably attributable to lesions in the posterior and posterolateral nuclei of the hypothalamus (experimentally placed lesions in these parts have been shown to cause hypothermia or poikilothermia in monkeys).

The topography of the neuropathologic changes in patients who die in the chronic stages of the disease, when the amnesic symptoms are established, is much the same as the changes in the acute stages of Wernicke disease. Apart from the expected differences in age of the glial and vascular reactions, the only important difference has to do with the involvement of the medial dorsal and anterior nuclei of the thalamus. The medial parts of these nuclei were consistently involved in the patients who

had shown the Korsakoff amnesic state during life; they were not affected in patients who had had no persistent amnesic symptoms in the series of Victor, Adams, and Collins (1989). The mammillary bodies were affected in all the patients, both those with the amnesic defect and those without. These observations suggest that the lesions responsible for the memory disorder are those of the thalami, predominantly of parts of the medial dorsal nuclei (and their connections with the medial frontal and temporal lobes and amygdaloid nuclei), and not those of the mammillary bodies, as is frequently stated. It is notable that the hippocampal formations, the site of damage in most other types of Korsakoff memory loss, are intact.

Treatment of the Wernicke-Korsakoff Syndrome

Wernicke disease constitutes a medical emergency; its recognition (or even the suspicion of its presence) requires the *administration of thiamine*. The prompt use of thiamine prevents progression of the disease and reverses those lesions that have not yet progressed to the point of fixed structural change. As emphasized earlier, in patients who show only ocular signs and ataxia, the administration of thiamine is crucial in preventing the development of an irreversible amnesic state.

Although 2 to 3 mg of thiamine may be sufficient to modify the ocular signs, much larger doses are needed to sustain improvement and replenish the depleted thiamine stores—initially, 50 to 200 mg intravenously and a similar dose mg intramuscularly—the latter being repeated each day until the patient resumes a normal diet. Certain writings indicate that initial doses of 500 mg are necessary to fully reverse the manifestations of Wernicke disease and prevent progression to the point of a Korsakoff syndrome. It appears that these higher doses, given for several days parenterally, are needed to replete vitamin levels in alcoholic and nutritionally deprived patients (see the articles by Thomson et al), but the need for high-dose regimens to reverse Wernicke disease is based on less-persuasive data. Nonetheless, current guidelines from the Royal College of Physicians, given by Thomson, promote high-dose regimens and seem advisable. The risks of administering parenteral thiamine have probably been overstated; anaphylactic reactions occurred in 0.1 percent of the series of Wrenn and colleagues and minor reactions in 1 percent.

To avoid precipitating Wernicke disease, it has become standard practice in emergency departments to administer 100 mg or more of thiamine in malnourished or alcoholic patients if intravenous fluids that contain glucose are being infused. Magnesium is given as well because it is required as cofactor for thiamine activity. It is similarly advisable to give B vitamins to alcoholic patients who are seen for other reasons in the emergency department so as to raise body stores of thiamine and other vitamins. The chronic alcoholic (or the nonalcoholic with persistent vomiting) exhausts thiamine in a matter of 7 or 8 weeks, during which time the administration of glucose may serve to precipitate Wernicke disease or cause an early form of the disease to progress rapidly. The

further management of Wernicke disease involves the use of a balanced diet and all the B vitamins, as the patient is usually deficient in more than thiamine alone.

A different problem in management may arise once the patient has recovered from Wernicke disease and the amnesic syndrome becomes prominent. Only a minority of such patients (fewer than 20 percent in Victor's series) recover entirely; moreover, the time of recovery may be delayed for several weeks or even months, and then it proceeds very slowly over a period of many months. The extent to which the amnesic symptoms will recover cannot be predicted during the acute stages of the illness. Interestingly, the alcoholic Korsakoff patient, once more or less recovered, seldom demands alcohol but will drink it if it is offered.

Infantile Wernicke–Beriberi Disease

This designates an acute and frequently fatal disease of infants, which until recently was common in rice-eating communities of the Far East. It affects only breast-fed infants, usually in the second to the fifth months of life. Acute cardiac symptoms dominate the clinical picture, but neurologic symptoms (aphonia, strabismus, nystagmus, spasmodic contraction of facial muscles, and convulsions) have been described in many of the cases. This syndrome can be reversed dramatically by the administration of thiamine, so that some authors prefer to call it *acute thiamine deficiency in infants*. In the few neuropathologic studies that are available, changes like those of Wernicke disease in the adult have been described. Occasionally, there are outbreaks of this condition due to inadequately formulated baby foods that lack thiamine.

Infantile beriberi bears no consistent relationship to beriberi in the mother. Infants of mothers with overt signs of beriberi may be quite normal. The absence of beriberi in the mothers of affected infants suggests that infantile beriberi might be due to the result of a toxic factor in breast milk, but such a factor, if it exists, has never been isolated. The levels of thiamine in the breast milk of such mothers have not been measured, however.

Rarely, the clinical manifestations of beriberi in infancy represent an inherited (autosomal recessive) thiamine-dependent state, responding to the continued administration of massive doses of thiamine (Mandel et al; see also Table 41-3, further on).

NUTRITIONAL POLYNEUROPATHY (NEUROPATHIC BERIBERI)

(See also Chap. 46)

Most physicians in the Western world have only a dim notion about beriberi, which they recall as an ill-defined, predominantly cardiac disorder occurring among people whose diet was dominated by polished rice. The milling process, or “polishing,” removes the husk that contains most of the vitamin nutrients. In fact, beriberi is a distinct clinical entity that is not confined to any particular part of the world. Essentially, it is a disease of the heart and of

the peripheral nerves (which may be affected separately), with or without edema, the latter feature providing the basis for the old division into "wet" and "dry" forms. The cardiac manifestations range from tachycardia and exertional dyspnea to acute and rapidly fatal heart failure, the latter being the most dramatic but uncommon manifestation of beriberi. Here we emphasize the peripheral neuropathy, or *neuropathic beriberi*.

That beriberi is essentially a disorder of the peripheral nerves was established in the late nineteenth century by the studies of the Dutch investigators Eijkman, Pekelharing and Winkler, and Grijns. Only after beriberi gained acceptance as a nutritional disease (this followed Funk's discovery of vitamins in 1911) was it suspected that the neuropathy of alcoholics was also nutritional in origin. The similarity between beriberi and alcoholic neuropathy was commented upon by several authors, but it was Shattuck, in 1928, who first seriously discussed the relationship of the 2 disorders. He suggested that "polyneuritis of chronic alcoholism was caused chiefly by failure to take or assimilate food containing a sufficient quantity B vitamins and might properly be regarded as true beriberi." Convincing evidence that "alcoholic neuritis" is not a result of the neurotoxic effect of alcohol was supplied by Strauss. He allowed 10 patients to continue their daily consumption of whiskey while they consumed a well-balanced diet supplemented with yeast and vitamin B concentrates; the peripheral nerve symptoms improved in every case. The observations made by Victor (1984) support Strauss's contention that alcoholic polyneuropathy is essentially a nutritional disease.

Clinical Features

The symptomatology of nutritional polyneuropathy is diverse. In fact, many patients are asymptomatic and evidence of peripheral nerve disease is found only by clinical or electromyographic examination. The mildest neuropathic signs are thinness and tenderness of the leg muscles, loss or depression of the Achilles reflexes and perhaps of the patellar reflexes and at times, a patchy blunting of pain and touch sensation over the feet and shins.

Most patients, however, are symptomatic and have weakness, paresthesias, and pain as the usual complaints. The symptoms are insidious in onset and slowly progressive, but occasionally they seem to evolve or to worsen rapidly over a matter of days. The initial symptoms are usually referred to the distal portions of the limbs and progress proximally if the illness remains untreated. The feet are always affected earlier and more severely than the hands. Usually some aspect of motor disability is part of the chief complaint, but in about one-third of the patients the main complaints are pain and paresthesias. It is this painful syndrome that has been the most prominent feature in the patients we have encountered in recent years. The discomfort takes several forms: a dull, constant ache in the feet or legs; sharp and lancinating pains, momentary in duration, like those of *tabes dorsalis*; sensations of cramping or tightness in the muscles of the feet and calves; or band-like feelings around the legs. Coldness of the feet is a common complaint but is

not corroborated by palpation. Far more distressing are feelings of heat or "burning" affecting mainly the soles, less frequently the dorsal aspects of the feet. These dysesthesias fluctuate in severity and characteristically are worsened by contact stimuli, sometimes to the point where the patient cannot walk or bear the touch of bedclothes, despite the relative preservation of motor power (allodynia). The term *burning feet* has been applied to this syndrome, but it is not particularly apt, as the patient also complains of other types of paresthesias, dysesthesias, and pain, and these symptoms may involve the hands as well as the feet.

Examination discloses varying degrees of motor, sensory, and reflex loss. As the symptoms suggest, the signs are symmetrical, and more severe in distal than in proximal portions of the limbs, and often confined to the legs. In some cases, the disproportionate affection of motor power may be striking, taking the form of a foot- and wrist-drop, but the proximal muscles are usually affected as well (indicated, for example, by climbing stairs or by difficulty in arising from a squatting position). In a few patients, the weakness appears to be most severe in the proximal muscles. Absolute paralysis of the legs had been observed in the past only rarely; immobility caused by contractures at the knees and ankles in neglected patients was a more common occurrence. Tenderness of muscles on deep pressure is a highly characteristic finding, elicited most readily in the muscles of the feet and calves. In the arms, tendon reflexes are sometimes retained despite a loss of strength in the hands. In patients in whom pain and dysesthesias are prominent and motor loss is slight, the reflexes at knee and ankle may be retained or even of greater than average briskness. This attests to the predominant affection of the small nerve fibers.

Excessive sweating of the soles and dorsal aspects of the feet and of the volar surfaces of the hands and fingers is a common manifestation of alcohol-induced nutritional neuropathy. Postural hypotension is sometimes associated, all symptoms indicative of involvement of the peripheral sympathetic nerve fibers.

Sensory loss or impairment may involve all the modalities, although one may be affected out of proportion to the others, usually pain and temperature. One cannot predict from the patient's symptoms which mode of sensation might be affected disproportionately. In patients with impairment of superficial sensation (i.e., touch, pain, and temperature), the border between impaired and normal sensation is not sharp but shades off gradually over a considerable vertical extent of the limbs.

Patients in whom pain is the outstanding symptom do not constitute a distinct group in terms of their neurologic signs. Pain and dysesthesias may be prominent in patients with either severe or slight degrees of motor, reflex, and sensory loss. The term *hyperesthetic* is used commonly to designate the exquisitely painful form of neuropathy but is not well chosen; as pointed out in Chap. 8, one is usually able, by using finely graded stimuli, to demonstrate an elevated threshold to painful, thermal, and tactile stimuli in the "hyperesthetic" zone. Once the stimulus is perceived, however, it has a painful and diffuse, unpleasant quality (hyperpathia).

Tactile evocation of pain or burning is an example, as mentioned, of allodynia.

In most patients with nutritional polyneuropathy, only the limbs are involved and the abdominal, thoracic, and bulbar muscles are usually spared; however, we have encountered 2 cases in which there was sensory loss in the pattern of an escutcheon over the anterior thorax and abdomen. In the most advanced instances of neuropathy, hoarseness and weakness of the voice and dysphagia as a result of degeneration of the vagus nerves may be added to the clinical picture.

Some idea of the incidence of the motor, reflex, and sensory abnormalities and the combinations in which they occur can be obtained from Table 41-1, which is based on Victor's (1984) examination of 189 nutritionally depleted alcoholic patients. Noteworthy is the fact that only 66 (35 percent) of the 189 patients showed the clinical picture of polyneuropathy in its entirety, that is, a symmetrical impairment or loss of tendon reflexes, sensation, and motor power affecting legs more than the arms and the distal more than the proximal segments of the limbs. In the remaining patients, the motor-reflex-sensory signs occurred in various combinations.

Stasis edema and pigmentation, glossiness, and thinness of the skin of the lower legs and feet are common findings in patients with any severe form of neuropathy. Major dystrophic changes, in the form of perforating planar ulcers and painless destruction of the bones and joints of the feet ("Charcot forefeet"), have been described but are rare. Repeated trauma to insensitive parts and superimposed infection are thought to be responsible for the neuropathic arthropathy, as discussed in Chaps. 8 and 46.

The CSF is usually normal, although a modest elevation of protein content is found in a small number. Findings of nerve conduction studies include mild to moderate degrees of slowing of motor and sensory conduction and a marked reduction in the amplitudes of sensory action potentials; the motor conduction velocities in distal segments of the nerves may be reduced, while conduction in proximal segments is normal. Denervated muscles show fibrillation potentials in a pattern that is consistent with more severe involvement peripherally.

Pathologic Features

The essential change is one of axonal degeneration, with destruction of both axon and myelin sheath. Segmental demyelination occurs only in a small proportion of fibers. The most pronounced changes are observed in the distal parts of the longest and largest myelinated fibers in the crural and, to a lesser extent, brachial nerves. In advanced cases, the changes extend into the anterior and posterior nerve roots. The vagus and phrenic nerves and paravertebral sympathetic trunks may be affected in advanced cases. Anterior horn and dorsal root ganglion cells undergo chromatolysis, indicating axonal damage. Secondary changes in the posterior columns are seen in some cases.

Pathophysiology

The nutritional factor(s) responsible for the neuropathy of alcoholism and beriberi has not been defined precisely. Because of the difficulty in producing peripheral neuropathy in mammals by means of a thiamine-deficient diet, the idea that thiamine is the antineuritic vitamin was questioned in the past. Very few of the animal experiments undertaken to settle this point were satisfactory from a nutritional and pathologic point of view. Nevertheless, several studies in birds and humans do indeed indicate that uncomplicated thiamine deficiency may result in peripheral nerve disease. The necessity of either accepting or rejecting the specific role of thiamine became less urgent when it was demonstrated, in both animals and humans; a deficiency of pyridoxine or of pantothenic acid could also result in degeneration of the peripheral nerves (Swank and Adams).

The question of whether polyneuropathy in the alcoholic patient might be a result of the direct toxic effects of alcohol and not of a nutritional deficiency has been raised from time to time (see the preceding text and Denny-Brown and Behse and Buchthal). The evidence for this view is not compelling, either on clinical or on experimental grounds, as already mentioned (see reference to Strauss, in introductory section on nutritional neuropathy). The data presented more recently by Koike and colleagues, ostensibly in favor of the existence of a true alcoholic neuropathy, in our view present no convincing support of a direct toxic effect of alcohol. In the end, we view alcoholic-beriberi neuropathy as a multiple B-vitamin deficiency. The interested reader will find a detailed critique of this subject in the chapters by Victor and by Windebank in the second and third editions, respectively, of *Peripheral Neuropathy*, edited by Dyck and coworkers.

Treatment and Prognosis

The first consideration is to supply adequate nutrition over a long period in the form of a balanced diet supplemented with B vitamins (equally important is to make certain that the patient follows the prescribed diet). If persistent vomiting or other gastrointestinal complications prevent the patient from eating, parenteral feeding becomes necessary; the vitamins may be given intramuscularly or added to intravenous fluids.

Table 41-1

CLINICAL FINDINGS IN NUTRITIONAL POLYNEUROPATHY

NEUROPATHIC ABNORMALITY	LEGS (189 CASES)	ARMS (57 CASES)
Loss of reflexes alone	45 (24) ^a	6 (10) ^b
Loss of sensation alone	10 (5)	10 (18)
Weakness alone	—	5 (9)
Weakness and sensory loss	2 (1)	10 (18)
Reflex and sensory loss	40 (21)	2 (3)
Sensory, motor, and reflex loss	66 (35)	17 (30)
Data incomplete	26 (14)	7 (12)

^aFigures in parentheses indicate percent of 189 cases.

^bFigures in parentheses indicate percent of 57 cases.

Where pain and sensitivity of the feet are the major complaints, the pressure of bedclothes may be avoided by placing a cradle support over the legs. Aching of the limbs may be related to their immobility, in which case they should be moved passively on frequent occasions. Aspirin or acetaminophen is usually sufficient to control hyperpathia and allodynia; occasionally codeine or methadone must be added. Obviously, opiates and addicting synthetic analgesics should be avoided if possible, but we have resorted to fentanyl patches for short periods in a few severely affected patients. Some of our patients with severe burning pain (similar to causalgia) in the feet had in the past been helped temporarily by blocking the lumbar sympathetic ganglia or by epidural injection of analgesics. The response to phenytoin, carbamazepine, and gabapentin has been inconsistent, but they are widely used. Adrenergic-blocking medication has been of little value and mexiletine, in our experience, of uncertain benefit.

The regeneration of peripheral nerves, which may take many months, will be of little avail if the muscles have been allowed to undergo contracture and the joints to become fixed. In cases of severe paralysis, molded splints should be applied to the arms, hands, legs, and feet during periods of rest. Pressure on the heels and elbows can be avoided by padding the splints and by turning the patient frequently or by asking the patient to do so. As function returns, more vigorous physiotherapeutic measures can be undertaken.

Recovery from nutritional polyneuropathy is a slow process. In the mildest cases there may be a considerable restoration of motor function in a few weeks. In severe forms of the disease, many months may pass before the patient is able to walk unaided. The sensory features and pain in particular may be slower to recover, having taken over a year in one of our recently observed patients. The slowness of recovery creates a special problem for the alcoholic patient, in whom the great danger to continued recovery is the resumption of drinking and inadequate diet.

Riboflavin Deficiency (Vitamin B₂ Deficiency)

Whether or not riboflavin deficiency leads to neurologic symptoms has been controversial. In the past, there were claims that glossitis, cheilosis, and neuropathy were caused by riboflavin deficiency, but its effects were never isolated. It is a component of general malnutrition, making it difficult to separate the cause of various disorders. Night blindness seems, however, to be caused by B₂ deficiency. Antozzi and coworkers reported that a metabolic disorder similar to the Reye syndrome can be caused by riboflavin deficiency and is correctable by administration of riboflavin alone. The affected infants in their studies were hypoglycemic, hypotonic, and episodically weak and unresponsive. Generally, 15 mg per day in divided doses is used for replacement, but restoration of a normal diet is paramount.

Antozzi and colleagues also recorded instances of disease in older children and adults, manifesting as a type of lipid storage polyomyopathy as a result of either

a deficiency or malabsorption of riboflavin. Presumably, a disorder of flavin metabolism had caused an impairment of both beta-oxidation of fatty acids and respiratory chain I and II complexes. Serum creatine phosphate was normal in these individuals, but carnitine was reduced. The oral administration of 200 mg of riboflavin and 4 g of carnitine per day relieved the symptoms. We have had no experience with such cases.

PELLAGRA (NIACIN, NICOTINIC ACID, B₃ DEFICIENCY)

In the early 1900s, pellagra attained epidemic proportions in the southern United States and in the alcoholic population of large urban centers. Since 1940, it has diminished greatly because of the general practice of enriching bread with niacin. Nevertheless, among the vegetarian, maize-eating people of underdeveloped countries, and among the black population of South Africa, pellagra is still a common disease (Bomb et al; Shah et al; Ronthal and Adler). In developed countries, pellagra is practically confined to alcoholics (Ishii and Nishihara; Spivak and Jackson; Serdaru et al).

Clinical Features

In its fully developed form, pellagra affects the skin, alimentary tract, and hematopoietic and nervous systems. The early symptoms may be mistaken for those of a psychiatric disorder. Insomnia, fatigue, nervousness, irritability, and feelings of depression are common complaints; taken together they have the character of neurasthenia. Examination discloses mental dullness, apathy, and a mild impairment of memory. Sometimes an acute confusional psychosis dominates the clinical picture. Untreated, these symptoms may progress to a dementia. Pellagra may not only produce mental impairment but occasionally result from it, by virtue of anorexia and refusal of food. The dermatologic feature, often the aspect that permits one to make a confident diagnosis, is a *scaly dermatitis in sun-exposed areas*, followed by hyperpigmentation of these areas. Diarrhea and glossitis or other forms of mucous membrane disorder may be accompaniments (hence the alliterative triad dementia-dermatitis-diarrhea; the "3 Ds"). The *spinal cord* manifestations have not been clearly delineated, but in general, the signs are referable to both posterior and lateral columns, predominantly the former, and thereby simulating SCD. Signs of *peripheral neuropathy* are relatively less common and are indistinguishable from those of neuropathic beriberi.

Pathologic Changes

These are most readily discerned in the large cells of the motor cortex (Betz cells), and to a lesser extent in the smaller pyramidal cells of the cortex, the large cells of the basal ganglia, the cranial motor and cerebellar dentate nuclei, and the anterior horn cells of the spinal cord. The affected neurons are swollen and rounded, with eccentric nuclei and loss of the Nissl bodies that have the appearance of

a secondary axonal reaction. However, in the pathologic material presented by Hauw and associates, these chromatolytic changes were most pronounced in the brainstem nuclei (upper reticular and pontine) and not in the Betz cells. They concluded that the neuronal changes were not caused by a retrograde axonal lesion but did not comment on the status of the spinal cord or nerves. The few studies of the peripheral nerves in pellagra have disclosed changes like those in alcoholics and other patients with nutritional deficiency.

The spinal cord lesions in pellagra take the form of a symmetrical degeneration of the dorsal columns, especially of Goll, and to a lesser extent of the corticospinal tracts. The posterior column degeneration is likely to be secondary to degeneration of the dorsal root ganglion cells or posterior roots. The reason for the corticospinal tract degeneration is not clear.

Etiology

It has been known since 1937, when Elvehjem and coworkers showed that nicotinic acid cured black tongue, a pellagra-like disease in dogs, that this vitamin is effective in the treatment of pellagra. Many years before, Goldberger had demonstrated the curative effects of dietary protein and proposed that pellagra was caused by a lack of specific amino acids (see Terris). Now it is known that pellagra may result from a deficiency of either nicotinic acid or tryptophan, the amino acid precursor of nicotinic acid. One milligram of nicotinic acid is formed from 60 mg of tryptophan, a process for which pyridoxine is essential. The relationship of niacin to tryptophan metabolism explains the frequent occurrence of pellagra in persons who subsist mainly on corn, which contains only small amounts of tryptophan and niacin, some of the niacin being in bound form and unavailable for absorption.

It should be pointed out that in experimental subjects, only the cutaneous-gastrointestinal-neurasthenic manifestations of pellagra have been produced by diets that are tryptophan or niacin deficient; neurologic abnormalities have not resulted from these diets (Goldsmith). As a corollary, only the dermal, gastrointestinal, and neurasthenic manifestations respond to treatment with niacin and tryptophan; neurologic disturbances in pellagrins have proved to be recalcitrant to prolonged treatment with the vitamin, although the peripheral nerve disorder may subsequently respond to treatment with thiamine. In monkeys, degeneration of peripheral nerves and the cerebrocortical changes of pellagra were induced by a deficiency of pyridoxine (Victor and Adams, 1956). Swank and Adams described degeneration of the peripheral nerves in pyridoxine- and pantothenic acid-deficient swine, and Vilter and colleagues produced polyneuropathy in human subjects rendered pyridoxine deficient; these subjects also showed seborrheic dermatitis and glossitis (indistinguishable from that of niacin deficiency) and the cheilosis and angular stomatitis that are usually attributed to riboflavin deficiency. The foregoing observations indicate that certain lingual and cutaneous manifestations of pellagra may be produced by a deficiency of pyridoxine or other B vitamins, and that the neurologic

manifestations of pellagra are most likely caused by pyridoxine deficiency.

In the special case of Hartnup disease in infants (which resembles pellagra in most respects including the dermatitis), a secondary niacin deficiency is believed to result from the high excretion of indicans and indole metabolites (see Chap. 37).

Treatment

The administration of niacin 500 mg per day for approximately 3 weeks reverses the process. If the patient is unable to take oral medications, intravenous doses of 100 mg per day for 5 to 7 days are utilized. If the patient is simultaneously deficient in pyridoxine, as for example when INH is used for tuberculosis treatment, the pyridoxine must also be replaced in order to allow the conversion of dietary tryptophan to endogenous niacin.

Nicotinic Acid-Deficiency Encephalopathy

Under this title, Jolliffe and coworkers, in 1940, described an acute cerebral syndrome in alcoholic patients consisting of clouding of consciousness, progressing to extrapyramidal rigidity and tremors ("cogwheel" rigidity) of the extremities, uncontrollable grasping and sucking reflexes, and coma. Some of their patients showed overt manifestations of nutritional deficiency, such as Wernicke disease, pellagra, scurvy, and polyneuropathy. These authors concluded that the encephalopathy represented an acute form of nicotinic acid deficiency, as most of their patients recovered when treated with a diet of low vitamin B content supplemented by intravenous glucose and saline and large doses of nicotinic acid. Sydenstricker and colleagues (1938) had previously reported the salutary effects of nicotinic acid on the unresponsive state observed in elderly undernourished patients, and Spillane (1947) described a similar syndrome and response to nicotinic acid in the indigent Arab population of the Middle East.

The status of this syndrome and its relation to pellagra are uncertain. The clinical, nutritional, and pathologic features were never delineated precisely. Serdaru and associates reported 22 presumed examples of this syndrome in the alcoholic population of the Salpêtrière clinic in Paris, all diagnosed retrospectively after the finding in postmortem material of pellagra-like changes in nerve cells. The prominent features were confusional states, paratonic rigidity, ataxia, and polymyoclonia, a picture somewhat like that described by Jolliffe and coworkers. Skin lesions were absent. We have not encountered identical cases among the undernourished patients in the alcoholic population.

Pyridoxine (Vitamin B₆) Deficiency

Pyridoxine deficiency or excess has been associated with a sensory polyneuropathy. The occurrence of neuropathy caused by INH was recognized in the early 1950s, soon after the introduction of this drug for the treatment of tuberculosis. It was characterized by paresthesia and burning pain of the feet and legs, followed by weakness

of these parts and loss of ankle reflexes. Rarely, with continued use of the drug, the hands were affected as well. The nature of INH-induced neuropathy was clarified by Biehl and Vilter who found that isoniazid causes a marked excretion of pyridoxine and that the administration of pyridoxine in conjunction with INH prevents the development of neuropathy. Because of this simple preventive measure, very few examples of INH-induced neuropathy are now observed. Hydralazine, closely related in structure to INH, when used in the past caused the formation of pyridoxal-isoniazid complexes (hydrazones), which make pyridoxal (the main form of vitamin B₆) unavailable to the tissues. The neuropathy responds favorably to discontinuation of the drug and the administration of pyridoxine.

Pyridoxine deficiency also leads to homocystinemia because the vitamin is a coenzyme for the conversion of homocystine to cystathionine. Vascular thrombosis may result from the excess homocystine.

Severe pyridoxine deficiency in animals and humans also causes *seizures*. This was first observed in swine by Swank and Adams, and later in infants who were maintained on a milk formula lacking in pyridoxine. A pyridoxine-responsive seizure disorder (pyridoxine dependency) of the neonatal period is discussed in Chap. 16.

Treatment

For pyridoxine deficiency caused by malnutrition, the treatment is 50 mg per day orally for several weeks, followed by 2 mg per day and resumption of a normal diet. When the deficiency results from a pyridoxine antagonist such as INH, penicillamine, hydralazine, or cycloserine, the treatment is 50 mg per day, only when the antagonist is in use. Treatment for the inherited form with convulsions is discussed in the section on neonatal seizures in Chap. 16. Lifelong supplementation is required after the seizures are aborted with a large intravenous dose of the vitamin.

Pyridoxine Toxicity

Paradoxically, the *consumption of large amounts of pyridoxine* (mainly by vitamin faddists) may also cause a sensory peripheral neuropathy or ganglionopathy (Schaumburg et al; Albin et al). There is no weakness; the symptoms, including ataxia and areflexia, are purely sensory and can be quite disabling. Symptoms may extend to the trunk, scalp, and face. Improvement is the rule when the drug is withdrawn. This disorder is probably a direct toxic effect of pyridoxine on dorsal root ganglion cells.

Folate (B₉) Deficiency

Despite the frequency of folic acid deficiency and its hematologic effects, its role in the pathogenesis of nervous system disease has not been established beyond doubt (see reviews by Crellin et al and by Carney). However, folate antagonists such as methotrexate are known to cause a neuropathy that is probably predicated on the vitamin deficiency. The polyneuropathy that occasionally complicates the chronic administration of phenytoin has also been attributed, on uncertain grounds,

to folate deficiency. Botez and colleagues have described a group of 10 patients with sensorimotor polyneuropathy (4 also had spinal cord disease) presumably because of intestinal malabsorption; all the patients improved over several months while receiving large doses of folic acid. This experience is unique, however. The possible role of folate deficiency in the pathogenesis of spinal cord disease was mentioned previously in relation to vitamin B₁₂ deficiency, and its putative role in psychiatric disease has been discussed by Carney. In such cases of folate deficiency, if subacute combined degeneration or mental changes occur, they must be rare.

The folate deficiency of pregnancy is a special case that is known to increase the incidence of neural tube defects.

For nutritional folate deficiency, difficult to separate from the lack of other vitamins, replacement is with 1 mg per day. In pregnant women, higher doses are used, separately from a multivitamin preparation in order to avoid vitamin A toxicity. When a folate antagonist is the underlying cause, folinic acid (leukovorin, citrovorum factor) 15 mg orally is given every 6 h for 10 doses starting after methotrexate infusion.

Pantothenic Acid Deficiency

A predominantly sensory neuropathy also has been induced, again in swine, by Swank and Adams, and later in humans by a deficiency of pantothenic acid (a constituent of coenzyme A [CoA]), as reported by Bean and colleagues. In some patients, the administration of pantothenic acid has reportedly reversed the painful dysesthesias of the "burning foot" syndrome.

VITAMIN B₁₂ (COBALAMIN) DEFICIENCY (SUBACUTE COMBINED DEGENERATION)

The spinal cord, brain, optic nerves, and peripheral nerves are all affected by vitamin B₁₂ (cobalamin) deficiency, giving rise to a classic neurologic syndrome. The spinal cord is usually affected first and often exclusively. The term *subacute combined degeneration* (SCD) is customarily reserved for the spinal cord lesion of vitamin B₁₂ deficiency and serves to distinguish it from other types of spinal cord diseases that happen to involve the posterior and lateral columns (loosely referred to as *combined system disease*). Whether a peripheral neuropathy is a primary component of the disease or is secondary to damage of the posterior root fibers of entry in the dorsal cord has been debated, but the available pathologic evidence favors the latter, except perhaps for a few advanced cases, in which other nutritional deficiencies could have been responsible.

The hematologic effects of vitamin B₁₂ deficiency, when they result from *pernicious anemia*, are distinctive insofar as they usually result not from a dietary lack of vitamin B₁₂ but from the failure to transfer minute amounts of this nutrient across the intestinal mucosa, "starvation in the midst of plenty," as Castle aptly put it.

This failure derives from the chronic absence of an intrinsic factor, which is secreted (along with hydrochloric acid) by the parietal cells of the gastric mucosa and transports cobalamin ("extrinsic factor") to the ileum, where it is absorbed into the portal venous system. This is referred to as a *conditioned deficiency*, as it is conditional on the lack of an intrinsic factor. Minot and Murphy's clinical experiment that showed the cure of the neurologic process by the feeding of liver, or parenteral liver extract that contained an "extrinsic factor" later found to be cobalamin, was a remarkable feat of translational medicine. A movie can be seen depicting this work at: <http://bloodjournal.hematologylibrary.org/content/107/12/4970.1/suppl/DC1>. It was Castle, experimenting on himself, who isolated the "intrinsic factor" that facilitates absorption of the vitamin.

The hematologic and neurologic manifestations of vitamin B₁₂ deficiency often complicate many of the malabsorptive disorders, including poor nutrition in the elderly, especially those with atrophic gastritis, but also individuals of any age with celiac sprue; gastric or ileal resections; overgrowth of intestinal bacteria in "blind loops," anastomoses, diverticula, and other conditions resulting in intestinal stasis; and infestation with cobalamin-metabolizing fish tapeworm (*Diphyllobothrium latum*). Uncommon instances of vitamin B₁₂ deficiency are observed in lactovegetarians and in infants nursed by mothers deficient in vitamin B₁₂; vitamin B₁₂ deficiency may also be a result of a rare genetic defect of methylmalonyl-CoA mutase as discussed further on.

It should be further commented that interference with methionine synthetase, a methylcobalamin-dependent enzyme, can be produced by exposure to nitrous oxide. Chronic exposure can produce the entire subacute combined syndrome but more often, an individual is marginally deficient, often but not always elderly, and even short exposure may then induce symptoms. A megaloblastic anemic state, as well as the neurologic features of SCD, is thereby induced by the gas. This illness, cleverly named "anesthesia paresthetica" by Kinsella and Green, arises in operating room personnel (we have seen it in several anesthesia nurses), occasionally in dentists, and in abusers of the gas (whippets) to obtain a "high." Their serum B₁₂ levels are usually in the low-normal range, and measurements of methylmalonic acid are greatly elevated (see further on).

Clinical Manifestations

Symptoms of nervous system disease occur in the majority of patients with pernicious anemia and in most with B₁₂ deficiency of other sources. The patient first notices mild general weakness and paresthesias consisting of tingling, "pins and needles" feelings, or other vaguely described sensations. The paresthesias involve the hands and feet, more often and first in the hands, and tend to be constant and steadily progressive and the source of much distress. As the illness progresses, the gait becomes unsteady and stiffness and weakness of the limbs, especially of the legs, develop. If the disease remains untreated, an ataxic paraplegia evolves with variable degrees of spasticity.

Early in the course of the illness, when only paresthesia is present, there may be no objective sign. Later, examination discloses a disorder of the posterior and lateral columns of the spinal cord, predominantly of the former. *Loss of vibration sense is the most consistent sign*; it is more pronounced in the feet and legs than in the hands and arms and frequently extends over the trunk. Position sense is usually impaired in parallel. The motor signs, usually limited to the legs, include a mild symmetrical loss of strength in proximal limb muscles, spasticity, enhanced tendon reflexes, clonus, and extensor plantar responses. At first, the patellar and Achilles reflexes are diminished as frequently as they are increased; they may even be absent. This is most likely the result of a neuropathy due to multiple vitamin deficiencies as cases of pure cobalamin loss, for example due to nitrous oxide, almost never obliterate the tendon reflexes. This controversy regarding the presence of a polyneuropathy as a component of SCD has already been alluded to. The gait at first is predominantly ataxic, later ataxic and spastic.

Loss of superficial sensation below a segmental level on the trunk should suggest an alternative diagnosis involving the spinal cord. However, 2 of our patients have described a band-like sensation around the thorax. A defect of cutaneous sensation may take the form of impaired tactile, pain, and thermal sensation over the limbs in a distal distribution, implicating the small fibers of the peripheral nerves or the spinothalamic tracts, but such findings are relatively uncommon. The Lhermitte phenomenon (paresthesia down the spine or across the shoulders induced by rapid flexion of the neck) may be found if sought but is a sign more often allied with multiple sclerosis. The nervous system involvement in SCD is roughly symmetrical and distal, and sensory disturbances precede the motor ones; predominantly motor involvement from the beginning and a definite asymmetry of motor or sensory findings maintained over a period of weeks or months or prominent truncal or facial symptoms should always cast doubt on the diagnosis.

Cognitive symptoms and signs are frequent, ranging from irritability, apathy, somnolence, suspiciousness, and emotional instability to a marked confusional or depressive psychosis or dementia. Lindenbaum and coworkers have reported cases in which neuropsychiatric symptoms, responsive to vitamin B₁₂, were present without spinal cord or peripheral nerve abnormalities. In our clinical material, symptoms of dementia or psychosis have not been frequent and always followed the spinal cord disorder. Perhaps a slight degree of mental illness is all that is seen in early stages.

Visual impairment caused by optic neuropathy occasionally may be an early or sole manifestation of pernicious anemia; examination discloses roughly symmetrical centrocecal scotomata and optic atrophy in the most advanced cases. That visually evoked potentials may be abnormal in vitamin B₁₂-deficient patients without clinical signs of visual impairment suggests that the visual pathways are affected more often than is evident from the neurologic examination alone. A small number of patients have symptoms of autonomic dysfunction, including urinary sphincteric symptoms and impotence.

The CSF is usually normal; in some cases there is a moderate increase in protein. The nerve conduction studies may show slowing of sensory conduction or reduced-amplitude sensory potentials, but they are as often normal in early cases. Frequently, according to Hemmer and colleagues, somatosensory evoked potentials are delayed or absent; these changes are known to recover with treatment. Quite remarkable in corresponding to the locus of pathologic change, as these and other authors have indicated, is the finding on MRI of a T2 hyperintensity that demarcates the posterior columns of the cord and sometimes the lateral columns, as shown in Fig. 41-3. In a few of our patients these have taken the form solely of well-defined linear changes over a long extent of the posterior columns of the cervical cord.

Neuropathologic Changes

The pathologic process takes the form of a diffuse, although uneven, degeneration of white matter of the spinal cord and occasionally of the brain. The earliest histologic event is swelling of myelin sheaths, characterized by the formation of intramyelinic vacuoles and separation of myelin lamellae. This is followed by a coalescence of small foci of tissue destruction into larger ones, imparting a vacuolated, sieve-like appearance to the tissue, an appearance also observed in the myelopathy of AIDS and rarely in lupus erythematosus. The myelin sheaths and axis cylinders are both involved in the degenerative

process, the former more obviously and perhaps earlier and more severely than the latter. There is relatively little fibrous gliosis in the early lesions, but in more chronic ones, particularly those in which considerable tissue is destroyed, the gliosis is pronounced. The changes begin in the posterior columns of the lower cervical and upper thoracic segments of the cord and spread from this region up and down the cord as well as forward into the lateral and anterior columns. The lesions are not limited to systems of fibers within the posterior or lateral columns but are scattered irregularly through the white matter, thereby representing a myelinopathy.

In rare instances, foci of spongy degeneration are found in the optic nerves and chiasm and in the central white matter of the brain (Adams and Kubik). The peripheral nerves may show a loss of myelin, but there is no unequivocal evidence that axons are significantly affected.

Agamanolis and colleagues (1978) showed that monkeys sustained on a vitamin B₁₂-deficient diet for a prolonged period develop neuropathologic changes indistinguishable from those of SCD in humans. The time required for the production of nervous system changes in monkeys, 33 to 45 months, is comparable to the time required to deplete the vitamin B₁₂ stores of patients with pernicious anemia in whom parenteral vitamin B₁₂ therapy had been discontinued. It is noteworthy that vitamin B₁₂-deprived monkeys do not become anemic despite the prolonged period of vitamin B₁₂ deficiency. Also in

Figure 41-3. Sagittal (*left image*) and axial (*right image*) T2 MRI in subacute combined degeneration (SCD) showing abnormal hyperintensity in the posterior columns. The patient had markedly reduced vibration and position sense and a Romberg sign; the tendon reflexes were preserved and there were no corticospinal tract or peripheral nerve signs.

distinction to the human condition, involvement of the optic nerves is particularly severe in the monkey and probably precedes the degeneration of the spinal cord. The optic nerve lesions appear first in the papillomacular bundles, in the retrobulbar portions of the nerves; it subsequently spreads beyond the confines of this bundle and caudally in the optic nerves, chiasm, and tracts. These changes are much the same as those of "Tobacco-Alcohol Amblyopia" (see the section on this subject further on). The peripheral nerves are not affected in the experimentally produced vitamin B₁₂ deficiency.

Paresthesia, impairment of deep sensation, and ataxia are caused by lesions in the posterior columns. Weakness, spasticity, increased tendon reflexes, and Babinski signs depend on involvement of the corticospinal tracts. The spinothalamic tracts may rarely be involved in the pathologic process, which explains the rare finding of a sensory level for pain and temperature on the trunk. The distal and symmetrical impairment of superficial sensation and loss of tendon reflexes that occur in advanced cases, however, may be explained by involvement of peripheral nerves and are then reflected in nerve conduction studies (see further on, under "Diagnosis").

Pathogenesis

Methylcobalamin is an essential cofactor in the conversion of homocysteine to methionine. An impairment of this reaction caused by a deficiency of cobalamin is thought to cause a failure of DNA synthesis, accounting for the hematologic abnormalities, particularly for the production of megaloblasts. However, because neurons do not divide, this sequence of chemical events does not explain the central nervous system abnormalities. One of the better-understood functions of vitamin B₁₂ is its role as a coenzyme in the methylmalonyl-CoA mutase reaction. In this reaction, which is a key step in propionate metabolism, methylmalonyl-CoA is transformed to succinyl-CoA, which subsequently enters the Krebs cycle. A lack of the cobalamin-dependent enzyme methylmalonyl-CoA mutase leads to the accumulation of methylmalonyl-CoA and its precursor, propionyl-CoA. According to this mechanism, propionyl-CoA displaces succinyl-CoA, which is the usual primer for the synthesis of even-chain fatty acids; this results in the anomalous insertion of odd-chain fatty acids into membrane lipids, such as are found in myelin sheaths. Conceivably, this biochemical abnormality underlies the lesions of myelinated fibers that characterize the disease. However, Carmel and associates described a hereditary form of cobalamin deficiency in which methylmalonyl-CoA mutase activity was normal, despite the presence of typical neurologic abnormalities. In their view, the primary failure is one of methylation of homocysteine to methionine, that is, a failure of the methionine synthetase reaction, for which the coenzyme methylcobalamin is necessary.

Evidence for the latter view comes also from the observations, mentioned earlier, that prolonged administration of nitrous oxide (N₂O) may produce not only megaloblastic changes in the marrow (Amess et al), but also a sensorimotor polyneuropathy, often combined with signs of involvement of the posterior and lateral columns

of the spinal cord (Layzer). Probably N₂O produces its effects by inactivating the methylcobalamin-dependent enzyme, methionine synthetase. These and other hypotheses are discussed by Jandl, Carmel and colleagues, and Beck (1988).

The role of *folate deficiency* in the genesis of SCD is less certain. One known clinical mistake has been to treat pernicious anemia by giving folic acid; this corrects the anemia but may worsen or even evoke the spinal cord lesions. Nevertheless, there have been a few reported examples of cerebral and spinal cord lesions indistinguishable from those caused by vitamin B₁₂ deficiency in patients with defective folate metabolism, both in adults with acquired deficiency (Pincus) and in children with an inborn metabolic error (Clayton et al). The current view, however, is that folate deficiency alone does not produce SCD.

Diagnosis

The main differential diagnostic considerations of the combined sensory and motor features are cervical spondylosis (see Chaps. 11 and 44), multiple sclerosis of the cervical cord (see Chap. 36), rarities such as the female carrier state of adrenoleukodystrophy (see Chap. 37), and, most importantly, non-B₁₂-deficient combined system disease caused by low levels of serum copper (see Chap. 44). The last of these refers to a myelopathic process that affects the posterior and lateral columns subacutely in a manner identical to that of subacute combined degeneration but unassociated with any form of B₁₂ deficiency or related enzyme derangement. Somewhat to our surprise, the copper disorder has been as frequent as the classic type caused by B₁₂ deficiency in our clinics. This entity is described more extensively in Chap. 44. One remarkable circumstance, with which we have had experience, is the creation of severe SCD including paralysis in a B₁₂-deficient patient whose myelopathic symptoms were misattributed to cervical spondylosis and who had an operation for spondylosis in which spondylosis in nitrous oxide was used as anesthesia.

The chief obstacle to *early diagnosis* of SCD is the lack of parallelism that may exist between the hematologic and neurologic signs, particularly in patients who have taken dietary or medicinal folate. Anemia may also at times be absent, sometimes for many months, even in patients who have not taken folate. For example, in a retrospective study of 141 patients with neuropsychiatric abnormalities caused by cobalamin deficiency, there were 19 patients in whom both the hematocrit and mean red blood cell volume were normal (Lindenbaum et al); in these patients, subtle morphologic abnormalities such as hypersegmented polymorphonuclear leukocytes and megaloblastosis in bone marrow smears were almost always found if carefully sought.

Laboratory Diagnosis

Serum cobalamin should be measured whenever the diagnosis of vitamin B₁₂ deficiency is in question. Microbiologic assay (using *Euglena gracilis*) is the most accurate measurement, but the method is time-consuming and cumbersome and has been replaced by a commercial radioisotope dilution assay (the inexpensive chemiluminescence assay is an alternative but slightly less dependable). With the

radioassay, a serum B₁₂ level below 100 pg/mL is usually associated with neurologic symptoms and signs of vitamin B₁₂ deficiency. A level below 200 pg/mL that is unassociated with symptoms calls for further investigation of cobalamin deficiency. However, even serum levels of 200 to 300 pg/mL may still be associated (in 5 to 10 percent of cases) with cobalamin deficiency. High serum concentrations of cobalamin metabolites, methylmalonic acid (normal range, 73 to 271 nmol/L), and homocysteine (normal range 5.4 to 16.2 mmol/L) are additional reliable indicators of an intracellular cobalamin deficiency and can be used to corroborate the diagnosis in cases of low-mid-range B₁₂ levels (Allen et al; Lindenbaum et al). It must be emphasized that the serum cobalamin level is not a measure of total-body cobalamin. In a patient who stops absorbing ingested cobalamin, the serum levels may remain in the normal range for months or years despite decreasing tissue reserves. In patients who have received vitamin B₁₂ parenterally, the 2-stage Schilling test is a more reliable indicator of cobalamin deficiency because it uncovers a defect in absorption of the vitamin; however, the Schilling test has been largely supplanted for routine diagnosis by the measurement of antibodies to intrinsic factor and parietal cells.

Achlorhydria is almost invariably present in patients with pernicious anemia; its presence can be inferred by measuring the serum gastrin level. Antibodies to gastric parietal cells are also present in as many as 90 percent of patients with cobalamin deficiency, specifically in those with pernicious anemia as opposed to those with diminished B₁₂ intake, but this test, although diagnostically specific, is positive in only 60 percent of cases. A relationship between helicobacter gastritis and autoimmunity against gastric parietal cells is being explored.

Low cobalamin levels with or without the clinical signs of deficiency may occur in patients with atrophic gastritis or after subtotal gastrectomy as mentioned. The malabsorption in such cases is thought to be because of a failure to extract cobalamin from food rather than a failure of the intrinsic factor mechanism ("food-cobalamin malabsorption"). Because the absorption of free cobalamin is normal, the Schilling test is unimpaired (Carmel, 1990). Infection of the gastric mucosa with *Helicobacter pylori* has been implicated in some cases. There are also rare inherited defects in the gene for intrinsic factor that render it ineffective.

The results of nerve conduction tests have varied in vitamin B₁₂-deficient patients. Early in the course of SCD, nerve conduction may be normal, but some patients have slowing of distal sensory conduction; others have found reduced amplitudes and minor signs of denervation, suggestive of axonal change. This again raises the controversy regarding the presence of a peripheral nerve disorder in uncomplicated B12 deficiency. Authoritative texts indicate that a neuropathy is present but certainly, such involvement is not integral to the disease as many patients with prominent neurological manifestations, particularly early in the course, have normal nerve conduction studies. In patients with normal peripheral nerve studies, the somatosensory evoked potentials usually show abnormalities attributable to central conduction delays, implicating the posterior columns as the cause of

the sensory symptoms (Fine and Hallett). In advanced cases, motor conduction and late responses may be affected to a slight degree. These ambiguities reflect the inconsistent and poorly understood role of the peripheral neuropathic component of this disease.

The MRI lesions in the posterior columns were described earlier; they extend through the cervical and upper thoracic cords and, less often, to the lateral columns. The frequency of these findings, however, is not known, and their absence cannot be considered evidence against the diagnosis.

Treatment

The diagnosis of pernicious anemia demands the administration of vitamin B₁₂ and the continuation of treatment for the rest of the patient's life. In cases of pernicious anemia, the patient is given 1,000 µg of cyanocobalamin or hydroxocobalamin intramuscularly each day for several days. The usual approach is to repeat the injection weekly for a month and then monthly for an indefinite period. Although most of the injected cobalamin is excreted, these patients must be flooded with the vitamin because the repletion of cobalamin tissue stores is a direct function of the dose.

In recent years, the notion that all forms of B₁₂ deficiency must be circumvented by parenteral administration of the vitamin has been questioned and the use of oral cobalamin 500 to 1,000 µg daily has been used as an alternative, particularly for maintenance treatment. Several studies have indicated the effectiveness of this approach in elderly patients with poor B₁₂ absorption and in persons with restricted diets, such as vegans, but we would express reservation regarding the use of oral replacement in the treatment of manifest subacute combined degeneration with neurologic manifestations until further studies have been published.

The most important factor influencing the response to treatment is the duration of symptoms; age, sex, and the degree of anemia are of lesser importance. The greatest improvements occur in patients whose disturbance of gait has been present for less than 3 months and recovery is usually complete if therapy is instituted within a few weeks after the onset of symptoms. All neurologic symptoms and signs may improve, mostly during the first 3 to 6 months of therapy, and then at a slower tempo during the ensuing year or even longer. In practically all instances, there is some degree of improvement after treatment, although in cases of longest duration, the best that can be accomplished is an arrest of progression.

DISORDERS CAUSED BY DEFICIENCIES OF FAT-SOLUBLE VITAMINS

Vitamin E Deficiency

This occurs in 2 types: a defect in intestinal absorption and an inherent hepatic enzyme deficiency that blocks incorporation of vitamin E into lipoprotein. A rare neurologic disorder of childhood, sometimes later in life, consisting essentially of spinocerebellar degeneration in association with polyneuropathy and

pigmentary retinopathy, has been attributed to a deficiency of vitamin E consequent to prolonged intestinal fat malabsorption (Muller et al; Satya-Murti et al). The same mechanism has been proposed to explain the neurologic disorders that sometimes complicate abetalipoproteinemia (see Chap. 37), fibrocystic disease (Sokol et al), celiac sprue disease, and extensive intestinal resections (Harding et al). Vitamin E deficiency has also been observed in young children with chronic cholestatic hepatobiliary disease (Rosenblum et al).

Ataxia, loss of tendon reflexes, ophthalmoparesis, proximal muscle weakness with elevated serum creatine kinase, and decreased sensation are the usual manifestations of vitamin E deficiency. These symptoms are referable to parts of the nervous system and musculature that are found to be diseased in animals deprived of vitamin E: degeneration of Clark columns, spinocerebellar tracts, posterior columns, nuclei of Goll and Burdach, and sensory roots (Nelson et al). Local differences in the natural concentration of vitamin E in various parts of the nervous system and musculature are believed to account for the distribution of the lesions. In affected children, neurologic function improves after long-term daily supplementation with high doses of vitamin E.

In recent years there have been reports of a form of spinocerebellar degeneration attributable to an inherited but conditioned deficiency of vitamin E that may closely mimic the phenotype of Friedreich ataxia ("familial isolated vitamin E deficiency" as discussed in Chap. 39). The onset is usually in early adolescence, but there is variability, particularly among different families. In these patients, absorption and transport of vitamin E to the liver is normal, but hepatic incorporation of tocopherol (the active form of vitamin E) into very-low-density lipoproteins is defective (Traber et al). The abnormality has been traced to a mutation in *TTPA*, the gene encoding α -tocopherol transfer protein (Gotoda et al). In a sense, this is a vitamin deficiency conditioned by a genetic mutation. An important feature of these cases is that chronic oral administration of large doses of vitamin E can halt and even reverse progression of the ataxia (Gabsi et al).

Vitamins A and D Deficiencies

Neurologic disorders caused by a lack or excess of these fat-soluble vitamins have been reported, but they are rare. Vitamin A deficiency sometimes occurs with malabsorption syndromes, causing impairment of vision. *Excess of vitamin A* in children or adults may result in the syndrome of *pseudotumor cerebri* (see Chap. 30). Vitamin D deficiency is associated with hypoparathyroidism or a malabsorption state that leads to hypocalcemia, proximal muscle weakness, and rickets.

NUTRITIONAL SYNDROMES OF UNCERTAIN ETIOLOGY

Several related conditions of nutritional deficiency overlap in their presentations and have in common an uncertainty as to the primary cause. In all likelihood, there is

a combination of factors, perhaps conditioned by genetic susceptibility. Here we refer especially to a syndrome of spastic ataxia, blindness, and a severe painful neuropathy with glossitis but there are other derivative syndromes that we discuss in this section.

Nutritional Spinal Spastic and Ataxic Syndrome

This syndrome is observed occasionally in nutritionally depleted alcoholics. The main clinical signs are spastic weakness of the legs, with absent abdominal and increased tendon reflexes, clonus, extensor plantar responses, and a loss of position and vibratory senses. In our experience, this syndrome has usually been associated with other nutritional disorders such as Wernicke disease and peripheral and optic neuropathy. In prisoner-of-war camps, the "spastic syndrome" was observed in association with mental and emotional changes and dimness of vision, and at times with widespread muscular rigidity, confusion, coma, and death. The latter syndrome has never been studied pathologically, so that it is impossible to state whether the lesions are the same as or different from those of pellagra or from Strachan syndrome, described further on.

The syndromes of tropical spastic paraparesis and of lathyrism, another form of spastic paraplegia common in India and certain parts of Africa, were for many years suspected of being nutritional in origin but are now known to be caused by a virus and a toxin, respectively. These and other types of tropical spastic paraplegia are discussed in greater detail with the spinal cord diseases (see Chap. 44). A chronic tropical disease of the peripheral nerves, called "ataxic neuropathy of Nigeria," has been attributed to the ingestion of inadequately detoxified cassava (Osuntokun). Another form of spastic ataxia, called "konzo," has been attributed to the production of cyanide by an ingested toxic glycoside in individuals who are protein deficient. The differential diagnosis of progressive spastic ataxia is quite broad and includes multiple sclerosis.

Nutritional Optic and Peripheral Neuropathy, "Tobacco-Alcohol Amblyopia," and Strachan Syndrome (See also Chap. 13)

These terms refer to a characteristic form of visual impairment that results from nutritional deficiency. The defect in vision is the result of a lesion of the optic nerves, more or less confined to the region of the papillomacular bundle. Typically, the patient complains of dimness or blurring of vision for near and distant objects, evolving gradually over a period of several days or weeks. Examination discloses a reduction in visual acuity because of the presence of central or centrocecal scotomata, which are larger for colored than for white test objects. Pallor of the temporal portion of the optic disc is observed in some cases. These abnormalities are bilateral and roughly symmetrical and, if untreated, may progress to blindness and irreversible optic atrophy. With normal diet and vitamin supplements improvement occurs in almost all cases but the most chronic

ones; the degree of recovery depends on the severity of the amblyopia and particularly on its duration before therapy is instituted.

Although the precise deficiency responsible for this disease cannot be determined, its nutritional basis was established beyond doubt during World War II and the Korean War, when innumerable instances were observed in prisoners of war who had been confined for prolonged periods under conditions of severe dietary deprivation. Fisher described the optic nerve lesions in 4 such patients who had died of unrelated causes between 8 and 10 years after the onset of amblyopia. In each case, there was a loss of myelin and axis cylinders restricted to the region of the papillomacular fibers. Of the 4 cases, 3 also showed demyelination of the posterior columns of the spinal cord, no doubt an expression of the associated sensory polyradiculopathy.

In the Western world, a visual disorder indistinguishable clinically and pathologically from that observed in prisoners of war is observed infrequently, mainly among undernourished alcoholics. For many years this had been referred to as *tobacco-alcohol amblyopia*, with the implication that the visual loss is a result of the toxic effects of alcohol, tobacco, or both. Actually, the evidence is overwhelming that so-called tobacco-alcohol amblyopia is caused by nutritional deficiency and not by toxic exposure. A specific nutrient has not been identified, however. There are data in humans and animals that under certain conditions a deficiency of one or more of the B vitamins: thiamine, vitamin B₁₂, and perhaps riboflavin, may cause degenerative changes in the optic nerves, a situation that pertains in the peripheral nerves as well. Part of the confusion in delineating a specific cause has been sporadic outbreaks of optic neuropathy in underdeveloped countries that may have been caused by a disseminated ingested toxin as described further on.

In the 1960s, a popular theory held that the combined effects of vitamin B₁₂ deficiency and chronic poisoning by cyanide (generated in tobacco smoke) were responsible for "tobacco amblyopia." Vitamin B₁₂ deficiency is a rare but undoubted cause of optic neuropathy, as noted further on, but the notion that cyanide or other substances in tobacco smoke have a damaging effect on the optic nerves is unsupported (see reviews of Potts and of Victor [1970]). Instances of Leber hereditary optic atrophy, a mitochondrial disorder, may be also mistaken for "tobacco-alcohol amblyopia," an error that should be made less often because Leber disease disorder can now be identified by mitochondrial DNA testing.

Recent outbreaks of an apparently nutritional or perhaps toxic optic neuropathy occurred in Cuba during the period 1991 to 1993 and in Tanzania. In both instances the optic neuropathy was frequently associated with peripheral neuropathy. The association of this epidemic with widespread dietary deprivation and the salutary response of both optic and peripheral nerve symptoms to treatment with B vitamins suggests a nutritional causation (see Centers for Disease Control and Prevention and the report of the Cuba Neuropathy Field Investigation Team), but a toxic cause could not be excluded. Shortly thereafter, Plant and colleagues reported on a similar outbreak of optic and peripheral neuropathy from Tanzania.

There remains to be considered a neuropathic syndrome that almost certainly is nutritional in origin but does not conform clinically to beriberi or pellagra, the classic deficiency diseases. This syndrome was originally observed by Strachan in 1897 among Jamaican sugarcane workers. The main symptoms in his patients were pain, numbness, and paresthesias of the extremities; objectively there was ataxia of gait, weakness, wasting, and loss of deep tendon reflexes and sensation in the limbs. Dimness of vision and impairment of hearing were common findings, as were soreness and excoriation of the mucocutaneous junctions of the mouth. This disorder, originally known as "Jamaican neuritis," was quickly recognized in other parts of the world, particularly in the undernourished populations of tropical countries. Subsequently, many cases of this syndrome were observed in the besieged population of Madrid during the Spanish Civil War and during World War II among prisoners of war in North Africa and the Far East.

The clinical descriptions from these varied sources are not entirely uniform, but certain features are common to all of them and occur with sufficient frequency to allow the delineation of the neurologic syndrome; it appears to be almost identical to the one described by Strachan. The core disorder is combined optic and peripheral neuropathy. The latter consists mainly of sensory symptoms and signs, and the former of the subacute evolution of failing vision, which, if untreated, progresses to complete blindness and pallor of the optic discs. Deafness and vertigo are uncommon, but in some outbreaks among prisoners of war, these symptoms were frequent enough to earn the epithet "camp dizziness." In all these respects, the syndrome differs from beriberi. Along with the neurologic signs there may be varying degrees of stomatoglossitis, corneal degeneration, and genital dermatitis (the orogenital syndrome). The mucocutaneous lesions are unlike those of pellagra and riboflavin deficiency.

There have been only a few neuropathologic studies of this syndrome. Aside from the changes in the papillomacular bundle of the optic nerve, which are similar to the deficiency amblyopia discussed previously, the most consistent abnormality has been a loss of myelinated fibers in each column of Goll adjacent to the midline. Fisher interpreted this change to indicate a degeneration of the central processes of the bipolar sensory neurons of the dorsal root ganglia (i.e., the dorsal roots). The fact that the primary sensory neuron is the main site of the neuropathic disorder is consistent with the predominantly sensory symptomatology. The present authors find it difficult to draw a sharp dividing line between the nutritional peripheral (and optic) neuropathy described previously and the Strachan syndrome.

"Alcoholic" Cerebellar Degeneration

This term refers to a common and uniform type of degeneration of the vermal and anterior lobes of the cerebellum in alcoholics. Its incidence was in the past about

twice that of Wernicke disease, and like the latter, it is considerably more frequent in men than in women. It is characterized clinically by a wide-based stance and gait, varying degrees of instability of the trunk, and ataxia of the legs, the arms being affected to a lesser extent and often not at all. Nystagmus and dysarthria are infrequent. In addition to an ataxic (intention) tremor, there may be a tremor of the fingers or hands resembling 1 of the 2 types of parkinsonian tremor, but appearing only when the limbs are placed in certain sustained postures. Mauritz and coworkers demonstrated that the instability of the trunk in these cases consists of a specific 3-Hz rhythmic swaying in the anteroposterior direction; by contrast, patients with lesions of the cerebellar hemispheres show only slight postural instability without directional preponderance.

In most cases, the cerebellar syndrome evolves over a period of several weeks or months, after which it remains unchanged for many years. In others, it develops more rapidly or more slowly, but in these cases also the disease eventually stabilizes. Occasionally, the cerebellar disorder progresses in a saltatory manner, the symptoms worsening in relation to a severe infectious illness or an attack of delirium tremens.

The *pathologic changes* consist of a degeneration of all the neurocellular elements of the cerebellar cortex but particularly of the Purkinje cells in the anterior and superior aspects of the vermis. The cerebellar atrophy is readily visualized by CT (Fig. 41-4) and MRI.

Two particular forms of this syndrome have not been emphasized sufficiently. In one, the clinical abnormalities are limited to an instability of station and gait, individual movements of the limbs being unaffected. The pathologic changes in such cases are restricted to the anterosuperior portions of the vermis. A second type is strikingly acute but transient. Here, except for their reversibility, the cerebellar symptoms are identical to those that characterize the chronic, fixed form of the disease. In this transient type, the derangement is only one of function ("biochemical lesion") and has probably not progressed to the point of fixed structural changes. These forms of cerebellar disease, and particularly the restricted and reversible varieties, cannot be distinguished from the cerebellar manifestations of Wernicke disease either on pathologic or on clinical grounds. It is our opinion that the cerebellar ataxia of Wernicke disease and that referred to as *alcoholic cerebellar degeneration* are based on the same disease process, the former term being applicable when the cerebellar abnormalities are associated with ocular and mental signs and the latter when the cerebellar syndrome stands alone and becomes persistent. Alcoholic cerebellar degeneration is in all likelihood a result of nutritional deficiency and not of the toxic effects of alcohol, for reasons already indicated. Insofar as the cerebellar ataxia usually improves to some extent under the influence of thiamine alone (see earlier, under "Wernicke-Korsakoff Syndrome [Thiamine (B₁) Deficiency]"), it is likely that a deficiency of this vitamin is in whole or part responsible for the cerebellar lesion, but this has not been proven.

Figure 41-4. CT from a 60-year-old alcoholic patient showing prominence of midline cerebellar sulci (*upper image*). A broad-based gait and ataxia of the legs had been present for many years. Death was from myocardial infarction. The cerebellum, cut in the midsagittal plane (*lower image*), shows folial atrophy of the anterosuperior vermis, characteristic of alcoholic cerebellar degeneration.

Marchiafava-Bignami Disease (Degeneration of the Corpus Callosum)

In 1903, the pathologists Marchiafava and Bignami described a unique alteration of the corpus callosum in 3 alcoholic patients. In each case, coronal sectioning of the fixed brain disclosed a pink-gray discoloration of the central portion of the corpus callosum throughout the longitudinal extent of this structure. Microscopically, the lesion proved to be confined to the middle lamina (which makes up about two-thirds of the thickness of the corpus callosum), in which there was a loss of myelin and, to some degree, of the axis cylinders; macrophages were abundant in the altered zone, and astrocytic proliferation had followed. The clinical observations in these patients were few and incomplete. In 1907, Bignami described a case in which the corpus callosum lesion was accompanied by a similar lesion in the central portion of the anterior commissure.

These early reports were followed by a spate of articles that confirmed and amplified the original clinical and pathologic findings. By 1922, about 40 cases of this disorder had been described in the Italian literature (Mingazzini). With 1 exception, all the reported cases were in males, and all these men were insatiable drinkers. They drank red wine for the most part, but other forms of liquor as well. Beginning in 1936, with the report of King and Meehan, the disease came to be recognized throughout the world, and the notions that it had a predilection for drinkers of red wine and a special national predisposition or geographic locale were abandoned. The location of the white matter lesion was later appreciated by MRI to be variable with only a propensity for the corpus callosum.

Pathologic Features

Marchiafava-Bignami disease is more readily defined by its pathologic than its clinical features. The principal alteration, as mentioned, is usually in the middle portion of the corpus callosum, which on gross examination appears rarefied and sunken and reddish or gray-yellow in color, depending on its age. In the anterior portion of the corpus callosum, the lesion tends to be more severe in the midline than in its lateral parts; in the splenium, however, the opposite may pertain. The most chronic lesion takes the form of a centrally placed gray cleft or cavity, with collapse of the surrounding tissue and reduction in thickness of the corpus callosum. Microscopically, corresponding to the gross lesions, one observes clearly demarcated zones of demyelination, with variable involvement of the axis cylinders and an abundance of fatty macrophages with gliosis at the margins. Inflammatory changes are absent.

Infrequently, lesions of a similar nature are found in the central portions of the anterior and posterior commissures and the brachia pontis. These zones of myelin destruction are surrounded by a rim of intact white matter. The predilection of this disease process for commissural fiber systems has been stressed, but it is certainly not confined to these fibers. Symmetrically placed lesions have been observed in the columns of Goll, superior cerebellar peduncles, and cerebral hemispheres, involving the centrum semiovale and extending, in some cases, into the adjacent convolutional white matter. As a rule, the internal capsule and corona radiata, subcortical arcuate fibers, and cerebellum are spared. In several cases, the lesions of deficiency amblyopia (see earlier) have been added; in others, the lesions of Wernicke disease.

Many of the reported cases, as first pointed out by Jequier and Wildi, have involved cortical lesions of a special type: The neurons in the third layer of the frontal and temporal lobe cortices had disappeared and were replaced by a fibrous gliosis. Morel, who first described this *cortical laminar sclerosis*, did not observe its association with Marchiafava-Bignami disease. However, when Jequier and Adams reviewed his original cases (unpublished), all had Marchiafava-Bignami disease. In a subsequent report by Delay and colleagues comprising 14 cases of cortical laminar sclerosis, the cortical lesion

was also consistently associated with a corpus callosum lesion. We believe the cortical lesions are best explained as secondary to the callosal degeneration.

Clinical Features

The disease affects persons in middle and late adult life. With few exceptions, the patients have been males and severe chronic alcoholics. The clinical features of the illness are otherwise quite variable, and a clear-cut syndrome has not emerged. Many patients have presented in a state of terminal stupor or coma, precluding a detailed neurologic assessment. In others, the clinical picture was dominated by the manifestations of chronic inebriation and alcohol withdrawal, namely tremor, seizures, hallucinosis, and delirium tremens. In some of these patients, following the subsidence of the withdrawal symptoms, no signs of neurologic disease could be elicited, even in the end stage of the disease, which lasted for several days to weeks. In yet another group, a progressive dementia has been described, evolving slowly over a year before death. Emotional disorders, dysarthria, slowing and unsteadiness of movement, transient sphincteric incontinence, hemiparesis, and apractic or aphasic disorders have been reported. The last stage of the disease is characterized by physical decline, seizures, stupor, and coma. An impressive feature of these varied neurologic deficits in some patients has been their tendency toward remission when nutrition was restored.

In 2 cases that have come to our attention, the clinical manifestations were essentially those of bilateral frontal lobe disease: motor and mental slowness, apathy, prominent grasping and sucking reflexes, gegenhalten, incontinence, and a slow, hesitant, wide-based gait. In both these cases, the neurologic abnormalities evolved over a period of about 2 months, and both patients recovered within a few weeks of hospitalization. Death occurred several years later as a result of liver disease and subdural hematoma, respectively. In each case, autopsy disclosed an old lesion typical of Marchiafava-Bignami disease confined to the central portion of the most anterior parts of the corpus callosum, but one had to look closely to see the gray line of gliosis.

In view of the great variability of the clinical picture and the obscurity in many patients of subtle mental and neurologic abnormalities by the effects of chronic inebriation and other alcoholic neurologic disorders, the diagnosis of Marchiafava-Bignami disease is understandably difficult. In fact, it is rarely made during life, but the CT and MRI have disclosed typical but unsuspected examples (see Kawamura et al). In some cases studied sequentially, MRI has disclosed demyelination, swelling, and necrosis of the corpus callosum with extension toward the subcortical white matter. In a few cases these findings have reversed over time after vitamin therapy, leaving residual callosal atrophy (Gambini et al). The occurrence, in a chronic alcoholic, of a frontal lobe syndrome or a symptom complex that points to a diagnosis of frontal or corpus callosum tumor but in whom the symptoms remit should suggest the diagnosis of Marchiafava-Bignami disease. The image appearance

may be easily mistaken for multiple sclerosis, gliomatosis cerebri, or progressive multifocal leukoencephalopathy.

Pathogenesis and Etiology

Originally, Marchiafava-Bignami disease was attributed to the toxic effects of alcohol, but this is an unlikely explanation in view of the prevalence of alcoholism and the rarity of corpus callosum degeneration. Furthermore, the distinctive callosal lesions have not been observed with other neurotoxins. Very rarely, undoubted examples of Marchiafava-Bignami disease have occurred in abstainers, so that alcohol cannot be an indispensable factor. A nutritional etiology has been invoked, but the putative factor that is deficient has not been determined. This view is underscored by reports of improvement in a few, but not all, cases following administration of thiamine. The mechanisms involved in the selective demyelination and noninflammatory necrosis of particular areas of white matter remain to be elucidated. Perhaps, when its mechanism becomes known, Marchiafava-Bignami disease, like central pontine myelinolysis (which it resembles histologically), will have to be considered in a chapter other than one on nutritional disease.

PROTEIN-CALORIE MALNUTRITION AND DEVELOPMENTAL DELAY

(See also Chap. 38)

There is increasing evidence that severe dietary deprivation during critical phases of brain development may result in permanent impairment of cerebral function and in developmental delay. Inasmuch as there are an estimated 100 million children in the world who are undernourished and suffer from varying degrees of protein, calorie, and other dietary inadequacies, this is one of the most pressing problems in medicine and society.

The literature is too large to review here, but excellent critiques have been provided by Winick, Birch and coworkers, Latham, and Dodge and colleagues. In contrast to the devastating effect of protein-calorie malnutrition (PCM) on body growth, brain weight is only slightly reduced. Nevertheless, on the basis of experiments in dogs, pigs, and rats, it is evident that prenatal and early postnatal malnutrition retards cellular proliferation in the brain. All cells are affected, including oligodendroglia, with a proportional reduction in myelin. Also, the process of dendritic branching may be retarded by early malnutrition. A limited number of studies in humans suggest that PCM has a similar effect on the brain during the first 8 months of life. In animals, varying degrees of recovery from the effects of early malnutrition are possible if normal nutrition is reestablished during the vulnerable periods. Presumably this is true for humans as well, although proof is difficult to obtain. In every series of severely undernourished infants and young children who have been observed for a period of many years, a variable proportion has been developmentally delayed to a modest degree; the majority recovers, however (Galler). Unfortunately, the neurologic and intellectual

consequences of PCM have defied accurate assessment because of the difficulty of isolating the effects of severe malnutrition from those of infection, social deprivation, genetic mechanisms, and other factors.

Nutritional Deficiencies Secondary to Malabsorption

The vitamins known to be essential to the normal functioning of the central and peripheral nervous systems cannot be synthesized by the human organism. Each is ingested as an essential part of the normal diet and absorbed in certain regions of the gastrointestinal tract. Impairment or failure of absorption caused by diseases of the gastrointestinal tract gives rise to several malabsorption syndromes, some of which have already been referred to, for example, malabsorptive vitamin E deficiency. In these diseases, the site of the block in transport from the intestinal lumen varies; it may be at the surface of the enterocytes or at their interface with the lymphatic channels and portal capillaries.

Table 41-2, which is modified from Pallis and Lewis, lists the main malabsorptive diseases and their relationships to the intestinal abnormalities. Of all these diseases, celiac sprue (gluten enteropathy) is the most common. The neurologic complications of this disorder, in our experience, have taken the form of a symmetrical, predominantly sensory polyneuropathy, as described in Chap. 46. However, other complications have been described, notably a progressive cerebellar syndrome with cortical, dentate, and olivary cell loss. The cerebellar changes may be coupled with a symmetrical demyelination of the posterior columns, producing a spinocerebellar disorder similar to that of vitamin E deficiency, but in the latter case, vitamin E supplementation has no consistent effect. Others have remarked on a high incidence of depression and other psychiatric disturbances in adult patients with celiac sprue, as also discussed in Chap. 40. Unexplained seizures are also said to occur.

Polyneuropathy and SCD of the spinal cord manifesting themselves many years after gastrectomy are encountered only rarely. The neurology of gastrointestinal disease has also been reviewed by Perkin and Murray-Lyon.

INHERITED VITAMIN-RESPONSIVE NEUROLOGIC DISEASES

(See Table 41-3 and Chap. 37)

Although humans lack the capacity to synthesize essential vitamin molecules, they are nonetheless able to use them in a series of complex chemical reactions involved in intestinal absorption, transport in the plasma, entry into the organelles of many organs, activation of the vitamin into coenzyme, and, finally, their interaction with certain specific apoenzyme proteins. This compels consideration of another aspect of nutrition wherein one or more of these steps in vitamin utilization may be defective because of a genetic abnormality. Under

Table 41-2

MECHANISMS WHEREBY MALABSORPTION MAY BE RELATED TO NEUROLOGIC DISEASE

GASTROINTESTINAL DEFECT	SUBSTANCE MALABSORBED	ASSOCIATED NEUROLOGIC DISORDER
Localized gastric lesions:		
Pernicious anemia	Vitamin B ₁₂	Myelopathy, optic neuropathy, etc.
Congenital lack of intrinsic factor	Vitamin B ₁₂	Myelopathy, neuropathy, etc.
Partial gastrectomy	Vitamin B ₁₂ Vitamin D	Myelopathy, neuropathy, etc. Osteomalacic myopathy
Lesions of small intestine:		
Predominantly proximal	? Water-soluble vitamins Vitamin D Folic acid	? Hypovitaminosis B ? Osteomalacic myopathy Probably none
Predominantly distal	Vitamin B ₁₂	Neuropathy, myelopathy, etc.
Diffuse		Myoclonus, ataxia, etc.
Bacterial contamination of small bowel (jejunal diverticulosis, blind-loop syndrome, strictures)	Vitamin B ₁₂	Neuropathy, myelopathy, etc.
Congenital absorptive defect		
	"Neutral" amino acids Tryptophan Methionine Folic acid Vitamin B ₁₂	Hartnup disease "Blue diaper" syndrome "Oast-house" urine disease Mental retardation, seizures, ataxia, choreoathetosis Neuropathy, myelopathy
Transmucosal transport disorders associated with steatorrhea:		
Endocrine causes		Xerophthalmia Keratomalacia
Postirradiation		? Osteomalacic myopathy
Drug induced		
Defective synthesis of chylomicrons with prolonged intestinal malabsorption	Vitamin E (carrier lipoprotein not synthesized in liver)	Bassen-Kornzweig disease, spinocerebellar degen- eration with polyneuropathy
Infiltration of villous cores	Fats (defective chylomicron release)	Encephalopathy of Whipple disease
Competition for essential nutrients (e.g., fish tapeworm)	Vitamin B ₁₂	Neuropathy, myelopathy

Source: Reproduced by permission from Pallis and Lewis.

these circumstances, the signs of vitamin deficiency result not from vitamin deficiency in the diet but from a genetically deranged control mechanism. In some instances the defect is only quantitative, and by loading the organism with a great excess of the vitamin in question, the biochemical abnormality can be overcome. The aforementioned special type of vitamin E deficiency

that results from an inherited inability to incorporate the vitamin into lipoproteins falls into this category, the diseases of which, being of hereditary type, have already been described in Chap. 37. Rosenberg has listed the most important of these hereditary vitamin-responsive diseases, which we have abstracted for the reader in Table 41-3.

Table 41-3

VITAMIN-RESPONSIVE INHERITED DISORDERS AFFECTING THE NERVOUS SYSTEM

VITAMIN	DISORDER	THERAPEUTIC DOSE	ENZYMATIC DEFECT	NEUROLOGIC MANIFESTATIONS
Thiamine (B ₁)	Branched-chain ketoaciduria	5–20 mg	Branched-chain ketoacid decarboxylase	Lethargy, coma
	Lactic acidosis	5–20 mg	Pyruvate carboxylase	Mental retardation
	Pyruvic acidemia	5–20 mg	Pyruvate dehydrogenase	Cerebellar ataxia
	Anemia	50 mg	—	Same as thiamine-deficient beriberi of infancy and childhood
Pyridoxine (B ₆)	Homocystinuria	>25 mg	Cystathionine synthase	Mental retardation, cerebrovascular accidents, psychoses
	Infantile convulsions	10–50 mg	Glutamic acid decarboxylase	Seizures
	Xanthurenic aciduria	5–10 mg	Kynureninase	Mental retardation
Cobalamin (B ₁₂)	Methylmalonic aciduria	1,000 g	Methylmalonyl-CoA mutase apoenzyme	Lethargy, coma, psychomotor retardation
	Methylmalonic aciduria and homocystinuria	>500 g	Defects in synthesis of adenosylcobalamin and methylcobalamin	Developmental arrest, cerebellar ataxia
Folic acid	Megaloblastic anemia	<0.05 mg	Folate deficiency	Mental retardation
	Formiminotransferase deficiency	>5 mg	Intestinal malabsorption of formiminotransferase	Mental retardation
	Homocystinuria and hypomethioninemia	>10 mg	N ⁵ , N ¹⁰ -Methylenetetrahydrofolate reductase	Schizophrenic syndrome
Biotin	β -Methylcrotonylglycinuria	\uparrow 5–10 mg	β -Methylcrotonyl-CoA carboxylase	Mental retardation
	Propionic acidemia	\uparrow 5–10 mg	Propionyl-CoA carboxylase	Lethargy, coma
Nicotinamide	Hartnup disease	>400 mg	Intestinal malabsorption of tryptophan	Cerebellar ataxia

Alcohol and Alcoholism

Intemperance in the use of alcohol creates many problems in modern society, the importance of which can be judged by the emphasis it has received in contemporary writings, both literary and scientific. These problems may be divided into three categories: psychologic, medical, and sociologic. The main psychologic issue regards why a person drinks excessively, often with full knowledge that such action will result in physical injury and even death. The medical problem embraces all aspects of alcoholic addiction and habituation as well as the diseases that result from the abuse of alcohol. The sociologic problem encompasses the effects of sustained drinking on the patient's work, family, and community. Some idea of the enormity of these problems can be gleaned from figures supplied by the secretary of Health and Human Services, which indicate that up to 40 percent of medical and surgical patients have alcohol-related problems and that these patients account for 15 percent of all healthcare costs. Several surveys have suggested a rate of alcohol dependence of 3 to 5.5 percent of adults. A minimum of 3 percent of deaths in the United States are attributable to alcohol-related causes. More striking, but not at all surprising, is the fact that alcohol intoxication is responsible for approximately 45 percent of fatal motor vehicle accidents and 22 percent of boating accidents. It requires little imagination to conceive the havoc wrought by alcohol in terms of suicide, accidents, crime, mental and physical disease, and disruption of family life. Finally, the problems engendered by excessive drinking cannot easily be separated from one another.

Etiology of Alcoholism

The cause of alcoholism as an addiction remains as obscure as it is for other forms of dependence and addiction, although environmental, cultural, and genetic factors are clearly implicated. No single personality type has been shown to predict reliably who will become addicted to alcohol. Similarly, no particular aspect of alcohol metabolism has been found to account for the development of addiction, with the possible exception of aldehyde dehydrogenase (see further on). Some persons drink excessively and become alcoholic in response to a profoundly disturbing personal or family problem, but most do not. Alcoholism may develop in response to a depressive illness, more so in women than in men, but

far more often depression is a consequence of drinking. Social and cultural influences are undoubtedly important in the genesis of alcoholism as evidenced, for example, by the remarkably high incidence of alcoholism and drinking problems in the American Indian and Eskimo populations and by the disparity in the prevalence of alcoholism, within a single community, among various ethnic groups. However, no ethnic or racial group and no social or economic class are exempt.

The importance of genetic factors in alcoholism has been amply identified. Goodwin and coworkers studied adopted Danish men whose biologic parents were alcoholic and control subjects whose biologic parents were not alcoholic. All of the subjects had been adopted before the age of 5 weeks and had no knowledge of their biologic parentage. Twenty percent of the offspring of biologic alcoholic parents, but only 5 percent of the control subjects, had become alcoholics by the age of 25 to 29 years. A Swedish adoption study (Bohman) and one in the United States (Cadoret et al) corroborate these findings. Family studies disclose a three- to fourfold increased risk for alcoholism in sons and daughters of alcoholics, and twin studies show a twofold higher concordance rate for alcoholism in monozygotic than in dizygotic pairs. Details of these studies can be found in the comprehensive reviews of the genetics of alcoholism by Grove and Cadoret and by Schuckit. The search goes on for a biologic trait, or marker, that would identify those who are genetically vulnerable to the development of alcoholism, but none has proved to be sufficiently practical or sensitive to identify all such persons (Reich).

Pharmacology and Physiology of Alcohol

Ethyl alcohol, or ethanol, is the active ingredient in beer, wine, whiskey, gin, brandy, and other alcoholic beverages. The stronger spirits contain enanthic ethers, which provide flavor but have no important pharmacologic properties. In some preparations, impurities such as amyl alcohol (fusel oil) and acetaldehyde act like alcohol but are more toxic.

Alcohol is metabolized chiefly by oxidation, less than 10 percent being excreted chemically unchanged in the urine, perspiration, and breath. The energy liberated by the oxidation of alcohol (7 kcal/g) can be utilized as completely as that derived from the metabolism of other

carbohydrates. However, calories from alcohol are empty of nutrients such as proteins and vitamins and cannot be used in the repair of damaged tissue. All ingested alcohol, except that metabolized by alcohol dehydrogenase in the stomach wall, is carried by the portal system to the liver. Here several enzyme systems independently oxidize alcohol to acetaldehyde. The most important of these, accounting for 80 to 90 percent of ethanol oxidation *in vivo*, are alcohol dehydrogenase (ADH) and its isoenzymes. This reaction leads to the formation of acetaldehyde and the reduction of nicotinic acid dehydrogenase (NAD) to nicotinamide adenine dinucleotide (NADH). A second pathway of lesser importance involves catalase, which is located in the peroxisomes and mitochondria; a third uses the "microsomal ethanol oxidizing system" (MEOS), located mainly in the microsomes of the endoplasmic reticulum. The details of the process by which acetaldehyde is metabolized are still not settled. Most likely it is converted by aldehyde dehydrogenase to acetate. Acetaldehyde has a number of unique biochemical effects that are not produced by alcohol alone. Persons who flush easily after ingestion of alcohol (Chinese, Japanese, and other Asians) differ from "nonflushers" with respect to the metabolism of acetaldehyde rather than to the metabolism of alcohol. The flushing reaction has been traced to a deficiency of aldehyde dehydrogenase activity (Harada et al). The low rate of alcoholism among Asians is said to be related to the flushing reaction (which is, in effect, a modified alcohol-disulfiram reaction; see further on), but this can hardly be the case, as North American Indians, a group with a high incidence of alcoholism, show the same reaction.

A scale relating various degrees of functional impairment to blood alcohol levels in *nonhabituated* persons was constructed many years ago by Miles. At a blood alcohol level of 30 mg/dL, a mild euphoria was detectable, and at 50 mg/dL, mild incoordination. At 100 mg/dL, ataxia was obvious; at 200 mg/dL, there was confusion and a reduced level of mental activity; at 300 mg/dL, the subjects were stuporous; and a level of 400 mg/dL—accompanied by deep anesthesia—was potentially fatal. These figures are valid provided that the alcohol content in the blood rises steadily over a 2-h period.

For all practical purposes, once the absorption of alcohol has ended and equilibrium has been established with the tissues, *ethanol is oxidized at a constant rate, independent of its concentration in the blood* (about 150 mg alcohol per kilogram of body weight per hour, or about 1 oz of 90-proof whiskey per hour). Actually, slightly more alcohol is metabolized per hour when the initial concentrations are very high, and repeated ingestion of alcohol may facilitate its metabolism, but these increments are of little clinical significance. In contrast, the rate of oxidation of acetaldehyde does depend on its concentration in the tissues. This fact is of importance in connection with the drug disulfiram (Antabuse), which acts by raising the tissue concentration necessary for the metabolism of a certain amount of acetaldehyde per unit of time. The patient taking both disulfiram and alcohol will accumulate an inordinate amount of acetaldehyde, resulting in nausea, vomiting, and hypotension, sometimes so pronounced in degree as to

be fatal. Certain other drugs—notably the sulfonylureas, metronidazole, and furazolidone—have effects like those of disulfiram but are less potent.

Alcohol acts directly on neuronal membranes in a manner akin to that of the general anesthetics. These agents, as well as barbiturates and benzodiazepines, are lipid-soluble and are thought to dissolve in the cell membranes (in direct relation to the degree of their lipid solubility). With continued ingestion of alcohol, the neuronal membranes ostensibly "rigidify" and become resistant to the fluidizing effect of alcohol (Chin and Goldstein; Harris et al). It is unlikely, however, that these changes in the physical properties of cell membranes are in themselves sufficient to alter cell function. Probably of equal importance are the effects of alcohol on membrane receptor systems that regulate ion channels, particularly the chloride and calcium channels. One likely site that relates to the acute intoxicating effects of alcohol is a receptor for the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) and its associated chloride-ion channel. Benzodiazepine antagonists appear to block the potentiation by alcohol of GABA-induced chloride flux. Like the GABA-chloride channel, the *N*-methyl-D-aspartate (NMDA) receptors, which transduce signals carried by glutamate (the major excitatory transmitter in the brain), are sensitive to extremely low concentrations of alcohol. There is also evidence that alcohol selectively potentiates serotonin receptor-ion currents, and the activity of this receptor has been implicated in alcohol- and drug-seeking behavior and addiction.

The effect of chronic administration of alcohol is to increase the number of neuronal calcium channels in the cell membrane. Moreover, calcium channel blockers, given during chronic administration, prevent both the increase in neuronal calcium channels and the development of tolerance to alcohol (Dolin and Little). The significance of these findings has been demonstrated by Little and colleagues, who showed that calcium channel blockers, given to chronically intoxicated animals after withdrawal, prevent withdrawal convulsions.

The molecular mechanisms involved in alcohol intoxication and tolerance are obviously more complex than the foregoing remarks would indicate (see reviews by Charness and by Samson and Harris). There is now a vast literature on this subject, much of it contradictory and a unified concept of the role of neurotransmitters and their receptors and modulators in the production of alcohol intoxication and tolerance has yet to emerge. The part played by internal cellular messengers, which have attracted much attention in the field of addiction, is also currently under investigation.

Alcohol Tolerance A scale of blood concentrations such as the one previously described has virtually no value in the chronic alcoholic patient, as it does not take into account the phenomenon of tolerance. It is common knowledge that a habituated person can drink more and show fewer effects than the moderate drinker or abstainer. This phenomenon accounts for the surprisingly large amounts of alcohol that the chronic drinker can consume without showing significant signs of drunkenness. Sober-appearing alcoholics may have blood alcohol levels of 400

to 500 mg/dL. This aspect of tolerance must be considered in judging the significance of a single estimation of the blood alcohol concentration as an index of functional capacity. The mechanisms that underlie tolerance and addiction are just beginning to be understood. There is little evidence that an enhanced rate of alcohol metabolism can adequately account for the degree of tolerance observed in alcoholics. An increase of neuronal adaptation to alcohol is a more likely explanation. Theoretically, the factors that are operative in this adaptation are the increasing resistance of neuronal membranes to the effects of alcohol and an increase in the number of neuronal calcium channels in the cell membrane.

CLINICAL EFFECTS OF ALCOHOL ON THE NERVOUS SYSTEM

Alcohol functions as a central nervous system (CNS) depressant. Some of the early effects of alcohol, such as garrulousness, aggressiveness, excessive activity, and increased electrical excitability of the cerebral cortex—all of them suggestive of cerebral stimulation—are thought to be caused by the inhibition of certain subcortical structures (possibly the high brainstem reticular formation) that ordinarily modulate cerebrocortical activity. Similarly, the initial hyperactivity of tendon reflexes may represent a transitory escape of spinal motor neurons from higher inhibitory centers. With increasing amounts of alcohol, however, the depressant action involves the cortex as well as other brainstem and spinal neurons. All manner of motor functions—whether the simple maintenance of a standing posture, the control of speech and eye movements, or highly organized and complex motor skills—are adversely affected by alcohol. The movements involved in these acts are not only slower than normal but also more inaccurate and random in character and therefore less well adapted to the accomplishment of specific ends.

Alcohol also impairs the efficiency of mental function by interfering with the speed of perception and the ability to persist in mental processing. The learning process is slowed and rendered less effective. Facility in forming associations, whether of words or of figures, and the ability to focus, sustain attention, and concentrate are reduced. Finally, alcohol impairs the faculties of judgment and discrimination and, all in all, the ability to think and reason clearly.

A number of neurologic disorders are characteristically associated with alcoholism. The factor common to all of them, of course, is the abuse of alcohol, but the mechanism by which alcohol produces its effects varies widely from one group of disorders to another and in many cases, the essential problem is one of nutritional deficiency as discussed in the preceding chapter. The classification that follows is based for the most part on known mechanisms.

- I. Alcohol intoxication—drunkenness, coma, paradoxical excitement (“pathologic intoxication”), “blackouts”
- II. Abstinence or withdrawal syndrome—tremulousness, hallucinosis, seizures, delirium tremens

- III. Nutritional diseases of the nervous system accompanying alcoholism (see Chap. 41)
 - A. Wernicke-Korsakoff syndrome
 - B. Polyneuropathy
 - C. Optic neuropathy (“tobacco-alcohol amblyopia”)
 - D. Pellagra
- IV. Diseases of uncertain pathogenesis associated with alcoholism
 - A. Cerebellar degeneration
 - B. Marchiafava-Bignami disease
 - C. Central pontine myelinolysis
 - D. “Alcoholic” myopathy and cardiomyopathy
 - E. Alcoholic dementia
 - F. Cerebral atrophy
- V. Fetal alcohol syndrome
- VI. Neurologic disorders resulting from cirrhosis and portal-systemic shunts (see Chap. 40)
 - A. Hepatic stupor and coma
 - B. Chronic hepatocerebral degeneration
- VII. Traumatic brain lesions acquired during intoxication—subdural hematoma, cerebral contusion

Alcohol Intoxication and Related Disorders

The usual manifestations of alcohol intoxication are so commonplace that they require little elaboration. They consist of varying degrees of exhilaration and excitement, loss of restraint, irregularity of behavior, loquacity and slurred speech, incoordination of movement and gait, irritability, drowsiness, and, in advanced cases, sleepiness, stupor, and coma. There are several *complicated* types of alcohol intoxication, which are considered below.

As has been indicated, the symptoms of alcoholic intoxication are the result of the depressant action of alcohol on cerebral and spinal neurons. In this respect alcohol acts on nerve cells in a manner akin to the general anesthetics and can cause coma. Unlike the anesthetics, however, the margin between the dose of alcohol that produces surgical anesthesia and that which dangerously depresses respiration is a narrow one, a fact that adds an element of urgency to the diagnosis and treatment of alcoholic coma. One must also be alert to the possibility that other sedative-hypnotic drugs may have potentiated the depressant effects of alcohol. Another treacherous situation is that of traumatic brain injury that is complicated by intoxication, a circumstance that is prone to misinterpretation because of uncertainty as to the main cause of stupor or coma.

Pathologic Intoxication

Despite what has been said earlier, on rare occasions, alcohol has an exclusively excitatory rather than a sedative effect. This reaction has been referred to in the past as *pathologic*, or *complicated*, *intoxication* and as *acute alcoholic paranoid state*. Because all forms of intoxication are *pathologic*, *atypical intoxication* or *idiosyncratic alcohol intoxication* are more appropriate designations. Nevertheless, the term *pathologic intoxication* is still widely used. The boundaries of this syndrome have never been clearly drawn. In the past, variant forms of delirium tremens and epileptic

phenomena, as well as psychopathic and criminal behavior, were indiscriminately included. Now the term is generally used to designate an outburst of blind fury with assaultive and destructive behavior. Often the patient is subdued only with difficulty. The attack terminates with deep sleep, which occurs spontaneously or in response to parenteral sedation; on awakening, the patient has no memory of the episode. Lesser degrees are also known wherein the patient, after several drinks, repeatedly commits gross social indiscretions. Allegedly this reaction may follow the ingestion of a small amount of alcohol, but in some of the patients we have observed the amount has often been substantial. Unlike the usual forms of alcohol intoxication and withdrawal, the atypical form has not been produced in experimental subjects, and the diagnosis depends upon the aforementioned arbitrary criteria.

Pathologic intoxication has been ascribed to many factors, but there are no meaningful data to support any of them. However, an analogy may be drawn between pathologic intoxication and the paradoxical reaction that occasionally follows the administration of barbiturates or other sedative drugs. The few patients we have seen, mostly young men of college age or slightly older, have been docile and seemingly well adjusted when not drinking. Usually, they have avoided alcohol after a first episode of this sort, but there have been exceptions.

The main disorders to be distinguished from pathologic intoxication are temporal lobe seizures that occasionally take the form of outbursts of rage and violence and the explosive episodes that characterize the behavior of certain sociopaths. The diagnosis in these cases may be difficult and depends on eliciting the other manifestations of temporal lobe epilepsy or sociopathy. *Pathologic intoxication* may require the use of restraints and the parenteral administration of diazepam (5 to 10 mg) or haloperidol (2 to 5 mg), repeated once after 30 to 40 min if necessary.

Alcoholic “Blackouts”

In the language of the alcoholic, the term *blackout* refers to an interval of time, during a period of severe intoxication, for which the patient later has no memory—even though the state of consciousness, as observed by others, was not grossly altered during that interval. However, a systematic assessment of mental function during the amnesic period has usually not been made. A few observations indicate that it is short-term (retentive) memory rather than immediate or long-term memory that is impaired; this feature and the subsequent amnesia for the episode are vaguely reminiscent of the disorder known as *transient global amnesia* (see Chap. 21) but without the incessant repetitive questioning and competence in non-memory mental activities that characterize the latter.

Blackouts may occur at any time in the course of alcoholism, even during the first drinking experience, and they certainly have happened in persons who never became alcoholic. The salient facts are that there is a degree of intoxication that interferes with the registration of events and the formation of memories during the period of intoxication and that the amount of alcohol consumed in moderate social drinking will rarely produce this effect.

Treatment of Severe Alcohol Intoxication

Coma caused by alcohol intoxication represents a medical emergency. The main objective of treatment is to prevent respiratory depression and its complications as described in Chap. 17. One would like to lower the blood alcohol level as rapidly as possible. The previously favored administration of fructose or of insulin and glucose for this purpose is now known to be of little value. Analeptic drugs such as amphetamine and various mixtures of caffeine and picrotoxin are antagonistic to alcohol only insofar as they are overall nervous system excitants but they do not hasten the oxidation of alcohol and are not clinically useful. The use of hemodialysis should be considered in comatose patients with extremely high blood alcohol concentrations (>500 mg/dL), particularly if accompanied by acidosis, and in those who have concurrently ingested methanol or ethylene glycol or some other dialyzable drug.

Methyl, Amyl, and Isopropyl Alcohols and Ethylene Glycol

Poisoning with alcohols other than ethyl alcohol is a rare but catastrophic occurrence. *Amyl alcohol* (fusel oil) and *isopropyl alcohol* are used as industrial solvents and in the manufacture of varnishes, lacquers, and pharmaceuticals; in addition, isopropyl alcohol is readily available as a rubbing alcohol. Intoxication may follow the ingestion of these alcohols or inhalation of their vapors. The effects of both are much like those of ethyl alcohol, but much more toxic. They also have in common the generation of acidosis, usually with an anion gap and if a sample of serums obtained soon after the ingestion, an osmolar gap that represents the molecules of the circulating alcohol.

Methyl alcohol (methanol, wood alcohol) is a component of antifreeze and many combustibles and is used in the manufacture of formaldehyde, as an industrial solvent, and as an adulterant of alcoholic beverages, the latter being the most common source of methyl alcohol intoxication. The oxidation of methyl alcohol to formaldehyde and formic acid proceeds relatively slowly; thus, signs of intoxication do not appear for several hours or may be delayed for a day or longer. Many of the toxic effects are like those of ethyl alcohol, but in addition severe methyl alcohol poisoning may produce serious degrees of acidosis (with an anion gap). The characteristic features of this intoxication, however, are damage to retinal ganglion cells—giving rise to scotomata and varying degrees of blindness, dilated unreactive pupils, and retinal edema—and bilateral degeneration of the putamens, readily visible on CT scans. Survivors may be left blind or, less often, with putamenal necrosis and dystonia or Parkinson disease (McLean et al). The most important aspect of treatment is the intravenous administration of large amounts of sodium bicarbonate to reverse acidosis. Hemodialysis and 4-methylpyrazole (see later) may be useful adjuncts because of the slow rate of oxidation of methanol.

Ethylene glycol, an aliphatic alcohol, is a commonly used industrial solvent and the major constituent of antifreeze. In the latter form, it is sometimes consumed by skid-row alcoholics (5,000 cases of poisoning annually

in the United States) and in suicide attempts with disastrous results. At first the patient merely appears drunk, but after a period of 4 to 12 h, hyperventilation and severe metabolic acidosis develop, followed by confusion, convulsions, coma, and renal failure and death in rapid succession. Cerebrospinal fluid lymphocytosis is a common but not invariable feature. The metabolic acidosis is a result of the conversion of ethylene glycol by alcohol dehydrogenase into glycolic acid, thus producing an anion gap that reflects the presence of this additional substance in the blood. (The anion gap has been defined in different ways, but the most convenient is the difference between the positive ion Na^+ and the sum of negative ions, Cl^- plus HCO_3^- [venous CO_2 is used for the latter]; a value greater than 12 is considered a gap.) The cause of the renal toxicity is less clear—probably it is a result of the formation of oxalate from glycolate and the deposition of oxalate crystals in renal tubules. (One of our recent patients had hippurate crystals in the urine, a finding that is more characteristic of toluene ingestions.) These crystals appear in the urine and sometimes in the cerebrospinal fluid (CSF) and aid in diagnosis.

Treatment of Nonethanol Alcohol Intoxication

The treatment of ethylene glycol poisoning has, until relatively recently, consisted of hemodialysis and the intravenous infusion of sodium bicarbonate and ethanol, the latter serving as a competitive substrate for alcohol dehydrogenase. However, the use of ethanol in this regimen is problematic. Baud and colleagues, and more recently Brent and colleagues and Jacobsen, have advocated the use of intravenous 4-methylpyrazole (fomepizole), which is a far more effective inhibitor of alcohol dehydrogenase than is alcohol. They recommend this form of treatment for methanol poisoning as well. Information from the American Academy of Toxicology is cited in a review of the use of fomepizole by Brent, which is recommended to the interested reader. Generally, for either methanol or ethylene glycol, a plasma level of the alcohol above 20 mg/dL, or above 10 mg/dL when combined with an osmolal gap over 10 is considered appropriate to institute the drug. In the case of ethylene glycol, oxaluria and acidosis are additional factors that may precipitate treatment. Dialysis remains an essential therapy if cerebral and renal damage is not too advanced.

Some patients who recover from the acute renal and metabolic effects are left with multiple cranial nerve defects, particularly of the seventh and eighth nerves. The latter abnormalities develop 6 to 18 days after the ingestion of ethylene glycol and have been attributed to the deposition of oxalate crystals along the subarachnoid portions of the affected nerves (Spillane et al).

The Alcohol Abstinence, or Withdrawal, Syndrome

This is the well-known symptom complex of tremulousness, hallucinations, seizures, confusion, and psychomotor and autonomic overactivity. Although a sustained period of chronic inebriation is the most obvious factor in the causation of these symptoms, they become manifest

Figure 42-1. Relation of acute neurologic disturbances to cessation of drinking. The shaded drinking period is greatly foreshortened and not intended to be quantitative. The periodic notching in the baseline represents the tremulousness, nausea, and so on that occur following a night's sleep. The time relations of the various groups of symptoms to withdrawal are explained in the text. (Adapted from Victor M, Adams RD: The effect of alcohol on the nervous system. *Res Publ Assoc Res Nerv Ment Dis* 32:526, 1953, by permission.)

only after a period of relative or absolute abstinence from alcohol—hence the designation *abstinence*, or *withdrawal*, syndrome. Figure 42-1 illustrates this concept. Each of the major manifestations of the withdrawal syndrome may occur in more or less pure form and are so described below, but usually they occur in combination. Major withdrawal symptoms are observed mainly in the binge, or periodic, drinker, although the steady drinker is not immune if for some reason he stops drinking, such as during a hospital admission for surgery or a medical illness. The full syndrome, depicted further on, is called *delirium tremens*.

Tremulousness

The most common single manifestation of the abstinence syndrome is tremulousness, often referred to as “the shakes” or “the jitters,” combined with general irritability and gastrointestinal symptoms, particularly nausea and vomiting. These symptoms first appear after several days of drinking, usually in the morning after a night's abstinence. The patient “quiets his nerves” with a few drinks and is then able to drink for the rest of the day without undue distress. The symptoms return on successive mornings with increasing severity. The symptoms then become augmented, reaching their peak intensity 24 to 36 h after the complete cessation of drinking. *Generalized tremor* is the most obvious feature. It is of fast frequency (6 to 8 Hz), slightly irregular, and variable in severity, tending to diminish when the patient is in quiet surroundings and to increase with motor activity or emotional stress. The tremor may be so violent that the patient cannot stand without help, speak clearly, or eat without assistance. Sometimes there is little objective evidence of tremor, and the patient complains only of being “shaky inside.”

Within a few days, flushed facies, anorexia, tachycardia, and tremor characteristic of the mild withdrawal syndrome subside to a large extent, but overall alertness, tendency to

startle easily, and jerkiness of movement may persist for a week or longer. Feelings of uneasiness may not leave the patient completely for 10 to 14 days. According to Porjesz and Begleiter, certain electrophysiologic abnormalities (diminished amplitudes of sensory evoked potentials and prolonged latencies and conduction velocities of auditory brainstem potentials) remain altered long after the clinical abnormalities have subsided.

Hallucinations

Symptoms of disordered perception occur in about one-quarter of withdrawing hospitalized tremulous patients. The patient may complain of "bad dreams"—nightmarish episodes associated with disturbed sleep—which he finds difficult to separate from real experience. Sounds and shadows may be misinterpreted, or familiar objects may be distorted and assume unreal forms (illusions). There may also be more overt hallucinations, which are purely visual in type, mixed visual and auditory, tactile, or olfactory, in this order of frequency. There is little evidence to support the popular belief that certain visual hallucinations (bugs, pink elephants) are specific to alcoholism. Actually, the hallucinations comprise the full range of visual experience. They are more often animate than inanimate; persons or animals may appear singly or in panoramas, shrunken or enlarged, natural and pleasant, or distorted, hideous, and frightening. The hallucinosis may be an isolated phenomenon lasting for a few hours, and it may later be attended by other withdrawal signs.

Acute and Chronic Auditory Hallucinosis

A special type of alcoholic psychosis consisting of a more or less pure auditory hallucinosis has been recognized for many years. Kraepelin referred to it as the "hallucinatory insanity of drunkards," or "alcoholic mania." A report of 75 such cases was made by Victor and Hope. The central feature of the illness, in the beginning, is the occurrence of auditory hallucinations despite an otherwise clear sensorium during the withdrawal period; i.e., the patients are not disoriented or obtunded, and they have an intact memory. The hallucinations may take the form of unstructured sounds such as buzzing, ringing, gunshots, or clicking (the elementary hallucinations of Bleuler), or they may have a musical quality, like a low-pitched hum or chant. The most common hallucinations, however, are human voices. When the voices can be identified, they are often attributed to the patient's family, friends, or neighbors—rarely to God, radio, or television. The voices may be addressed directly to the patient, but more frequently, they discuss him in the third person. In the majority of cases, the voices are maligning, reproachful, or threatening in nature and are disturbing to the patient; a significant proportion, however, are not unpleasant and leave the patient undisturbed. To the patient, the voices are clearly audible and intensely real, and they tend to be exteriorized; i.e., they come from behind a radiator or door, from the corridor, or through a wall, window, or floor. Another feature of auditory hallucinosis is that the patient's response is more or less understandable in light of the hallucinatory content.

The patient may call on the police for protection or erect a barricade against invaders; he may even attempt suicide to avoid what the voices threaten. The hallucinations are most prominent during the night, and their duration varies greatly: they may be momentary, or they may recur intermittently for days on end and, in exceptional instances, for weeks or months.

While hallucinating, most patients have no appreciation of the unreality of their hallucinations. With improvement, the patient begins to question the inauthenticity and may be reluctant to talk about them and may even question his own sanity. Full recovery is characterized by the realization that the voices were imaginary and by the ability to recall, sometimes with remarkable clarity, some of the abnormal thought content of the psychotic episode.

A unique feature of this alcoholic psychosis is its evolution, in a small proportion of the patients, to a state of *chronic auditory hallucinosis*. The chronic disorder begins like the acute one, but after a short period, perhaps a week or two, the symptomatology begins to change. The patient becomes quiet and resigned, even though the hallucinations remain threatening and derogatory. Ideas of reference and influence and other poorly systematized paranoid delusions become prominent. At this stage the illness may be mistaken for paranoid schizophrenia and indeed was so identified by Bleuler. There are, however, important differences between the two disorders: the alcoholic illness develops in close relation to a drinking bout and the past history rarely reveals schizoid personality traits. Moreover, alcoholic patients with hallucinosis are not distinguished by a high incidence of schizophrenia within their families (Schuckit and Winokur; Scott), and a large number of such patients, whom our colleagues Victor and Adams evaluated long after their acute attacks, did not show signs of schizophrenia. There is some evidence that repeated attacks of acute auditory hallucinosis render the patient more susceptible to the chronic state.

Withdrawal Seizures ("Rum Fits")

In the setting of alcohol withdrawal either as relative or absolute abstinence following a period of chronic inebriation, convulsive seizures are common. More than 90 percent of withdrawal seizures occur during the 7- to 48-h period following the cessation of drinking, with a peak incidence between 13 and 24 h. During the period of seizure activity, the electroencephalogram (EEG) is usually abnormal, but it reverts to normal in a matter of days, even though the patient may go on to develop delirium tremens. During the period of seizure activity and for days afterwards, the patient is unusually sensitive to stroboscopic stimulation; almost half the patients respond with generalized myoclonus or a convulsive seizure (photoparoxysmal response).

Seizures occurring in the abstinence period have a number of other distinctive features. There may be only a single seizure, but in the majority of cases the seizures occur in bursts of 2 to 6 over a day, occasionally even more; only 2 percent of patients studied by Victor (1968) developed status epilepticus. The seizures are grand mal

in type, i.e., generalized, tonic-clonic convulsions with loss of consciousness. Focal seizures should always suggest the presence of a focal brain lesion (most often traumatic) in addition to the effects of alcohol. Twenty-eight percent of Victor's patients with generalized withdrawal seizures went on to develop delirium tremens (the percentage has been less in other series); almost invariably, the seizures preceded the delirium. The postictal confusional state may blend imperceptibly with the onset of the delirium, or the postictal state may have cleared over several hours or even a day or longer before the delirium sets in. Seizures of this type typically occur in a patient whose drinking history has extended over a period of many years and must be distinguished from other forms of seizures that have their onset in adult life. The term *rum fits*, or *whiskey fits*—the names sometimes used by alcoholics—is reserved for seizures with the attributes described here. This serves to distinguish them from seizures that occur in the interdrinking period, long after withdrawal has been accomplished.

It is important to note that the common idiopathic or posttraumatic forms of epilepsy are also influenced by alcohol. In these types of epilepsy, a seizure or seizures may be precipitated by only a short period of drinking (e.g., a weekend, or even one evening of heavy social drinking); perhaps unsurprisingly in these circumstances, the seizures occur not when the patient is intoxicated but usually the morning after, in the "sobering-up" period. Except for the transient dysrhythmia in the withdrawal period, the incidence of EEG abnormalities in patients who have had rum fits is no greater than in normal persons, in sharp contrast to the EEGs of nonalcoholic patients with recurrent seizures.

Treatment and Prevention of Withdrawal Seizures

Most patients during withdrawal do not require anti-epileptic drugs, as the entire episode of seizure activity—whether a single seizure or a brief flurry of seizures—may have terminated before the patient is brought to medical attention. The parenteral administration of diazepam or sodium phenobarbital early in the withdrawal period does, however, prevent withdrawal fits in patients with a previous history of this disorder, as well as in those who might be expected to develop seizures on withdrawal of alcohol. This approach has been supported by the observations of D'Onofrio and colleagues that intravenous lorazepam (2 mg in 2 mL of normal saline) was highly effective in preventing *recurrent seizures* after a first seizure in the same withdrawal period. Only 3 of 100 patients so treated had a second seizure within 48 h, compared to 21 of 86 untreated patients. The long-term administration of anticonvulsants is neither necessary nor practical: if such patients remain abstinent, they will be free of seizures; if they resume drinking, they usually abandon their medications. Furthermore, it is not certain that continued administration of anticonvulsants dependably prevents abstinence seizures. The rare instances of status epilepticus should be managed like status of any other type (see Chap. 16). In alcoholics with a history of idiopathic or posttraumatic epilepsy, the goal

of treatment should be abstinence from alcohol, because of the tendency of even short periods of drinking to precipitate seizures. Such patients need to be maintained on anticonvulsant drugs.

Delirium Tremens and Related Disorders

This is the most dramatic and grave of all the acute alcoholic illnesses. It is characterized by profound confusion, delusions, vivid hallucinations, tremor, agitation, and sleeplessness, as well as by the signs of increased autonomic nervous system activity—i.e., dilated pupils, fever, tachycardia, and profuse perspiration. The clinical features of delirium are presented in detail in Chap. 20 as they relate to delirium tremens (DTs) and to other illnesses that simulate it.

Delirium tremens develops in one of several settings. The patient, an excessive and steady drinker for many years, may have been admitted to the hospital for an unrelated illness, accident, or operation and, after 2 to 4 days, occasionally even later, becomes delirious. Or, following a prolonged drinking binge, the patient may have experienced several days of tremulousness and hallucinosis or one or more seizures and may even be recovering from these symptoms when delirium tremens develops, rather abruptly as a rule.

As to the frequency of delirium tremens, Foy and Kay reported an incidence of 0.65 percent of all patients admitted for other reasons to a large general hospital. Among 200 consecutive alcoholics admitted to a city hospital, Ferguson and colleagues reported that 24 percent developed delirium tremens; of these, 8 percent died—figures that are considerably higher than those recorded in our hospitals (see below). Of course, the reported incidence of delirium tremens will vary greatly, depending on the population served by a particular hospital.

In the majority of cases, delirium tremens is benign and short-lived, ending as abruptly as it begins. Consumed by relentless activity and wakefulness for several days, the patient falls into a deep sleep and then awakens lucid, quiet, and exhausted, with virtually no memory of the events of the delirious period. Less commonly, the delirious state subsides gradually with intermittent episodes of recurrence. In either event, when delirium tremens occurs as a single episode, the duration is 72 h or less in more than 80 percent of cases. Less frequently still, there may be one or more relapses, several episodes of delirium of varying severity being separated by intervals of relative lucidity—the entire process lasting for several days or occasionally for as long as 4 to 5 weeks.

In the past, approximately 15 percent of cases of delirium tremens ended fatally, but the figure now is closer to 5 percent. In many of the fatal cases there is an associated infectious illness or injury, but in others, no complicating illness is discernible. Many of the patients die in a state of hyperthermia; in some, death comes so suddenly that the nature of the terminal events cannot be determined. Reports of series of cases with a negligible mortality rate in delirium tremens can usually be traced to a failure to distinguish between delirium tremens and

the minor forms of the withdrawal syndrome, which are far more common and practically never fatal.

We make note here of our experience with delirium following the withdrawal of barbiturates (Romero et al), which is almost identical to the DTs, including the abrupt cessation of symptoms, as discussed in the section on “Barbiturate Abstinence, or Withdrawal, Syndrome” in Chap. 43.

There are also alcohol withdrawal states, closely related to delirium tremens and about as frequent, in which one facet of the delirium tremens complex assumes prominence, to the virtual exclusion of the other symptoms. The patient may simply exhibit a transient state of quiet confusion, agitation, or peculiar behavior lasting several days or weeks. Or there may be a vivid hallucinatory–delusional state and abnormal behavior consistent with the patient’s false beliefs. Unlike typical delirium tremens, the atypical states usually present as a single circumscribed episode without recurrences, are only rarely preceded by seizures, and do not end fatally.

Pathologic examination is singularly unrevealing in patients with delirium tremens. Edema and brain swelling have been absent in the authors’ pathologic material except when shock or hypoxia had occurred terminally. There have been no significant light microscopic changes in the brain, which is what one would expect in a disease that is essentially reversible. The EEG findings have been discussed in relation to withdrawal seizures.

Pathogenesis of the Tremulous-Hallucinatory-Delirious Disorders

Prior to 1950, it was the common belief that these symptoms represented the most severe forms of alcohol intoxication—an idea that fails to satisfy the simplest clinical logic. The symptoms of toxicity—consisting of slurred speech, uninhibited behavior, staggering gait, stupor, and coma—are in themselves distinctive and, in a sense, the opposite of the symptom complex of tremor, fits, and delirium. It is evident, from observations in both humans and experimental animals, that the most important and the one obligate factor in the genesis of delirium tremens and related disorders is the withdrawal of alcohol following a period of sustained chronic intoxication. Furthermore, the emergence of withdrawal symptoms depends on a rapid *decline* in the blood alcohol level from a previously higher level and not necessarily upon the complete disappearance of alcohol from the blood.

The mechanisms by which the withdrawal of alcohol produces symptoms are incompletely understood. In all but the mildest cases, the early phase of alcohol withdrawal is attended by a drop in serum magnesium concentration and a rise in arterial pH—the latter on the basis of respiratory alkalosis (Wolfe and Victor). Possibly the compounded effect of these two factors, both of which are associated with hyperexcitability of the nervous system, is responsible in part for seizures and for other symptoms that characterize the early phase of withdrawal. However, these factors alone are not explanatory. The molecular mechanisms that are thought to be operative in the genesis of alcohol tolerance and withdrawal have been mentioned earlier. The gabaergic system has been

most strongly implicated, in part because the receptors for this inhibitory transmitter are downregulated by chronic alcohol use, but the situation is not nearly so simple, insofar as the excitatory glutaminergic system is also inhibited by alcohol.

Laboratory Findings Rarely, blood glucose is seriously depressed in the alcohol withdrawal states. Ketoacidosis with normal blood glucose is another infrequent finding. Disturbances of electrolytes are of varying frequency and significance. Serum sodium levels are altered infrequently and are more often increased than decreased. The same is true for chloride and phosphate. Serum calcium and potassium are lowered in about one-quarter of patients. Most patients show some degree of hypomagnesemia, low P_{CO_2} , and high arterial pH—abnormalities that are probably important in the pathogenesis of withdrawal symptoms (see later). Abnormalities of the CSF occur unpredictably (it is usually normal), as do changes on CT scanning or MRI; they may indicate the presence of some medical or surgical complication. Enlargement of the third and lateral ventricles is a common finding (see later). The MRI is normal unless there is an incipient Wernicke disease, in which case lesions in the periaqueductal region and subthalamus may be evident, as described in the previous chapter.

Treatment of Delirium Tremens and Minor Withdrawal Symptoms (See Chap. 20)

The treatment of delirium tremens begins with a search for associated injuries (particularly head injury with cerebral lacerations or subdural hematoma), infections (pneumonia or meningitis), pancreatitis, and liver disease. Because of the frequency and seriousness of these complications, chest films and a CT scan should be obtained in most instances, and lumbar puncture should be performed if there is suspicion of meningitis. In severe forms of delirium tremens, the temperature, pulse, and blood pressure should be measured at frequent intervals in anticipation of peripheral circulatory collapse and hyperthermia, which, added to the effects of injury and infection, are the usual causes of death in this disease. In the case of hypotension, one must act quickly, using intravenous fluids and, if called for, vasopressor drugs. The occurrence of hyperthermia demands the use of a cooling mattress or evaporative cooling in addition to specific treatment for any infection that may be present.

An additional important element in treatment is the correction of fluid and electrolyte imbalance, particularly hypokalemia and severe hypomagnesemia. Severe degrees of agitation and perspiration may require the administration of up to 5 L of fluid daily, of which at least 1,500 to 2,000 mL should be normal saline. The specific electrolytes and the amounts that must be administered are governed by the laboratory values for these electrolytes. If the serum sodium is extremely low, one must be cautious in raising the level lest a central pontine myelinolysis be induced (see Chap. 40). In the rare case of hypoglycemia, the administration of glucose is an urgent matter. Patients who present with severe alcoholic ketoacidosis and normal or only slightly

elevated blood glucose concentrations usually recover promptly, without the use of insulin.

It must be emphasized, as it was in Chap. 41, that a *special danger attends the use of glucose solutions in alcoholic patients*. The administration of intravenous glucose may serve to consume the last available reserves of thiamine and precipitate Wernicke disease. Typically, these patients have subsisted on a diet disproportionately high in carbohydrate (in addition to alcohol, which is metabolized entirely as carbohydrate) and low in thiamine, and their body stores of B vitamins may have been further reduced by gastroenteritis and diarrhea. For this reason it is good practice to add B vitamins, specifically thiamine (which may also be supplemented by intramuscular injection), in all cases requiring parenterally administered glucose—even though the alcoholic disorder under treatment, e.g., delirium tremens, is not primarily caused by vitamin deficiency.

With respect to the use of medications to treat the withdrawal syndromes, it is important to distinguish between mild symptoms, which are essentially benign and responsive to practically any sedative drug, and full-blown delirium tremens. There is no certain way to predict whether a patient with the early signs of withdrawal will progress to delirium tremens. In the latter state, the object of therapy is to blunt the psychomotor and autonomic overactivity, prevent exhaustion, and facilitate the administration of parenteral fluid and nursing care; one should not attempt to suppress agitation “at all costs,” as doing so requires an amount of drug that might depress respiration.

A wide variety of drugs are effective in controlling withdrawal symptoms. The more popular ones have been chlorthalidopoxide (Librium), diazepam (Valium), and the ancillary medications, clonidine and beta-adrenergic blockers, and a number of both older and newer anticonvulsant drugs such as gabapentin, which may reduce the requirement for sedative drugs. There is little to choose among the primary sedative drugs in respect to their therapeutic efficacy. More importantly, there are few data to indicate that any one of them can prevent hallucinosis or delirium tremens, or shorten the duration, or alter the mortality rate of the latter disorder (Kaim et al). A contemporary summary of the medication management of withdrawal has been given by Kosten and O'Connor. In general, phenothiazine drugs should be avoided because they may reduce the threshold to seizures. Probably, the use of any of the diazepam medications is as effective as a single dose of lorazepam in prophylactically suppressing seizures (see earlier discussion).

If parenteral medication is necessary, we still prefer 10 mg of diazepam or chlorthalidopoxide given intravenously and repeated once or twice at 20- to 30-min intervals until the patient is calm but awake; we also favor midazolam in closely controlled circumstances when hyperactivity and hallucinosis are extreme. Beta-adrenergic-blocking agents, such as propranolol, labetalol, and atenolol, are helpful in reducing heart rate, blood pressure, and the tremor to some extent. Lofexidine, an α_2 -agonist that blocks autonomic

outflow centrally, and clonidine are similarly effective in reducing the severity of most of the withdrawal symptoms, but they are not recommended as the sole treatments. Corticosteroids have no place in the treatment of the withdrawal syndrome and more potent agents such as propofol are usually not necessary.

Wernicke-Korsakoff Syndrome and Alcoholic-Nutritional Diseases

(See Chap. 41)

Alcoholism provides the ideal setting for the development of nutritional diseases of the nervous system. Although only a small proportion of alcoholics develop nutritional diseases, the overall number of these diseases is substantial because of the frequency of alcoholism. The importance of the alcohol-induced deficiency diseases relates to the fact that they are preventable and, if neglected, may lead to permanent disability. These illnesses, particularly the Wernicke-Korsakoff syndrome, are discussed fully in Chap. 41. Contrary to popular opinion with regard to the prevention of Wernicke disease, the content of B vitamins in American beer and other liquors is so low as to have little nutritional value (Davidson).

Disorders of Uncertain Pathogenesis Associated With Alcoholism

Also discussed in Chap. 41 are *alcoholic cerebellar degeneration* and *Marchiafava-Bignami disease*. The former is almost certainly of nutritional origin; in the latter a nutritional-metabolic etiology seems likely but has not been established. Central pontine myelinolysis, although frequently observed in alcoholics, is more appropriately considered with the acquired metabolic disorders, usually the too rapid correction of hyponatremia (see Chap. 40). Certain disorders of skeletal and cardiac muscle associated with alcoholism (*acute alcoholic myopathy* and *cardiomyopathy*) are described in Chap. 51, with the myopathies caused by drugs and toxins. There remain to be discussed several diverse disorders that have been attributed to alcoholism but whose causal relationship to alcohol abuse, nutritional deficiency, or some other relevant factor is not clear.

Alcoholic Dementia and Cerebral Atrophy

The term *alcoholic dementia* is used widely and often indiscriminately to designate a presumably distinctive form of dementia that is attributable to the chronic, direct effects of alcohol on the brain. Unfortunately, a syndrome subsumed under the title of *alcoholic dementia* and its many synonyms that appear in the older literature (*alcoholic deteriorated state*, *chronic alcoholic psychosis*, *chronic or organic brain syndrome due to alcohol*) has never been delineated satisfactorily, either clinically or pathologically. In the *Comprehensive Textbook of Psychiatry*, it has been defined as “a gradual disintegration of personality structure, with emotional lability, loss of control, and dementia” (Sadock and Sadock). Purported examples of this state show a

remarkably diverse group of symptoms, including jealousy and suspiciousness; coarsening of moral fiber and other personality and behavioral disorders; deterioration of work performance, personal care, and living habits; and disorientation, impaired judgment, and defects of intellectual function, particularly of memory.

There have been many attempts to redefine alcoholic dementia. Cutting, as well as Lishman, expressed the view that the term *Korsakoff psychosis* should be limited to patients with a fairly pure disorder of memory of acute onset and that patients with more global symptoms of intellectual deterioration, of gradual evolution, be considered to have alcoholic dementia. These are rather weak diagnostic criteria. As pointed out in Chap. 41, *Korsakoff psychosis* may have an insidious onset and gradual progression, and patients with this disorder, in addition to an amnesic defect, characteristically show disturbances of cognitive functions that depend little or not at all on memory. More importantly, in none of the patients designated by these authors as having alcoholic dementia was there a neuropathologic examination, without which the clinical assessment must remain arbitrary and imprecise.

The pathologic changes that purportedly underlie primary alcoholic dementia are even less precisely defined than the clinical syndrome. Courville, whose writings have been quoted most frequently in this respect, described a series of cerebral cortical changes that he attributed to the toxic effects of alcohol. Some of them turn out on close inspection to be quite nonspecific, reflecting nothing more than the effects of aging or the insignificant artifacts of tissue fixation and staining. Harper and Blumbergs, and subsequently Harper and Kril, reported that the mean brain weight is decreased in alcoholics and the pericerebral space is increased in volume—findings that do no more than confirm the brain shrinkage that is demonstrable by CT scans in many alcoholics and is to some extent reversible with sustained abstinence (see later).

The majority of cases that come to autopsy with the label of *alcoholic dementia* prove simply to have the lesions of the Wernicke-Korsakoff syndrome. Traumatic lesions of varying degrees of severity are commonly added. Other cases show the lesions of Marchiafava-Bignami disease, hepatic encephalopathy, subdural hematomas, or an unrelated communicating hydrocephalus, Alzheimer disease, ischemic necrosis, or some other disease quite unrelated to alcoholism. Practically always in our material, the clinical state can be accounted for by one or a combination of these disease processes and there has been no need to invoke a hypothetical toxic effect of alcohol on the brain. This has also been the experience of Torvik and associates; with a few exceptions, such as coincidental Alzheimer disease, all their cases that had been diagnosed as having alcoholic dementia turned out, on neuropathologic examination, to have the chronic lesions of Wernicke-Korsakoff disease.

In brief, the most serious flaw in the concept of a primary alcoholic dementia is that it lacks a distinctive, well-defined pathology. Until such time as the morphologic basis is established, its status must remain

ambiguous. A more detailed discussion of this subject and of so-called alcoholic cerebral atrophy (see later) can be found in the review by Victor (1994).

Alcoholic cerebral atrophy likewise does not constitute a well-defined entity. The concept was the product originally of pneumoencephalographic studies. Relatively young alcoholics, some with and some without symptoms of cerebral disease were often found to have enlarged cerebral ventricles and widened sulci, mainly of the frontal lobes (see, e.g., reports of Brewer and Perrett and of Haug). Similar findings have been reported in chronic alcoholics examined by CT scanning and MRI (see review by Carlen et al). The clinical correlates of these radiologic findings are unclear. Wilkinson demonstrated that in clinically normal alcoholics, the radiologic measures of "brain atrophy" were age related; once the age factor was removed, the CT findings in these subjects did not differ significantly from those in nonalcoholic controls. However, from the studies by Harper and colleagues (1982 and 1985) it may indeed be the case that chronic exposure to alcohol induces cerebral atrophy, but this requires confirmation. The idea of alcoholic atrophy is open to criticism mainly on the grounds that dilated ventricles have in fact been reversible to a considerable extent when abstinence is maintained (Carlen et al; Lishman; Zipursky et al; Schroth et al).

Fetal Alcohol Syndrome

That parental alcoholism may have an adverse effect on the offspring has been a recurrent theme in medical writings. Probably the first allusion to such a relationship was that of Sullivan in 1899, who reported that the mortality among the children of drunken mothers was more than two times greater than that among children of nondrinking women of "similar stock." This increased mortality was attributed by Sullivan and later by Haggard and Jellinek to postnatal influences such as poor nutrition and a chaotic home environment, rather than to the intrauterine effects of alcohol. The idea that maternal alcoholism could damage the fetus was generally rejected and relegated to the category of superstitions about alcoholism or the claims of temperance ideologues.

In the late 1960s, the effects of alcohol abuse on the fetus were rediscovered, so to speak. Lemoine and associates in France, and then Ulleland and Jones and Smith in the United States, described a distinctive pattern of abnormalities in infants born of severely alcoholic mothers. They stated that the affected infants are small in length in comparison to weight, and most of them fall below the third percentile for head circumference. They are distinguished also by the presence of short palpebral fissures (shortened distance between inner and outer canthi) and epicanthal folds; maxillary hypoplasia, micrognathia, indistinct philtrum, and thin upper lip; and longitudinally oriented palmar creases, flexion deformities of the fingers, and a limited range of motion of other joints. Minor anomalies (usually spontaneously closing cardiac septal defects), anomalous external genitalia, and cleft lip and palate are much more frequent than in the general population. All of these features have

similarities to the syndrome described in a proportion of infants whose mothers had taken anticonvulsants during pregnancy, the “fetal anticonvulsant syndrome” (see Chap. 16). The newborn infants suck and sleep poorly, and many of them are irritable, restless, hyperactive, and tremulous; these last symptoms resemble those of alcohol withdrawal except that they persist.

The first long-term study of children with what has come to be called *fetal alcohol syndrome* (FAS) was reported by Jones and coworkers. Among 23 infants born to alcoholic mothers, there was a neonatal mortality of 17 percent; among the infants who survived the neonatal period, almost half failed to achieve normal weight, length, and head circumference or remained backward mentally to a varying degree, even under optimal environmental conditions. Several large groups of severely affected children have now been observed for 20 years or longer (see Streissguth). Distractibility, inattentiveness, hyperactivity, and impairment of fine motor coordination are prominent features in early childhood. Most such children fall into the category of attention-deficit hyperactivity disorder. Slow growth of head circumference is a consistent finding throughout infancy and childhood. The physical stigmata of the syndrome become less distinctive after puberty, but practically all adolescents are left with some degree of mental retardation and behavioral abnormalities.

The pathologic changes that underlie the syndrome have been studied in a small number of cases and no uniform change has emerged. Of some interest are observations such as those of Ikonmidu and coworkers that demonstrate a profound effect of alcohol exposure on the deletion of millions of neurons in the developing rat brain by a mechanism of apoptosis. The main vulnerability occurs during periods of synaptogenesis, which in humans extends from the sixth month of gestation onward.

It is noteworthy that infants born to nonalcoholic mothers who had been subjected to severe dietary deprivation during pregnancy (during World War II) were small and often premature, but these infants did not show the pattern of malformations that characterizes FAS. Alcohol readily crosses the placenta in humans and animals; in the mouse, rat, chick, miniature swine, and beagle dog, alcohol has been shown to have both embryotoxic and teratogenic effects. Thus, the evidence to date favors a toxic effect of alcohol, although a possible toxic effect of acetaldehyde and smoking and a possible contributory role for nutritional deficiency have not been totally excluded.

Unequivocal cases of FAS observed to date have occurred only in infants born to severely alcoholic mothers (many of them with delirium tremens and liver disease) who continued to drink heavily throughout pregnancy. It is important to state that a relationship to lesser degrees of alcohol intake is far less secure. Data derived from the collaborative study sponsored by the National Institutes of Health indicate that about one-third of the offspring of women who are heavy drinkers have FAS. Abel and Sokol have estimated that the worldwide incidence of

FAS is 1.9 per 1,000 live births and have pronounced it the leading known cause of mental retardation in the western world. The degree of maternal alcoholism that is necessary to produce the syndrome and the critical stage in gestation during which it occurs are still vague. The various teratogenic effects described earlier are estimated to occur in the embryonic period, i.e., in the first 2 months of fetal life. Other nonteratogenic effects appear to be related to periods during gestation when the fetus is exposed to particularly high alcohol levels.

A comprehensive and not outdated account of alcohol-related birth defects and the controversial issues surrounding this subject is contained in a special issue of *Alcohol Health and Research World*, published by the National Institutes of Health (Vol. 18, 1994).

Neurologic Complications of Alcoholic Cirrhosis and Portal–Systemic Shunts

This category of alcoholic disease is discussed in Chap. 40, in connection with the acquired metabolic disorders of the nervous system.

TREATMENT OF ALCOHOL DEPENDENCE

Following recovery from the acute medical and neurologic complications of alcoholism, the patient still must face the underlying problem of alcohol dependence. To treat only the medical complications and leave the management of the drinking problem to the patient alone is shortsighted. Almost always, drinking is resumed, with a predictable recurrence of medical illness. For this reason the medical profession must be prepared to deal with the addiction or at least to initiate treatment.

The problem of excessive drinking is formidable but not nearly as hopeless as it is generally made out to be (see review of O'Connor and Schottenfeld). A common misconception among physicians is that specialized training in psychiatry and an inordinately large amount of time are required to deal with the addictive drinker. Actually, a successful program of treatment can be initiated by any interested physician, using the standard techniques of history taking, establishing rapport with the patient, and setting up a schedule of frequent visits, although not necessarily for prolonged periods. Our position on this matter was reinforced by a controlled study of problem drinkers in whom treatment was equally successful whether carried out by general practitioners or by specialists (Drummond et al). O'Connor and Schottenfeld summarize the various approaches to the patient who has a drinking problem but is not yet alcohol dependent. They favor brief and focused interventions that point out the problem in unambiguous terms and offer empathetic advice; the physician is often the central person in this interaction.

It appears that the requisite for successful treatment is total abstinence from alcohol; for all practical purposes, this represents the only permanent solution. There are alcohol addicts who have been able to reduce their

intake of alcohol and eventually to drink in moderation, but they represent only a small proportion of the addicted population. Alcoholic patients must be made fully aware of the medical and social consequences of continued drinking. They must also be made to understand that because of some constitutional peculiarity (like that of the diabetic, who cannot handle sugar) they are incapable of drinking in moderation. These facts should be presented in much the same way as one would explain the essential features of any other disease; there is nothing to be gained from adopting a punitive or moralizing attitude. Yet patients should not be given the idea that they are in no way to blame for their illness; there appears to be an advantage in making them feel that they are responsible for doing something about their drinking.

A number of methods have proved valuable in the short- and long-term management of alcoholic patients. The more important of these are admission to a detoxification or special hospital unit, rehabilitative therapy, aversion treatment, the use of disulfiram (Antabuse), and the participation in self-help organizations for recovery from alcoholism. Detoxification clinics and special hospital units for the treatment of alcoholism are now widely available. The physician should be aware of all the community resources available for the management of this problem and should be prepared to take advantage of them in appropriate cases. Most inpatient programs include individual and group counseling, didactics about the illness and recovery, and family intervention. Outpatient treatment (of individuals or groups) is widely available, either from specialized facilities or from specialized therapists in general mental health facilities; family counseling is usually offered as well and is often beneficial. Most professional alcoholism treatment in the United States includes an introduction to the methods and utilization of Alcoholics Anonymous (AA; see below).

Disulfiram, less used in recent years, interferes with the metabolism of alcohol, so that a patient who takes both alcohol and disulfiram accumulates an inordinate amount of acetaldehyde in the tissues, resulting in nausea, vomiting, and hypotension, sometimes pronounced in degree. It is no longer considered necessary to demonstrate these effects to patients; it is sufficient to warn them of the severe reactions that may result if they drink while they have the drug in their bodies.

The opioid antagonist naltrexone (50 mg/d orally) or a long-acting injectable formulation has also been used for this purpose, with overall favorable results in numerous trials. The depot injectable form has the advantage of improving compliance in this population that is difficult to treat and to retain in clinical trials. The relevant trials and clinical implementation of naltrexone for alcohol dependence are summarized by Anton (2008). In Europe, modest success has been achieved with the GABA and glutamate modulator acamprosate (2,000 mg daily), but this drug is not yet available in the United States and some trials have shown it to be

ineffective. Putatively, a novel approach has been to block the addicting effects of alcohol on the mesolimbic dopaminergic system by the use of anticonvulsants such as topiramate. Johnson and colleagues were able to demonstrate a reduction in alcoholic intake in patients taking this drug, in comparison to placebo, albeit over only a 12-week period. The use of these medications and the possible reasons for conflicting results between studies are given in a review by Swift. A complex randomized trial conducted by Anton and colleagues (2006) compared naltrexone, cognitive-behavioral therapy, and both, and found that abstinence was most likely, in the short period of 4 months, with the drug alone or when combined with the psychologic therapy; those who received the cognitive therapy but neither naltrexone or a placebo pill did somewhat worse.

Treatment with disulfiram is instituted only after the patient has been sober for several days, preferably longer. It should never be given to patients with cardiac or advanced liver disease. Should the patient drink while taking disulfiram, the ensuing reaction is usually severe enough to require medical attention, and a protracted spree can thus be prevented. Disulfiram may cause a polyneuropathy if continued over months or years, but this is a rare complication.

Alcoholics Anonymous, an informal fellowship of recovering alcoholics, has proven to be the single most effective force in the rehabilitation of alcoholic patients. The philosophy of this organization is embodied in its "12 Steps," a series of principles for sober living that guide the patient to recovery. The AA approach stresses in particular the practice of making restitution, the necessity to help other alcoholics, trust in a higher power, the group confessional, and the belief that the alcoholic alone is powerless over alcohol. Although accurate statistics are lacking, it is said that about one-third of the members who express more than a passing interest in the program attain a state of long-sustained or permanent sobriety. The methods used by AA are not acceptable to every patient, but most who persist in its activities appear to benefit; in particular, the physician should not accept a patient's initial negative reaction as reason to abandon AA as a mode of treatment.

Finally, it should be noted that alcoholism is very frequently associated with psychiatric disease of other types, particularly sociopathy and affective illness (the term "dual diagnosis" is used by psychiatrists to denote this combination of psychopathologies). In the latter case, the prevailing mood is far more often one of depression than of mania and is more often encountered in women, who are more apt to drink under these conditions than are men. In these circumstances, expert psychiatric help should be sought, preferably from someone who is also familiar with addictive diseases.

The role of physicians in caring for patients with alcohol problems has been outlined by several governmental agencies and is summarized in the review article by O'Connor and Schottenfeld.

Disorders of the Nervous System Caused by Drugs, Toxins, and Chemical Agents

Subsumed under this title is a diverse group of disorders of the nervous system that result from drugs and other injurious or poisonous substances. The neurologist must be concerned with the myriad of chemical agents that have no therapeutic utility but may adversely affect the nervous system; they abound in the environment as household products, insecticides, industrial solvents and other poisons, as well as substances that may have therapeutic value but are used for their "recreational" psychotropic effects, or are conventional medications with known toxic effects and may be accidentally ingested. These constitute the field of neurotoxicology. Also among the neurotoxins are those generated by bacteria and other infectious organisms, as well as toxins several found in nature, such as marine toxins.

It would hardly be possible within one chapter to discuss the innumerable drugs and toxins that affect the nervous system. The interested reader is referred to a number of comprehensive monographs and references listed at the end of this chapter. In addition, a current handbook of pharmacology and toxicology is a useful part of the library of every physician.

The scope of this chapter is also limited because the therapeutic and adverse effects of many drugs are considered elsewhere in this volume in relation to particular symptoms and diseases. Thus, the toxic effects of ethyl, methyl, amyl, and isopropyl alcohol, as well as ethylene and diethylene glycol, are discussed in Chap. 42. The adverse effects of antibiotics on cochlear and vestibular function and on neuromuscular transmission are discussed in Chaps. 15 and 49, respectively. Many of the undesirable side effects of the common drugs used in the treatment of extrapyramidal motor symptoms, pain, headache, seizure and sleep disorders, psychiatric illnesses, and so forth are also considered in the chapters dealing with each of these disorders and in the chapters that cover psychiatric diseases. Cyanide and carbon monoxide poisoning are discussed in relation to anoxic encephalopathy (see Chap. 40). A number of therapeutic agents that predictably damage the peripheral nerves (e.g., cisplatin, disulfiram, vincristine) are mentioned in this chapter but are discussed further in Chap. 46, and those that affect muscle are included in Chap. 48, "Diseases of Muscle."

The presentation of this subject is introduced by some general remarks on the action of drugs on the

nervous system and is followed by discussion of the main classes of agents that affect nervous function. The references at the end of the chapter are listed in relation to each of these categories:

1. Opiates and synthetic analgesics
2. Sedative-hypnotic drugs
3. Antipsychosis drugs
4. Antidepressant drugs
5. Stimulants
6. Psychoactive drugs
7. Bacterial toxins
8. Plant poisons, venoms, bites, and stings
9. Heavy metals
10. Industrial toxins
11. Antineoplastic and immunosuppressive agents
12. Antibiotics
13. Cardioactive agents

GENERAL PRINCIPLES OF NEUROTOXICOLOGY

The rational use of any drug requires knowledge of the best route of administration, the drug's absorption characteristics, its distribution in the nervous system and other organs, and its biotransformations and excretion (*pharmacokinetics*). Because every drug, if given in excess, has some adverse effects, therapeutics and toxicology are inseparable.

All systems of neurons are not identical; each has its own vulnerabilities to particular drugs and toxic agents. This principle, originally enunciated by Oskar and Ceclie Vogt in their theory termed *pathoclisis* is now embodied as "selective vulnerability." For example, selective vulnerability explains the production of parkinsonism by the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), in which a synthetic toxin affects a progressive loss of melanin-bearing dopaminergic nigral neurons (see Chap. 39). Another example is the preferential effects of anesthetics on the neurons of the upper brainstem reticular formation. Not only may certain groups of nerve cells be selectively destroyed by a particular agent but particular parts of their structure may be altered. Drugs may be targeted

even to the terminal axons, dendrites, neurofilaments, or receptors on pre- and postsynaptic surfaces of neurons or to certain of their metabolic activities, whereby they synthesize and release neurotransmitters or maintain their cellular integrity by the synthesis of RNA, DNA, and other proteins. An intriguing but not yet fully established extension of this theme relates to the manner in which certain drugs or toxins affect individuals differently with a genetic disposition by way of single nucleotide polymorphisms; this is the emerging field of pharmacogenetics.

The same mechanisms by which drugs and toxins act on particular steps in the formation, storage, release, uptake, catabolism, and resynthesis of neurotransmitters such as dopamine, serotonin, norepinephrine, acetylcholine, and other catecholamines cannot be separated from their toxic effects. Johnston and Gross have summarized views of how these transmitters and modulating agents, by attaching to receptors at neuronal synapses, are able to increase or decrease the permeability of ion channels and stimulate or inhibit second cytoplasmic messengers (cyclic adenosine monophosphate [cAMP] and G-proteins). For example, drugs such as L-dopa, tryptophan, and choline enhance the synthesis of dopamine, serotonin, and acetylcholine, respectively, and may impart toxic effects through these same mechanisms. Baclofen modulates the release of gamma-aminobutyric acid (GABA), the main inhibitory transmitter in the central nervous system (CNS). Botulinum toxin prevents the release of acetylcholine in the neuromuscular junction and tetanus toxin does the same on GABA in Renshaw cells of the spinal cord. Benzodiazepines, bromocriptine, and methylphenidate are viewed as receptor agonists; the phenothiazines and anticholinergics act as receptor antagonists. Certain drugs enhance the activity of neurotransmitters by inhibiting their reuptake as, for example, the class of antidepressant drugs that has a relatively selective influence on the reuptake of serotonin. Others deplete existing neurotransmitters, as reserpine does for norepinephrine and another class of drugs promotes the release of preformed synaptic transmitters; amphetamines and modafinil are examples in this class. Amantadine, an antiviral agent, may promote the release of dopamine. One must not assume that these are the exclusive modes of action of each of these drugs; for example, cocaine acts as a direct stimulant and through the inhibition of reuptake of catecholamines.

Bioavailability

A majority of drugs that act on the nervous system are ingested; factors that govern their intestinal absorption must therefore be taken into account. Small molecules usually enter the plasma by diffusion, larger ones by pinocytosis. The substances with which the drugs are mixed; the presence of food, other drugs, or intestinal diseases; and the age of the patient all influence the rate of absorption and blood concentrations. Different calculations are necessary for intramuscular, subcutaneous, and intrathecal routes of administration. To some extent, the solubilities of drugs (in lipid or water) determine the

routes by which they can be given; some drugs, such as morphine, can be administered by numerous routes. Carried in the blood, the drug (or toxin) reaches many tissues, including the nervous system; protein binding in the plasma has an important influence on distribution. Many drugs and toxic substances bind to serum albumin and other serum proteins, limiting the availability of the ionized form. The common drug and toxin transformations involve hydroxylation, deamination, oxidation, and dealkylation, which enhance their solubility and elimination mainly by the kidney. Most of these catalytic processes occur in liver cells and utilize multiple enzymes.

To enter the extracellular compartment of the nervous system, a drug or toxic agent must transgress the tight capillary–endothelial barrier (blood–brain barrier) and the barrier between the blood and cerebrospinal fluid (blood–CSF barrier). Intrathecal injection circumvents these barriers, but then the agent tends to concentrate in the immediate subpial and subependymal regions. The process of movement from plasma to brain is by diffusion through capillaries or by facilitated transport. The solubility characteristics of the drug determine its rate of diffusion.

In the following discussion on neurotoxins, the reader will appreciate a number of phenomena: *tolerance* (lessening effect of increasing dose), *dependence* and *addiction* (insatiable need), *habituation*, *drug-seeking behaviors*, and *abstinence* with its associated *withdrawal effects*. These were described in Chap. 42 regarding alcoholism and are further elaborated in sections below. Particularly difficult in reference to drugs such as nicotine is the separation of habituation from addiction, i.e., of psychologic dependence from physical dependence (see further on).

The few examples given earlier are intended to provide a glimpse of the complex interactions between chemical agents and the cells of the nervous system. For more specific information, the reader is referred to *The Biochemical Basis of Neuropharmacology* by Cooper, Bloom, and Roth, a text that we have consulted through its many editions and to *Goodman and Gilman's The Pharmacological Basis of Therapeutics*.

OPIATES AND SYNTHETIC ANALGESIC DRUGS

The opiates, or opioids, strictly speaking, include all the naturally occurring alkaloids in opium, which is prepared from the seed capsules of the poppy *Papaver somniferum*. For clinical purposes, the term *opiate* refers only to the alkaloids that have a high degree of analgesic activity, i.e., morphine. The terms *opioid* and *narcotic-analgesic* designate drugs with actions similar to those of morphine. Compounds that are chemical modifications of morphine include diacetylmorphine, or heroin, hydromorphone (Dilaudid), codeine, hydrocodone, oxycodone (OxyContin), and from the Victorian era and later, laudanum and paregoric. A second class of opioids comprises the purely synthetic analgesics: meperidine (Demerol)

and its congeners, notably fentanyl, methadone, levorphanol, propoxyphene (Darvon), loperamide (the active ingredient in Imodium), and diphenoxylate (the main component of Lomotil). The synthetic analgesics are similar to the opiates in both their pharmacologic effects and patterns of abuse, the differences being mainly quantitative.

Opioids activate G-coupled transmembrane receptors, meaning they influence neuronal activity through the intermediate of cAMP; the receptor types are denominated as mu, delta, and kappa. An understanding of the clinical effects of opioids is clarified by the knowledge that these receptors are concentrated in the thalamus and dorsal root ganglia (mu receptors, pain), amygdala (affect) and brainstem raphe (alertness), and Edinger-Westphal nuclei (pupillary miosis). Receptors in the brainstem, also of the mu type, are involved in modulating respiratory responses to hypoxia and hypercarbia (respiratory suppression). Receptors are also widely distributed in neural components of other organs, particularly the gastrointestinal tract, accounting for the constipation that is an effect of the administration of this class of drugs.

The clinical effects of the opioids are considered from two points of view: acute poisoning and addiction.

Opioid Overdose

Because of the common, and particularly the illicit, use of opioids, poisoning is a frequent occurrence. This happens also as a result of ingestion or injection accidentally or with suicidal intent, errors in the calculation of dosage, the use of a substitute or contaminated street product, or unusual sensitivity. Children exhibit an increased susceptibility to opioids, so that relatively small doses may prove toxic. This is true also of adults with myxedema, Addison disease, chronic liver disease, and pneumonia. Acute poisoning may also occur in persons who are unaware that opioids available from illicit sources vary greatly in potency and that tolerance for opioids declines quickly after the withdrawal of the drug; upon resumption of the habit, a formerly well-tolerated dose can be fatal.

Unresponsiveness, shallow respirations, slow respiratory rate (e.g., 2 to 8 per min) or periodic breathing, pinpoint pupils, bradycardia, and hypothermia are the well-recognized clinical manifestations of acute opioid poisoning. In the most advanced stage, the pupils dilate, the skin and mucous membranes become cyanotic, and the circulation fails. Later in the course, pulmonary edema may arise, or aspiration pneumonia may become evident as summarized in the review of opioid overdose by Boyer. The immediate cause of death is usually respiratory depression with consequent asphyxia. Patients who suffer a cardiorespiratory arrest are sometimes left with all the known residua of anoxic encephalopathy (see Chap. 40). Mild degrees of intoxication are reflected by anorexia, nausea, vomiting, constipation, and loss of sexual interest. Toxicology screens for opiates may be useful but action must be taken before the results of these tests are completed.

Treatment of Overdose

This consists of the support of ventilation and administration of naloxone (Narcan), or the longer-acting nalmefene, both specific antidotes to the opiates and also to the synthetic analgesics. The dose of naloxone in adults is usually 0.05 mg and repeated in larger increments (the second dose is typically 2 mg) every 2 min to a dose of 15 mg *intravenously* as outlined by Boyer. For children, a higher initial dose of 0.1 mg/kg is recommended. The improvements in circulation and respiration and reversal of miosis are usually dramatic. Failure of naloxone to produce such a response should cast doubt on the diagnosis of opioid intoxication. If an adequate respiratory and pupillary response to naloxone is obtained, the patient should nonetheless be observed for up to 24 h and further doses of naloxone (50 percent higher than the ones previously found effective) can be given *intramuscularly* as often as necessary. An intravenous infusion of naloxone has been recommended if a long-acting narcotic is the cause of overdose. (It is well to inspect the patient for the presence of unnoticed fentanyl patches and establish if a long-acting drug has been available for abuse.)

Naloxone has less direct effect on consciousness, however, and the patient may remain drowsy for many hours. This is not harmful provided respiration is well maintained. Although nalmefene has a plasma half-life of 11 h, compared to 60 to 90 min for naloxone, it has no clear advantage in emergency practice. Gastric lavage is a useful measure if the drug was taken orally. This procedure may be efficacious many hours after ingestion, as one of the toxic effects of opioids is ileus, which causes some of the drug to be retained in the stomach. Concerns of precipitating opioid withdrawal by giving naloxone are generally unfounded.

Once the patient regains consciousness, complaints such as pruritus, sneezing, tearing, piloerection, diffuse body pains, yawning, and diarrhea may appear. These are the recognizable symptoms of the opioid abstinence, or withdrawal, syndrome described later. Consequently, an antidote must be used with great caution in an addict who has taken an overdose of opioid, because in this circumstance, it may precipitate withdrawal phenomena. Nausea and severe abdominal pain, presumably because of pancreatitis (from spasm of the sphincter of Oddi), are other troublesome symptoms of opiate use or withdrawal. Seizures are rare.

Opioid Addiction

Just 50 years ago there were an estimated 60,000 persons addicted to narcotic drugs in the United States, exclusive of those who were receiving drugs because of incurable painful diseases. This represented a relatively small public health problem in comparison with the abuse of alcohol and barbiturates. Moreover, opioid addiction was of serious proportions in only a few cities—New York, Chicago, Los Angeles, Washington, DC, and Detroit. Since the late 1960s, a remarkable increase in opioid (mainly heroin) addiction has taken place. The precise number of opioid addicts is unknown but is currently estimated by the Drug Enforcement Administration to

be well more than 500,000 (a disproportionate number in large cities). The problem assumes enormous importance when one recognizes that one-quarter of addicts are seropositive for HIV and are the chief source of transmission of AIDS to newborns and to the heterosexual nonaddicted population.

Etiology and Pathogenesis

A number of factors—socioeconomic, psychologic, and pharmacologic—contribute to the genesis of opioid addiction. The most susceptible subjects are young men living in the economically depressed areas of large cities but significant numbers are found in suburbs and in small cities. The onset of opioid use is usually in adolescence, with a peak at 17 to 18 years; fully two-thirds of addicts start using the drugs before the age of 21. Almost 90 percent engage in criminal activity to obtain their daily ration of drugs but most of them have a history of arrests or convictions predating their addiction. Also, many of them have psychiatric disturbances, conduct disorder and sociopathy being the most common (“dual-diagnosis,” in psychiatric jargon). Monroe and colleagues, using the Lexington Personality Inventory, examined a group of 837 opioid addicts and found evidence of antisocial personality in 42 percent, emotional disturbance in 29 percent, and thought disorder in 22 percent; only 7 percent were free of such disorders. Vulnerability to addiction was not confined to one personality type.

Association with addicts is the apparent explanation for becoming addicted. In this sense, opioid addiction is contagious, and partly as a result of this pattern, opioid addiction has attained epidemic proportions. A small, almost insignificant proportion of addicts are introduced to drugs by physicians in the course of an illness. Thus there has been a regrettable tendency not to prescribe opiates to patients with acute or chronic pain (e.g., cancer pain) because of the risk of addiction.

Opioid addiction consists of three recognizable phases: (1) intoxication, or “euphoria,” (2) pharmacogenic dependence or drug-seeking behavior (addiction), and (3) the propensity to relapse after a period of abstinence. Some of the symptoms of opioid intoxication have already been considered. In patients with severe pain or pain-anticipatory anxiety, the administration of opioids produces a sense of unusual well-being, a state that has traditionally been referred to as *morphine euphoria*. It should be emphasized that only a negligible proportion of such persons continue to use opioids habitually after their pain has subsided. The vast majority of potential addicts are not suffering from painful illnesses at the time they initiate opioid use, and the term *euphoria* is probably not an apt description of the initial effects. These persons, after several repetitions, recognize a “high,” despite the subsequent recurrence of unpleasant, or *dysphoric*, symptoms (nausea, vomiting, and faintness as the drug effect wanes).

The repeated self-administration of the drug is the most important factor in the genesis of addiction. Regardless of how one characterizes the state of mind that is produced by episodic injection of the drug, the individual quickly discovers the need to increase the

dose in order to obtain the original effects (*tolerance*). Although the initial effects may not be fully recaptured, the progressively increasing dose of the drug does relieve the discomfort that arises as the effects of each injection wear off. In this way a new *pharmacogenically induced* need is developed, and the use of opioids becomes self-perpetuating. At the same time a marked degree of *tolerance* is produced, so that enormous amounts of drugs, e.g., 5,000 mg of morphine daily, can eventually be administered without the development of toxic symptoms.

The pharmacologic (in contrast to psychologic) criteria of addiction, as indicated in Chap. 42 in regards to alcoholism, are *tolerance* and *physical dependence*. The latter refers to the symptoms and signs that become manifest when the drug is withdrawn following a period of continued use. These symptoms and signs constitute a specific clinical state, termed *the abstinence* or *withdrawal syndrome* (see later). The mechanisms that underlie the development of tolerance and physical dependence are not fully understood. However, it is known that opioids activate an opioid antinociceptive system (enkephalins, dynorphins, endorphins), which are opioid receptors and are located at many different levels of the nervous system (these were referred to earlier and are described in Chap. 8; see also the review of Fields). The desensitization of opioid receptors, probably mainly the mu type, accounts for tolerance through a mechanism of uncoupling of the receptor from the G-protein complex.

The Opioid Abstinence Syndrome

The intensity of the *abstinence* or *withdrawal* syndrome depends on the dose of the drug and the duration of addiction. The onset of abstinence symptoms in relation to the last exposure to the drug, however, is related to the pharmacologic half-life of the agent. With morphine, the majority of individuals receiving 240 mg daily for 30 days or more will show moderately severe abstinence symptoms following withdrawal. Mild signs of opiate abstinence can be precipitated by narcotic antagonists in persons who have taken as little as 15 mg of morphine or an equivalent dose of methadone or heroin tid for 3 days.

The abstinence syndrome that occurs in the morphine addict may be taken as the prototype. The first 8 to 16 h of abstinence usually pass asymptotically. At the end of this period, yawning, rhinorrhea, sweating, piloerection, and lacrimation are manifest. Mild at first, these symptoms increase in severity over a period of several hours and then remain constant for several days. The patient may be able to sleep during the early abstinence period but is restless, and thereafter insomnia remains a prominent feature. Dilatation of the pupils, recurring waves of “gooseflesh,” and twitching of the muscles appear. The patient complains of aching in the back, abdomen, and legs and of “hot and cold flashes”; he frequently asks for blankets. At about 36 h the restlessness becomes more severe, and nausea, vomiting, and diarrhea usually develop. Temperature, respiratory rate, and blood pressure are slightly elevated. All these symptoms reach their peak intensity 48 to 72 h after withdrawal and then gradually subside. The opioid

abstinence syndrome is rarely fatal (it is life-threatening only in infants). After 7 to 10 days, the clinical signs of abstinence are no longer evident, although the patient may complain of insomnia, nervousness, weakness, and muscle aches for several more weeks, and small deviations of a number of physiologic variables can be detected with refined techniques for up to 10 months (protracted abstinence).

Habituation, the equivalent of emotional or psychologic *dependence*, refers to the substitution of drug-seeking activities for all other aims and objectives in life. It is this feature that fosters relapse to the use of the drug long after the physiologic ("nonpurposive") abstinence changes seem to have disappeared. The cause for relapse is not fully understood. Theoretically, fragments of the abstinence syndrome may remain as a conditioned response, and these abstinence signs may be evoked by the appropriate environmental stimuli. Thus, when a "cured" addict returns to a situation where narcotic drugs are readily available or in a setting that was associated with the initial use of drugs, the incompletely extinguished drug-seeking behavior may reassert itself.

The characteristics of addiction and of abstinence are qualitatively similar with all drugs of the opiate group as well as the related synthetic analgesics. The differences are quantitative and are related to the differences in dosage, potency, and length of action. Heroin is 2 to 3 times more potent than morphine but the heroin withdrawal syndrome encountered in hospital practice is usually mild in degree because of the low dosage of the drug in the street product. Dilaudid (hydromorphone) is more potent than morphine and has a shorter duration of action; hence the addict requires more doses per day, and the abstinence syndrome comes on and subsides more rapidly. Abstinence symptoms from codeine, while definite, are less severe than those from morphine. The addiction liabilities of propoxyphene, a weak opioid, are negligible. Abstinence symptoms from methadone are less intense than those from morphine and do not become evident until 3 or 4 days after withdrawal; for these reasons methadone can be used in the treatment of morphine and heroin dependency (see further on). Meperidine addiction is of particular importance because of its high incidence among physicians and nurses. Tolerance to the drug's toxic effects is not complete, so that the addict may show tremors, twitching of muscles, confusion, hallucinations, and sometimes convulsions. Signs of abstinence appear 3 to 4 h after the last dose and reach their maximum intensity in 8 to 12 h, at which time they may be worse than those of morphine abstinence.

As to the biologic basis of addiction and physical dependence, our understanding is still very limited. Experiments in animals have provided insights into the neurotransmitter and neuronal systems involved. As a result of microdialyzing opiates and their antagonists into the central brain structures of animals, it has been tentatively concluded that mesolimbic structures, particularly the nucleus accumbens, ventral tegmentum of the midbrain, and locus ceruleus are activated or depressed under conditions of repeated opiate exposure. Thus, chronic opiate usage increases the levels of

intracellular messengers (G-proteins) as noted earlier that drive cAMP activity in the locus ceruleus and in the nucleus accumbens; blocking the expression of these proteins markedly increases the self-administration of opiates by addicted rats. As in alcoholism, certain subtypes of the serotonin and dopamine receptors in limbic structures have been implicated in the psychic aspects of addiction and habituation. These same structures are conceived as a common pathway for the impulse to human drives such as sex, hunger, and psychic fulfillment. Camí and Farré reviewed the neurochemical mechanism of addiction.

The *diagnosis* of addiction is usually made when the patient admits to using and needing drugs. Should the patient conceal this fact, one relies on collateral evidence such as miosis, needle marks, emaciation, abscess scars, or chemical analyses. Meperidine addicts are likely to have dilated pupils and twitching of muscles. The finding of morphine or opiate derivatives (heroin is excreted as morphine) in the urine is confirmatory evidence that the patient has taken or has been given a dose of such drugs within 24 h of the test. The diagnosis of opiate addiction is also at once apparent when the treatment of acute opiate intoxication precipitates a characteristic abstinence syndrome.

Treatment of the Opioid Abstinence Syndrome

Views on the nature of drug addiction and appropriate methods of treatment are as much national and sociologic as they are biologic. Berridge has reviewed some of these historically based factors in reference overall "harm reduction" by using heroin itself to treat heroin addiction. One approach that has achieved some degree of success over the past 40 years has been the substitution of methadone for opioid, in the ratio of 1 mg methadone for 3 mg morphine, 1 mg heroin, or 20 mg meperidine. Because methadone is long acting and effective orally, it needs to be given only twice daily by mouth—10 to 20 mg per dose being sufficient to suppress abstinence symptoms. After a stabilization period of 3 to 5 days, this dosage of methadone is reduced and the drug is withdrawn over a similar period. An alternative but probably less effective method has been the use of clonidine (0.2 to 0.6 mg bid for a week), a drug that counteracts most of the noradrenergic withdrawal symptoms; however, the hypotension that is induced by this drug may be a problem (Jasinski et al).

In Europe, addicts who could not be detoxified and kept free of drugs by any other means have been given diacetylmorphine, the active ingredient in heroin, with some success when compared in clinical trials to methadone (see Oviedo-Joekes et al). Special settings that are capable of medical reversal of overdose are required but the notion of overall reduction in personal and societal harm seems to be attained by even this seemingly extreme measure.

A rapid detoxification regimen that is conducted under general anesthesia was popular in a number of centers as a means of treating opiate addiction has now been largely abandoned for reasons of safety but it could be resurrected if other more conventional approaches continue to be futile. The technique

consisted of administering increasing doses of opioid receptor antagonists (naloxone or naltrexone) over several hours while the autonomic and other features of the withdrawal syndrome were suppressed by the infusion of propofol or a similar anesthetic, supplemented by intravenous fluids. Medications such as clonidine and sedatives were also given in the immediate postanesthetic period. There are substantial risks involved in this procedure and several deaths have occurred for which reason it has been all but abandoned. Furthermore, a number of patients continue to manifest signs of withdrawal after the procedure and require continued hospitalization.

Treatment of Opiate Habituation This is in some ways far more demanding than the treatment of opioid withdrawal and can be best accomplished in special facilities and programs that are devoted wholly to the problem. These are available in most communities. The most effective ones have been the ambulatory methadone maintenance clinics, where more than 100,000 former heroin addicts are participating in rehabilitation programs approved by the FDA. Methadone, in a dosage of 60 to 100 mg daily (sufficient to suppress the craving for heroin), is given under supervision day by day (less often with long-acting methadone) for months or years. Various forms of psychotherapy and social service counseling often administered by former heroin addicts are integral parts of the program.

The results of methadone treatment are difficult to assess and vary considerably from one program to another. Even the most successful programs suffer an attrition rate of approximately 25 percent when they are evaluated after several years. Of the patients who remain, the majority achieves a degree of social rehabilitation, i.e., they are gainfully employed and no longer engage in criminal behavior or prostitution.

The usual practice of methadone programs is to accept only addicts older than age 16 years with a history of heroin addiction for at least 1 year. This leaves many adolescent addicts untreated. The number of addicts who can fully withdraw from methadone and maintain a drug-free existence is very small. This means that the large majority of addicts now enrolled in methadone programs are committed to an indefinite period of methadone maintenance and the effects of such a regimen are uncertain.

An alternative method of ambulatory treatment of the opiate addict involves the use of narcotic antagonists, of which naloxone and naltrexone are the best known. The physical effects of abusing narcotics are thereby partially blocked, and there may be some degree of aversive conditioning if withdrawal symptoms are produced. Naltrexone is favored because it has a longer effect than naloxone, is almost free of agonist effects, and can be administered orally. Similar results have also been achieved with cyclazocine in a small number of highly motivated patients; this drug is administered orally in increasing amounts until a dosage of 2 mg/70 kg body weight is attained. The drug is taken bid (for 2 to 6 weeks) and is then withdrawn slowly.

More recently, interest has centered on the use of sublingual buprenorphine for the treatment of heroin

(and cocaine) abuse; this drug has both opioid agonist and antagonist properties; it mutes the effect of withdrawal, also serves as an aversive agent, and its abuse potential is relatively low. A randomized trial conducted by Fudala and colleagues has demonstrated the superiority over methadone of a combination of buprenorphine and naloxone combined with brief counseling in keeping opioid addicts in treatment and abstinent of abused drugs. This approach has been available in Europe for many years and has been adopted in the United States under a Department of Health-supervised program for primary care offices. In addition, there is evidence, based on animal experiments and experience with small numbers of addicts, that it may be useful for the treatment of dual dependence on cocaine and opiates (see Mello and Mendelson), but this has not been confirmed in other clinical trials.

Medical and Neurologic Complications of Opioid Use

In addition to the toxic effects of the opioid itself, the addict may suffer a variety of neurologic and infectious complications resulting from the injection of contaminated adulterants (quinine, talc, lactose, powdered milk, and fruit sugars) and of various infectious agents (injections administered by unsterile methods). The most important of these is HIV infection, but septicemia, endocarditis, and viral hepatitis may also occur. Particulate matter that is injected with heroin or a vasculitis that is induced by chronic heroin abuse may cause stroke by an incompletely understood *occlusion of cerebral arteries*, with hemiplegia or other focal cerebral signs. *Amblyopia*, probably as a result of the toxic effects of quinine in the heroin mixtures, has been reported, as well as *transverse myelopathy* and several types of *peripheral neuropathy*. The spinal cord disorder expresses itself clinically by the abrupt onset of paraplegia with a level on the trunk below which motor function and sensation are lost or impaired and by urinary retention. Pathologically, there is an acute necrotizing lesion involving both gray and white matter over a considerable vertical extent of the thoracic and occasionally the cervical cord. In some cases, a myelopathy has followed the first intravenous injection of heroin after a prolonged period of abstinence. We have also seen two cases of cervical myelopathy from heroin-induced stupor and a prolonged period of immobility with the neck hyperextended over the back of a chair or sofa.

In addition, we have observed several instances of a subacute progressive cerebral leukoencephalopathy after heroin use, similar to ones that occurred in Amsterdam in the 1980s, the result of inhalation of heroin or an adulterant (Wolters et al; Tan et al). Most instances of this leukoencephalopathy are the result of inhalation of heated heroin vapor in a practice known as "chasing the dragon." The clinical presentation has varied but generally includes stupor, coma, and death, after a latent period of hours or days. In one of our patients, the white matter changes were concentrated in the posterior regions of the hemispheres and in the internal capsules and, in one striking case, in the cerebellar white matter. The MRI is fairly characteristic and the white matter is vacuolated, sparing U-fibers, as indicated by Ryan and

colleagues, with an appearance that some authors have indicated simulates the spongiform change of prion disease. The pathophysiology is unknown but adulterants or mitochondrial damage has been suggested.

A similar leukoencephalopathy has also been reported in cocaine users, although a hypertensive encephalopathy or an adrenergic-induced vasculopathy may have played a role in these cases.

Damage to single peripheral nerves at the site of injection of heroin and from compression is a relatively common occurrence. However, bilateral compression of the sciatic nerves, the result of sitting or lying for a prolonged period in a stuporous state or in the lotus position, has occurred in several of our patients. In sciatic compression of this type, the peroneal branch has been more affected than the tibial, causing foot-drop with less weakness of plantar flexion. More difficult to understand in heroin abusers is the involvement of other individual nerves, particularly the radial nerve, and painful affection of the brachial plexus, apparently unrelated to compression and remote from the sites of injection. Possibly in some instances there was a vasculitis affecting peripheral nerves.

An acute generalized *myonecrosis* with myoglobinuria and renal failure has been ascribed to the intravenous injection of adulterated heroin. Brawny edema and fibrosing myopathy (Volkman contracture) are the sequelae of venous thrombosis resulting from the administration of heroin and its adulterants by the intramuscular and subcutaneous routes. Occasionally, there may be massive swelling of an extremity into which heroin had been injected subcutaneously or intramuscularly; infection and venous thrombosis appears to be involved in its causation.

The diagnosis of drug addiction always raises the possibility of an assortment of infectious complications: AIDS, syphilis, abscesses and cellulitis at injection sites, septic thrombophlebitis, hepatitis, and periarteritis from circulating immune complexes. Tetanus, endocarditis (mainly caused by *Staphylococcus aureus*), spinal epidural abscess, meningitis, brain abscess, and tuberculosis have occurred less frequently.

SEDATIVE-HYPNOTIC DRUGS

This class of drugs consists of two main groups. The first includes the barbiturates, meprobamate, and chloral hydrate. These drugs are now little used, having been largely replaced by a second group, the *benzodiazepines*, the most important of which are chlordiazepoxide (Librium), lorazepam (Ativan), alprazolam (Xanax), clonazepam (Klonopin), and diazepam (Valium). Closely related are the nonbenzodiazepine hypnotics, typified by zolpidem. The advantages of the benzodiazepine drugs are their *relatively* low toxicity and addictive potential and their minimal interactions with other drugs.

Barbiturates

In the past, about 50 barbiturates were marketed for clinical use, but now only a few are encountered with any regularity: pentobarbital (Nembutal), secobarbital

(Seconal), amobarbital (Amytal), thiopental (Pentothal), and phenobarbital. The first three were the ones most commonly abused. Barbiturates are also a component of combination preparations for the treatment of migraine (e.g., butalbital in Fiorinal).

Mechanism of Action

All the common barbiturates are derived from barbituric acid; the differences among them depend on variations in the side chains of the parent molecule. The potency of each drug is a function of the ionization constant and lipid solubility. The higher its lipid solubility, the greater the drug's central nervous system potency and the quicker and briefer its action. The lowering of plasma pH increases the rate of entry of the ionized form into the brain. The action of barbiturates is to suppress neuronal transmission, presumably by enhancing GABA inhibition at pre- and postsynaptic receptor sites, and to reduce excitatory postsynaptic potentials. The major points of action in the CNS are similar to those of alcohol and other coma-producing drugs; impaired consciousness or coma relates to inactivation of neurons in the reticular formation of the upper brainstem. The liver is the main locus of drug metabolism and the kidney is the method of elimination of the metabolites. The clinical problems posed by the barbiturates are different depending on whether the intoxication is acute or chronic.

Acute Barbiturate Intoxication

The symptoms and signs vary with the type and amount of drug as well as with the length of time that has elapsed since it was ingested. Pentobarbital and secobarbital produce their effects quickly and recovery is relatively rapid. Phenobarbital induces coma more slowly and its effects tend to be prolonged. In the case of long-acting barbiturates, such as phenobarbital and barbital, the hypnotic-sedative effect lasts 6 h or more after an average oral dose; with the intermediate-acting drugs such as amobarbital, 3 to 6 h; and with the short-acting drugs, secobarbital and pentobarbital, less than 3 h. Most fatalities follow the ingestion of secobarbital, amobarbital, or pentobarbital. The ingestion by adults of more than 3 g of these drugs at one time will prove fatal unless intensive treatment is applied promptly. The potentially fatal dose of phenobarbital is 6 to 10 g. The lowest plasma concentration associated with lethal overdose of phenobarbital or barbital has been approximately 60 mg/mL and that of amobarbital and pentobarbital, 10 mg/mL.

Severe intoxication occurs with the ingestion of 10 to 20 times the oral hypnotic dose. The patient cannot be roused by any means, i.e., the patient is comatose. Respiration is slow and shallow or irregular, and pulmonary edema and cyanosis may be present. The tendon reflexes are usually, but not invariably, absent. Most patients show no response to plantar stimulation, but in those who do, the responses are extensor. With deep coma, the corneal and gag reflexes may also be abolished. Ordinarily the pupillary light reflex is retained in severe intoxication and is lost only if the patient is asphyxiated; but in advanced cases, the pupils become miotic and poorly reactive, simulating opiate intoxication. At this point respiration is

greatly depressed and oculocephalic and oculovestibular reflex responses are usually abolished. In the early hours of coma, there may be a phase of flexor or extensor posturing or rigidity of the limbs, hyperactive reflexes, ankle clonus, and extensor plantar signs; persistence of these signs indicates that anoxic damage has been added. The temperature may be subnormal, the pulse is faint and rapid, and the blood pressure is greatly reduced. Failure of respiration to quicken on painful stimulation is an ominous sign.

There are few conditions other than barbiturate intoxication that cause a flaccid coma with small reactive pupils, hypothermia, and hypotension. A pontine hemorrhage may do so, but a hysterical trance or catatonic stupor does not present a problem in differential diagnosis. The use of gas and high-pressure liquid chromatography provides a reliable means of identifying the type and amount of barbiturate in the blood. A patient who has also ingested alcohol may be comatose with relatively low blood barbiturate concentrations. Contrariwise, the barbiturate addict may show only mild signs of intoxication with very high blood barbiturate concentrations.

Management In mild or moderate intoxication, recovery is the rule and special treatment is not required except to prevent aspiration. If the patient is unresponsive, special measures must be taken to maintain respiration and prevent infection. An endotracheal tube should be inserted, with suctioning as necessary. Any risk of respiratory depression or underventilation requires the use of a positive-pressure respirator.

Hemodialysis or hemofiltration with charcoal may be used in comatose patients who have ingested long-acting barbiturates and these treatments are particularly advisable if anuria or uremia has developed. Occasionally, in the case of a barbiturate addict who has taken an overdose of the drug, recovery from coma is followed by the development of abstinence symptoms, as described later.

Barbiturate Abstinence, or Withdrawal, Syndrome

Immediately following withdrawal, the patient seemingly improves over a period of 8 to 12 h, as the symptoms of intoxication diminish. Then a new group of symptoms develops, consisting of nervousness, tremor, insomnia, postural hypotension, and weakness. With chronic phenobarbital or barbital intoxication, withdrawal symptoms may not become apparent until 48 to 72 h after the final dose or it does not occur at all because of the slow metabolism and long half-life of these drugs. Generalized seizures with loss of consciousness may occur, usually between the second and fourth days of abstinence, but occasionally as long as 6 or 7 days after withdrawal. There may be a single seizure, several seizures, or, rarely, status epilepticus. Characteristically, in the withdrawal period, there is a greatly heightened sensitivity to photic stimulation, to which the patient responds with myoclonus or a seizure accompanied by paroxysmal changes in the EEG. The convulsive phase may be followed directly by a delusional-hallucinatory state or, as occurred in one of our cases (Romero et al), a full-blown delirium indistinguishable from delirium tremens. Death has been reported under these circumstances. The abstinence syndrome may occur in varying degrees

of completeness; some patients have seizures and recover without developing delirium, and others have a delirium without preceding seizures.

Chloral Hydrate

This is the oldest and one of the safest, most effective, and most inexpensive of the sedative-hypnotic drugs. After oral administration, chloral hydrate is reduced rapidly to trichloroethanol, which is responsible for the depressant effects on the CNS. A significant portion of the trichloroethanol is excreted in the urine as the glucuronide, which may give a false-positive test for glucose.

Tolerance and addiction to chloral hydrate develop only rarely; for this reason, it was in the past commonly used for insomnia. Poisoning with chloral hydrate is a rare occurrence and resembles acute barbiturate intoxication except for the finding of miosis, which is said to characterize the former. Treatment follows along the same lines as for barbiturate poisoning. Death from poisoning is because of respiratory depression and hypotension; patients who survive may show signs of liver and kidney disease. Combining alcohol and chloral hydrate, the popular "Mickey-Finn" of detective stories in the mid-last century, produced severe intoxication and amnesia.

Paraldehyde, another member of this group of sedative drugs, is no longer being manufactured in the United States, and chloral hydrate is now available mainly as an elixir for pediatric use.

Benzodiazepines

With the introduction of chlordiazepoxide in 1960 and the benzodiazepine drugs that followed (particularly diazepam), the older sedative drugs (barbiturates, paraldehyde, chloral hydrate) have become virtually obsolete. Indeed, the benzodiazepines are among the most commonly prescribed drugs in the world today. According to Hollister (1990), 15 percent of all adults in the United States use a benzodiazepine at least once yearly and about half this number use the drug for a month or longer.

The benzodiazepines have been prescribed frequently for the treatment of anxiety and insomnia, and they are especially effective when the anxiety symptoms are severe. Also, they have been used to control overactivity and destructive behavior in children and the symptoms of alcohol withdrawal in adults. Diazepam is particularly useful in the treatment of delirious patients who require parenteral medication. The benzodiazepines possess anticonvulsant properties, and the intravenous use of diazepam, lorazepam, and midazolam is an effective means of controlling status epilepticus, as described in Chap. 16. Diazepam in massive doses has been used with considerable success in the management of muscle spasm in tetanus and in the "stiff man" syndrome (see Chap. 55). Alprazolam has a central place in the treatment of panic attacks and other anxiety states, and as an adjunct in some depressive illnesses. It seems, however, to create more dependence than some of the others in its class.

Other important benzodiazepine drugs are lorazepam (Ativan), flurazepam (Dalmane), triazolam (Halcion),

clorazepate (Tranxene), temazepam (Restoril), oxazepam (Serax), alprazolam (Xanax) and other newer varieties, all widely used in the treatment of insomnia (see Chap. 19), and clonazepam (Klonopin), which is useful in the treatment of myoclonic seizures (see Chap. 16) and intention myoclonus (see Chaps. 6 and 40). Midazolam (Versed), a short-acting parenteral agent, is given frequently to achieve the brief sedation required for procedures such as MRI or endoscopy and is useful in the treatment of status epilepticus. Many other benzodiazepine compounds have appeared in recent years, but a clear advantage over the original ones remains to be demonstrated (Hollister, 1990).

The benzodiazepine drugs, like barbiturates, have a depressant action on the CNS by binding to specific receptors on GABA inhibitory systems. The newer nonbenzodiazepine sleeping medication differs from the benzodiazepines structurally but is pharmacologically similar in binding to similar gabaergic receptors. The benzodiazepines act in concert with GABA to open chloride ion channels and hyperpolarize postsynaptic neurons and reduce their firing rate. The primary sites of their action are the cerebral cortex and limbic system, which accounts for their anticonvulsant and anxiolytic effects.

While quite safe in the recommended dosages, they are far from ideal. They frequently cause unsteadiness of gait and drowsiness and at times syncope, confusion, and impairment of memory, especially in the elderly. If taken in large doses, the benzodiazepines can depress the state of consciousness, resembling that of other sedative-hypnotic drugs, but with less respiratory suppression and hypotension.

Flumazenil, a specific pharmacologic antagonist of the CNS effects of benzodiazepines, rapidly but briefly reverses most of the symptoms and signs of benzodiazepine overdose. It acts by binding to CNS diazepam receptors and thereby blocking the activation of inhibitory gabaergic synapses. Flumazenil also may be diagnostically useful in cases of coma of unknown etiology and in hepatic encephalopathy.

Signs of physical dependence and true addiction, although relatively rare, undoubtedly occur in chronic benzodiazepine users, even in those taking therapeutic doses. The withdrawal symptoms are much the same as those that follow the chronic use of other sedative drugs (anxiety, jitteriness, insomnia, seizures) but may not appear until the third day after the cessation of the drug and may not reach their peak of severity until the fifth day (Hollister, 1990). In chronic benzodiazepine users, the gradual tapering of dosage over a period of 1 to 2 weeks minimizes the withdrawal effects. However, we have observed numerous cases over the years in which the cessation of moderate doses of chronically used diazepam has resulted in one or more seizures. This is likely to happen when the patient is hospitalized for other reasons and the accustomed sleeping or anxiolytic medication is omitted.

Buspirone

A class of anti-anxiety agents, exemplified by the selective 5-HT_{1A} receptor serotonergic agonist buspirone, is

chemically and pharmacologically different from the benzodiazepines, barbiturates, and other sedatives. Its distinctive nature is confirmed by the observation that it does not block the withdrawal syndrome of other sedative-hypnotic drugs. Because of its apparently reduced potential for abuse and tolerance, it is not included in the list of controlled pharmaceutical substances in the United States but adverse interactions with monoamine oxidase (MAO) inhibitors are known. Its use with other psychotropic drugs is still under investigation (see Chap. 57).

ANTIPSYCHOSIS DRUGS

In the mid-1950s, a large series of pharmacologic agents, originally referred to as tranquilizers (later, as psychotropic or neuroleptic drugs), came into prominent use, mainly for the control of schizophrenia, psychotic states associated with "organic brain syndromes," and affective disorders (depression and bipolar disease). The mechanisms by which these drugs ameliorate disturbances of thought and affect in psychotic states are not fully understood, but presumably they act by blocking the postsynaptic mesolimbic dopamine receptors of which there are four subtypes, termed D1 through D4 on neuronal membranes (see Table 4-2, and discussion of dopamine receptor subtypes). The D2 receptors are located mainly in the frontal cortex, hippocampus, and limbic cortex, and the D1 receptors are in the striatum, as discussed in Chap. 4. The blockade of dopamine receptors in the striatum is probably responsible for the parkinsonian side effects of this entire class of drugs, and the blockade of another dopaminergic (tuberoinfundibular) system, for the increased prolactin secretion by the pituitary. These drugs also produce some adrenergic blocking effect. The newer "atypical" antipsychotic drugs, exemplified by clozapine, apparently achieve the same degree of D2 and D3 blockade in the temporal and limbic lobes while exhibiting substantially less antagonistic activity in the striatum—accounting also for their lesser parkinsonian side effects. These drugs also block subsets of serotonin receptors.

Since the introduction in the 1950s of the phenothiazine chlorpromazine as an anesthetic agent and the serendipitous discovery of its antipsychotic effect on schizophrenia, a large number of antipsychotic drugs have been marketed for clinical use. No attempt is made here to describe or even list all of them. Some have had only an evanescent popularity and others have yet to prove their value. Chemically, these compounds form a heterogeneous group. Eight classes of them are of particular clinical importance: (1) the phenothiazines; (2) the thioxanthenes; (3) the butyrophenones; (4) the rauwolfias alkaloids; (5) an indole derivative, loxapine, and a unique dihydroindolone, molindone; (6) a diphenylbutylpiperidine, pimozide; (7) dibenzodiazepines, typified by clozapine and olanzapine; and (8) a benzisoxazole derivative, risperidone. Molindone and loxapine are about as effective as the phenothiazines in the management of schizophrenia

and their side effects are similar, although claims have been made that they are less likely to induce tardive dyskinesias and seizures. Their main use is in patients who are not responsive to the older drugs or who suffer intolerable side effects from them.

The antipsychotic agents in the class of clozapine (which is less used than other agents in the class because of cases of aplastic anemia) have attracted great interest, because—as already mentioned—they are associated with relatively fewer extrapyramidal side effects. For this reason, they are particularly favored in controlling the confusion and psychosis of parkinsonian patients. The other new class of drugs, of which risperidone is the main example, also has fewer extrapyramidal side effects than the phenothiazines and a more rapid onset of action than the traditional antipsychotic medications. All of these newer medications produce the “metabolic syndrome” of weight gain, adverse lipid changes, and glucose intolerance. Pimozide may be useful in the treatment of haloperidol-refractory cases of Gilles de la Tourette syndrome (see Chap. 6); its main danger is its tendency to produce cardiac arrhythmias.

Phenothiazines

This group comprises chlorpromazine (Thorazine), promazine (Sparine), triflupromazine (Vesprin), prochlorperazine (Compazine), perphenazine (Trilafon), fluphenazine (Permitil, Prolixin), thioridazine (Mellaril), mesoridazine (Serentil), and trifluoperazine (Stelazine). In addition to their psychotherapeutic effects, these drugs have a number of other actions, so that certain members of this group are used as antiemetics (prochlorperazine) and antihistaminics (promethazine).

The phenothiazines have had their widest application in the treatment of the major psychoses, namely schizophrenia and, to a lesser extent, bipolar psychosis. Under the influence of these drugs, many patients who would otherwise have been hospitalized were able to live at home and even work productively. In the hospital, the use of these drugs has facilitated the care of hyperactive, delirious, and combative patients (see Chaps. 57 and 58 for details of this clinical use).

Side effects of the phenothiazines are frequent and often serious. All of them may cause a cholestatic type of jaundice, agranulocytosis, seizures, orthostatic hypotension, skin sensitivity reactions, mental depression, and, most importantly, immediate or delayed extrapyramidal motor disorders. The neuroleptic malignant syndrome is the most extreme complication and is discussed separately further on and in Chap. 53. The following types of extrapyramidal symptoms, also discussed in Chap. 6, have been noted in association with all of the phenothiazines as well as the butyrophenones, and to a lesser extent with metoclopramide and pimozide, which block dopaminergic receptors. These are summarized in Table 58-1.

1. A *parkinsonian syndrome* is the most common complication—masked facies, slight symmetric tremor, reduced blinking, generalized rigidity, shuffling

gait, and slowness of movement. These symptoms may appear after several days of drug therapy but more often after several weeks. Suppression of dopamine in the striatum (similar to the effect of loss of dopaminergic nigral cells that project to the striatum) is presumably the basis of the parkinsonian signs.

2. *Acute dyskinesic and dystonic reactions*, taking the form of involuntary movements of lower facial muscles (mainly around the mouth) and protrusion of the tongue (buccolingual or oral-masticatory syndrome), dysphagia, torticollis and retrocollis, oculogyric crises, and tonic spasms of a limb. These complications usually occur early in the course of administration of the drug, sometimes after the initial dose, in which case they recede dramatically upon immediate discontinuation of the drug and the intravenous administration of diphenhydramine hydrochloride or benztropine.
3. *Akathisia*, which is an inner restlessness reflected by a persistent shifting of the body and feet and an inability to sit still, such that the patient paces the floor or jiggles the legs constantly (see Chap. 6). Of all the phenothiazines, molindone has a tendency to cause akathisia. This disorder often responds to oral propranolol.
4. *Tardive dyskinesias* are a group of *late and persistent complications* of neuroleptic therapy, which may continue after removal of the offending drug, that comprises lingual-facial-buccal-cervical dyskinesias, choreoathetotic and dystonic movements of the trunk and limbs, diffuse myoclonus (rare), perioral tremor (“rabbit” syndrome), and dysarthria or anarthria. Snyder postulated that the movements are because of hypersensitivity of dopamine receptors in the basal ganglia, secondary to prolonged blockade of the receptors by antipsychotic medication. Baldessarini estimates that as many as 40 percent of patients receiving long-term antipsychotic medication develop tardive dyskinesia of some degree. The effect is likely a result of subcellular pathophysiologic alterations in the basal ganglia. Treatment is discussed later.
5. The *neuroleptic malignant syndrome* is discussed separately later because of its gravity and requirement for specific treatment.

Butyrophenones

Haloperidol (Haldol) is the only member of this group approved for use as an antipsychotic in the United States. It has much the same therapeutic effects as the phenothiazines in the management of acute psychoses and shares the same side effects as the phenothiazines, but exhibits little or no adrenergic blocking action. It is an effective substitute for the phenothiazines in patients who are intolerant of the latter drugs, particularly of their autonomic effects. It is also one of the main drugs for the treatment of Gilles de la Tourette syndrome (the other being pimozide; see Chap. 6) and the movement disorder of Huntington chorea.

Treatment of Neuroleptic Side Effects

As indicated earlier, acute dystonic spasms usually respond to cessation of the offending drug and to the administration of diphenhydramine. Administration of antiparkinsonian drugs of the anticholinergic type (trihexyphenidyl, procyclidine, and benzotropine) may hasten recovery from some of the acute symptoms. The purely parkinsonian syndrome usually improves as well, but the tardive dyskinesias stand apart because they may persist for months or years and may be permanent.

Oral, lingual, and laryngeal dyskinesias of the tardive type are affected relatively little by any antiparkinsonian drugs. Amantadine in doses of 50 to 100 mg tid has been useful in a few of the cases of postphenothiazine dyskinesia. Other drugs such as benzotropine have been tried in the treatment of regional and more generalized tardive dyskinesia with uncertain results. Nevertheless, there is a tendency for most of the obstinate forms to subside slowly even after several years of unsuccessful therapy. Once a tardive syndrome has been identified, several authoritative clinicians recommend a gradual reduction in the dose of the antipsychosis medication to the minimum necessary for the control of psychotic symptoms. Some reports favor the substitution of one of the newer "atypical" antipsychotic medications but no systematic study of their effectiveness has been undertaken.

For severe and recalcitrant cases, particularly those involving axial dystonias and similar disabling features, Fahn recommends administration of the dopamine-depleting drug tetrabenazine (similar but faster in action and less toxic than reserpine). This medication is given in doses of 75 to 300 mg/d. Jankovic and Beach report an 83 percent success rate using this approach for tardive dyskinesias. The medication is not easily available in the United States.

Neuroleptic Malignant Syndrome

This is the most dreaded complication of phenothiazine and haloperidol use; rare instances have been reported after the institution or the withdrawal of L-dopa and similar dopaminergic agents, as well as a few instances reported with the newer antipsychosis drugs. Its incidence has been calculated to be only 0.2 percent of all patients receiving neuroleptics (Caroff and Mann) but its seriousness is underscored by a mortality rate of 15 to 30 percent if not recognized and treated promptly. It may occur days, weeks, or months after neuroleptic treatment is begun.

The syndrome consists of hyperthermia, rigidity, stupor, unstable blood pressure, diaphoresis, and other signs of sympathetic overactivity, high serum creatine kinase (CK) values (up to 60,000 units), and, in some cases, renal failure because of myoglobinuria. The syndrome was first observed in patients treated with haloperidol, but since then other neuroleptic drugs have been incriminated, particularly the highly potent thioxanthene derivatives and the phenothiazines—chlorpromazine, fluphenazine, and thioridazine—but also, on rare occasions, the less potent drugs that are

used to control nausea, such as promethazine. It has become evident that the newer antipsychotic drugs, and specifically olanzapine, are also capable of inducing the syndrome but the risk in comparison to the first generation of antipsychotic drugs has not been established.

If treatment of the neuroleptic malignant syndrome is started early, when consciousness is first altered and the temperature is rising, bromocriptine in oral doses of 5 mg tid (up to 20 mg tid) will terminate the condition in a few hours. If oral medication can no longer be taken because of the patient's condition, dantrolene, 0.25 to 3.0 mg intravenously, may be lifesaving. Once coma has supervened, shock and anuria may prove fatal or leave the patient in a vegetative state. The rigors during high fever may cause muscle damage and myoglobinuria, and shock may lead to hypoxic-ischemic brain injury.

One pitfall is to mistake neuroleptic malignant syndrome for worsening of the psychosis and inadvisably administer more antipsychosis medication. Meningitis, heat stroke, lithium intoxication, catatonia, malignant hyperthermia, and acute dystonic reactions figure in the differential diagnosis. Of course, neuroleptic medication must be discontinued as soon as any of the severe extrapyramidal reactions are recognized. It has been common practice to avoid future administration of the offending neuroleptic but the risk of using another class of antipsychotic agents has not been fully addressed.

The neuroleptic malignant syndrome bears an uncertain relationship to *malignant hyperthermia* by way of its clinical aspects but also in its response to bromocriptine and dantrolene (see later). Malignant hyperthermia in susceptible individuals is triggered by inhalation anesthetics and skeletal muscle relaxants (see Chap. 53). This disorder was described before the introduction of neuroleptic drugs, and in a small proportion of cases, has been related to a mutation of the ryanodine receptor gene. A genetic factor may underlie a small number of cases of the neuroleptic malignant syndrome (a polymorphism in the D2 receptor gene; see Suzuki et al) possibly provoked by fatigue and dehydration. There is no evidence that the occurrence of one of these syndromes confers a susceptibility to the other.

ANTIDEPRESSION MEDICATIONS

Four classes of drugs—the MAO inhibitors, the tricyclic compounds, the serotonergic drugs, and lithium—are particularly useful in the treatment of depressive illnesses. The adjective *antidepressant* refers to their therapeutic effect and is employed here in deference to common clinical practice. *Antidepressive* or *antidepression* drugs would be preferable, as the term *depressant* still has a pharmacologic connotation that does not necessarily equate with the therapeutic effect.

Monoamine Oxidase Inhibitors

The observation that iproniazid, an inhibitor of MAO, had a mood-elevating effect in tuberculous patients initiated

a great deal of interest in compounds of this type and led quickly to their exploitation in the treatment of depression. Iproniazid proved exceedingly toxic to the liver, as were several subsequently developed MAO inhibitors; but other drugs in this class, much better tolerated, are still available. These include isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate), the latter two being the more frequently used. Tranylcypromine, which bears a close chemical resemblance to dextroamphetamine, may produce unwanted stimulation, but the most common adverse effect of all the MAO inhibitors is postural hypotension. Also, interactions with a wide array of other drugs and ingested substances may induce severe hypertension.

Monoamine oxidase is located on the outer surface of the mitochondria in neurons and is used in the catabolism of catecholamines (Coyle). In the gut and liver, the isoenzyme MAO-A normally serves to deaminate phenethylamine, tyramine, and tryptamine—all of which are products of protein catabolism. Inhibition of MAO-A allows these dietary amines, which have an amphetamine-like action, to enter the systemic circulation in increased quantities, thus releasing norepinephrine from sympathetic nerve endings and increasing heart rate and blood pressure. Most antidepressant medications are of this class. Medications used in Parkinson disease (see Chap. 39) inhibit the MAO-B isoenzyme, which deaminates phenylethylamine and trace amines, with a correspondingly lower risk of causing hypertension.

More relevant to their action as antidepressants, the MAO inhibitors have in common the ability to block the intraneuronal oxidative deamination of naturally occurring amines (norepinephrine, epinephrine, dopamine, and serotonin) and it has been suggested that the accumulation of these substances is responsible for the antidepressant effect. However, many enzymes other than monoamine oxidase are inhibited by MAO inhibitors, and the latter drugs have numerous actions unrelated to enzyme inhibition. Furthermore, many agents with antidepressant effects like those of the MAO inhibitors do not inhibit MAO. Therefore, one cannot assume that the therapeutic effect of these drugs has a direct relation to MAO inhibition in the brain.

The MAO inhibitors must be dispensed with caution and awareness of their potentially serious side effects. They may at times cause excitement, restlessness, agitation, insomnia, and anxiety, occasionally with the usual dose but more often with an overdose. Mania and convulsions may occur (especially in epileptic patients). Other side effects are muscle twitching and involuntary movements, urinary retention, skin rashes, tachycardia, jaundice, visual impairment, enhancement of glaucoma, impotence, sweating, muscle spasms, paresthesias, and a serious degree of orthostatic hypotension.

Patients taking MAO-A inhibitors must be warned against the use of phenothiazines, CNS stimulants, and tricyclic and serotonergic antidepressants (see later), as well as sympathomimetic amines and tyramine-containing foods. The combination of an MAO inhibitor and any of these drugs or amines may induce hypertension, atrial and ventricular arrhythmia, pulmonary edema, stroke, or death.

Sympathomimetic amines are contained in some commonly used cold remedies, nasal sprays, nose drops, and certain foods—aged cheese, beer, red wine, pickled herring, sardines, sausages, and certain preserved meat or fish. Exaggerated responses to the usual dose of meperidine (Demerol) and other narcotic drugs have also been observed sporadically; in these cases, respiratory function may be depressed to a serious degree, and hyperpyrexia, agitation, and pronounced hypotension may occur as well, sometimes with fatal issue. Unpredictable side effects may also accompany the simultaneous administration of barbiturates and MAO inhibitors. The abrupt occurrence of severe occipital headache, nausea, vomiting, pupillary dilatation, or visual blurring should suggest a hypertensive crisis. Treatment is with intravenous phentolamine 5 mg, nitroprusside, labetalol, or a calcium channel blocker administered slowly to prevent hypotension. Overdosage of MAO inhibitors may lead to coma, for which there is no treatment other than supportive care.

The therapeutic use of MAO inhibitors for depression is discussed in Chaps. 56 and 57, and for Parkinson disease, in Chap. 39.

Tricyclic Antidepressants

Soon after the first successes with MAO inhibitors, another class of tricyclic compounds appeared. The mode of action of these agents is not fully understood, but there is evidence that they block the reuptake of amine neurotransmitters, both norepinephrine and serotonin. Blocking this amine pump mechanism (called the presynaptic plasma transporter), which ordinarily terminates synaptic transmission, permits the persistence of neurotransmitter substances in the synaptic cleft and does no more than support the hypothesis that endogenous depression is associated with a deficiency of noradrenergic or serotonergic transmission.

These medications have been divided into classes of tertiary amines (imipramine, amitriptyline and doxepin, trimipramine), which have activity as reuptake inhibitors of norepinephrine and serotonin, and the secondary amines (desipramine, amoxapine, maprotiline, nortriptyline, protriptyline), which have a preferential effect on reuptake of norepinephrine. Subsequently, a number of additional antidepressant drugs were introduced. A full account of these drugs, which will not be attempted here, can be found in the chapters by Baldessarini listed in the references.

The tricyclic antidepressants and the serotonergic drugs discussed in the next section, are presently the most effective drugs for the treatment of patients with depressive illnesses, the former being particularly useful for those with anergic depressions, early morning awakening, and decreased appetite and libido. The side effects of the tricyclic drugs are less frequent and far less serious than those of the MAO inhibitors.

The tricyclic compounds are also potent anticholinergic agents, which accounts for their most prominent and bothersome side effects—orthostatic hypotension, urinary bladder weakness, drowsiness, confusion, blurred vision, and dry mouth. They may

also occasionally produce CNS excitation—leading to insomnia, agitation, and restlessness—but usually these effects are readily controlled by small doses of benzodiazepines given concurrently or in the evenings.

As indicated earlier, the tricyclic drugs should not be given with an MAO inhibitor; serious reactions have occurred when small doses of imipramine were given to patients who had discontinued the MAO in the previous days or week. Both the MAO inhibitors and the tricyclic antidepressants are dangerous drugs when taken in excess.

Tricyclic compounds are a cause of accidental poisoning and suicide of depressed patients. It is common for the intoxicated patient to have taken several drugs, in which case chemical analyses of the blood and urine are particularly helpful in determining the drugs involved and in sorting out therapeutic and toxic concentrations. Mortality from overdose is mostly a result of cardiac rhythm disturbances, particularly tachyarrhythmias, and impaired conduction (atrioventricular block). Treatment consists of gastric aspiration and instillation of activated charcoal and the addition of physostigmine to reverse serious arrhythmias; the short duration of action of physostigmine requires that frequent doses be given. Dialysis is of no value because of the low plasma concentrations of the drug.

Serotonin Reuptake Inhibitors and Related Drugs

The selective serotonin reuptake inhibitors (SSRIs) constitute a newer class of antidepressants; paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft) are common examples but they continue to be developed at a rapid pace. Of the several related drugs such as venlafaxine (Effexor), nefazodone (Serzone), mirtazapine (Remeron), citalopram (Celexa), trazodone (Desyrel) and bupropion (Wellbutrin), each has a novel structure that is not analogous to that of the other categories of antidepressants. They are believed to act similarly to the SSRI class by inhibiting the reuptake of serotonin and norepinephrine. This results in a potentiation of the actions of these neurotransmitters.

Because they do not bind as avidly as tricyclic drugs to the muscarinic and adrenergic receptors in the brain, they produce fewer side effects, but some patients complain of anxiety or insomnia when they are first introduced. These drugs share the same side effects to varying degrees, including the danger of concomitant MAO inhibitor administration.

The risk of seizures related to the taking of certain of these medications has been much discussed. For the most part, the risk is quite small but there is little information to guide their use in known epileptics. Several studies suggest that the frequency of convulsions may increase in such patients. Bupropion has been particularly associated with seizures in about 0.5 percent of patients treated at higher dose levels (over 400 mg/d) and this drug should not be used in individuals with a history of seizures.

The SSRI drugs are well tolerated, may be effective in a shorter time than the tricyclic agents, and are very

popular at the moment, but their long-term therapeutic usefulness in comparison with their predecessors remains to be determined (see review of Richelson). Fluoxetine has also been used with benefit in a group of autistic children (see “Course, Treatment, and Prognosis” under “Autism” in Chap. 38). Constipation, dry mouth, and reduced sexual potency are to be expected to some, but varying degrees. Hyponatremia is a rare complication.

Serotonin Syndrome

The symptoms of a “serotonin syndrome” that results from excessive intake of the above listed drugs or from the concurrent use of MAO inhibitors include confusion and restlessness, tremor, tachycardia, hypertension, clonus and hyperreflexia, shivering, and diaphoresis, as summarized by Boyer and Shannon. The long list of other medications, when used concurrently with SSRIs can produce the syndrome (including “triptans” for migraine), are noted in this reference.

The treatment is by discontinuation of the medication, reduction of temperature and hypertension, benzodiazepines to control agitation, and in severe cases, the addition of cyproheptadine, a 5-HT_{2A} receptor blocker. The typical dose is 4 to 8 mg every 4 to 6 h (or a higher initial dose); tablets are crushed and administered by nasogastric tube. Atypical antipsychosis agents with similar serotonin antagonist activity have also been used as treatment (olanzapine, chlorpromazine).

Lithium

The discovery of the therapeutic effects of lithium salts in mania has led to its widespread use in the treatment of bipolar disease (bipolar disorder). The drug has proved relatively safe and blood levels are easily monitored. Its value is much more certain in treatment of the manic phase of bipolar disorder and prevention of recurrences of cyclic mood shifts than it is in treatment of anxiety and depression. Guidelines for the clinical use of lithium are given in Chap. 57. Its mechanism of action is unclear but there is experimental evidence that lithium blocks the stimulus-induced release of norepinephrine and dopamine and enhances the reuptake of this amine—the opposite in a sense, of what occurs with the other classes of antidepressants.

With blood levels of lithium in the upper therapeutic range (therapeutic 0.6 to 1.2 mEq/L), it is not uncommon to observe a fast-frequency action tremor or asterixis, together with nausea, loose stools, fatigue, polydipsia, and polyuria. These symptoms usually subside with time. Above a level of 1.5 to 2 mEq/L, particularly in patients with impaired renal function or in those taking a thiazide diuretic, serious intoxication becomes manifest—clouding of consciousness, confusion, delirium, dizziness, nystagmus, ataxia, stammering, diffuse myoclonic twitching, and nephrogenic diabetes insipidus. Vertical (downbeating)nystagmus and opsoclonus (see Chap. 14) may also be prominent. A variety of skin problems is common including worsening of acne vulgaris. An uncommon toxic effect is the development of goiter but most patients remain euthyroid although the thyroid-stimulating

hormone (TSH) levels may increase slightly. The goiter usually requires no treatment but it is possible to administer thyroid hormone so as to cause the thyroid enlargement to regress.

The myoclonic state, particularly when combined with confusion and sharp waves in the EEG, may mimic Creutzfeldt-Jakob disease (see Chap. 33) but there should be no problem in diagnosis if the setting of the illness and the administration of lithium are known. At blood lithium concentrations above 3.5 mEq/L, these symptoms are replaced by stupor and coma, sometimes with convulsions, and may prove fatal.

Discontinuing lithium in the intoxicated patient, which is the initial step in therapy, does not result in immediate disappearance of toxic symptoms. This may be delayed by a week or two, and the diabetes insipidus may persist even longer. Fluids, sodium chloride, aminophylline, and acetazolamide promote the excretion of lithium. Lithium coma may require hemodialysis, which has proved to be the most rapid means of reducing the blood lithium concentration.

STIMULANTS

Drugs that act primarily as CNS stimulants assume clinical importance for several reasons, mainly in their use for sleep disorders and attention deficit disorder. Some members of this group, the amphetamines, are much abused and others are not infrequent causes of poisoning. Their main mechanism of action is the release of endogenous catecholamine from vesicles in the presynaptic terminals.

Amphetamines and Related Agents

The *amphetamines* (*d*-amphetamine, *d,l*-amphetamine, *pemoline*, *methamphetamine*, *methylphenidate*) are analeptics (CNS stimulants) and in addition have significant hypertensive, respiratory-stimulant, and appetite-depressant effects. They are effective in the management of narcolepsy but have been more widely and sometimes indiscriminately used for the control of obesity, the abolition of fatigue, and the treatment of hyperactivity in children (see Chap. 37 for full discussion). Undoubtedly, they are able to reverse fatigue, postpone the need for sleep, and elevate mood but these effects are not entirely predictable and the user must compensate for the period of wakefulness with even greater fatigue and often with depression that follows. The intravenous use of a high dose of amphetamine produces an immediate feeling of ecstasy.

Because of the popularity of the amphetamines and the ease with which they can be procured, instances of acute and chronic intoxication are frequently seen. Methamphetamine is the most frequently abused in this category, as intravenous "crystal" or smoked as "ice." The toxic signs are essentially an exaggeration of the activating effects—restlessness, excessive speech and motor activity, tremor, and insomnia. Severe intoxication gives rise to hallucinations, delusions, and changes in affect and thought processes—a state that may be indistinguishable from paranoid schizophrenia. An amphetamine-associated

vasculopathy and intracerebral and subarachnoid hemorrhage are well recognized but rare complications of chronic or acute intoxication (Harrington et al and Chap. 34). Similar cerebrovascular complications may appear with sympathomimetic agents contained in over-the-counter cold medications and in dieting aids. Phenylpropanolamine has been implicated most often but ephedrine, cocaine (see below), and similar agents rarely have the same effects and induce a vasculopathy. The pathogenesis of the vascular lesion is unknown (both vasospasm and arteritis have been reported).

Chronic use of amphetamines can lead to a high degree of tolerance and psychologic dependence. Withdrawal of the drug after sustained oral or intravenous use is regularly followed by a period of prolonged sleep (a disproportionate amount of which is rapid eye movement [REM] sleep), from which the patient awakens with a ravenous appetite, muscle pains, and feelings of profound fatigue and depression. Treatment consists of discontinuing the use of amphetamine and administering antipsychosis drugs. Hypertension may need to be treated until the effect of the drug has waned.

Cocaine

The conventional use of cocaine as a local anesthetic has for many years been overshadowed by its illicit and widespread use as a stimulant and mood elevator. Cocaine is abused intranasally ("snorted"), smoked, or injected intravenously or intramuscularly. There has been an alarming escalation in the use of cocaine, mainly because a relatively pure and inexpensive form of the free alkaloid base ("crack") became readily available in the 1980s. This form of cocaine is heat-stable and therefore suitable for smoking. According to the National Household Survey on Drug Abuse, there are an estimated 600,000 frequent cocaine users in the United States. (Frequent use was arbitrarily defined as use on 51 or more days during the preceding year.) The number of occasional users (less than 12 days in the preceding year) was 2.4 million. These figures are probably subject to significant underreporting.

A sense of well-being, euphoria, loquacity, and restlessness are the familiar effects. Pharmacologically, cocaine is thought to act like the tricyclic antidepressants; i.e., it blocks the presynaptic reuptake of biogenic amines, thus producing vasoconstriction, hypertension, and tachycardia and predisposing to generalized tremor, myoclonus, seizures, and psychotic behavior. It has an additional weaker action, similar to amphetamines, of causing the release of endogenous monoamines. The cocaine abuser readily develops psychologic dependence and habituation, i.e., an inability to abstain from frequent compulsive use. The manifestations of physical dependence are more subtle and difficult to recognize. Nevertheless, abstinence from cocaine following a period of chronic abuse is regularly attended by insomnia, restlessness, anorexia, depression, hyperprolactinemia, and signs of dopaminergic hypersensitivity—a symptom complex that constitutes an identifiable withdrawal syndrome.

With the increasingly widespread use of cocaine, a variety of new complications continues to emerge. The symptoms of severe intoxication (overdose), noted above, may lead to coma and death and require emergency treatment in an intensive care unit, along the lines indicated for the management of other forms of coma. Seizures often occur in this setting and are treated more effectively with benzodiazepines than with standard anticonvulsant drugs. Spontaneous subarachnoid or intracerebral hemorrhage and cerebral infarction have rarely followed the intranasal use and smoking of cocaine (Levine et al). These complications could be the result of acute hypertension induced by the sympathomimetic actions of cocaine and the incidence of vascular malformations appears to be higher in those patients who have a cerebral hemorrhage (see Chap. 34). Cocaine and amphetamines also, on occasion, produce a state of generalized vasospasm leading to multiple cortical infarctions and posterior white matter changes that are evident on imaging studies, essentially a form of hypertensive encephalopathy (see Chap. 34). Roth and colleagues have described 39 patients who developed acute rhabdomyolysis after cocaine use; 13 of these had acute renal failure, severe liver dysfunction, and disseminated intravascular coagulation and 6 of them died. Some reports indicate that cocaine use during pregnancy may cause fetal damage, abortion, or persistent signs of toxicity in the newborn infant.

Anxiety, paranoia, and other manifestations of psychosis may develop within several hours of cocaine use. These complications are best treated with antipsychosis drugs, particularly haloperidol.

Khat and Cathionine Stimulants

The psychostimulant khat is used widely in certain countries, mainly in the Far East. The khat leaf is chewed to release cathionine that produces euphoria by an amphetamine-like effect. A chemically designed congener, the *N*-methyl analog of cathionine, or methcathinone ("Jeff," "Cat," "mulka," and other street names), is manufactured from over-the-counter cold medications such as ephedrine, pseudoephedrine, and phenylpropanolamine and is frequently abused. In Russia and some other countries, potassium permanganate is used to reduce the basic substances and is a source of a manganese-induced extrapyramidal syndrome. Furthermore, entirely synthetic cathionones, often called "bath salts," although they have no relation to that original product, are amphetamine-like substances that are taken orally or nasally and produce rapid activation of behavior and sympathetic hyperactivity.

HALLUCINOGENS

Included in this category is a heterogeneous group of drugs, the primary effect of which is to alter perception, mood, and thinking out of proportion to other aspects of cognitive function and consciousness. This group of drugs comprises lysergic acid diethylamide (LSD), *phenylethylamine derivatives* (mescaline or peyote),

psilocybin, certain indolic derivatives, cannabis (marijuana), *phencyclidine* (PCP), and a number of less important compounds. They are also referred to as psychoactive or psychotomimetic drugs or as hallucinogens and psychedelics. The problems raised by the nontherapeutic use of these drugs, which has declined somewhat but is still of serious proportions, have been reviewed by Nicholi and by Verebey and their associates.

Marijuana

During the past three decades, the prevalence of marijuana use in the United States has declined by about half but it is still the most commonly used illicit drug in the United States. The effects, when taken by inhaling the smoke from cigarettes or pipe, are prompt in onset and evanescent. With low doses, the symptoms are like those of mild alcohol intoxication (drowsiness, euphoria, dulling of the senses, and perceptual distortions). With increasing amounts, the effects are similar to those of LSD, mescaline, and psilocybin (see later); they may be quite disabling for many hours. With even larger doses, severe depression and stupor may occur, but death is rare (for a full account, see Hollister [1988]). No damage to the nervous system has been found after chronic use.

As summarized by Iverson, this agent activates the CB₁ receptor, mainly on gabanergic neurons in the hippocampus, amygdala, and cortex. Activation of the receptor inhibits the release of oligopeptide neurotransmitters and monoamines. They also have complex electrophysiologic effects on neurons.

Reverse tolerance to marijuana (i.e., increasing sensitization) may be observed initially, but on continued use, tolerance to the euphoriant effects develops. In one of the few experimental studies of chronic marijuana use, the subjects reported feeling "jittery" during the first 24 h after abrupt cessation of smoking marijuana, although no objective withdrawal signs could be detected. Chronic intoxicated users demonstrate reduced cognitive performance, but according to Iverson, a persistent cognitive decline has not been shown definitely.

The mild antiemetic effects of marijuana coupled with euphoria have led to its use. Putative effects on spasticity and on neuropathic pain have not been adequately substantiated.

Synthetic Cannabinoids

With the cathionines discussed above, this is a new class of synthetic drugs; they go by the names of "Spice," "K2," "K4," and others. These agents bind even more avidly to cannabinoid receptors than does the original drug and produce a heightened stimulant effect. Agitation, delusions, and paranoia result, a veritable psychosis, and some patients we have admitted have been physically almost uncontrollable, only to awaken and have entirely normal affect and cognition. Because the synthetic agents are chemically quite different from cannabis, they do not appear on conventional toxicology-drug screens. Treatment of intoxication is by diazepam and haloperidol but often to little avail until the drug is metabolized.

Mescaline, LSD, and Psilocybin

These drugs produce much the same clinical effects if given in comparable amounts. The perceptual changes are the most dramatic: the user describes vivid visual hallucinations, alterations in the shape and color of objects, unusual dreams, and feelings of depersonalization. An increase in auditory acuity has been described but auditory hallucinations are rare. Cognitive functions are difficult to assess because of inattention, drowsiness, and inability to cooperate in mental testing. The somatic symptoms consist of dizziness, nausea, paresthesia, and blurring of vision. Sympathomimetic effects—pupillary dilatation, piloerection, hyperthermia, and tachycardia—are prominent, and the user may also show hyperreflexia, incoordination of the limbs, and ataxia.

Tolerance to LSD, mescaline, and psilocybin develops rapidly, even on a once-daily dosage. Furthermore, subjects tolerant to any one of these three drugs are cross-tolerant to the other two. Tolerance is lost rapidly when the drugs are discontinued and no characteristic signs of physical dependence ensue. In this sense, addiction does not develop, although users may become psychologically dependent upon the drugs.

These drugs are taken by “drugheads” (a colorful term we have retained from the previous authors to describe individuals who use any agent that alters consciousness) and by many college and high school students for a way of socializing, for conformity, or for reasons that even they cannot ascertain. There is some evidence that marijuana is a “gateway” drug that engenders further experimentation with more dangerous substances.

The use of these drugs may be attended by a number of serious adverse reactions taking the form of acute panic attacks (“bad trip”), long-lasting psychotic states resembling paranoid schizophrenia, and flashbacks (spontaneous recurrences of the original LSD experience, sometimes precipitated by smoking marijuana and accompanied by panic attacks). Serious physical injury may follow upon impairment of the user’s critical faculties. Numerous claims have been made that LSD and related drugs are effective in the treatment of mental disease and a wide variety of social ills, and that they have the capacity to increase one’s intellectual performance, creativity, and self-understanding. To date, no acceptable studies validate any of these claims.

Phencyclidine (“Angel Dust”) and “Ecstasy”

During the early 1970s, the abuse of phencyclidine (PCP) and its analogues was a significant problem. The popularity of these drugs has dropped, but some illicit use continues because they are relatively cheap, easily available, and quite potent. (Their manufacture as a veterinary anesthetic was stopped in 1979.) Phencyclidine is taken in the form of a granular powder, frequently mixed with other drugs, and is smoked or snorted. It is usually classified as a hallucinogen, although it also has stimulant and depressant properties. The effects of intoxication are like those of LSD and other hallucinogens, and resemble

those of an acute schizophrenic episode, which may last several days to a week or longer. After the ingestion of a large amount (10 mg or more) of phencyclidine, it is present in the blood and urine for only a few hours sometimes making its detection difficult.

Toxicity from the illicit use of “ecstasy” (methylenedioxymethamphetamine [MDMA]) during parties (“raves”) has increased as a result of its ill-founded reputation for safety. It appears to cause a release of both serotonin and dopamine in the brain, and produces an elated state similar to the effects of cocaine. Seizures, cerebral hemorrhages, and psychosis have been reported in previously healthy individuals (Verebey et al).

DISORDERS CAUSED BY BACTERIAL TOXINS

The most important diseases in this category are *tetanus*, *botulism*, and *diphtheria*. Each is caused by an extraordinarily powerful bacterial toxin that acts primarily on the nervous system.

Tetanus

The cause of this disease is the anaerobic, spore-forming rod *Clostridium tetani*. The organisms are found in the feces of some humans and many animals, particularly horses, from which they readily contaminate the soil. The spores may remain dormant for many months or years, but when they are introduced into a wound, especially if a foreign body or purulent bacteria are present, they are converted into their vegetative forms, which produce the exotoxin *tetanospasm*. In developing countries, tetanus is still a common disease, particularly in newborns, in whom the spores are introduced via the umbilical cord (*tetanus neonatorum*). In the United States, the incidence rate of tetanus is about 1 per million people per year. Injection of contaminated heroin is a significant cause. Approximately 67 percent of all injuries leading to tetanus occur from deep scratches and puncture wounds in the home, and approximately 20 percent from deep scratches and puncture wounds in gardens and on farms.

Since 1903, when Morax and Marie proposed their theory of centripetal migration of the tetanus toxin, it has been taught that spread to the nervous system occurs via the peripheral nerves, the toxin ascending in the axis cylinders or the perineural sheaths. Modern studies, using fluorescein-labeled tetanus antitoxin, have disclosed that the toxin is also widely disseminated via blood or lymphatics, probably accounting for the generalized form of the disease. However, in local tetanus (see Chap. 55), the likely mode of spread to the CNS is indeed by retrograde axonal transport.

Mode of Action of Tetanus Toxin

Like botulinum toxin, the tetanus toxin is a zinc-dependent protease. It blocks neurotransmitter release by cleaving surface proteins of the synaptic vesicles, thus preventing the normal exocytosis of neurotransmitter.

The toxin interferes with the function of the reflex arc by the blockade of inhibitory transmitters, mainly GABA, at presynaptic sites in the spinal cord and brainstem. The Renshaw cell, the source of recurrent inhibition of spinal and brainstem motor neurons, is preferentially affected. Elicitation of the jaw jerk, for example, is normally followed by the abrupt suppression of motor neuron activity, manifested in the electromyogram (EMG) as a "silent period" (see further on). In the patient with tetanus, there is a failure of this inhibitory mechanism, with a resulting increase in activation of the neurons that innervate the masseter muscles (*trismus*, or lockjaw). Of all neuromuscular systems, the masseter innervation seems to be the most sensitive to the toxin. Not only do afferent stimuli produce an exaggerated effect, but they also abolish reciprocal innervation, allowing both agonists and antagonists to contract, giving rise to the characteristic muscular spasm of tetanus (see below). In addition to its generalized effects on the motor neurons of the spinal cord and brainstem, there is evidence that the toxin acts directly on skeletal muscle at the point where the axon forms the endplate (accounting perhaps for localized tetanus) and also upon the cerebral cortex and the sympathetic nervous system in the hypothalamus.

The incubation period varies greatly, from a day or two to a month or longer. Long incubation periods are associated with mild and localized types of the disease.

Clinical Features

There are several clinical types of tetanus, usually designated as local, cephalic, and generalized.

Generalized Tetanus This is the most common form. It may begin as local tetanus that becomes generalized after a few days, or it may be diffuse from the beginning. Trismus is frequently the first manifestation. In some cases this is preceded by a feeling of stiffness in the jaw or neck, slight fever, and other general symptoms of infection. The localized muscle stiffness and spasms spread quickly to other bulbar muscles as well as those of the neck, trunk, and limbs. A state of unremitting rigidity develops in all the involved muscles: the abdomen is board-like, the legs are rigidly extended, and the lips are pursed or retracted (*risus sardonicus*); the eyes are partially closed by contraction of the orbicularis oculi, or the eyebrows are elevated by spasm of the frontalis. Superimposed on this persistent state of enhanced muscle activity are paroxysms of tonic contraction or spasm of muscles (tetanic seizures or "convulsions"), which occur spontaneously or in response to the slightest external stimulus. They are agonizingly painful. Consciousness is not lost during these paroxysms. The tonic contraction of groups of muscles results in opisthotonos or in forward flexion of the trunk, flexion and adduction of the arms, clenching of the fists, and extension of the legs. Spasms of the pharyngeal, laryngeal, or respiratory muscles carry the constant threat of apnea or suffocation. Fever and pneumonia are common complications. Large swings in blood pressure and heart rate as well as profuse diaphoresis are typical, mainly in response to the intense muscular contractions but they may also be related to the action of the toxin on

the CNS. Death is usually attributable to asphyxia from laryngospasm, to heart failure, or to shock, the latter resulting from the action of the toxin on the hypothalamus and sympathetic nervous system.

Generalized spasms and rigidity of trunk and limbs developing in a neonate a few days after birth should always suggest the diagnosis of tetanus. This form of tetanus occurs when there has been inadequate sterile treatment of the umbilical cord stump in a neonate born to an unimmunized mother.

Local Tetanus This is the most benign form. The initial symptoms are stiffness, tightness, and pain in the muscles in the neighborhood of a wound, followed by twitchings and brief spasms of the affected muscles. Local tetanus occurs most often in relation to a wound of the hand or forearm, rarely in the abdominal or paravertebral muscles. Gradually, some degree of continuous involuntary spasm becomes evident. There is sustained tautness of the affected muscles and resistance of the part to passive movement. Superimposed on this background of more or less continuous motor activity are brief, intense spasms, lasting from a few seconds to minutes and occurring spontaneously or in response to all variety of stimulation (Struppler et al). Early in the course of the illness there may be periods when the affected muscles are palpably soft and appear to be relaxed. A useful diagnostic maneuver at this stage is to have the patient perform some repetitive voluntary movements, such as opening and closing the hand, in response to which there occurs a gradual increase in the tonic contraction and spasms of the affected muscles, followed by spread to neighboring muscle groups (recruitment spasm). Even with mild localized tetanus there may be slight trismus, a useful diagnostic sign.

Symptoms may persist in localized form for several weeks or months. Gradually the spasms become less frequent and more difficult to evoke, and they finally disappear without residue. Complete recovery is to be expected, as there are no pathologic changes in muscles, nerves, spinal cord, or brain, even in the most severe generalized forms of tetanus.

Cephalic Tetanus This form of tetanus follows wounds of the face and head. The incubation period is short, 1 or 2 days as a rule. The affected muscles (most often facial) are weak or paralyzed. Nevertheless, during accessions of tetanic spasm, the palsied muscles are seen to contract. Apparently, the disturbance in the facial motoneurons is sufficient to prevent voluntary movement but insufficient to prevent the strong reflex impulses that elicit facial spasm. The spasms may involve the tongue and throat, with persistent dysarthria, dysphonia, and dysphagia. Ophthalmoparesis is known to occur but is difficult to verify because of severe blepharospasm. In a strict sense, these cephalic forms of tetanus are examples of local tetanus that frequently becomes generalized. Many cases prove fatal.

Diagnosis

This is made from the clinical features and a history of preceding injury. The latter is sometimes disclosed only

after careful questioning, the injury having been trivial, forgotten and entirely healed. The organisms may or may not be recovered from the wound by the time the patient receives medical attention; other laboratory tests, apart from the EMG, are of little value. Serum CK may be moderately elevated if the rigidity is generalized. The EMG recorded from muscles in spasm shows continuous discharges of normal motor units like those recorded from a forceful voluntary muscle contraction. Most characteristic of tetanus, as mentioned earlier, is a loss of the physiologic silent period that occurs 50 to 100 ms after reflex contraction. This pause, normally produced by the recurrent inhibition of Renshaw cells, is blocked by tetanus toxin. In generalized tetanus the loss of the silent period can almost always be demonstrated in the masseter, and it is found in a muscle affected by local tetanus. Interestingly, the silent period is preserved in the stiff man syndrome (see Chap. 55).

Tetany caused by hypocalcemia, the spasms of strychnine poisoning or black widow spider bite, trismus as a result of painful conditions in and around the jaw, the dysphagia of rabies, hysterical spasms, rigidity and dystonic spasms caused by neuroleptic drugs, and the spasms of the stiff man syndrome all resemble the spasms of tetanus but should not be difficult to distinguish when all aspects of these disorders are considered. Nonetheless, the diagnosis is difficult to bring to mind in a nonendemic area.

The death rate from tetanus is approximately 50 percent overall; it is highest in newborns, heroin addicts, and patients with the cephalic form of the disease. The patient usually recovers if there are no severe generalized muscle spasms during the course of the illness or if the spasms remain localized.

Treatment

This is directed along several lines. At the outset, a single dose of antitoxin (3,000 to 6,000 U of tetanus immune human globulin) should be given along with a 10-day course of penicillin (1.2 million U of procaine penicillin daily), metronidazole (500 mg q6h intravenously or 400 mg rectally), or tetracycline (2 g daily). These drugs are effective against the vegetative forms of *C. tetani*. Immediate surgical treatment of the wound (excision or debridement) is imperative, and the tissue around the wound should be infiltrated with antitoxin.

Survival depends on expert and constant nursing in an intensive care unit and may be necessary for weeks. Tracheostomy is a requisite in all patients with recurrent generalized tonic spasms and should not be delayed until apnea or cyanosis has occurred. The patient must be kept as quiet as possible to avoid stimulus-induced spasms. This requires a darkened, quiet room and the judicious use of sedation. The benzodiazepines are the most useful drugs for both sedation and muscle relaxation; diazepam 120 mg/d or more can be given in frequent divided doses if ventilatory support is available; alternatively midazolam or propofol can be used in a continuous intravenous infusion. Short-acting barbiturates and chlorpromazine may also be useful, as may be morphine. Intrathecal baclofen and continuous atropine infusions have been used with success in severe

cases, and intramuscular injections of botulinum toxin may be used for trismus and local spasm. The aim of therapy is to suppress muscle spasms and to keep the patient drowsy to avoid the horrible discomfort of the spasms. All treatments and manipulations should be kept to a minimum and coordinated so that the patient may be sedated beforehand.

Failure of these measures to control the tetanic paroxysms requires that intravenous administration of neuromuscular blocking agents such as pancuronium or vecuronium be used to abolish all muscle activity; appropriate sedative medication is instituted for as long as necessary, breathing being maintained by a positive-pressure respirator. Many intensive care units favor the use of neuromuscular paralytic drugs in all but the mildest cases. Further details concerning treatment can be found in the review by Farrar and colleagues.

All persons should be immunized against tetanus and receive a booster dose of toxoid every 10 years—a practice that is frequently neglected in the elderly. Injuries that carry a threat of tetanus should receive toxoid if the patient has not received a booster injection in the preceding year, and a second dose of toxoid is needed 6 weeks later. If the injured person has not received a booster injection since the original immunization, he should receive an injection of both toxoid and human antitoxin; the same applies to the injured person who has never been immunized. An attack of tetanus does not confer permanent immunity and persons who recover should be actively immunized.

Diphtheria

Diphtheria, an acute infectious disease caused by *Corynebacterium diphtheriae*, is now quite rare in the United States and Western Europe. The faucial-pharyngeal form of the disease, which is the most common clinical type, is characterized by the formation of an inflammatory exudate of the throat and trachea; at this site, the bacteria elaborate an exotoxin, which affects the heart and nervous system in approximately 20 percent of cases.

The involvement of the nervous system follows a predictable and biphasic pattern (Fisher and Adams). It begins locally, with *palatal paralysis* (nasal voice, regurgitation, and dysphagia) between the fifth and twelfth days of illness. At this time or shortly afterward, other cranial nerves (trigeminal, facial, vagus, and hypoglossal) may also be affected. *Ciliary body paralysis* with loss of accommodation and blurring of vision but with preserved light reaction usually appears in the second or third week (the opposite of the Argyll Robertson reaction). Rarely, the extraocular muscles are weakened. The cranial nerve signs may clear without further involvement of the nervous system, or a delayed sensorimotor polyneuropathy may develop between the fifth and eighth weeks of the disease. The latter varies in severity from a mild, predominantly distal polyneuropathy of the limbs to a rapidly evolving, ascending paralysis, like that of the Guillain-Barré syndrome; CSF findings are similar as well (acellular fluid with elevated protein). The neuropathic symptoms

progress for a week or two, and if the patient does not succumb to respiratory paralysis or cardiac failure (cardiomyopathy), these conditions stabilize and then improve slowly and more or less completely.

The early oropharyngeal symptoms, the ciliary paralysis with relatively retained pupillary response to light, and subacute evolution of a delayed symmetrical sensorimotor peripheral neuropathy distinguish diphtheria from other forms of polyneuropathy. The long latency between the initial infection and the involvement of the nervous system has no clear explanation. In experimental animals, Waksman and colleagues demonstrated that the toxin reaches the Schwann cells in the most vascular parts of the peripheral nervous system within 24 to 48 h of infection but its metabolic effect on cell membranes extends over a period of weeks. The toxin produces demyelination in the proximal parts of spinal nerves, in dorsal root ganglia, and in spinal roots. The cardiac musculature and the conducting system of the heart undergo mild focal necrosis.

The source of diphtheritic infection may be extrafacial—a penetrating wound, skin ulcer, or infection of the umbilicus in the neonate. The systemic and neurologic complications of faucial diphtheria can also be observed in the extrafacial form of the disease (wound infection) after a similar latent period. It is probable, therefore, that the toxin reaches neural sites via the bloodstream; but in addition, some action is exerted locally, as evidenced by palatal paralysis in faucial cases and by initial weakness and sensory impairment in the neighborhood of the infected wound.

There is no specific treatment for the neurologic complications of diphtheria. It is generally agreed that the administration of antitoxin within 48 h of the earliest symptoms of the primary diphtheritic infection lessens the incidence and severity of the peripheral nerve complications. The polyneuropathy of diphtheria is discussed further in Chap. 46.

Botulism

Botulism is a rare form of food-borne illness caused by the exotoxin of *Clostridium botulinum*. Outbreaks of poisoning are most often caused by ingested bacteria contained in home-preserved than in commercially canned products, and vegetables and home-cured ham are incriminated more commonly than are other food products. Very rarely, a contaminated wound is the source of infection. Although the disease is ubiquitous, five western states (California, Washington, Colorado, New Mexico, and Oregon) account for more than half of all reported outbreaks in the United States. *Neonatal and infantile forms* of the disease have been reported. These are a result of absorption of the toxin formed by germination of ingested spores (rather than ingestion of preformed toxin), an important source of which is contaminated natural (raw) honey. A few adult cases may have a similar source.

It is now well established on the basis of observations in both animals and humans that the primary site of action of toxin is at a neuromuscular junction, more specifically

on the presynaptic membrane. The toxin interferes with the release of acetylcholine from peripheral motor nerves at the neuromuscular synapse. The physiologic defect is similar to the one that characterizes the myasthenic syndrome of Lambert-Eaton (see Chap. 53) but different from that of myasthenia gravis.

Symptoms usually appear within 12 to 36 h of ingestion of the tainted food. Anorexia, nausea, and vomiting occur in most patients. As a rule, blurred vision and diplopia are the initial neural symptoms; their association with ptosis, strabismus, and extraocular muscle palsies, particularly of the sixth nerve, may at first suggest a diagnosis of myasthenia gravis. In botulism, however, accommodation is lost and the pupils are often unreactive to light. Other symptoms of bulbar involvement—nasality of voice, hoarseness, dysarthria, dysphagia, and an inability to phonate—follow in quick succession. These, in turn, are followed by progressive weakness of the muscles of the face, neck, trunk, and limbs, and by respiratory insufficiency. Despite the oropharyngeal weakness, it is not unusual for the gag reflex to be retained. Tendon reflexes are lost in cases of severe generalized weakness. These symptoms and signs evolve rapidly, over 2 to 4 days as a rule, and may be mistaken for those of the Guillain-Barré syndrome. Sensation remains intact, however, and the spinal fluid shows no abnormalities. Severe constipation is characteristic of botulism, perhaps as a result of paresis of smooth muscle of the intestine. Consciousness is retained throughout the illness unless severe degrees of anoxia develop as a result of respiratory failure. In the past, the mortality was greater than 60 percent, but it has declined greatly in recent decades, with improvements in the intensive care of acute respiratory failure and the effectiveness of *C. botulinum* antitoxins.

The clinical diagnosis can be confirmed by electrophysiologic studies. Specifically, there is reduced amplitude of evoked muscle potentials and an increase in amplitude with rapid repetitive nerve stimulation (the opposite of what is found in myasthenia gravis). In patients who recover, improvement begins within a few weeks, first in ocular movement, then in other cranial nerve functions. Complete recovery of paralyzed limb and trunk musculature may take many months.

The three types of botulinum toxins—A, B, and E—cannot be distinguished by their clinical effects alone, so that the patient should receive the trivalent antiserum as soon as the clinical diagnosis is made. This antitoxin can be obtained from the Centers for Disease Control and Prevention, Atlanta, Georgia. An initial dose of 10,000 U is given intravenously after intradermal testing for sensitivity to horse serum, followed by daily doses of 50,000 U intramuscularly until improvement begins. Penicillin or metronidazole are given to eradicate the organism in a wound (but are not as useful if the exogenous preformed toxin has been ingested).

Guanidine hydrochloride (50 mg/kg) has been somewhat useful in reversing the weakness of limb and extraocular muscles. Antitoxin and guanidine probably change the course of the illness relatively little and recovery depends on the effectiveness of respiratory care,

maintenance of fluid and electrolyte balance, prevention of infection, and so on.

The therapeutic injection of small quantities of botulinum toxin into a muscle affected by dystonia or spasticity will weaken or paralyze it for weeks to months (see Chap. 6). Mild symptoms of botulism can occur with relatively large doses, mainly affecting the oropharyngeal and ciliary muscles.

POISONING CAUSED BY PLANTS, VENOMS, BITES, AND STINGS

Ergotism

Ergotism is the name applied to poisoning with ergot, a drug derived from the rye fungus *Claviceps purpurea*. Ergot is used therapeutically to control postpartum hemorrhage caused by uterine atony; one of its alkaloids, ergotamine, is used in the treatment of migraine (see Chap. 10), and a class of dopamine agonists used in the treatment of Parkinson disease has ergot activity (see Chap. 39). Chronic and repeated use of the drug is the usual cause of ergotism; acute overdosage in the postpartum state or in the treatment of migraine may cause an alarming rise in blood pressure.

Two types of ergotism are recognized: *gangrenous*, which is caused by a vasospastic, occlusive process in the small arteries of the extremities, and *convulsive*, or *neurogenic*, ergotism. The latter is characterized by fasciculations, myoclonus, and spasms of muscles, followed by seizures. In nonfatal cases, a tabes-like neurologic syndrome may develop, with loss of knee and ankle jerks, ataxia, and impairment of deep and superficial sensation. The pathologic changes consist of degeneration of the posterior columns, dorsal roots, and peripheral nerves, but they have been poorly described. The relation of these changes to ergot poisoning is not clear, because most of the cases occurred in areas where malnutrition was endemic. The authors have had no experience with this condition.

Lathyrism

Lathyrism is a neurologic syndrome characterized by the relatively acute onset of pain, paresthesia, and weakness in the lower extremities, progressing to a permanent spastic paraplegia. It is a serious medical problem in India and in some North African countries and is probably caused by a toxin contained in the chickling vetch pea, *Lathyrus*, a legume that is consumed in excess quantities during periods of famine. This disorder is discussed further with the spinal cord diseases (see Chap. 44).

Mushroom Poisoning

The gathering of wild mushrooms, a popular pastime in late summer and early fall, always carries with it the danger of poisoning. As many as 100 species of mushrooms are poisonous. Most of them cause only transient

gastrointestinal symptoms but some elaborate toxins that can be fatal. The most important of these toxins are the cyclopeptides, which are contained in several species of *Amanita phalloides* and *muscaria* and account for more than 90 percent of fatal mushroom poisonings. These toxins disrupt RNA metabolism, causing hepatic and renal necrosis. Symptoms of poisoning with *Amanita* usually appear between 10 and 14 h after ingestion and consist of nausea, vomiting, colicky pain, and diarrhea, followed by irritability, restlessness, ataxia, hallucinations, convulsions, and coma. There may be added evidence of a neuromyopathy presenting as flaccid areflexic paralysis, high serum CK, diminished EMG potentials, and fiber necrosis.

Other important mushroom toxins are methylhydrazine (contained in the *Gyromitra* species) and muscarine (*Inocybe* and *Clitocybe* species). The former gives rise to a clinical picture much like that caused by the cyclopeptides. The symptoms of muscarine poisoning, which appear within 30 to 60 min of ingestion, are essentially those of parasympathetic stimulation—miosis, lacrimation, salivation, nausea, vomiting, diarrhea, perspiration, bradycardia, and hypotension. Tremor, seizures, and delirium occur in cases of severe poisoning.

The mushroom toxins have no effective antidotes. If vomiting has not occurred, it should be induced with ipecac, following which activated charcoal should be administered orally in order to bind what toxin remains in the gastrointestinal tract. A local poison control center may help identify the poisonous mushroom and its toxin. Even more important, the gathering and ingestion of field varieties of mushrooms should be left to those absolutely certain of their identity.

Buckthorn Poisoning

A rapidly progressive and sometimes fatal paralysis follows the ingestion of the small fruit of the buckthorn shrub that is indigenous to northern Mexico and the neighboring southwestern parts of the United States. The responsible toxin causes a predominantly motor polyneuropathy, probably of axonal type. Except for a normal spinal fluid protein concentration, the disorder closely resembles Guillain-Barré syndrome and tick paralysis (see later), and its recognition depends on awareness of ingestion of the fruit in endemic areas.

Neurotoxin Fish Poisoning (Ciguatera)

Ingestion of marine toxins that block neural sodium channels is a common form of poisoning throughout coastal areas and islands of the world. It results from eating fish that have fed on toxin-containing microscopic dinoflagellates. Reef fish and shellfish ingest high concentrations of these organisms during periodic upswings in the population of the dinoflagellates. They may be so profuse as to color the surrounding water (red tide).

Although the toxins differ (tetrodotoxin—puffer fish; ciguatoxin—snails; saxitoxin and brevetoxin—shellfish), the neurologic and gastrointestinal symptoms that follow the ingestion of poisoned fish are similar. The initial

symptoms are diarrhea, vomiting, or abdominal cramps coming on minutes to hours after the ingestion. These are followed by paresthesias that begin periorally and then involve the limbs distally. Hot and cold sensory stimuli (e.g., ice cream) are characteristically associated with electrical-like or burning paresthesias in the mouth. Muscle aches and shooting pains are also mentioned by most patients. In puffer fish poisoning, and in advanced stages of poisoning from other fish, weakness occurs, and there have been a few reports of coma and of respiratory failure.

The recognition of this type of fish poisoning is straightforward in endemic areas, in some of which there is a seasonal clustering of cases. In tourists returning home from endemic areas, and in persons consuming imported fish, the illness may be mistaken for Guillain-Barré syndrome. Prominent perioral paresthesias should suggest the correct diagnosis. Supportive treatment is all that is required but treatment with intravenous mannitol is said to hasten recovery.

Pearn has reviewed the biochemistry and physiologic and clinical effects of the various marine toxins and points out a form of chronic intoxication that is apparently endemic in certain island communities. The main chronic effects are severe fatigue and asthenic weakness. The problem of distinguishing this syndrome from depression is acknowledged by the author and the cases on which we have consulted locally almost always fall into the psychiatric category. One of our patients developed chronic paresthesias.

Venoms, Bites, and Stings

Although relatively rare, they are nonetheless important causes of mortality. The venoms of certain species of snakes, lizards, spiders (especially the black widow spider, see Chap. 55), and scorpions contain neurotoxins that may cause a fatal depression of respiration and curare-like paralysis of neuromuscular transmission. In the United States, there are approximately 8,000 poisonous snake bites per year. Some, such as the coral snake envenomation, are neurotoxic, producing pupillary dilatation, ptosis, ocular palsies, ataxia, and respiratory paralysis. Others (rattlesnakes, water moccasin snakes) cause tissue necrosis and circulatory collapse. These are reviewed by Gold and colleagues. The serious effects of *Hymenoptera stings* (bees, wasps, hornets, and fire ants) are mainly the result of hypersensitivity and anaphylaxis. Several instances of cerebral and myocardial infarction have been reported after bee and wasp stings (Crawley et al). A substantial inception has been the development of an antivenom for scorpion stings that can be administered in parallel with diazepam to children and results in more rapid resolution of paralysis and respiratory failure (Boyer and colleagues). All of these disorders are discussed in detail in *Harrison's Principles of Internal Medicine*.

Tick Paralysis

This rare condition is the result of a toxin secreted by the gravid tick. In Canada and the northwestern

United States, the wood tick *Dermacentor andersoni* is mainly responsible; in the southeastern United States it is *Dermacentor variabilis*, a dog tick (the tick in Australia is the *Ixodes holocyclus*), but various other ticks occasionally may have the same effect. Most cases occur in children because their small body mass renders them susceptible to the effects of relatively small amounts of the toxin. The illness arises almost exclusively in the spring when the mature gravid ticks are most plentiful. The illness is more common and is generally more severe in cases on the Australian continent than it is in North America. Clinical manifestations require that the tick be attached to the skin for several days.

The neurotoxin causes a generalized, flaccid, areflexic paralysis, appearing over 1 or 2 days and thereby mimicking the Guillain-Barré syndrome. In a few cases, several days of ataxia and areflexia precede the paralysis but sensory loss tends to be minimal. External ophthalmoplegia, which occurred in 5 of the 6 children described by Grattan-Smith and colleagues, is exceptional, judging by other reports; internal ophthalmoplegia and pharyngeal weakness are also known to occur, and while not typical, raise the possibility of botulism or diphtheria. The CSF is normal and electrophysiologic studies show reduction in the amplitude of the muscle action potentials but normal or only slightly slowed nerve conduction. Prominent ptosis and neck weakness may also raise the question of a neuromuscular process, but repetitive stimulation testing is normal or evokes only a slight decrement or increment in some cases.

The ticks tend to attach to the hairlines or in the matted hair of the scalp, neck, and pubis, where a careful search will reveal them (for which reason nurses and electroencephalography technicians often are most likely to find them; see Felz et al). The diagnosis is much in the awareness of clinicians in endemic areas during the tick season, for they are gratified with rapid and dramatic improvement when the tick is removed. The paralysis has been reported to become transiently worse after tick removal in some of the Australian cases.

From a neurologic point of view, *Lyme disease* is a far more common tick-borne disorder. The causative agent is *Borrelia burgdorferi*, a spirochetal organism. The disorder is discussed fully with other infectious diseases in Chap. 32 and in Chap. 46, with the neuropathies.

HEAVY METALS

Lead

The causes and clinical manifestations of lead poisoning are quite different in children and adults.

Lead Poisoning in Children

In the United States, this disease has been identified most often in 1- to 3-year-old children who inhabit urban slum areas where old, deteriorated housing prevails. (Lead paint was used in most houses built before 1940 and in many built before 1960.) The chewing of leaded paint is

promoted by compulsive ingestion (pica) from window-sills and painted plaster walls. The development of an acute encephalopathy is the most serious complication, resulting in death in 5 to 20 percent of cases and in permanent neurologic and mental deficits in more than 25 percent of survivors.

Clinical Manifestations These develop over a period of 3 to 6 weeks. The child becomes anorectic, less playful and less alert, and more irritable. These symptoms may be misinterpreted as a behavior disorder or a manifestation of mental retardation. Intermittent vomiting, vague abdominal pain, clumsiness, and ataxia may be added. If these early signs of intoxication are not recognized and the child continues to ingest lead, more flagrant signs of acute encephalopathy may develop—most frequently in the summer months, for reasons that are not understood. Vomiting becomes more persistent, apathy progresses to drowsiness and stupor interspersed with periods of hyperirritability, and, finally, seizures and coma supervene. This syndrome may evolve in a period of a week or less, most rapidly in children younger than 2 years of age; in older children, it is more likely to develop in recurrent and less severe episodes. This clinical syndrome must be distinguished from tuberculous meningitis, viral meningoencephalitis, and the various conditions causing acute increased intracranial pressure. Usually, in lead encephalopathy, the CSF is under increased pressure with manifest papilledema, and there may be a slight lymphocytic pleocytosis and elevated protein but normal glucose values. It follows that lumbar puncture should be done with caution and only if it is essential for diagnosis.

Diagnosis Because the symptoms of plumbism are nonspecific, the diagnosis depends on an appreciation of the potential causative factors and the results of certain laboratory tests. Lead lines at the metaphyses of long bones and basophilic stippling of red cells are seen but are too inconstant to be relied on, but basophilic stippling of bone marrow erythroblasts is uniformly increased. Impairment of heme synthesis, which is exquisitely sensitive to the toxic effects of lead, results in the increased excretion of urinary coproporphyrin (UCP) and of Δ -aminolevulinic acid (ALA). These urinary indices and the lead concentrations in the serum bear an imperfect relationship to the clinical manifestations. In the test for UCP, which is readily performed in the clinic and emergency department, a few milliliters of urine are acidified with acetic acid and shaken with an equal volume of ether; if coproporphyrin is present, the ether layer will reveal a reddish fluorescence under a Wood lamp. This test is strongly positive when the whole blood concentration of lead exceeds 80 mg/dL. The diagnosis can be confirmed by promoting lead excretion with calcium disodium edetate (CaNa_2 ethylenediaminetetraacetic acid [EDTA]), given in three doses (25 mg/kg) at 8-h intervals. Excretion of over 500 mg in 24 h is indicative of plumbism. The measurement of zinc protoporphyrin (ZPP) in the blood is another reliable means of determining the presence and degree of lead exposure. The binding of erythrocyte protoporphyrin to zinc occurs when lead impairs the normal binding of

erythrocyte protoporphyrin to iron. Elevated ZPP can also be induced when access to iron is limited by other conditions, such as iron deficiency anemia.

At blood lead concentrations of 70 mg/dL symptoms may be minimal, but acute encephalopathy may occur abruptly and unpredictably, for which reason the child should be hospitalized for chelation therapy (see below). Some children with a blood lead level of 50 mg/dL may have symptoms of severe encephalopathy, whereas others may be asymptomatic. In the latter case, an attempt should be made to discover and remove the source of lead intoxication and the child should be reexamined at frequent intervals. The seriousness of lead encephalopathy is indicated by the fact that most of the children who become stuporous or comatose remain mentally retarded despite treatment. The physician's aim, therefore, is to institute treatment before the severe symptoms of encephalopathy have become manifest.

Pathology In children who die of acute lead encephalopathy, the brain is massively swollen, with herniation of the temporal lobes and cerebellum, multiple microscopic ischemic foci in the cerebrum and cerebellum, and endothelial damage and deposition of proteinaceous material and mononuclear inflammatory cells around many of the small blood vessels. There are also hyperplastic changes in arteries and arterioles and in some places, perivascular infiltrates of lymphocytes and mononuclear cells. In the territories of some of these vessels there are foci of ischemic necrosis with surrounding glial reaction appropriate for the age of the lesion. Similar changes are present in the kidney.

Treatment The plan of therapy includes the establishment of urinary flow, following which intravenous fluid therapy is restricted to basal water and electrolyte requirements. In cases of acute encephalopathy, combined chelation therapy with 2,3-dimercaptopropanol (British anti-Lewisite [BAL]; 12 to 24 mg/kg) and CaNa_2 EDTA (0.5 to 1.5 g/m² body surface area) for 5 to 7 days. This is followed by a course of oral penicillamine (40 mg/kg, not exceeding 1 g/d). In acute cases the goal is to reduce the serum lead levels below 40 mg/dL. Once the absorption of lead has ceased, chelating agents remove lead only from soft tissues and not from bone, where most of the lead is stored. Any intercurrent illness may result in a further mobilization of lead from bones and soft tissues and an exacerbation of symptoms of lead intoxication.

Repeated doses of mannitol may be used for relief of cerebral edema. Microcytic hypochromic anemia is treated with iron once the chelating agents have been discontinued. Seizures are best controlled with intravenous diazepam or midazolam.

Prevention The prevention of re-intoxication (or initial intoxication) demands that the child be removed from the source of lead. Although this is axiomatic, it is often difficult to accomplish, despite the best efforts of local health departments and hospital and city social workers. Nevertheless, an attempt to eliminate the environmental factor must be made in each case. Such attempts, among other things, have resulted in a marked decrease in the incidence of acute lead encephalopathy

in the past two decades. Although florid examples of this encephalopathy are now uncommon, undue exposure to lead (blood levels greater than 30 mg/dL) remains inordinately prevalent and a continuing source of concern to public health authorities.

As to the levels that pose a danger to the child, there is still some uncertainty. Rutter, who reviewed all of the evidence up to 1980, concluded that persistent blood levels above 40 mg/dL may cause slight cognitive impairment and, less certainly, an increased risk of behavioral difficulties. More recently, Canfield and colleagues reported, from a prospective study of 172 children, that even lower levels may induce a decline in IQ at 3 and 5 years of age. These data require confirmation before general acceptance. Further compounding the problem of interpreting low-level lead exposure in children with blood lead concentrations below 45 g/dL is the observation by Rogan and colleagues that treatment with succimer, while successful in reducing lead levels, did not improve cognitive or behavioral function.

The oral lead chelator succimer is approved for outpatient treatment of asymptomatic children with blood lead levels higher than 45 mg/dL. A 3-week course of treatment is given, with weekly monitoring of blood lead levels to identify lead mobilization from bones and soft tissues (Jorgensen).

In 1988, on the basis of epidemiologic and experimental studies in the United States, Europe, and Australia, the Agency for Toxic Substances and Disease Registry set a much lower threshold for neurobehavioral toxicity (10 to 15 mg/dL). It estimated that 3 to 4 million American children have blood levels in excess of this amount. Needleman and colleagues studied the long-term effects of low doses of lead in asymptomatic children, 132 of whom had had demonstrable levels of lead in the dentin of shed teeth (average 24 mg/dL). Eleven years later, the children were found to have behavioral abnormalities proportionate to their early lead levels. In comparison to a normal population, more had dropped out of school and more had lower vocabulary and grammatical reasoning scores, more reading difficulty, poorer hand-eye coordination performance, slower finger-tapping rates, and longer reaction times. The authors claimed to have eliminated other confounding variables such as lower social class and genetic factors. These findings are similar to those of the long-term studies of Baghurst and colleagues (see also Mahaffey). There are no adequate pathologic or MRI studies of such cases.

Lead Intoxication in Adults

Lead intoxication in adults is much less common than in children. The hazards to adults are the result of inhaling the dust of inorganic lead salts and the fumes from the burning of objects containing lead or involvement in processes that require the remelting of lead. Painting, printing, pottery glazing, lead smelting, welding, and storage battery manufacturing are the industries in which these hazards are likeliest to occur. In the past, miners and brass foundry and garage workers (during automobile radiator repair, when soldered joints were heated) were the ones

most at risk. Currently, other, sometimes idiosyncratic, sources are more common. For example, the authors have encountered a striking case of lead encephalopathy in a man of Indian origin who was taking large amounts of an Ayurvedic herbal remedy for arthritis. The first manifestation was a series of generalized seizures followed by a fluctuating encephalopathy. His serum lead level was 70 mg/dL, and 24-h urine collection contained 1,550 mg of lead (normal being less than 400 mg). There was a T2-weighted hyperintensity in the cerebral cortex. Whitfield and colleagues reviewed 23 instances of lead encephalopathy in adults. At the time of their report most cases were caused by moonshine (homemade whiskey from lead-lined stills). More recently, most cases have been from various herbal medications, as already mentioned. Combined lead and arsenic poisoning from herbal compounds is also known.

The usual manifestations of lead poisoning in adults are colic, anemia, and peripheral neuropathy. Encephalopathy of the type described above is decidedly rare. Lead colic, frequently precipitated by an intercurrent infection or by alcohol intoxication, is characterized by severe, poorly localized abdominal pain, often with rigidity of abdominal muscles but without fever or leukocytosis. The pain responds to the intravenous injection of calcium salts, at least temporarily, but responds poorly to morphine. Mild anemia is common. A black line of lead sulfide may develop along the gingival margins. Peripheral neuropathy, usually a bilateral wrist drop, is a rare manifestation and is discussed in Chap. 46.

The diagnostic tests for plumbism in children are generally applicable to adults, with the exception of bone films, which are of no value in the latter. Also, the treatment of adults with chelating agents follows the same principles as in children.

Intoxication with tetraethyl and tetramethyl (organic) lead, used as additives in gasoline, is caused by inhalation of gasoline fumes. It occurs most often in workers who clean gasoline storage tanks. Insomnia, irritability, delusions, and hallucinations are the usual clinical manifestations, and a maniacal state may develop. The hematologic abnormalities of inorganic lead poisoning are not found, and chelating agents are of no value in treatment. Organic lead poisoning is usually reversible, but fatalities have been reported. The pathologic changes have not been well described.

Arsenic

In the past, medications such as Fowler solution (potassium arsenite) and the arsphenamines, used in the treatment of syphilis, were frequent causes of intoxication, but now the most common cause is the suicidal or accidental ingestion of herbicides, insecticides, or rodenticides containing copper acetoarsenite (Paris green) or calcium or lead arsenate. In rural areas, arsenic-containing insecticide sprays are a common source of poisoning. Arsenic is used also in the manufacture of paints, enamels, and metals; as a disinfectant for skins and furs; and also

in galvanizing, soldering, etching, and lead plating. Occasional cases of poisoning are reported in relation to these occupations. Arsenic is still contained in some topical creams and oral solutions that are used in the treatment of psoriasis and other skin disorders and in some herbal remedies.

Arsenic exerts its toxic effects by reacting with the sulfhydryl radicals of certain enzymes necessary for cellular metabolism. The effects on the nervous system are those of an encephalopathy or peripheral neuropathy. The latter may be the product of chronic poisoning or may become manifest between 1 and 2 weeks after recovery from the effects of acute poisoning. It takes the form of a distal axonopathy that is described in Chap. 46. In cases of arsenical polyneuropathy we have cared for, a distal sensorimotor areflexic syndrome developed subacutely. At autopsy there was a dying back pattern of myelin and axons with macrophage and Schwann cell reactions and chromatolysis of motor neurons and sensory ganglion cells. The CNS appeared normal.

The symptoms of encephalopathy (headache, drowsiness, mental confusion, delirium, and convulsive seizures) may also occur as part of acute or chronic intoxication. In the latter case, they are accompanied by weakness and muscular aching, hemolysis, chills and fever, mucosal irritation (in patients exposed to arsine gas), diffuse scaly desquamation, and transverse white lines, 1 to 2 mm in width, above the lunula of each fingernail (Mees lines). Acute poisoning by the oral route is associated with severe gastrointestinal symptoms, shock and death in a large proportion of patients. The CSF is normal. Examination of the brain in such cases discloses myriads of punctate hemorrhages in the white matter. Microscopically, the lesions consist of capillary necrosis and of pericapillary zones of degeneration, which, in turn, are ringed by red cells (brain purpura). These neuropathologic changes are not specific for arsenical poisoning, but have been observed in such diverse conditions as pneumonia, gram-negative bacillary septicemia from urinary tract infections, sulfonamide and phosgene poisoning, dysentery, disseminated intravascular coagulation, and others.

The diagnosis of arsenical poisoning depends on the demonstration of increased levels of arsenic in the hair and urine. Arsenic is deposited in the hair within 2 weeks of exposure and may remain fixed there for long periods. Concentrations of more than 0.1 mg arsenic per 100 mg hair are indicative of poisoning. Arsenic also remains within bones for long periods and is slowly excreted in the urine and feces. Excretion of more than 0.1 mg arsenic per liter of urine is considered abnormal; levels greater than 1 mg/L may occur soon after acute exposure. We would caution, however, that individuals who consume fish on a regular basis, as occurs in coastal regions, may have slightly or moderately elevated levels of arsenic and that various conditions such as neuropathy and amyotrophic lateral sclerosis (ALS) may be mistakenly attributed to this innocuous finding. The levels return to normal within a few months of abstaining from fish.

The CSF protein level may be raised (50 to 100 mg/dL).

Treatment Acute poisoning is treated by gastric lavage, vasopressor agents, dimercaprol (BAL), maintenance of renal perfusion, and exchange transfusions if massive hemoglobinuria occurs. Once polyneuropathy has occurred, it is little affected by treatment with BAL, but other manifestations of chronic arsenical poisoning respond favorably. There has been a gradual recovery from the polyneuropathy under our care.

Manganese

Manganese poisoning results from the chronic inhalation and ingestion of manganese particles and occurs in miners of manganese ore and in workers who separate manganese from other ore. Several clinical syndromes have been observed. The initial stages of intoxication may be marked by a prolonged confusional-hallucinatory state. Later, the symptoms are predominantly extrapyramidal. They are often described as parkinsonian in type, but in the patients seen by the authors, the resemblance was not close: an odd gait ("cock" walk), dystonia and rigidity of the trunk, postural instability, and falling backward were features seen in two South American miners. Others, however, have reported stiffness and awkwardness of the limbs, often with tremor of the hands, "cogwheel" phenomenon, gross rhythmic movements of the trunk and head, and retropulsive and propulsive gait. Corticospinal and corticobulbar signs may be added. Progressive weakness, fatigability, and sleepiness as well as psychiatric symptoms (manganese madness) are other clinical features. Rarely, severe axial rigidity and dystonia, like those of Wilson disease, are said to have been the outstanding manifestations. The emergence of an extrapyramidal syndrome from the use of illicit drugs that are synthesized with potassium permanganate has already been mentioned in relation to the cathionine stimulants.

Neuronal loss and gliosis, affecting mainly the pallidum and striatum but also the frontoparietal and cerebellar cortex and hypothalamus, have been described, but the pathologic changes have not been carefully studied.

Treatment

The neurologic abnormalities have not responded to treatment with chelating agents. In the chronic dystonic form of manganese intoxication, dramatic and sustained improvement has been reported with the administration of L-dopa; patients with the more common parkinsonian type of manganese intoxication have shown only slight, if any, improvement with L-dopa.

Mercury

Mercury poisoning arises in two forms, one caused by inorganic compounds (elemental or mercury salt) and the other, more dangerous, caused by organic mercury. The sources of potential exposure are reviewed by Clarkson. Among the *organic compounds*, methylmercury gives rise to a wide array of serious neurologic symptoms that may be delayed for days or weeks after exposure, including tremor of the extremities, tongue, and lips; mental

confusion; and a progressive cerebellar syndrome, with ataxia of gait and arms, intention tremor, and dysarthria. Choreoathetosis and parkinsonian facies have also been described. Changes in mood and behavior are prominent, consisting at first of subjective weakness and fatigability and later of extreme depression and lethargy alternating with irritability. This *delayed form of subacute mercury poisoning* has been reported in chemical laboratory workers after exposure to methyl mercury compounds. These agents, particularly dimethylmercury, are extremely hazardous because they are absorbed transdermally and by inhalation, allowing severe toxicity to occur with even brief contact. In a fatal case of a chemist reported by Nierenberg and colleagues, a rapidly progressive ataxia and stupor progressing to coma developed 154 days after exposure. Cerebellar function was most severely impaired, and visual function was affected.

The pathologic changes are characterized by a striking degeneration of the granular layer of the cerebellar cortex, with relative sparing of the Purkinje cells and neuronal loss and gliosis of the calcarine cortex and to a lesser extent of other parts of the cerebral cortex, similar to the Minamata disease cases described later.

The chronic form of *inorganic mercury poisoning* occurs in persons exposed to large amounts of the metal used in the manufacture of thermometers, mirrors, incandescent lights, x-ray machines, and vacuum pumps. Because mercury volatilizes at room temperature, it readily contaminates the air and then condenses on the skin and respiratory mucous membranes. Nitrate of mercury, used formerly in the manufacture of felt hats ("mad hatters"), and phenyl mercury, used in the paper, pulp, and electrochemical industries, are other sources of intoxication. Paresthesias, lassitude, confusion, incoordination, and intention tremor are characteristic, and, with continued exposure, a delirious state occurs. Headache, various bodily pains, visual and hearing disorders, and corticospinal signs may be added, but their pathologic basis is unknown. The term *erethism* was coined to describe the timidity, memory loss, and insomnia that were said to be characteristic of chronic intoxication. If the exposure is more than a minimal degree over a long period, gastrointestinal disturbances are prone to occur (anorexia, weight loss), as well as stomatitis and gingivitis with loosening of the teeth.

Acute exposure to inorganic mercury in larger amounts is even more corrosive to the gastrointestinal system and produces nausea, vomiting, hematemesis, abdominal pain, and bloody diarrhea, as well as renal tubular necrosis.

Isolated instances of *polyneuropathy* associated with exposure to mercury have also been reported (Albers et al; Agocs et al) and may be responsible for the paresthesias that accompany most cases, as well as the acrodynic syndrome described below. The polyneuropathy associated with mercury poisoning is discussed in Chap. 46.

The presence of mercury in industrial waste has contaminated many sources of water supply and fish, which are ingested by humans and cause mercurial

poisoning. So-called Minamata disease is a case in point. Between 1953 and 1956, a large number of villagers living near Minamata Bay in Kyushu Island, Japan, were afflicted with a syndrome of chronic mercurialism, traced to the ingestion of fish that had been contaminated with industrial wastes containing methylmercury. Concentric constriction of the visual fields, hearing loss, cerebellar ataxia, postural and action tremors, and sensory impairment of the legs and arms and sometimes of the tongue and lips were the usual clinical manifestations. The syndrome evolved over a few weeks. Pathologically there was diffuse neuronal loss in both cerebral and cerebellar cortices, most marked in the anterior parts of the calcarine cortex and granule cell layer of the cerebellum. CT scans in survivors, years after the mass poisoning, disclosed bilaterally symmetrical areas of decreased attenuation in the visual cortex and diffuse atrophy of the cerebellar hemispheres and vermis, especially the inferior vermis (Tokuomi et al).

A painful neuropathy of children (acrodynia) has been traced to mercury exposure from interior latex paint, to calomel (mercurous chloride), to teething powders, and to a mercuric fungicide used in washing diapers (Agocs et al; Clarkson). Albers and colleagues observed the appearance of symptoms (mild decrease in strength, tremor, and incoordination) 20 to 35 years after exposure to elemental mercury. These authors believed that the natural neuronal attrition with aging had unmasked the neurologic disorder, a theory that we cannot validate.

The authors believe it worth mentioning that there is no convincing evidence linking typical dietary ingestion of fish containing metallic compounds such as mercury and any neurologic or developmental disease. The inhalation of vaporized mercury as a result of extensive dental work, or simply the presence of a large number of fillings ("amalgam illness"), is alleged to affect the peripheral nerves or to cause fatigue, but the connection is also highly doubtful as is the alleged relationship between vaccines containing mercury preservatives (thiomersal) and autism.

Treatment In the treatment of chronic mercury poisoning, penicillamine has been the drug of choice, because it can be administered orally and appears to chelate mercury selectively, with less effect on copper, which is an essential element in many metabolic processes. Dimercaptosuccinic acid (succimer), which is also given orally and has few side effects, will probably prove to be a superior form of treatment (Clarkson). Because it increases the concentration of mercury in the brain, BAL is an unsuitable chelating agent.

Phosphorus and Organophosphate Poisoning

Nervous system function may be deranged as part of acute and frequently fatal poisoning with inorganic phosphorus compounds (found in rat poisons, roach powders, and match heads). More important clinically is poisoning with organophosphorus compounds, the best known of which is triorthocresyl phosphate (TOCP).

Organophosphates are widely used as *insecticides*. Since 1945, approximately 15,000 individual compounds

in this category have come into use. Certain ones, such as tetraethylpyrophosphate, have been the cause of major outbreaks of neurologic disorder, especially in children. These substances have an acute anticholinesterase effect but no delayed neurotoxic action. Chlorophos, which is a 1-hydroxy-2,2,2-trichlorethylphosphonate, is an exception; it has both an acute and delayed action, as does TOCP.

The *immediate* anticholinesterase effect manifests itself by headache, vomiting, sweating, abdominal cramps, salivation, wheezing (secondary to bronchial spasm), miosis, and muscular weakness and twitching. Most of these symptoms can be reversed by administration of atropine and pralidoxime. The *delayed effect* manifests 2 to 5 weeks following acute organophosphorus insecticide poisoning. This takes the form of a distal symmetrical sensorimotor (predominantly motor) polyneuropathy, progressing to muscle atrophy (see Chap. 46). Recovery occurs to a variable degree and then, in patients poisoned with TOCP, signs of corticospinal damage become detectable. The severity of paralysis and its permanence vary with the dosage of TOCP. Whether a polyneuropathy can arise without the preceding symptoms of cholinergic toxicity is debated; however, based on a review of the subject and a study of 11 patients exposed to these agents, 3 of whom later acquired sensory neuropathy, Moretto and Lotti express the view that such an occurrence must be rare.

In addition to the acute and delayed neurotoxic effects of organophosphorus, an *intermediate syndrome* has been described (Senanayake and Karalliedde). Symptoms appear 24 to 96 h after the acute cholinergic phase and consist of weakness or paralysis of proximal limb muscles, neck flexors, motor cranial nerves, and respiratory muscles. Respiratory paralysis may prove fatal. In patients who survive, the paralytic symptoms last for 2 to 3 weeks and then subside. The intermediate and delayed symptoms do not respond to atropine or other drugs.

Several striking outbreaks of TOCP poisoning have been reported. During the latter part of the prohibition era and to a lesser extent thereafter, outbreaks of so-called jake paralysis were traced to drinking an extract of Jamaica ginger that had been contaminated with TOCP. Adams had examined several "ginger jake" patients many years later and related to us that he found only signs of corticospinal disease. Presumably in the early stage of this disease they were obscured by the neuropathy. Another outbreak occurred in Morocco in 1959, when lubricating oil containing TOCP was used deliberately to dilute olive oil. Several other outbreaks have been caused by the ingestion of grain and cooking oil that had been stored in inadequately cleaned containers previously used for storing TOCP.

The effect of TOCP on the peripheral nervous system has been studied extensively in experimental animals. In cats, there occurs a dying back from the terminal ends of the largest and longest medullated motor nerve fibers, including those from the annulospiral endings of the muscle spindles (Cavanagh and Patangia). The long fiber tracts of the spinal cord show a similar dying-back phenomenon. Abnormal membrane-bound vesicles

and tubules were observed by Prineas to accumulate in axoplasm before degeneration. These effects have been traced to the inhibitory action of TOCP on esterases. There is still uncertainty as to the details of these reactions, and no treatment for the prevention or control of the neurotoxic effects has been devised.

Thallium

In the late nineteenth century, thallium was used medically in the treatment of venereal disease, ringworm, and tuberculosis, and later in rodenticides and insecticides. Poisoning was fairly common. Sporadic instances of poisoning still occur, usually as a result of accidental or suicidal ingestion of thallium-containing rodenticides and rarely from overuse of thallium-containing depilatory agents. Patients who survive the effects of acute poisoning develop a rapidly progressive and painful sensory polyneuropathy, optic atrophy, and occasionally ophthalmoplegia—followed, 15 to 30 days after ingestion, by diffuse alopecia (see Chap. 46). The latter feature should always suggest the diagnosis of thallium poisoning, which can be confirmed by finding this metallic element in the urine. Two of our patients had a severe sensory and mild motor polyneuropathy and alopecia, from which they were recovering months later. It is not uncommon for the neuropathy to have a painful component involving acral regions. The condition can end fatally. The use of potassium chloride by mouth may hasten thallium excretion.

Other Metals

Iron, antimony, tin, aluminum, zinc, barium, bismuth, copper, silver, gold, platinum, and lithium may all produce serious degrees of intoxication. The major manifestations in each case are gastrointestinal or renal, but certain neurologic symptoms—notably headache, irritability, confusional psychosis, stupor, coma, and convulsions—may be observed in any of these if the poisoning is severe, often as a terminal event.

Gold preparations, which are still used occasionally in the treatment of arthritis, may, after several months of treatment, give rise to focal or generalized myokymia and a rapidly progressive, symmetrical polyneuropathy (Katrak et al). The adverse effects of *platinum* are discussed later, with the antineoplastic agents. *Lithium* was discussed earlier.

Mentioned here is a novel but quite rare *cobalt-chromium metallosis* due to the leaching of metals from prosthetic hips into surrounding tissues. A painful sensorimotor polyneuropathy has been reported, in some patients accompanied by hearing loss. Although only a few cases have been documented, the process has attracted considerable attention and our only encounter with it has been the ill-advised revision of hip implants for nondescript sensory symptoms, similar to the peculiar obsession with removing dental fillings for erroneously diagnosed mercury poisoning.

Attention already has been drawn to the possible causative role of *aluminum intoxication* in so-called dialysis

dementia or encephalopathy (see Chap. 43). Removal of aluminum from the water used in renal dialysis has practically eliminated this disorder. It should be noted that the neuropathologic changes in experimental aluminum intoxication (see later) are not those observed in dialysis dementia. Perl and colleagues have reported the accumulation of aluminum in tangle-bearing neurons of patients with Alzheimer disease and in the Guamanian Parkinson–dementia–ALS complex. However, analysis of neuritic plaques by nuclear microscopy, without using chemical stains, failed to demonstrate the presence of aluminum (Landsberg et al). The significance of these findings remains to be determined. Longstreth and colleagues described a progressive neurologic disorder consisting of intention tremor, incoordination, and spastic paraparesis in 3 patients who had worked for more than 12 years in the same pot room of an aluminum smelting plant. Similar cases clearly attributable to aluminum intoxication have not been reported, however.

Organic compounds of *tin* may seriously damage the nervous system. Diffuse edema of the white matter of the brain and spinal cord has been produced experimentally with *triethyltin*. Presumably, this was the basis of the mass poisoning produced by a triethyltin-contaminated drug called Stalinon. The illness was characterized by greatly elevated intracranial pressure and by a spinal cord lesion in some cases (Alajouanine et al). *Trimethyltin* intoxication is much rarer; seizures are the main manifestation. Experimental studies in rats have shown neuronal loss in the hippocampus, largely *sparing* the Sommer sector, with later involvement of neurons in the pyriform cortex and amygdala (see review by LeQuesne).

A stereotyped episodic encephalopathy has been associated with *bismuth intoxication*, usually arising from the ingestion of bismuth subgallate. Large outbreaks have been reported in Australia and France (Burns et al; Buge et al). The onset of the neurologic disturbance is usually subacute, with a mild and fluctuating confusion, somnolence, difficulty in concentration, tremulousness, and sometimes hallucinations and delusions. With continued ingestion of bismuth, there occurs a rapid (24 to 48 h) worsening of the confusion and tremulousness, along with diffuse myoclonic jerks, seizures, ataxia, and inability to stand or walk. These symptoms regress over a few days to weeks when the bismuth is withdrawn, but some patients have died of acute intoxication. High concentrations of bismuth were found in the cerebral and cerebellar cortices and in the nuclear masses throughout the brain. These concentrations can be recognized as hyperdensities in the CT scan (Buge et al).

Industrial Toxins

Some of these, the heavy metals, already have been considered. In addition, a large number of synthetic organic compounds are widely used in industry and are frequent sources of toxicity, and the list is constantly being expanded. The reader is referred to the references at the end of the chapter, particularly to the most current text, edited by Spencer and Schaumburg, for details

concerning these compounds. Here we can do little more than enumerate the most important ones: chlorinated diphenyls (e.g., dichlorodiphenyltrichloroethane [DDT]) or chlorinated polycyclic compounds (Kepone), used as insecticides; diethylene dioxide (Dioxane); carbon disulfide; the halogenated hydrocarbons (methyl chloride, tetrachloroethane, carbon tetrachloride, trichloroethylene, and methyl bromide); naphthalene (used in moth repellants); benzene (gasoline); benzene and its derivatives (toluene, xylene, nitrobenzene, phenol, and amyl acetate [banana oil]); and the hexacarbon solvents (*n*-hexane and methyl-*n*-butyl ketone).

With a few exceptions, the acute toxic effects of these substances are much the same from one compound to another. In general, the primary effect is on nonneurologic structures. Neural symptoms consist of varying combinations of headache, restlessness, drowsiness, confusion, delirium, coma, and convulsions, which, as a rule, occur late in the illness or preterminally. Some of these industrial toxins (carbon disulfide, carbon tetrachloride and tetrachloroethane, acrylamide, *n*-hexane, and diethylene glycol [Sterno; see Rollins]) may cause polyneuropathy, which becomes evident with recovery from acute toxicity.

Extrapyramidal symptoms may result from chronic exposure to carbon disulfide. A syndrome of persistent fatigue, lack of stamina, inability to concentrate, poor memory, and irritability has also been attributed to chronic exposure to solvents, but these symptoms are quite nonspecific, and evidence for such a syndrome is unsupported by convincing experimental or epidemiologic studies.

Of the aforementioned industrial toxins, the ones most likely to cause neurologic disease are *toluene* (methyl benzene) and the *hexacarbon*s. The chronic inhalation of fumes containing toluene (usually in glue, contact cement, or certain brands of spray paint) may lead to severe and irreversible tremor and cerebellar ataxia, affecting movements of the eyes (opsoclonus, ocular dysmetria) and limbs, as well as stance and gait. Cognitive impairment is usually associated; corticospinal tract signs, progressive optic neuropathy, sensorineural hearing loss, and hyposmia occur in some patients. Generalized cerebral atrophy and particularly cerebellar atrophy are evident in CT scans (Fornazzari et al; Hormes et al). Also, it has become apparent that acute toluene intoxication is an important cause of seizures, hallucinations, and coma in children (King et al).

The prolonged exposure to high concentrations of *n*-hexane or methyl-*n*-butyl ketone may cause a sensorimotor neuropathy, so-called glue-sniffer's neuropathy (see Chap. 46). These solvents are metabolized to 2,5-hexanedione, which is the agent that damages the peripheral nerves. The neuropathy may result from exposure in certain industrial settings (mainly the manufacture of vinyl products) or, more often, from the deliberate inhalation of vapors from solvents, lacquers, glue, or glue thinners containing *n*-hexane (see also Chap. 46). Impure trichloroethylene, through its breakdown product dichloroacetylene, has a predilection for the trigeminal nerve, which can be damaged selectively.

Hydrogen peroxide poisoning, usually by accidental ingestion, causes multiple small cerebral infarcts through a mechanism of gas embolus (Ijichi et al). Most cases have been reversible. According to Humberston and colleagues (cited by Ijichi et al) 120 mL of 35 percent hydrogen peroxide releases 14 L of oxygen on contact with organic tissue. The lung is involved, and the unmistakable brain lesions consist of tiny gas bubbles concentrated in parasagittal watershed areas.

ANTINEOPLASTIC AND IMMUNOSUPPRESSIVE AGENTS

The increasing use of potent antineoplastic agents has given rise to a diverse group of neurologic complications, the most important of which are summarized here. A more detailed account of these agents—as well as the neurologic complications of corticosteroid therapy, immunosuppression, and radiation—can be found in the monograph edited by Rottenberg and in the review of Tuxen and Hansen and in appropriate chapters of the book. The neurotoxic effects of certain agents used in the treatment of brain tumors are specifically considered in Chap. 31.

Vincristine

This drug is used in the treatment of acute lymphoblastic leukemia, lymphomas, and some solid tumors. Its most important toxic side effect, and the one that limits its use as a chemotherapeutic agent, is a peripheral neuropathy. Paresthesias of the feet, hands, or both may occur within a few weeks of the beginning of treatment; with continued use of the drug, a progressive symmetrical neuropathy evolves (mainly sensory with reflex loss). Cranial nerves are affected less frequently, but ptosis and lateral rectus, facial, and vocal cord palsies have been observed. Autonomic nervous system function may also be affected: constipation and impotence are frequent complications; orthostatic hypotension, atonicity of the bladder, and adynamic ileus are less frequent. The polyneuropathy caused by vincristine is described more fully in Chap. 46. Inappropriate antidiuretic hormone secretion and seizures have been reported but are uncommon.

Although rarely noted in the literature, the authors have seen an instance of reversible posterior leukoencephalopathy with cortical blindness and headache after a single dose of vincristine, identical to the syndrome reported with the use of calcineurin inhibitors (see further on).

The neural complications of *vinblastine* are similar to those of vincristine but are usually avoided because bone marrow suppression limits the dose of the drug that can safely be employed. *Vinorelbine* is a more recently introduced semisynthetic vinca alkaloid. It has much the same antitumor activity as vincristine but is supposedly less toxic.

Cisplatin

Cisplatin, a heavy metal that inhibits DNA synthesis, is effective in the treatment of gonadal and head and neck

tumors, as well as carcinoma of the bladder, prostate, and breast. The dose-limiting factors in its use are nephrotoxicity and vomiting and a peripheral neuropathy (see Chap. 46). The latter manifests itself by numbness and tingling in fingers and toes, sometimes painful—symptoms that are being observed with increasing frequency. This toxic manifestation appears to be related to the total amount of drug administered, and it usually improves slowly after it has been discontinued. Biopsies of peripheral nerve have shown a primary axonal degeneration. Approximately one-third of patients receiving this drug also experience tinnitus or high-frequency hearing loss or both. Ototoxicity is also dose related, cumulative, and only occasionally reversible. Retrobulbar neuritis occurs rarely. Seizures associated with drug-induced hyponatremia and hypomagnesemia have been reported.

Paclitaxel and Docetaxel

Taxol (paclitaxel) and Taxotere (docetaxel) are newer anticancer drugs derived from the bark of the western yew. Both are particularly useful in the treatment of ovarian and breast cancer, but they have a wide range of antineoplastic activities. A purely or predominantly sensory neuropathy is a common complication. These drugs are thought to cause neuropathy by their action as inhibitors of the depolymerization of tubulin, thereby promoting excessive microtubule assembly within the axon. The neuropathy is dose-dependent, occurring with doses greater than 200 mg/m² of paclitaxel and at a wide range of dose levels for docetaxel (generally greater than 600 mg/m²). Symptoms may begin 1 to 3 days following the first dose and affect the feet and hands simultaneously. Autonomic neuropathy (orthostatic hypotension) may occur as well. The neuropathy is axonal in type, with secondary demyelination, and is at least partially reversible after discontinuation of the drug.

Procarbazine

This drug, originally synthesized as an MAO inhibitor, is now an important oral agent in the treatment of Hodgkin disease and other tumors. It has also proved to be especially effective in the treatment of oligodendrogliomas. Neural complications are infrequent and usually take the form of somnolence, confusion, agitation, and depression. Diffuse aching pain in proximal muscles of the limbs and mild symptoms and signs of polyneuropathy occur in 10 to 15 percent of patients treated with relatively high doses. A reversible ataxia has also been described. Procarbazine, taken in conjunction with phenothiazines, barbiturates, narcotics, or alcohol, may produce serious degrees of oversedation. Other toxic reactions, such as orthostatic hypotension, are related to its inhibition of MAO.

L-Asparaginase

This enzymatic inhibitor of protein synthesis is used in the treatment of acute lymphoblastic leukemia. Drowsiness, confusion, delirium, stupor, coma, and diffuse EEG slowing are the common neurologic effects and are dose related

and cumulative. They may occur within a day of onset of treatment and clear quickly when the drug is withdrawn, or they may be delayed in onset, in which case they persist for several weeks. These abnormalities are at least in part attributable to the systemic metabolic derangements induced by L-asparaginase, including liver dysfunction.

In recent years, increasing attention has been drawn to cerebrovascular complications of L-asparaginase therapy, including ischemic and hemorrhagic infarction and cerebral venous and dural sinus thrombosis. Fineberg and Swenson analyzed the clinical features of 38 such cases. These cerebrovascular complications are attributable to transient deficiencies in plasma proteins that are important in coagulation and fibrinolysis.

5-Fluorouracil

This is a pyrimidine analogue, used mainly as a secondary treatment of cancer of the breast, ovary, and gastrointestinal tract. A small proportion of patients receiving this drug develop dizziness, cerebellar ataxia of the trunk and the extremities, dysarthria, and nystagmus—symptoms that are much the same as those produced by cytarabine (ara-C; see below). These abnormalities must be distinguished from metastatic involvement of the cerebellum and paraneoplastic cerebellar degeneration. The drug effects are usually mild and subside within 1 to 6 weeks after discontinuation of therapy. The basis of this cerebellar syndrome is unknown.

Methotrexate (See also Chap. 31)

Administered in conventional oral or intravenous doses, methotrexate (MTX) is not usually neurotoxic. However, given intrathecally to treat meningeal leukemia or carcinomatosis, MTX commonly causes aseptic meningitis, with headache, nausea and vomiting, stiff neck, fever, and cells in the spinal fluid. Very rarely, probably as an idiosyncratic response to the drug, intrathecal administration results in an acute paraplegia that may be permanent. The pathology of this condition has not been studied.

The most serious and more common of the neurologic problems associated with systemic MTX chemotherapy is leukoencephalopathy or leukomyelopathy, especially when it is given in combination with cranial or neuraxis radiation therapy. This develops several months after repeated intrathecal or high systemic doses of the drug, and a few milder cases are known to have occurred without radiation treatments, i.e., with oral or intravenous MTX alone, such as the case reported by Worthley and McNeil. We have seen one such instance in a woman receiving oral MTX for a systemic vasculitis; no alternative explanation for widespread white matter changes and mild dementia could be discerned. Nonetheless, this must be quite uncommon. The full-blown syndrome consists of the insidious evolution of dementia, pseudobulbar palsy, ataxia, focal cerebral cortical deficits, or paraplegia. Milder cases show only radiographic evidence of a change in signal intensity in the posterior cerebral white matter ("posterior leukoencephalopathy") that is similar to the

Figure 43-1. Toxic reversible posterior leukoencephalopathy. Axial fluid-attenuated inversion recovery (FLAIR) MRI in a patient with cortical blindness and severe headache days after receiving vincristine. This syndrome and radiographic findings are more typical following the use of cyclosporine, FK-506, and other chemotherapies. Compare this image to the similar conditions of hypertensive encephalopathy and toxemia shown in Fig. 34-29.

imaging findings that follow cyclosporine use (see further on) and hypertensive encephalopathy (Fig. 43-1). In severe cases, the brain shows disseminated foci of coagulation necrosis of white matter, usually periventricular, which can be detected with CT and MRI.

Mineralizing microangiopathy (fibrosis and calcification of small vessels, mainly in the basal ganglia) is yet another complication of MTX therapy. It may occur with MTX treatment or with cranial irradiation but is particularly common when both forms of treatment are combined. The present authors have the impression that the severe necrotic lesions possess features comparable to (and therefore may be the result of) the coagulative necrosis of radiation encephalopathy.

The Nitrosoureas

Carmustine (BCNU) and lomustine (CCNU) are nitrosoureas used to treat malignant cerebral gliomas. They are not neurotoxic when given in conventional intravenous doses, but intracarotid injection of the drugs may cause orbital, eye, and neck pain, focal seizures, confusion, and possibly focal neurologic deficits. Postmortem examinations of patients who had been treated with intravascular BCNU have disclosed a diffuse vasculopathy

characterized by fibrinoid necrosis and microthrombi and diffuse foci of swollen axis cylinders and myelin vacuolization (Burger et al; Kleinschmidt-de Masters).

Cytarabine (Ara-C)

This drug, long used in the treatment of acute nonlymphocytic leukemia, is not neurotoxic when given in the usual systemic daily doses of 100 to 200 mg/m². The administration of very high doses (up to 30 times the usual dose) induces remissions in patients' refractory to conventional treatments. It also may produce, however, a severe degree of cerebellar degeneration in a considerable proportion of cases (4 of 24 reported by Winkelman and Hines). Ataxia of gait and limbs, dysarthria, and nystagmus develop as early as 5 to 7 days after the beginning of high-dose treatment and worsen rapidly. Postmortem examination has disclosed a diffuse degeneration of Purkinje cells, most marked in the depths of the folia, as well as a patchy degeneration of other elements of the cerebellar cortex. Other patients receiving high-dose ara-C have developed a mild, reversible cerebellar syndrome with the same clinical features. Because patients older than 50 years of age are said to be far more likely to develop cerebellar degeneration than those younger than 50 years of age, the former should be treated with a lower dosage (Herzig et al).

Calcineurin Inhibitors (Cyclosporine, Tacrolimus, Sirolimus)

These immunosuppressive drugs are used to prevent transplant rejection and to treat aplastic anemia and certain intrinsic immune diseases. Tremor is perhaps the most frequent side effect and myoclonus may be added. Sometimes these impart a stuttering character to speech. Headache and insomnia are common. Seizures may be a manifestation of toxicity, but the cause may lie with the other complications of organ transplantation and immunosuppression. Wijdicks has reviewed the neurologic effects of these drugs.

A posterior leukoencephalopathy syndrome (PRES, see Chap. 34) resembling hypertensive encephalopathy—headache, vomiting, confusion, seizures, and visual loss (cortical blindness)—may follow the use of either drug and with an expanding list of other agents including some of the new monoclonal antibodies used in the treatment of cancer and autoimmune diseases (Table 43-1). There does not seem to be a consistent dose-response effect, drug levels often being in the therapeutic range.

The appearance on CT scans and MRI of symmetrical signal and density changes mainly in the posterior white matter likewise conform to the pattern that is seen in hypertensive encephalopathy (reversible posterior leukoencephalopathy [RPLE] or PRES). Lesions may also appear subcortically in the frontal and parietal lobes. Interferon treatment for malignant melanoma and a number of other chemotherapeutic agents have been associated with the same condition. Hinchey and colleagues have described several such cases and suggested that cyclosporine alters the blood-brain

Table 43-1

NON-VASCULAR CAUSES OF REVERSIBLE POSTERIOR LEUKOENCEPHALOPATHY (SEE ALSO CHAP. 34)

Methotrexate (intravenous and rarely oral)
Calcineurin inhibitors (cyclosporine, tacrolimus, sirolimus)
Cyclophosphamide
Interferon (intravenous)
L-Asparaginase
Vincristine
Cisplatin
Cytarabine
Gemcitabine
Doxorubicin
Etoposide
Intravenous immunoglobulin
Granulocyte colony stimulating factor
Erythropoietin
Rituximab
Surafinib
Sunitinib
Bevacizumab
Combination chemotherapies, particularly those including cyclophosphamide or cytarabine

barrier and that the fluid overload and hypertension which accompanies the use of cyclosporine underlies the radiologic changes. A variety of psychotic syndromes with delusions, paranoia, and visual hallucinations also have been ascribed to the use of these drugs (see Wijdicks).

Thalidomide

Despite the catastrophic effects of thalidomide on the developing fetus (following its introduction as a soporific in 1957), this drug has now found several specific uses in the treatment of immunologic, neoplastic, and infectious diseases. It is effective in the treatment of leprosy, erythema nodosum, and the oral ulcerations of AIDS and Behçet disease. Experimental uses include suppression of graft-versus-host reactions and inhibition of blood vessel proliferation in vascular tumors such as renal cell cancer. A dose-dependent sensory neuropathy is the limiting factor in its use, and serial electrophysiologic testing is recommended if the medication is to be prescribed for protracted periods. Of course, it must not be given to a woman who is or might be pregnant.

Antibiotics and Other Medications

Numerous antibiotics, cardioactive medications, and other drugs may have adverse effects on the central or peripheral nervous system. Some of the latter are addressed in Chap. 46. Here we mention mainly that penicillin and its derivatives such as imipenem, and to a lesser degree, the cephalosporins, are capable of causing seizures when high serum concentrations are attained. This is favored in most instances by concomitant renal failure.

Other important examples of antibiotic toxicity are optic neuropathy caused by ethambutol toxicity; ototoxicity and neuromuscular blockade from aminoglycoside and

fluoroquinolone antibiotics (see Chap. 41); peripheral neuropathy, encephalopathy, and an Antabuse-like reaction to alcohol in patients taking metronidazole; a metronidazole-induced polyneuropathy, isoniazid (INH) neuropathy and optic neuropathy, and possibly a peripheral neuropathy caused by chloramphenicol.

Woodruff and colleagues, as well as others, reported a curious and reversible cerebellar syndrome caused by *metronidazole* with MRI signal changes in the dentate nuclei, or more widespread signal changes in other parts of the brainstem and cerebral white matter as noted by Kim and coworkers, who carried out an MIR study of 7 patients. Dysarthria, confusion, and gait ataxia seem to form the core of the clinical syndrome but imaging changes may be found coincidentally as well.

The most notorious toxic consequences with this group of drugs were seen with *clioquinol*, which was sold as Entero-Vioform and was used in many parts of the world to prevent traveler's diarrhea and as a treatment for chronic gastroenteritis. In 1971, clinical observations began to appear in medical journals of a subacute myelo-optic neuropathy (SMON). During the 1960s, more than 10,000 cases of this disease were collected in Japan by

Tsubaki and colleagues. Usually the illness began with ascending numbness and weakness of the legs, paralysis of sphincters, and autonomic disorder. Later, vision was affected. The onset was acute in about two-thirds of the cases and subacute in the remainder. The occurrence of these neurologic complications was found to be related to the prolonged use of clioquinol. In Japan, the drug was withdrawn from the market, and the incidence of SMON immediately fell, supporting the theory that it was caused by the drug. Recovery was usually incomplete.

Also mentioned here, because neurologists are often asked to consult on these cases, is a curious effect of the anesthetic propofol. Seizures and myoclonic-like movements have been seen in a small number of individuals, presumably as an idiosyncratic effect. Sometimes these take the form of less-organized twitching, opisthotonus, or involuntary movements. Some inhaled anesthetics such as enflurane can cause seizures in susceptible patients. In our own experience, the seizures have occurred in the first hour after emergence from anesthesia, but as many cases are reported with seizures occurring during induction, emergence, and after the use of the drug (see Walder).

PART 5

DISEASES OF SPINAL CORD, PERIPHERAL NERVE, AND MUSCLE

This page intentionally left blank

Diseases of the Spinal Cord

Diseases of the nervous system may be confined to the spinal cord where they produce a number of distinctive syndromes. These relate to the special anatomic features of the cord, such as its prominent function in sensorimotor conduction and relatively primitive reflex activity; its long, cylindrical shape; its small cross-sectional size; the peripheral location of myelinated fibers next to the pia; the special arrangement of its blood vessels; and its intimate relationship to the vertebral column. Woolsey and Young estimated that approximately 30 diseases are known to affect the spinal cord, of which half are seen with regularity. These processes express themselves in a number of readily recognized ways and, as will be evident, certain diseases preferentially produce special syndromes. This syndromic grouping of the spinal cord disorders, which is in keeping with the general plan of this book, greatly facilitates clinical diagnosis.

The main syndromes considered in this chapter are (1) a complete or almost complete sensorimotor myelopathy that involves most or all of the ascending and descending tracts (transverse myelopathy); (2) a combined painful radicular and transverse cord syndrome; (3) the hemicord (Brown-Séquard) syndrome; (4) a ventral cord syndrome, sparing posterior column function; (5) a high cervical–foramen magnum syndrome; (6) a central cord or syringomyelic syndrome; (7) a syndrome of the conus medullaris; and (8) a syndrome of the cauda equina. In addition, an important distinction is made between lesions within the cord (*intramedullary*) and those that compress the cord from without (*extramedullary*). Some of the anatomic and physiologic considerations pertinent to an understanding of disorders of the cord and of the spine can be found in Chaps. 3, 9 (Figs. 9-5 and 9-7), and Chap. 11, on motor paralysis, somatic sensation, and back pain, respectively. The typical spinal cord syndromes are represented most perfectly by tumor compression that originates in an adjacent vertebral body; this important process is therefore described as a model in the introductory section and again in a later part of the chapter.

THE SYNDROME OF ACUTE PARAPLEGIA OR QUADRIPLÉGIA CAUSED BY TRAUMATIC AND OTHER PHYSICAL FACTORS (TRANSVERSE MYELOPATHY)

This syndrome is best considered in relation to trauma, its most frequent cause, but it occurs also as a result of other acute damage including infarction or hemorrhage and with rapidly advancing compressive, necrotizing, demyelinating, or inflammatory lesions. Each of these categories of acute spinal cord disease is discussed in the following pages. For convenience we have included in this group radiation myelopathy, which is transverse but evolves subacutely.

Traumatic Injuries of the Spine and Spinal Cord

Throughout recorded medical history, advances in the understanding of spinal cord disease have coincided largely with periods of warfare. The first thoroughly documented study of the effects of sudden total cord transection was by Theodor Kocher in 1896, based on his observations of 15 patients. During World War I, Riddoch, and later Head and Riddoch, gave what are now considered the classic descriptions of spinal transection in humans; Lhermitte and Guillain and Barré are credited with refining those observations. Little could be done for patients in that era and fully 80 percent died in the first few weeks (from infections); survival was possible only if the spinal cord lesion was partial. World War II marked a turning point in the understanding and management of spinal injuries. The advent of antibiotics and the ability to control skin, bladder, and pulmonary infections permitted the survival of unprecedented numbers of soldiers with cord injuries and provided the opportunity for long-term observation. In special centers, and the care and rehabilitation of the paraplegic patient were brought to a high level. Studies conducted

in these centers greatly enhanced our knowledge of the functional capacity of the chronically isolated spinal cord. Kuhn, Munro, Martin and Davis, Guttman, Pollock, and Pollock and associates made particularly important contributions to this subject.

Mechanisms of Spinal Injury

The usual circumstances of spinal cord injury, in approximate order of frequency in civilian practice are motor vehicle and motorcycle accidents, falls (sometimes during a state of alcoholic intoxication), gunshot or stab wounds, diving accidents, crushing industrial injuries, and birth injury. In the United States, the annual incidence of spinal cord injury has been given as 5 cases per 100,000 population; males predominate (4:1). Each year approximately 3,500 persons die in relation to their spinal injury, and another 5,000 are left with complete or nearly complete loss of spinal cord function.

Although trauma may involve the spinal cord alone, the vertebral column is almost invariably injured at the same time. Often there is an associated cranial injury as pointed out in Chap. 35.

A useful classification of *vertebral column injuries* divides them into fracture–dislocations, pure fractures, and pure dislocations. The spinal cord that is situated beneath any of these injuries is traumatized by direct compression as a result of dislocation of spinal bones, or by buckling of the ligaments inside the spinal canal. The relative frequency of the three types is about 3:1:1. Except for bullet, shrapnel, and stab wounds, a direct blow to the spine is a relatively uncommon cause of serious spinal cord injury. In civilian life, most fractures and dislocations of the spinal column are the result of force applied at a distance from the site of the disruption of the spinal column. Specifically, all three types of spinal injury are typically produced by a vertical compression of the spinal column, to which either anteroflexion or retroflexion (hyperextension) is added. The most important variables in the mechanics of vertebral injury are the structure of the bones and ligaments at the level of the injury and the intensity, direction, and point of impact of the force. The main elements of the spine are illustrated in Chap. 11.

In keeping with the mechanism of force applied at a distance, blows to the head may result in cervical spinal injuries. If a hard object at high velocity strikes the cranium, a skull fracture occurs, the force of the injury being absorbed mainly by the elastic quality of the skull. If the traumatizing force is relatively soft yet unyielding, or is applied more slowly, the spine, and particularly its most mobile (cervical) portion, will be the part injured. If the neck happens to be rigid and straight and the force is applied quickly to the head, the atlas and the odontoid process of the axis may fracture.

In the case of *cervical flexion injury*, the head has usually been bent sharply forward when the force is applied. The cervical vertebrae are forced together at the level of maximum stress, driving the anteroinferior edge of the upper vertebral body into the one below, sometimes splitting it in two. The posterior part of the fractured body is displaced backward and compresses the cord.

Concomitantly, there is tearing of the interspinous and posterior longitudinal ligaments. Less severe degrees of anteroflexion injury produce only dislocation of adjacent cervical vertebrae at one of several levels. Vulnerability to the effects of anteroflexion (and to some extent to retroflexion injuries) is increased by the presence of cervical spondylosis or ankylosing spondylitis or by a congenital narrowness of the spinal canal.

In *cervical hyperextension injuries*, the mechanism is one of vertical compression with the head in an extended position. Stress is mainly on the posterior elements (the laminae and pedicles) of the midcervical vertebrae (C4 to C6), or sometimes at higher levels (see the named fractures below), which may be fractured unilaterally or bilaterally, and on the anterior ligaments. This dual disruption in the spinal architecture allows for displacement of one vertebral body upon the adjacent one and compresses the cord between the laminae of the lower vertebra and the body of the one above.

However, spinal cord trauma may also occur from hyperextension injury without apparent damage or misalignment of the vertebrae. In these instances, the spinal cord damage, which can be nonetheless profound and permanent, is considered to be caused by a sudden inward bulge of the ligamentum flavum or by transient vertebral dislocation that is permitted because of ligamentous disruption; when viewed with imaging studies, the vertebral bodies are found to have spontaneously realigned. In such cases, rupture of the supporting ligamentous elements and spinal instability can be revealed by gentle flexion and extension of the neck under radiologic observation, which demonstrates movement of the vertebra in relation to an adjacent one. CT and plain lateral spine films are satisfactory means of demonstrating the vertebral injury but the tearing and bulging of ligaments from vertebral dislocation are more dependably demonstrated by MRI.

Another potential mechanism of cord and spinal root injury involving extremes of extension and flexion of the neck is so-called whiplash or recoil injury, most often the result of an automobile accident. When a vehicle is struck sharply from behind, the head of the occupant is flung back uncontrollably, or if a fast-moving vehicle stops abruptly, there is sudden forward flexion of the neck, followed by retroflexion. Under these conditions the occipitonal and sternocleidomastoid muscles and other supporting structures of the neck and head are affected much more often than the spinal cord or roots. Nevertheless, in rare instances, quadriparesis, temporary or permanent, results from a violent whiplash injury. The exact mechanism of neural injury in these circumstances is not clear; perhaps there is a transient posterior dislocation of a vertebral body, a momentary buckling of the ligamentum flavum, or retropulsion of the intervertebral disc into the spinal canal. Other ostensible results of whiplash, such as dizziness, are highly controversial and are discussed in Chap. 11. However, the main comment to be made regarding whiplash is that all manner of neurologic symptoms have been uncritically and inappropriately

attributed to it, often with implications for medicolegal and disability determinations.

The presence of a congenitally narrow cervical spinal canal or of acquired spinal diseases such as cervical spondylosis, rheumatoid arthritis, or ankylosing spondylitis adds greatly to the hazard of damage to the cord or roots. Neck trauma of almost any configuration may in particular aggravate preexisting spondylotic symptoms. There are in addition examples of spinal cord compression that result from prolonged static hyperextension of the cervical spine during a protracted period of stupor. This accounts for some cases of quadriplegia following a period of sustained unresponsiveness due to opiate or sedative drug overdose (Ell et al). Arterial hypotension may be an added factor in some instances.

A special type of spinal cord injury, occurring most often in wartime, is one in which a high-velocity missile penetrates the vertebral canal and damages the spinal cord directly. In some cases the missile strikes the vertebral column without entering the spinal canal but disrupts and virtually shatters the intradural contents or produces lesser degrees of spinal cord dysfunction. Or, the transmitted shock wave from a bullet passing nearby the vertebral column causes paralysis of spinal cord function that is largely reversible in a day or two (*spinal cord concussion*, which is described further on).

Acute traumatic paralysis may also be the indirect consequence of a vascular mechanism, mainly through infarction from fibrocartilaginous emboli arising in an intervertebral disc that has ruptured into a radicular artery or vein of the cord. Or a traumatic dissecting aneurysm of the aorta may occlude the segmental arteries of the spinal cord, as in the cases reported by Weisman and Adams and by Kneisley. One striking variant of this type of vascular injury is infarction of the upper cervical cord, resulting in hemi-, tri-, or tetraplegia, from dissection of one or both vertebral arteries and occlusion of their tributary anterior spinal arteries at the cervicomedullary junction.

Vertebral fracture and dislocation An analysis from a former era of 2,000 cases of spinal injury collected from the medical literature by Jefferson up to 1927 is still valid and showed that most vertebral injuries occurred at the levels of the first and second cervical, fourth to sixth cervical, and eleventh thoracic to second lumbar vertebrae. Industrial accidents most often involved the thoracolumbar vertebrae. Impact to the head with the neck flexed or sharply retroflexed, as mentioned earlier, was the main cause of injuries to the cervical region. These are not only the most mobile portions of the vertebral column but also the regions in which the cervical and lumbar enlargements of the cord greatly reduce the space between neural and bony structures. The thoracic cord is relatively small and its spinal canal is capacious; additional protection is provided by the high and overlapping articular facets, making dislocation difficult, and limitations in anterior displacement of vertebral bodies imposed by the thoracic cage.

Several configurations of vertebral fractures are common enough that they are designated by eponyms

or descriptive terms. The knowledgeable clinician has some familiarity with them. They are summarized in Table 44-1. They include the Jefferson fracture, hangman's fracture, the Chance fracture, atlanto-axial (C1-C2) and the more common atlanto-occipital fracture-dislocation, including fracture of the dens of C-2. Regarding hangman's fracture, contrary to the popular notion, most penal hangings do not cause vertebral bony disruption and death is instead by strangulation; a more common mechanism for hangman's fracture is an elderly person who falls and strikes the chin, causing hyperextension of the neck. The majority of fatal cases of cervical spine injury are from fracture-dislocations of the upper cervical spine (C1 to C3 vertebrae, thus encompassing atlanto-occipital and atlanto-axis dislocations with sudden respiratory paralysis).

Acute Evaluation of the Spine-Injured Patient

The level of the spinal cord damage and, by implication, the level of disruption of the spinal column, can be determined from clinical findings. Diaphragmatic paralysis occurs with lesions of the upper three cervical segments (transient arrest of breathing from brainstem paralysis is common in severe head injury). Complete paralysis of the arms and legs usually indicates a fracture or dislocation at the fourth to fifth cervical vertebrae. If the legs are paralyzed and the arms can still be abducted and flexed, the lesion is likely to be at the fifth to sixth cervical vertebrae. Paralysis of the legs and only the hands indicates a lesion at the sixth to seventh cervical level. Below the cervical region, the spinal cord segments and roots are not directly opposite their similarly numbered vertebrae (Fig. 44-1). The spinal cord ends at the first lumbar vertebra, usually at its rostral border. Vertebral column lesions below this point give rise predominantly to cauda equina syndromes; these carry a better prognosis than injuries to the lower thoracic vertebrae, which involve both cord and multiple roots.

The level of sensory loss on the trunk, as determined by perception of pinprick, is an accurate guide to the level of the lesion, with a few qualifications. (See Figs. 9-1, 9-3, and 9-4 for maps of the sensory dermatomes.) Lesions of the lower cervical cord, even if complete, may spare sensation down to the nipple line because of the contribution of the C3 and C4 cutaneous branches of the cervical plexus, which variably innervate skin below the clavicle. Or a lesion that involves only the outermost fibers of the spinothalamic pathways results in a sensory level (to pain and temperature) well below the level of the lesion. In all cases of spinal cord and cauda equina injury, the prognosis for recovery is more favorable if any movement or sensation is elicitable during the first 48 to 72 h.

If the spinal column can be examined safely, it should be inspected and palpated for angulations or irregularities and gently percussed to detect underlying bony injury. Collateral injury of the thorax, abdomen, and long bones should be sought and cranial injury is a concern if the mechanism of direct spinal impact is not known from the history.

Table 44-1

MAJOR VERTEBRAL FRACTURES AND DISLOCATIONS

NOMENCLATURE	MECHANISM	IMAGING	STABILITY	CLINICAL EFFECTS ^a
Atlanto-occipital dislocation	Rotatory force to head	Displacement of occipital condyles in relation to lateral masses of C1	Unstable	Common in children; fatal if severe
Atlanto-axial dislocation	Rotatory mechanism common in children; flexion in adults	Dislocation of C1-C2 facet	Unstable	Varies from asymptomatic to severe myelopathy
Jefferson fracture (C1)	Axial downward force on vertex of head	Bilateral anterior and posterior arch fractures	Stable	Usually asymptomatic; transverse ligament may be disrupted
Odontoid (dens) fractures (C2)	Hyperflexion	Fracture through C2 ^b : Type 1: tip of dens Type 2: base of dens Type 3: body of C2	Type 2 most "unstable" and unlikely to heal spontaneously	Varies from asymptomatic to tetraparesis
Hangman's fracture (C2)	Hyperextension with axial loading	Fractures through pedicles of C2	Usually stable	Most are asymptomatic
Subaxial fracture-dislocation	Severe flexion	Dislocation (perched or jumped) of facets with reversal of normal "shingled" appearance	Poor	Occurs at any level C3 to T1; common cause of traumatic tetra- and quadriplegia; vertebral artery dissection
Burst fracture (thoracolumbar)	Axial loading	Fracture through vertebral body with loss of height	Variable	Root compression from retropulsion of bone fragment
Chance fracture (thoracolumbar)	Flexion of lower thoracic spine—"seat-belt" injury	Same as burst fracture but includes fractures through facets and posterior elements	Variable	Commonly asymptomatic
Compression (wedge) fracture (thoracolumbar)	Hyperflexion	Wedging of anterior vertebral body, no loss of height and no subluxation	Usually stable	Local pain, rarely neurologic deficit

^aPain at the site of the fracture or dislocation is common to all these injuries.

^bThese features are in addition to local pain over the site of the vertebral injury.

A neurologic examination with recording of motor, sensory, and sphincter function is necessary to follow the clinical progress of spinal cord injury. A common practice is to define the injury according to the standards of the American Spinal Injury Association and to assign the injury to a point on the ASIA Impairment, or AIS (a derivative of the formerly used Frankel scale). A paraphrased version that we have found useful is presented here with comments regarding functional ability from the Frankel scale:

- A. *Complete*: no sensory or motor function below the level of the lesion including in the sacral segments
- B. *Sensory incomplete*: sensory function is preserved but motor function is lost below the zone of injury
- C. *Motor incomplete* (first grade): motor function is reduced in *more than half* of key muscles below the level of the lesion; this usually renders the patient unable to walk. (Reduced motor function is defined

as active movement in a full range of motion only if gravity is eliminated.)

- D. *Motor incomplete* (second grade): motor function is reduced in *fewer than half* of key muscles below the level of the lesion; this usually allows standing and walking
- E. *Normal*: reflexes may be abnormal

Obviously, groups C, D, and E have a more favorable prognosis for recovery of ambulation than does groups A and B.

In cases of suspected spinal injury, the immediate concern is that movement (especially flexion) of the cervical spine be avoided. The patient should ideally be placed supine on a firm, flat surface (with one person assigned, if possible, to keeping the head and neck immobile) and should be transported by a vehicle that can accept the litter. The board may be placed under the patient, gently

Figure 44-1. The relationship of spinal segments and roots to the vertebral bodies and spinous processes. The cervical roots (except C8) exit through foramina above their respective vertebral bodies, and the other roots issue below these bodies. (From Haymaker and Woodhall: *Peripheral Nerve Injuries*, 2nd ed. Philadelphia, Saunders, 1953, by permission.)

rolling him to one side with the head, neck, and body held in alignment. If moving the patient is not feasible, the neck may be immobilized in place with a form collar or an equivalent device that is contrived at the scene, or even the examiner's hands held firmly along the cervical spine. The patient should ideally be transported by an ambulance equipped with spine boards, to which the head is fixed by straps. This provides a more effective means of immobilization than sandbags or similar objects placed on each side of the head and neck. On arrival at the hospital, it is prudent to have the cervical spine remain immobilized until a lateral film or a CT or MRI of the cervical spine can be obtained, with the qualifications below.

Several schemes have been devised for determining which patients may require imaging; these are comparable to "rules" for the use of imaging in head injury that are discussed in Chap. 35. The two more widely cited ones for spinal injury are those of the NEXUS group (Hoffman et al) and the "Canadian C-spine Rule" (Stiell et al). The former identifies those at low risk for spinal cord injury on the basis of the absence of posterior midline cervical-spine tenderness, no evidence of intoxication, a normal level of alertness (thereby allowing accurate reporting of the circumstances of injury and the presence of neck pain, and suggesting there has not been serious brain injury), no focal neurologic deficit, and no other painful injuries that distract the patient from reporting neck pain. The Canadian rule has been found to be slightly more sensitive and specific (this has been disputed); it is based on three high-risk criteria: age older than 65 years, a dangerous mechanism of injury, and limb paresthesias; and on any of six features that are associated with low-risk of cord injury: simple rear-end motor vehicle collision, sitting position in the emergency department, being ambulatory at any time after injury, delayed (not immediate) onset of neck pain, absence of midline cervical-spine tenderness, coupled with the ability to turn the head 45 degrees in both directions without pain.

Pathology of Traumatic Spinal Cord Injury

As a result of squeezing or shearing of the spinal cord, there is destruction of gray and white matter and a variable amount of hemorrhage, chiefly in the more vascular central parts. These changes, designated as *traumatic necrosis* of the cord, are maximal at the level of injury and at one or two segments above and below it. Rarely is the cord cut in two, and seldom is the pia-arachnoid lacerated. Separation of the components of traumatic necrosis, such as *hematomyelia*, *concussion*, *contusion*, and *hematorrhachis* (bleeding into the spinal canal) is not of great value either clinically or pathologically. As the lesion heals, it leaves a gliotic focus or cavitation with variable amounts of hemosiderin and iron pigment. Progressive cavitation (*traumatic syringomyelia*) may develop after an interval of months or years and, as the cavity enlarges beyond the main lesion, lead to a delayed central or incomplete transverse cord syndrome. In some instances, the lesion is virtually restricted to the centrally situated gray matter, giving rise to segmental weakness and sensory loss in the arms with few long tract signs. This is

the *central cervical cord syndrome*, also called the *Schneider syndrome* (see further on). Fragments of the central cord syndrome commonly occur as transient phenomena that reverse over several days.

Experimental Spinal Cord Injury

Investigation of the pathophysiology of acute spinal cord injury dates from the experimental studies of Allen in the early 1900s. His method consisted of dropping graded weights onto the dura-covered thoracic cord of surgically prepared animals. The technique was refined over the years by precise measurements of the velocity, force, and direction of the dropped weights. This type of impact on the cord, of sufficient severity to render the animal immediately paraplegic and abolish sensory-evoked responses from structures below the lesion, indicates that action potentials can no longer be conducted across the injured spinal cord segment. No histologic changes, by either light or electron microscopy, can be detected for several minutes after impact. The earliest tissue alterations consist of hyperemia and small hemorrhages in the central gray matter. By 1 h, the microscopic hemorrhages coalesce and become macroscopically visible. Tissue oxygen saturation is diminished in the region. Within 4 h, the central part of the cord swells and a spreading edema pervades the surrounding white matter; however, necrosis may not be evident for up to 8 h, an observation that has led to numerous strategies designed to spare the neurons and long tracts. Surgical intervention to minimize white matter edema—such as laminectomy and myelotomy—spinal cord cooling, hyperbaric exposure, and the administration of pharmacologic measures have been tried but, for the most part, have had no meaningful effects on the evolving lesion.

Certain mechanisms that are thought to be operative in the death of cerebral neurons exposed to ischemia or to traumatic forces have also been invoked in spinal cord injury but with limited evidence to support this commonality. These include release of excitotoxins such as glutamate and exposure of neurons to calcium and free radicals. Despite early experiments implicating neurotransmitters or opioid-like substances, later work failed to substantiate this or other similar secondary mechanisms. One problem with all the experimental work is that it only imperfectly reproduces spinal injury in humans. Most recent work in the field of spinal cord injury has been on regeneration of spinal tissue across gaps in the cord using stem cells, gene therapy, and tissue scaffolding made of artificial or in vitro cell structures. None has yet proved satisfactory for clinical implementation.

Clinical Effects of Spinal Cord Injury

When the spinal cord is suddenly and severely impacted, three disorders of function are at once evident: (1) all voluntary movement in parts of the body below the lesion is immediately lost; (2) sensation from the lower parts of the body is abolished; and (3) reflex functions in segments of the isolated spinal cord are suspended. The last effect, termed *spinal shock*, involves tendon as well as autonomic reflexes. This state is of variable duration

(1 to 6 weeks but sometimes far longer) and is so dramatic that Riddoch used it as a basis for dividing the clinical effects of spinal cord transection into two stages, that of spinal shock with areflexia followed by a stage of heightened reflex activity.

The separation of these stages is not as sharp as this statement might imply. Less complete or less sudden lesions of the cord result in little or no spinal shock. The features of complete functional spinal cord transection are now presented in detail because of their practical value and the special place they occupy in classic neurology.

Spinal Shock The loss of motor function at the time of injury, tetraplegia with lesions of the fourth to fifth cervical segments or above, and paraplegia with lesions of the thoracic cord, are accompanied by immediate atonic paralysis of bladder and bowel, gastric atony, loss of sensation below a level corresponding to the spinal cord lesion, muscular flaccidity, and almost complete suppression of spinal segmental reflex activity below the lesion. As a result of their sudden separation from higher levels of control, the neural elements below the lesion essentially fail to perform their normal function. As dramatic as this state of reflex paralysis is, its physiologic basis is incompletely understood. Also impaired in the segments below the lesion is the control of autonomic function. Vasomotor tone, sweating, and piloerection in the lower parts of the body are temporarily abolished. As a result, there may be severe systemic hypotension that itself contributes to spinal cord damage. The lower extremities lose heat if left uncovered, and they swell if dependent. The skin over time becomes dry and pale, and ulcerations may develop over bony prominences. The sphincters of the bladder and the rectum remain contracted to some degree because of the loss of the normal inhibitory influence of higher centers, but the detrusor of the bladder and smooth muscle of the rectum become atonic. Urine accumulates until the intravesicular pressure is sufficient to overcome the sphincters, causing overflow incontinence. There is also passive distention of the bowel, retention of feces, and absence of peristalsis (paralytic ileus). Genital reflexes (penile erection, bulbocavernosus reflex, contraction of dartos muscle) are abolished or profoundly depressed.

The duration of the stage of spinal shock varies considerably. In a small number (5 of Kuhn's 29 patients, for example) it is permanent, or only fragmentary reflex activity is regained, even many years after the injury. In such patients, the spinal segments below the level of transection may have themselves been injured, perhaps by a vascular mechanism, although this explanation is unproven. More likely there is a loss of the brainstem–spinal facilitatory mechanisms and an increase in inhibitory activity in the isolated segments. In other patients, minimal genital and flexor reflex activity can be detected within a few days of the injury and minimal reflex activity appears within a period of 1 to 6 weeks. Usually the bulbocavernosus reflex is the first to return. Contraction of the anal sphincter can be elicited by plantar or perianal stimulation, and other genital reflexes reappear at about the same time. The F-waves, electrophysiologic responses

that reflect the functioning of the motor neurons of the isolated segment of the cord, are suppressed until spasticity supervenes, at which time they become overly easy to elicit. Noxious stimulation of the plantar surfaces evokes a tremulous twitching and brief flexion or extension movements of the great toes.

The explanation of spinal shock, which is brief in sub-mammalian animals and more lasting in higher mammals, especially in primates, is believed to be the sudden interruption of suprasegmental descending fiber systems that normally keep the spinal motor neurons in a continuous state of readiness. In the cat and monkey, Fulton found the facilitatory tracts in question to be the reticulospinal and vestibulospinal. Subsequent studies showed that in monkeys, some degree of spinal shock could result from interruption of the corticospinal tracts alone. This is probably not a significant factor, however, at least in humans, because spinal shock does not result from acute cerebral and brainstem lesions that interrupt the corticospinal tracts.

Stage of Heightened Reflex Activity This is the more familiar condition of spasticity that emerges some time after spinal injury and is also typical of most of the non-traumatic subacute myelopathies that have developed more slowly than traumatic injuries and have not had a period of spinal shock. A few weeks after an acute traumatic injury, all reflex responses, which are initially minimal and unsustainable, become stronger and more easily elicitable and as time passes, come to include additional and more proximal muscles. Gradually, the typical pattern of heightened flexion reflexes emerges: dorsiflexion of the big toe (Babinski sign); fanning of the other toes; and later, flexion or slow withdrawal movements of the foot, leg, and thigh with contraction of the tensor fascia lata muscle (the last several features referred to as "triple flexion"). Tactile stimulation of the foot may suffice as a stimulus, but a painful stimulus is more effective. The Achilles reflexes and then the patellar reflexes return. Retention of urine becomes less complete, and at irregular intervals urine is expelled by spontaneous contractions of the detrusor muscle. Reflex defecation also begins. After several months the withdrawal reflexes become greatly exaggerated, to the point of flexor spasms, and they may be accompanied by profuse sweating, piloerection, and automatic emptying of the bladder (occasionally of the rectum). This is the "mass reflex," which can be evoked by stimulation of the skin of the legs or by some interoceptive stimulus, such as a full bladder. Varying degrees of heightened flexor reflex activity may last for years, or indefinitely. Heat-induced sweating is defective, but reflex-evoked ("spinal") sweating may be profuse (see Kneisley). In such cases the lateral horn cells in much of the thoracic cord are still viable and have been disinhibited. Above the level of the lesion, thermoregulatory sweating may be exaggerated in order to compensate for the loss of evaporative cooling of lower segments, and there is cutaneous flushing, hypertension that causes pounding headache and reflex bradycardia. This syndrome ("autonomic dysreflexia") is episodic and occurs in response to a certain stimuli, such as a distended bladder or rectum. It has been ascribed to the reflex release

of adrenaline from the adrenal medulla and of norepinephrine from the disinhibited sympathetic terminals caudal to the lesion but is exaggerated by defective baroreceptor compensatory reflexes as discussed in Chap 27.

Extensor reflexes and tone eventually develop in most cases (18 of 22 of Kuhn's patients who survived more than 2 years), but their appearance does not lead to the abolition of the exaggerated flexor reflexes. The overactivity of extensor muscles may appear as early as 6 months after the injury, but this only happens, as a rule, after the flexor responses are fully developed. Extensor responses are at first manifest in certain muscles of the hip and thigh and later of the leg. In a few patients, extensor reflexes are organized into support reactions sufficient to permit *spinal standing*. Kuhn observed that extensor movements were at first provoked most readily by a sudden shift from a sitting to a supine position and later by proprioceptive stimuli (squeezing of the thigh muscles) and tactile stimuli from wide areas. Marshall, in a study of 44 patients with chronic spastic paraplegia of spinal origin, found all possible combinations of flexor and extensor reflexes; the type of reflex obtained was determined by the intensity and duration of the stimulus (a mild prolonged noxious stimulus evoked an ipsilateral extensor reflex; an intense brief stimulus, a flexor response).

From these observations one would suspect that the ultimate posture of the legs—flexion or extension—does not depend solely on the completeness or incompleteness of the spinal cord lesion, as originally postulated by Riddoch. The development of *paraplegia in flexion* (extreme flexion of the hips and knees, as in a fetal position) relates also to the level of the lesion, being seen most often with cervical lesions and progressively less often with more caudal ones. Greatly troubling to the spinal patient are repeated flexor spasms, which are more frequent with higher lesions of the cord, and the ensuing contractures ultimately produce a fixed flexor posture. Furthermore, reduction of flexor spasms by elimination of nociceptive stimuli (infected bladder, decubitus, etc.) favors an extensor posture of the legs (*paraplegia in extension*). According to Guttmann, the positioning of the limbs during the early stages of paraplegia influences their ultimate posture. Thus, prolonged fixation of the paralyzed limbs in adduction and semiflexion favors subsequent paraplegia in flexion. Placing the patient prone or placing the limbs in abduction and extension facilitates the development of predominantly extensor postures. Nevertheless, strong and persistent extensor postures are usually observed only with partial lesions of the spinal cord.

A number of sensory phenomena are expected after functional cord transection. The main one, of course, is the loss of all sensibility below the lesion, i.e., the sensory level. Of some interest is the fact that many patients report sensory symptoms in segments of the body below the level of their transection. Thus, a tactile stimulus above the level of the lesion may be felt below the transection (a type of synesthesia). Patients describe a variety of paresthesias, the most common being a dull, burning pain in the lower back and abdomen, buttocks,

and perineum. We have encountered several patients in whom aching testicular or rectal pain was a very distressing problem. The pain may be intense and last for a year or longer, after which it gradually subsides. It persists after rhizotomy but can be abolished by anesthetizing the stump of the proximal (upper) segment of the spinal cord, according to Pollock and coworkers. Transmission of sensation over splanchnic afferents to levels of the spinal cord above the lesion, the conventional explanation, is therefore not the most plausible one.

The overactivity of sensory systems in the isolated segments of the spinal cord has several explanations. One assumes that suprasegmental inhibitory influences have been removed by the transection, so that afferent sensory impulses evoke exaggerated nocifensive and phasic and tonic myotatic reflexes. But isolated neurons also become hypersensitive to neurotransmitters. Since the early experiments of Cannon and Rosenblueth, it has been known that section of sympathetic motor fibers leaves the denervated structures hypersensitive to epinephrine and to acetylcholine.

Various combinations of residual deficits (of lower and upper motor neurons and sensory neurons) are to be expected. High cervical lesions, for example, may result in extreme and prolonged tonic spasms of the legs as a result of release of tonic myotatic reflexes. Under these circumstances, attempted voluntary movement may excite intense contraction of all flexor and extensor muscles lasting for several minutes. Segmental damage in the low cervical or lumbar gray matter, destroying inhibitory Renshaw neurons, may release activity of remaining anterior horn cells, leading to spinal segmental spasticity.

Any residual symptoms persisting after 6 months are likely to be permanent, although in a small proportion of patients some return of function (particularly sensation) is possible after this time. Loss of motor and sensory function above the lesion, coming on years after the trauma, is the result of an enlarging cavity in the proximal segment of the cord (see further on, under "Syringomyelia [Syrinx]").

Transient Cord Injury (Spinal Cord Concussion)

These terms refer to a transient loss of motor sensory function of the spinal cord that recovers within minutes or hours but may persist in mild form for days or more. In most instances, the symptoms are rapidly diminishing and few neurologic abnormalities are found at the time of the first examination. There are a number of such transient syndromes: bibrachial weakness; quadriplegia (occasionally hemiparesis); paresthesias and dysesthesias in a similar distribution to the weakness; or sensory symptoms alone ("burning hands syndrome"). In the first and last of these, transient dysfunction of the central gray matter of the cervical cord is implicated. It is assumed that the cord undergoes some form of elastic deformation when the cervical spine is compressed or hyperextended; however, the same effects can be produced by direct blows to the spine or forceful falls flat on the back and occasionally, by a sharp fall on the tip of the coccyx. Little

is known of the physiologic mechanisms that underlie these reversible syndromes.

Spinal cord concussion from direct impact is observed most frequently in athletes engaged in contact sports (football, rugby, and hockey). An incomplete and reversible myelopathy is referable to the site and level of the injury. A congenitally narrow cervical canal is thought to predispose to spinal cord concussion and to increase the risk of recurrence. As with cerebral concussion, particularly if there have been previous concussions, a difficult decision arises—whether or not to allow resumption of competitive sports. There are no reliable data on which to base this decision, only guidelines that tentatively allow continued participation, after an unspecified period of rest, if the deficit has been brief. It is, however, advisable in most cases to be certain that spinal instability has not been induced by the injury. This can be ascertained from flexion and extension X-ray images of the affected spinal region. The subject is reviewed by Zwimpfer and Bernstein. In athletic contact injury, unilateral arm and hand paresthesias are more common than symptoms of both arm, but they are usually from stretching of the brachial plexus on one side (a "stinger"), rather than from a cord injury.

Central Cord ("Schneider") Syndrome and Cruciate Paralysis A special form of acute cervical cord injury implicates mainly central cord damage, resulting in the loss of motor function solely or more severely in the upper limbs than in the lower ones, and it particularly affects the hands. Bladder dysfunction with urinary retention occurs in some cases and sensory loss is often slight (hyperpathia over the shoulders and arms may be the only sensory abnormality). Many of these instances are reversible but damage to the centrally situated gray matter may leave an atrophic, areflexic paralysis of the arms and hands and a segmental loss of pain and thermal sensation from interruption of crossing pain and thermal fibers. Retroflexion injuries of the head and neck are the ones most often associated with the central cord syndrome, but other causes include hematomyelia, fibrocartilaginous embolism, and infarction from dissection of the vertebral artery in the medullary-cervical region as mentioned earlier in the chapter (see Morse for further discussion).

According to Dickman and colleagues, approximately 4 percent of patients who survive injuries of the very rostral cervical cord demonstrate a very limited form of the central cord syndrome, recognized by Nielson and named by Bell, "cruciate paralysis." The weakness is very selective, being practically limited to the arms, a feature that is attributable to the segregation within the pyramidal decussation of corticospinal fibers to the arms (being rostral) and to the legs (more caudally situated). The arm weakness may be asymmetrical or even unilateral and sensory loss is inconsistent. The patients described have had contusions of the C1-C2 region. Whether the lesion lies strictly within the decussating corticospinal tract or involves central gray matter is not always clear; MRI findings have implicated the latter, as described by Inamasu et al.

Management of Spinal Injury

For some time, many centers administered methylprednisolone in high dosage (bolus of 30 mg/kg followed by 5.4 mg/kg every hour), beginning within 8 h of the injury and continued for 23 h. This measure, according to the multicenter National Acute Spinal Cord Study (Bracken et al, 1990) resulted in a slight improvement in both motor and sensory function. The therapeutic value of this measure has since been questioned after reanalysis of the data (Nesathurai; Hurlbert) and it is no longer considered essential. Hypotension is treated with infusions of normal saline and may require the transient use of pressor agents. The use of hypothermia with cooling blankets or the infusion of cooled saline is under investigation to protect spinal tissue but has not been validated.

Next, imaging examinations are undertaken to determine the alignment of vertebrae and pedicles, fracture of the pedicle or vertebral body, compression of the spinal cord or cauda equina as a consequence of malalignment, or bone debris in the spinal canal, and the presence of tissue damage within the cord. MRI is ideally suited to display these processes, but if it is not available, myelography with CT scanning is an alternative. Instability of the spinal elements can often be inferred from dislocations or from certain fractures of the pedicles, pars interarticularis, or transverse processes, but gentle flexion and extension of the injured areas must sometimes be undertaken and plain films obtained in each position.

If a cervical spinal cord injury is associated with vertebral dislocation, traction on the neck may be necessary to secure proper alignment and maintain immobilization. Depending on the nature of the injury, this is accomplished by use of a halo brace, which, of all the appliances used for this purpose provides the most rigid external fixation of the cervical spine. This type of fixation is usually continued for 4 to 6 weeks, after which a rigid collar may be substituted.

Concerning the early surgical management of spinal cord injury, there have traditionally been two perspectives. One, represented by Guttman and others, advocated reduction and alignment of the dislocated vertebrae by traction and immobilization until skeletal fixation is obtained, and then rehabilitation. The other approach, represented by Munro and later by Collins and Chehrazi, proposed early surgical decompression, correction of bony displacements, and removal of herniated disc tissue and intra- and extramedullary hemorrhage; often the spine is fixed at the same time by a bone graft or other form of stabilization. The issue of acute decompressive surgery remains contentious to the present day. The MRI has altered these empirical approaches by allowing the early demonstration of hematomas and other sources of compression that may be amenable to surgery. With clinical evidence of a complete spinal cord lesion, most surgeons do not favor early surgery.

The results of the conservative and aggressive surgical plans of management for incomplete cord injuries have been difficult to compare and have not been evaluated with modern neurologic techniques. Collins, a participant in the National Institutes of Health (NIH)

study of acute management of spinal cord injury 20 years ago, concluded that the survival rate was increased as a result of early surgical stabilization of fractures and fixation of the spine. Others, however, have not been able to document a reduction in neurologic disability and have increasingly been inclined toward nonoperative management of both complete and partial spinal cord lesions (see, for example, Clark; Murphy et al). Many North American neurosurgeons take the less aggressive stance, delaying operation or operating only on patients with compound wounds or those with progression or worsening of the neurologic deficit despite adequate reduction and stabilization. In each case, the approach is guided by the specific aspects of the injuries; ligamentous disruption, presence of hematoma, misalignment-displacement of spinal segments, instability of the injury, and fracture type.

The greatest risks to the patient with spinal cord injury occur in the first 10 days when gastric dilatation, ileus, shock, and infection are threats to life. According to Messard and colleagues, the mortality rate falls rapidly after 3 months; beyond this time, 86 percent of paraplegics and 80 percent of quadriplegics will survive for 10 years or longer. In children, the survival rate is even higher according to DeVivo and colleagues, who found that the cumulative 7-year survival rate in spinal cord-injured children (who had survived at least 24 h after injury) was 87 percent. Advanced age at the time of injury and being rendered completely quadriplegic were the worst prognostic factors.

The aftercare of patients with paraplegia, in addition to substantial psychological support to allow accommodation to new limitations while encouraging a productive life, is concerned with management of bladder and bowel disturbances, care of the skin, prevention of pulmonary embolism, and maintenance of nutrition. Decubitus ulcers can be reduced by frequent turning to avoid pressure necrosis, use of special mattresses, and meticulous skin care. Deep decubitus lesions require debridement and full-thickness grafting. At first, continual catheterization is necessary; then, after several weeks, the bladder can be managed by intermittent catheterization once or twice daily, using a scrupulous aseptic technique. Close surveillance is needed for bladder infection, which is treated promptly should it occur. Bacteriuria alone is common and does not require treatment with antibiotics unless there is associated pyuria. Morning suppositories and periodically spaced enemas are effective means of controlling fecal incontinence. Chronic pain (present in 30 to 50 percent of cases) requires the use of nonsteroidal antiinflammatory medication, injections of local anesthetics, and transcutaneous nerve stimulation. A combination of carbamazepine or gabapentin and either clonazepam or tricyclic antidepressants may be helpful in cases of burning leg and trunk pain. Remaining pain may require more aggressive therapy, such as epidural injections of analgesics or corticosteroids or an implanted spinal cord stimulator that is applied to the dorsal columns or an analgesic pump, but often even these measures are ineffective. Fentanyl transcutaneous patches may be tried. Spasticity and flexor spasms may be troublesome; oral

baclofen, diazepam, or tizanidine may provide some relief. In permanent spastic paraplegia with severe stiffness and adductor and flexor spasms of the legs, intrathecal baclofen, delivered by an automated pump in doses up to 400 mg/d, has also been helpful. The drug is believed to act at the synapses of spinal reflexes (Penn and Kroin). Selective injection of botulinum toxin may provide relief of some spastic deformities and of spasms. One must always be alert to the threat of pulmonary embolism from deep-vein thrombi, although the incidence is surprisingly low after the first several months. Physical therapy, muscle reeducation, and the proper use of braces are all important in the rehabilitation of the patient. All this is best carried out in special centers.

Radiation Injury of the Spinal Cord

Delayed necrosis of the spinal cord and brain are recognized sequela of radiation therapy for tumors in the thorax and neck. Mediastinal irradiation for Hodgkin disease or for other lymphomas is a typical setting for the development of these complications up to decades later. A lower motor neuron syndrome, presumably a result of injury to the gray matter of the spinal cord, may also follow radiation therapy in which the cord was inside the zone of treatment, as described below.

Transient Radiation Myelopathy

An “early” type of radiation myelopathy (appearing 3 to 6 months after radiotherapy) is characterized mainly by spontaneous uncomfortable sensations in the extremities. The paresthesias may be evoked by neck flexion (Lhermitte symptom). In one of our patients there was impairment of vibratory and position sense in the legs, but no weakness or signs of spinothalamic tract damage. The sensory abnormalities disappear after a few months and, according to Jones, are not followed by the delayed progressive radiation myelopathy described below. The pathology of the early and transient radiation myelopathy has not been fully elucidated, but there is a spongy appearance of the white matter with demyelination and depletion of oligodendrocytes.

Delayed Progressive Radiation Myelopathy

This is one of the most dreaded complications of radiation therapy. It is a progressive myelopathy that follows, after a variable latent period, the radiation of malignant lesions in the vicinity of the spinal cord. The incidence of this complication is difficult to determine because many patients die of their malignant disease before the myelopathy has fully evolved but it is estimated to be between 2 and 3 percent (Palmer). According to Douglas and colleagues, patients who have undergone hyperthermia as an adjunctive treatment for cancer are particularly vulnerable to radiation myelopathy.

Clinical Features The neurologic disorder first appears 6 months or more after the course of radiation therapy, usually between 12 and 15 months (latent periods as long as 60 months or longer have been reported).

The onset is insidious, usually with sensory symptoms—paresthesias and dysesthesias of the feet or a Lhermitte phenomenon, and similar symptoms in the hands in cases of cervical cord damage. Weakness of one or both legs usually follows the sensory loss. Initially, local pain is absent, in distinction to the effects of spinal metastases. In some cases, the sensory abnormalities are transitory as in the syndrome described above; more often, additional signs make their appearance and progress, at first rapidly and then more slowly and irregularly, over a period of several weeks or months, with involvement of the corticospinal and spinothalamic pathways. The neurologic disturbance may take the form of a Brown-Séquard syndrome, but with progression it is usually overtaken by a transverse myelopathy.

Reagan and coworkers, who have had considerable experience with this condition, described yet another myelopathic radiation syndrome, namely, a slowly evolving amyotrophy, with weakness and atrophy of muscles and areflexia in parts of the body supplied by anterior horn cells of the irradiated spinal segments. Most patients with this form of the disease die within a year of onset. Knowledge of the pathology is incomplete. This syndrome is reminiscent of the delayed motor neuron myelopathy following electrical or lightning injury described in the next section. There is also an unusual paraneoplastic variety of poliomyelopathy and an even less common necrotic myelopathy, mentioned below and in Chap. 31.

The CSF in delayed progressive radiation transverse myelopathy is normal except for a slight elevation of protein content in some cases. MRI of the affected segments of cord demonstrates abnormal signal intensity, decreased in T1-weighted and increased in T2-weighted images. Early in the course of the myelopathy the cord may be swollen, and there is often heterogeneous enhancement with gadolinium infusion. The location of the lesion corresponds to the irradiated portal, which can be identified by the radiation effect on the marrow of the overlying vertebral bodies. The spinal cord lesion tends to be more extensive in rostral-caudal dimension than the usual vascular or demyelinating myelopathy. These are important points to establish, because a mistaken diagnosis of intraspinal tumor or of a dural arteriovenous fistula may lead to an unnecessary operation or further irradiation.

Pathologic Findings Corresponding with the level of the radiated area and extending over several segments, there is an irregular zone of coagulation necrosis involving both white and gray matter, the former to a greater extent than the latter. Varying degrees of secondary degeneration are seen in the ascending and descending tracts. Vascular changes—necrosis of arterioles or hyaline thickening of their walls and thrombotic occlusion of their lumens—are prominent in the most severely damaged portions of the cord. Most neuropathologists have attributed the parenchymal lesion to the blood vessel changes; others believe that the degree of vascular change is insufficient to explain the necrosis (Malamud et al; Burns et al). Certainly, the most severe changes in

the cord are consistent with infarction, but the insidious onset and slow, steady progression of the disorder and the coagulative nature of the necrosis would then have to be explained by a steady succession of vascular occlusions. Exceptional instances, in which a transverse myelopathy has developed within a few hours of radiation treatment (as described by Reagan et al), are more readily explained by thrombotic occlusion of a large spinal artery.

Neurologists associated with cancer treatment centers are sometimes confronted with a patient who exhibits the late development (up to 10 to 15 years after radiation) of a slowly progressive sensorimotor paralysis of only one limb (motor weakness predominates) or one region of the body. This usually represents damage in the peripheral nervous system. Examples that we have encountered are multiple cranial neuropathies after radiation of nasopharyngeal tumors, cervical and especially brachial neuropathies after laryngeal and breast cancers, and lumbosacral plexopathies and cauda equina damage with pelvic radiation. These are discussed further in Chap. 46, on diseases of the peripheral nerves.

Treatment and Prevention Kagan and colleagues have determined the tolerance of the adult human spinal cord to radiation, taking into account the volume of tissue irradiated, the duration of the irradiation, and the total dose. They reviewed all of the cases in the literature up to 1980 and concluded that radiation injury could be avoided if the total dose was kept below 6,000 cGy and was given over a period of 30 to 70 days, provided that each daily fraction did not exceed 200 cGy and the weekly dose was not in excess of 900 cGy. It is noteworthy that in the cases reported by Sanyal and associates, the amount of radiation surpassed these limits. Forewarned with this knowledge, radiation specialists have the impression that the incidence of this complication is decreasing. Of course, if the underlying neoplasm is likely to be imminently fatal, palliative radiation can exceed these limits.

A number of case reports remark on temporary improvement in neurologic function after the administration of corticosteroids. This therapy should be tried because in some patients it appears to arrest the process short of complete destruction of all sensory and motor tracts. Claims have also been made of regression of early symptoms in response to the administration of heparin split products and of hyperbaric oxygen, but most have not been confirmed.

Spinal Cord Injury Caused by Electric Currents and Lightning

Among acute physical injuries to the spinal cord, those caused by electric currents and lightning, despite their rarity, are of great interest because they produce unusual clinical syndromes. Electrical forces can also injure the brain and peripheral nerves. These effects are noted only briefly here, because they are infrequent. It is the spinal cord that is most consistently and severely damaged.

Electrical Injuries

In the United States, inadvertent contact with an electric current causes approximately 1,000 deaths annually and

many more nonfatal but serious injuries. About one-third of the fatal accidents result from contact with household currents.

The factor that governs the damage to the nervous system is the amount of current, or amperage, with which the victim has contact, not simply the voltage, as is generally believed. In any particular case, the duration of contact with the current and the resistance offered by the skin to current (greatly reduced if the skin is moist or a body part is immersed in water) are of importance. The physics of electrical injuries is much more complex than these brief remarks indicate (for a full discussion, see the reviews by Panse and by Winkelman).

Any part of the peripheral or central nervous system may be injured by electric currents and lightning. The effects may be immediate, which is understandable, but of greater interest are the instances of neurologic damage that occur after a delay of 1 day to 6 weeks (1 week on average) and a rarer syndrome of anterior horn cell damage that arises after many years. The immediate effects are the result of direct heating of the nervous tissue, but the pathogenesis of the delayed effects is not well understood. They have been attributed to vascular occlusive changes induced by the electric current, a mechanism proposed to underlie the similar delayed effects of radiation therapy (see earlier). However, the latent period is measured in many months or a few years rather than in days and the course is more often progressive than self-limited. Moreover, the few postmortem studies of myelopathy as a consequence of electrical injury have disclosed a widespread demyelination of long tracts, to the point of tissue necrosis in some segments, and relative sparing of the gray matter, but no abnormalities of the blood vessels. There may also be spinal fracture from the vigorous muscle contraction.

The extraordinary syndrome of focal muscular atrophy occurring with a delay of weeks to years after an electric shock has been described by Panse under the title *spinal atrophic paralysis*. It occurs when the path of the current, usually of low voltage, is from arm to arm (across the cervical cord) or from an arm to leg. When the head is one of the contact points, the patient becomes unconscious or suffers tinnitus, deafness, or headache for a short period following the injury. Pain and paresthesias occur immediately in the involved limb but these symptoms are transient. Mild weakness, also unilateral, is immediate, followed in several weeks or months by muscle wasting, most often taking the form of segmental muscular atrophy. The syndrome simulates a regional form of amyotrophic lateral sclerosis (ALS) or transverse myelopathy (most patients have some degree of weakness and spasticity of the legs). However, we have encountered cases of asymmetric and profound atrophic weakness of the arms that began almost two decades after the shock and progressed over many years without long tract signs, both with a previously presumed diagnosis of amyotrophic lateral sclerosis. In contrast to injuries caused by high current, which affects mainly the spinal white matter (see earlier), it is the gray matter that is injured in cases of spinal atrophic paralysis, at least as judged from the clinical effects.

In a small number of surviving patients, after an asymptomatic interval of days to months, there has been an apoplectic onset of hemiplegia with or without aphasia or a striatal or brainstem syndrome, presumably because of thrombotic occlusion of cerebral vessels with infarction of tissue, but this condition has not been well studied.

The separate issue of the relationship of electrical shock exposure and the later development of typical ALS is quite controversial. Most series are hampered by retrospective acquisition of data about the shock. Although we have encountered a few remarkable instances of this association, including two who developed severe amyotrophy of the limb that was in contact with the electrical source many years before, a relationship to typical motor neuron disease has been considered coincidental.

Lightning Injuries

The factors involved in injuries from lightning are less well defined than those from electric currents, but the effects are much the same. Direct strikes are often fatal; nearby strikes produce neurologic damage as described below. Topographic prominences such as trees, hills, and towers are struck preferentially, so these should be avoided; a person caught in the open should curl up on the ground, lying on one side with legs close together.

Arborescent red lines or burns on the skin indicate the point of contact of the energy generated by direct or nearby lightning. The path through the body can be approximately deduced from the clinical sequelae. Death is a result of ventricular fibrillation or of the effects of intense desiccating heat on the brain. Lightning that strikes the head is particularly dangerous, proving fatal in 30 percent of cases. Most persons struck by lightning are initially unconscious, irrespective of where they are struck. In those who survive, consciousness is usually regained rapidly and completely. Rarely, unconsciousness or an agitated-confusional state may persist for a week or two. Persistent seizures are surprisingly rare.

There is usually a disturbance of sensorimotor function of a limb or all the limbs, which may be pale and cold or cyanotic. As a rule, these signs are also evanescent, but in some instances they persist, or an atrophic paralysis of a limb or part of a limb makes its appearance after a symptom-free interval of several months as in the case of electrical injury.

A severe, predominantly motor polyneuropathy has been reported to appear after a variable interval and, while it bears similarities to the motor neuron disorder ostensibly associated with electrical injury discussed in the section above, there is a more persuasive relationship to the less common event of lightning. There are also a few cases on record of recovery from generalized polyneuropathy after lightning injury, but our experience with one case was of profound generalized axonal damage with little recovery (see Chap. 46).

Myelopathy Following Spinal Anesthesia

This subject is introduced here with the other forms of spinal cord injury for want of a better way to categorize it. A transient and often asymmetric paraparesis is known

to occur following prolonged spinal anesthesia but this is probably the result of a temporary effect of the injected agents on the cauda equina roots (see Chap. 46). A more serious and permanent injury has been caused by inadvertent injection of anesthetic directly into the conus medullaris (see Hamandi et al; Wilkinson et al). The patient reports leg weakness and numbness on one side immediately with the injection or upon awakening if sedation has been used. The MRI reveals an eccentrically placed traumatic lesion within the caudal spinal cord. Although this complication is rare, it has occurred even when experienced anesthesiologists perform the procedure; misidentification of the L3-L4 spinal interspace has been cited as the problem. Flat-tipped needles are as likely to cause injury to the conus as are ones with sharp beveled tips. Arachnoiditis from irritative agents, no longer used to any great extent, in the past caused a myelopathy (see Chap. 11).

MYELITIS (INFLAMMATORY MYELOPATHIES)

In the nineteenth century, almost every disease of the spinal cord was labeled myelitis. Morton Prince, writing in *Dercum's Textbook of Nervous Diseases* in 1895, referred to traumatic myelitis, compressive myelitis, and so on, obviously giving a rather imprecise meaning to the term. Gradually, knowledge of neuropathology advanced, and one disease after another was removed from this category until only the verifiably inflammatory ones remained.

The spinal cord is known to be the locus of a limited number of infective and noninfective inflammatory processes, some causing selective destruction of neurons, others affecting primarily white matter (tracts), and yet another group involving the meninges and white matter or leading to a necrosis of both gray and white matter. Other special terms, qualifying *myelitis*, are used to indicate more precisely the distribution of the process: if confined to gray matter, the proper expression is *poliomyelitis*; if to white matter, *leukomyelitis*. If approximately the whole cross-sectional area of the cord is involved at one or more levels, the process is said to be a *transverse myelitis* (although the term is still used more broadly for many myelitides); if the lesions are multiple and widespread over a long vertical extent, the modifying adjectives *diffuse* or *disseminated* are used and recently *longitudinally extensive myelopathy* has been introduced to denote a special form of necrotic myelopathy that is associated in most cases with particular circulating autoantibodies (see Chap. 36). The term *meningomyelitis* refers to combined inflammation of meninges and spinal cord and *meningoradiculitis* to combined meningeal and root involvement. An inflammatory process limited to the spinal dura is called *pachymeningitis*, and if infected material collects in the epidural or subdural space, it is called *epidural* or *subdural spinal abscess* or *granuloma*, as the case may be. The adjectives *acute*, *subacute*, and *chronic* denote the tempo of evolution of myelitic symptoms—namely, more or less within days, 2 to 6 weeks, or more than 6 weeks, respectively. The main causes of myelitis are listed below.

Classification of Inflammatory Diseases of the Spinal Cord

- I. Viral myelitis (Chap. 33)
 - A. Enteroviruses (groups A and B Coxsackievirus, poliomyelitis, others)
 - B. Herpes zoster
 - C. Myelitis of AIDS
 - D. Epstein-Barr virus (EBV), cytomegalovirus (CMV), herpes simplex
 - E. Rabies
 - F. Arboviruses-Flaviviruses (Japanese, West Nile, etc.)
 - G. HTLV-I (human T-cell lymphotropic virus type I; tropical spastic paraparesis)
- II. Myelitis secondary to bacterial, fungal, parasitic, and primary granulomatous diseases of the meninges and spinal cord (Chap. 32)
 - A. *Mycoplasma pneumoniae*
 - B. Lyme disease
 - C. Pyogenic myelitis
 1. Acute epidural abscess and granuloma
 2. Abscess of spinal cord
 - D. Tuberculous myelitis (Chap. 32)
 1. Pott disease of the spine with secondary cord compression
 2. Tuberculous meningomyelitis
 3. Tuberculoma of spinal cord
 - E. Parasitic and fungal infections producing epidural granuloma, localized meningitis, or meningomyelitis and abscess, especially certain forms of schistosomiasis (Chap. 32)
 - F. Syphilitic myelitis (Chap. 32)
 1. Chronic meningoradiculitis (tabes dorsalis)
 2. Chronic meningomyelitis
 3. Meningovascular syphilis
 4. Gummatous meningitis including chronic spinal pachymeningitis
 - G. Sarcoid myelitis (Chap. 32)
- III. Myelitis of noninfectious inflammatory type (Chap. 36)
 - A. Postinfectious and postvaccinal myelitis
 - B. Acute and chronic relapsing or progressive multiple sclerosis (MS)
 - C. Subacute necrotizing myelitis, neuromyelitis optica (NMO, Devic disease; longitudinally extensive myelopathy) due to antibodies against aquaporin (Chap. 36)
 - D. Myelopathy with lupus or other forms of connective tissue disease and antiphospholipid antibody
 - E. Paraneoplastic myelopathy and poliomyelitis (Chap. 31)

From this outline it is evident that many different and totally unrelated diseases are under consideration and that a general description cannot possibly encompass such a diversity of processes. Overall, myelitis caused by multiple sclerosis and postinfectious processes are the most common causes in practice. This was the case in the series collected by de Seze and colleagues (2001a); Nowak and coworkers reported a similar distribution. Many of the myelitides are considered elsewhere in this volume in

relation to the diseases of which they are a part. Here it is only necessary to comment on the principal categories and to describe a few of the common subtypes.

Viral Myelitis (See also Chap. 33)

The enteroviruses, of which Coxsackie and poliomyelitis are examples, herpes zoster, arboviruses such as West Nile and the equine encephalitic viruses, and HIV are the important members of this category. The enteroviruses in particular have an affinity for neurons of the anterior horns of the spinal cord and the motor nuclei of the brainstem (i.e., they are neuronotropic and cause a disease that can be generically termed *poliomyelitis*), and herpes zoster virus has a clear affinity for the dorsal root ganglia; hence the disturbances of function are in terms of motor and sensory neurons, respectively, not of spinal tracts. We have cared for several patients who have had destruction of anterior horn cells as a consequence of an enterovirus other than poliomyelitis virus (see further on). West Nile virus shows the same proclivity to damage anterior horn cells. The onset of these conditions is acute and takes the form of a febrile meningomyelitis. Although there are fever, systemic symptoms, and sometimes, cutaneous features (in the case of zoster), it is the nervous system disorder that is most significant. The patient suffers the immediate effects of nerve cell destruction, and some degree of improvement nearly always follows as some neurons recover. Later in life, possibly as the neuronal loss of aging reduces the number of anterior horns, there may be an apparent increased loss of strength in muscles originally weakened by poliomyelitis ("postpolio" syndrome).

Relatively infrequent examples of a more or less transverse myelitis caused by herpes simplex virus (HSV types 1 and 2), varicella-zoster virus (VZV), CMV, EBV, any of the hepatitis viruses, and SV70 virus (causing epidemic conjunctivitis) have been reported, some in patients with immunodeficiency states, mainly AIDS. The situation is complex clinically, as most of these agents may also elicit a postinfectious variety of myelitis, described further on in this chapter and in Chaps. 33 and 36. HSV type 2 and CMV infections may also produce an acute lumbosacral radiculitis with urinary retention (Elsberg syndrome). A few cases of zoster myelitis have shown evidence of extensive inflammatory necrosis of the spinal cord with involvement of sensory and motor tracts, causing acute paraplegic and tetraplegic transverse syndromes. Pleocytosis in the cerebrospinal fluid and isolation of the viral DNA from the cerebrospinal fluid confirm the diagnosis of a primary viral infection as discussed in Chap. 33.

There are other rare forms of poliomyelitic reactions of unknown, possibly viral etiology. One such condition presents as an acute febrile or afebrile meningomyelitis and leaves all the limbs paralyzed and flaccid, sparing the brainstem and affecting the diaphragm to a variable extent. Several such patients have harbored a cancer or Hodgkin disease, and the pathology was more typical of a poliomyelitic viral infection rather than of the usual paraneoplastic syndromes (Chap. 31). Involvement of the

white matter with sensory and motor paralysis below the level of a lesion has also been reported in so-called “dumb” rabies (in contrast to the usual form of “mad” or “furious” rabies encephalitis), and in an infection transmitted by the bite of a monkey, called the *B virus*. These are decidedly rare. More common are the viral myelopathy of HIV-AIDS and of HTLV-I infection. With these exceptions, one may say that myelitis that expresses itself mainly by dysfunction of motor and sensory tracts will usually prove not to be viral in origin but rather to one of the disease processes in category III (noninfectious, inflammatory) of the preceding classification, for example, multiple sclerosis. The unique myelopathies of HIV and of human HTLV infections are described below.

Vacuolar Myelopathy With HIV

(See also “AIDS Myelopathy” in Chap. 33)

As the neurology of AIDS has been elucidated, the clinical and pathologic characteristics of a viral myelopathy have been studied in detail. The frequency of this condition is impressive—it was present in 20 of 89 successive cases of AIDS on whom a postmortem examination was performed by Petito and colleagues. Often, the clinical symptoms and signs of spinal cord disease are obscured by a neuropathy or one or more of the cerebral disorders that complicate AIDS either because of HIV or due to an opportunistic infection (CMV, toxoplasmosis, progressive multifocal leukoencephalopathy [PML]). In 5 cases of severe vacuolar myelopathy in the aforementioned series, there was leg or leg and arm weakness, often asymmetrical and developing over a period of weeks, to which the signs of sensory tract involvement and sphincteric disorder were added. A sensory ataxia has also been a common early feature in our experience. The CSF shows a small number of lymphocytes, a slight elevation of protein, and, occasionally, bizarre giant cells.

The white matter of the spinal cord is vacuolated, by which is meant a ballooning within myelin sheaths of the long tracts. The changes are most severe in thoracic segments with the posterior and lateral columns are affected diffusely. Axons are involved to a lesser degree, and lipid-laden macrophages are present in abundance. Similar vacuolar lesions may be seen in the brain in some cases. The lesions in the spinal cord resemble those of subacute combined degeneration but levels of vitamin B₁₂ and folic acid are normal. (A similar lesion was found in one of our patients with myelopathy from chronic lupus erythematosus.)

The antiretroviral drugs that slow the progress of AIDS, with the exception of a few cases, seem to have little effect on the myelopathy and one can only resort to symptomatic treatment of spasticity.

Tropical Spastic Paraparesis Caused by Human T-Cell Lymphotropic Virus Type I (HTLV-I)

This disease was brought to the attention of neurologists 50 years ago through the observations and writings of Cruickshank. However, it is only more recently that a

chronic infective-inflammatory disease of the spinal cord caused by the retrovirus HTLV-I has been discovered and its connection to what had been called tropical myelitis, appreciated. The implications of this discovery are potentially broad and extend even to the demyelinating and possibly the degenerative diseases.

Spinal cord disease of this type has been reported from the Caribbean islands, southeastern United States, southern Japan, South America, and Africa. The clinical picture is one of a slowly progressive paraparesis with increased tendon reflexes and Babinski signs; disorder of sphincteric control is usually an early feature but symmetric paresthesias, reduced vibratory and position senses, and ataxia follow over several months or years. A few patients have had an associated polyneuropathy, as in Cruickshank's early cases. The upper extremities are usually spared (except for lively tendon reflexes), as are cerebral and brainstem functions.

The CSF contains small numbers of T-lymphocytes (10 to 50/mm³), normal concentrations of protein and glucose, and an increased content of immunoglobulin (Ig) G with antibodies to HTLV-I. The diagnosis is confirmed by the detection in the serum of the antibodies to the virus. Thinness of the spinal cord is evident on MRI and subcortical cerebral white matter lesions may be seen as well. Neuropathologic study has documented an inflammatory myelitis with focal spongiform, demyelinating, and necrotic lesions, perivascular and meningeal infiltrates of inflammatory cells, and focal destruction of gray matter. The posterior columns and corticospinal tracts are the main sites of disease, most evident in the thoracic cord.

Because of slow evolution, the clinical picture can easily be confused with that of progressive spastic paraplegia of the hereditary variety, sporadic motor neuron disease, or the chronic phase of multiple sclerosis. There are also similarities with the AIDS myelopathy described earlier, but the other features of HIV infection are absent. There are reports of improvement with intravenous administration of gamma globulin but these have not been consistent and had no effect in two of our patients.

Myelitis Secondary to Bacterial, Fungal, Parasitic, and Granulomatous Diseases

(See also Chap. 32)

With few exceptions, this class of spinal cord disease seldom offers difficulty in diagnosis. The CSF usually holds the clue to causation. In most cases, the inflammatory reaction in the meninges is only one manifestation of a generalized (systemic) disease process. The spinal lesion may involve primarily the pia-arachnoid (leptomeningitis), the dura (pachymeningitis), or the epidural space, e.g., taking the form of a compressive abscess or granuloma; or it may reside in the adjacent spinal bones. In some acute forms both the spinal cord and meninges are simultaneously affected, or the cord lesions may predominate. Chronic spinal meningitis may involve the pial arteries or veins; and as the inflamed vessels become thrombosed, infarction (myelomalacia) of the spinal cord

results. Chronic meningeal inflammation may provoke a progressive constrictive pial fibrosis (spinal arachnoiditis) that virtually strangulates the spinal cord. In certain cases, spinal roots become progressively damaged, especially the lumbosacral ones, which have a long meningeal exposure. Posterior roots, which enter the subarachnoid space near arachnoid villi (where CSF is resorbed) tend to suffer greater injury than anterior ones (as happens in tabes dorsalis). Interestingly, there are cases of chronic cerebrospinal meningitis that remain entirely without symptoms until the spinal cord or roots become involved.

The infrequent but curious bacterial myelitis caused, or in some way precipitated, by the atypical pneumonia agent *M. pneumoniae* has come to be viewed as a postinfectious immune disease, as discussed in Chap. 32. However, portions of the DNA from this organism have been found in the spinal fluid early in the course of illness in some cases, suggesting the possibility of a direct bacterial infection of the spinal cord. It is not known whether antibiotic treatment alters the course of the illness.

Syphilitic myelitis is also discussed in Chap. 32. *Bacterial abscess of the spinal cord* is rare, especially in comparison to epidural spinal abscess, and it is recognized by MRI. At times, it stands as a single pyogenic metastasis from a distant infection and subsequent bacteremia, but more often there has been spread from a contiguous infected surgical site or a fistulous connection with a superficial paraspinal abscess. Vertebral osteomyelitis is addressed further on in relation to epidural abscess.

Sarcoid Myelitis (See also “Sarcoidosis” in Chap. 32)

Sarcoid granulomas may occur as one or more intramedullary spinal cord masses, as in the cases reported by Levivier and colleagues. In our experience, the granulomatous lesion, which may be focal or multifocal, simulates demyelinating disease with respect to its tendency to relapse and remit and in its response to corticosteroids. An asymmetrical ascending paraparesis and bladder disturbance have been the main features in our patients. Usually there is evidence of systemic sarcoidosis and the CSF is abnormal (increase in cells and protein; glucose usually normal), but we have encountered a few instances of sarcoid restricted to the spinal cord before it was evident in the mediastinum (i.e., thoracic CT failing to demonstrate hilar adenopathy or diffuse parenchymal lung disease). Elevation of the spinal fluid IgG concentration and oligoclonal bands may be found, but they are not consistent features; often there are activated histiocytes in the CSF.

The use of angiotensin-converting enzyme levels in the CSF to distinguish sarcoidosis from multiple sclerosis suffers from the lack of normative values for this test, but it is reported in some small series to be elevated in two-thirds of patients. The MRI is abnormal and the conus or other portions of the cord reveal intramedullary lesions. The most characteristic finding, however, is a multifocal-subpial nodular enhancement of the meninges adjacent to a lesion within the cord or nerve roots—a picture that resembles neoplastic meningeal infiltration. The diagnosis can be confirmed by mediastinal lymph node biopsy or

by the far less desirable method of biopsy of the spinal meninges, spinal roots and affected subpial cord.

On occasion, a number of other rare granulomatous conditions cause an intrinsic or, more often, extrinsic compressive myelopathy; these, include brucellosis, xanthogranulomatosis, and eosinophilic granuloma. The diagnosis may be suspected if the systemic disease is apparent at the time but usually, only the histology of a surgical specimen reveals the underlying process.

Spinal Epidural Abscess

This condition is worthy of emphasis because the diagnosis is often missed or mistaken for another disease, sometimes with disastrous results. Children or adults may be affected. Infection of the epidural space has a wide variety of sources. *Staphylococcus aureus* is the most frequent etiologic agent, followed in frequency by streptococci, gram-negative bacilli, and anaerobic organisms. An injury to the back, often trivial at the time, furunculosis or other skin or wound infection, or a bacteremia may permit seeding of the spinal epidural space or of a vertebral body. This gives rise to osteomyelitis with extension of the purulent process to the epidural space. Occasionally, the spread is from an infected disc. Another source is bacteremia in a drug addict following the use of nonsterile needles or the injection of contaminated drugs.

Organisms may be introduced into the epidural space during spinal surgery or rarely via a lumbar puncture needle during epidural or spinal anesthesia or from epidural injections of steroid or other therapeutic agents; the localization is then over the lumbar and sacral roots. In these cases of *cauda equina epidural abscess*, back pain may be severe but neurologic symptomatology is minimal unless the infection extends upward to the upper lumbar and thoracic segments of the spinal cord. It must be acknowledged that some, even fulminant, cases have no clear source in the body for the bacterial abscess.

At first, the purulent process in the cervical or thoracic region is accompanied only by low-grade fever and aching local back pain, usually intense, in most cases followed within a day or several days by radicular pain. Headache and nuchal rigidity are sometimes present; more often there are just persistent pain and a disinclination to move the back. After several days, there may be a rapidly progressive paraparesis associated with sensory loss in the lower parts of the body and sphincteric paralysis. Percussion of the spine elicits considerable tenderness over the site of the infection. Examination discloses all the signs of a complete or partial transverse cord lesion, including at times the elements of spinal shock if paralysis has evolved rapidly.

Diagnosis The diagnosis can usually be ascertained from MRI (Fig. 44-2) but care must be taken to obtain images from levels rostral and caudal enough to detect the infected collection. There may be enhancement of the margins of the purulent collection after several days.

If a diagnostic spinal puncture is performed, the CSF usually contains white cells but of surprisingly small number (fewer than 100/mm³), both polymorphonuclear leukocytes and lymphocytes, unless of course, the needle

Figure 44-2. MRI of spinal epidural abscess compressing the dorsolateral cervical spinal cord. Sagittal (*left*) and axial (*right*) T1 gadolinium-enhanced images show the peripherally enhancing pyogenic collection (*arrows*) which extends over several vertebral segments.

penetrates the abscess, in which case pus is obtained. The CSF protein content is high, (100 to 400 mg/100 mL or more) but the glucose is normal. Elevation of the sedimentation rate, C-reactive protein, and peripheral neutrophilic leukocytosis are additional indicators to the diagnosis. The last of these tests is abnormal in two-thirds of cases. Blood cultures demonstrate the organism in a similar proportion. Cultures from the CSF are infrequently positive. The decades old series reported by Baker and colleagues is still a valuable reference, as is the more recent discussion by Darouiche. The differential diagnosis includes other forms of spinal cord compression and, in cases with areflexic spinal shock, tetraparesis and respiratory failure, Guillain-Barré syndrome.

Treatment The foregoing clinical findings call for MRI to be performed relatively quickly or CT myelography if MRI is not possible, to demonstrate the mass of the abscess and to determine its level. If not treated surgically by laminectomy and drainage before the onset of paralysis, the spinal cord lesion, which is probably partly a result of venous ischemia, becomes more or less irreversible. Broad-spectrum antibiotics in large doses must be given initially and the choice of treatment is then refined based on cultures from the abscess or the blood, or on a presumed source of bacteria, usually found to be staphylococcus.

When osteomyelitis of a vertebral body is the primary abnormality, the epidural extension may implicate only a few spinal sensory and motor roots, leaving long tracts and other intramedullary structures intact. In some

cases with cervical epidural abscesses, stiff neck, fever, and deltoid-biceps weakness are the main neurologic abnormalities. Having emphasized the urgency of treatment, there are instances of small epidural abscesses that do not compress the cord and are limited to one or at most two levels for which we have avoided surgery by administering antibiotics alone. Also, lumbar epidural abscess and cauda equina compression without neurologic signs may be, in some cases, treated solely with antibiotics, although many surgeons favor drainage, which must be undertaken in any case, if osteomyelitis develops. Antibiotics are continued for several weeks, and the patient should be examined at regular intervals and have sequential MRI scans of the affected region.

Even after apparently successful drainage and antibiotic treatment of an epidural abscess, there may be a slowly progressive and then static syndrome of partial spinal cord compression. This is the result of formation of a fibrous and granulomatous reaction at the operative site. Distinguishing this sterile inflammatory mass from residual epidural abscess is quite difficult, even with enhanced MRI, but persistent fever, leukocytosis, and an elevated sedimentation rate, C-reactive and peripheral white blood cell count suggest that surgical drainage of the abscess was incomplete.

Spinal subdural abscess due to bacterial infections also occur and, clinically, are virtually indistinguishable from epidural ones on clinical grounds. The MRI will usually clarify the situation but a clue is provided by the CT myelogram, in which the subdural lesion has a less

sharp margin and usually, a greater vertical extent. The epidural and subdural infections, if they smolder owing to delayed diagnosis or inadequate therapy, may also evolve into a local chronic adhesive meningomyelitis.

Subacute pyogenic infections and *granulomatous infections* (tuberculous, fungal) may also arise in the spinal epidural space, as noted below.

Spinal Cord Abscess

Purulent collections within the substance of the cord was first described by Hart in 1830 and, although it is rare, 73 cases had been reported by 1994 (Candon and Frerebeau). In some instances, the patient was known to have had systemic bacterial infection, septicemia, or endocarditis; in others, there was a contiguous abscess in the skin or subcutaneous tissues with a fistula to the spinal cord through an intervertebral foramen. Spinal cord abscess is a rare complication of spinal dysraphism or of a developmentally open dorsal fistulous tract. The symptoms are indistinguishable from those of epidural abscess, namely, spinal and radicular pain followed by sensory and motor paralysis; the CSF findings are also the same. Woltman and Adson described a patient in whom surgical drainage of an encapsulated intramedullary abscess led to recovery, and Morrison and associates reported a similar case caused by *Listeria monocytogenes*, which was successfully drained and the meningeal infection suppressed by ampicillin and chloramphenicol. There was no way to be certain of the diagnosis prior to the availability of MRI.

Vertebral Bacterial Osteomyelitis

This process is presented in juxtaposition to epidural abscess, with which it is closely aligned. As with other forms of osteomyelitis, vertebral infection is typically due to hematogenous implantation of bacteria during episodes of bacteremia or, it is associated with the exogenous introduction of bacteria during spinal surgery, particularly if catheters or other devices, including for spinal stabilization, are incorporated. In the case of postsurgical infection, coagulase-negative staphylococci or propionibacterium are almost always implicated, whereas with bacteremia, a number of low-virulence organisms including staphylococcus are found and multiple organisms may be involved. The source of bacteremia may be urinary infection, endocarditis, or intravenous drug abuse but many affected individuals also have diabetes, are immunosuppressed, or receiving dialysis for renal failure. In the group of immunocompromised patients, unusual or endemic organisms such as *Brucella* may be found. However, in almost half of patients who have not had surgery, no source is identified. Approximately one-fifth of cases have an associated epidural abscess, as discussed above. This is often indicated by an increase in local back pain or extremely severe pain from the onset.

The lumbar spine is the region most affected. The typical presentation is relatively nondescript with back pain, elevated white blood cell count and see-reactive protein level. Fever, however, is inconsistent. Several

types of imaging studies may be used to demonstrate the infection, however, MRI more dependably than CT shows edema within the bone marrow and, if there is destruction of the disc adjacent to an effective vertebral body, infection is almost certain. Technetium bone scans were popular for the demonstration of osteomyelitis in general but the findings may be nonspecific. A well-known adage is that neoplasms affecting the vertebral body do not cross the disc space.

A point of contention has been the need for biopsy of the affected bone when blood cultures are negative and no obvious source of infection in the body can be found. This procedure is generally suggested although extension of the infection from the vertebral body to the paravertebral or epidural spaces may also be performed under CT guidance.

Initiating therapy with oral fluoroquinolones, with or without rifampin, has been suggested as a broad approach while the specific infecting bacteria are identified. Therapy is generally continued for at least 4 to 6 weeks, if not longer but no clear guidance is available on the appropriate duration. Surgical removal of infected bone is generally not undertaken unless the osteomyelitis is the result of implanted hardware during previous spinal surgery. Almost invariably, this hardware must be removed. Surveillance for persistent infection after treatment is probably appropriate but the MRI has not proven useful for this purpose. Inflammatory markers in the blood are apparently more dependable. A thorough review of this subject can be found in the clinical practice article by Zimmerli.

Tuberculous Spinal Osteomyelitis (Pott Disease)

Tuberculous osteomyelitis of the spine with kyphosis (Pott disease) is well known in regions of endemic tuberculosis. Children and young adults are most often affected. The osteomyelitis is the result of reactivation of tuberculosis at a site previously established by hematogenous spread. An infectious endarteritis causes bone necrosis and collapse of a thoracic or upper lumbar (less often cervical) vertebral body resulting in a characteristic angulated kyphotic deformity (Fig. 44-3); any degree of additional rotary instability allows the emergence of a gibbus deformity. Most patients have some active tuberculous infection as evidenced by fever, night sweats, and other constitutional symptoms; the sedimentation rate is invariably elevated but the degree may be slight. A compressive myelopathy occurs in some cases as a result of the spinal deformity, but it is infrequent and an epidural tuberculous abscess is a more common cause of cord compression (see below). What is surprising to us about Pott disease is the excellent result that may be obtained by external stabilization of the spine and long-term antituberculous medication. A recent young patient of ours was saved from an operation by the intercession by telephone of his father, a physician from India. Although there is some controversy regarding spinal surgery, it is certainly required in the presence of severe deformities or a compressive myelopathy as noted in Chap. 32.

Figure 44-3. Sagittal T2-weighted MRI in Pott tuberculous spine disease. The angulated deformity of the thoracic spine is highly characteristic. (Courtesy of Dr. Randall Edgell, New York University Medical Center.)

Tuberculous Myelitis and Epidural Abscess

Solitary tuberculoma of the spinal cord as part of a generalized infection is a rarity. More often, pus or caseous granulation tissue extrudes from an infected vertebra and gives rise to an epidural compression of the cord (Pott paraplegia, as distinct from Pott disease). Occasionally tuberculous meningitis may result in pial arteritis and spinal cord infarction. The paraplegia may appear before the tuberculous meningitis is diagnosed. All these forms of tuberculosis are infrequent in the United States and Western Europe, but we see a new case every several years in a patient who had spent his earlier life in India or Africa. Additional comments can be found in Chap. 32.

Meningomyelitis Caused by Fungus and Parasitic Diseases

A wide variety of fungal and parasitic agents may involve the spinal meninges. Such infections are rare, and some do not occur at all in the United States or are limited to certain geographic areas, particularly among immigrant populations. *Actinomyces*, *Blastomyces*, *Coccidioides*, and *Aspergillus* may invade the spinal epidural space via intervertebral foramina or by extension from a vertebral osteomyelitic focus. *Cryptococcus*, which causes meningoencephalitis and, rarely, a cerebral granuloma, in our experience, seldom causes spinal lesions. Hematogenous metastases to the spinal cord or meninges may occur in

both blastomycosis and coccidioidomycosis. Occasionally an echinococcal infection of the posterior mediastinum may extend to the spinal canal (epidural space) via intervertebral foramina and compress the spinal cord.

Schistosomiasis (bilharziasis) is a recognized cause of myelitis in the Asia, Africa, and South America. The spinal cord is a target for all three common forms of *Schistosoma*: *S. haematobium*, *S. japonicum*, and *S. mansoni*, but most particularly the last of these (see “Schistosomiasis” in Chap. 32). The schistosomal ova evoke an intense granulomatous myelomeningoradiculitis. The lesions are destructive of gray and white matter, with ova in arteries and veins leading to vascular obstruction and ischemia (Scrimgeour and Gajdusek). Less often, a localized granuloma gives rise to a cord syndrome and, rarely, the disease takes the form of an acute transverse myelitis with massive necrosis of cord tissue (Queiroz et al). A pruritic “swimmer’s itch” at the site of entry of the parasite is reported by many patients in the days prior to the myelopathy. In the often cited review by Scrimgeour and Gajdusek, the latency between exposure and symptoms was 38 days to several years. We have cared for several patients over the years in whom the spinal cord in the low thoracic and lumbar region was infected approximately 3 weeks after they swam in contaminated water during an east African vacation and then returned home to the United States. The CSF showed only a slight elevation of protein, but in almost all cases there is a pronounced pleocytosis ranging from 5 to 500 lymphocytes/mm³ and the glucose is normal or minimally reduced. Systemic and CSF eosinophilia are variable so are not dependable for diagnosis. The diagnosis is confirmed by the finding of elevated titers of antibody directed against the schistosome in the CSF or blood. There are usually oligoclonal bands of IgG in the CSF as well. The parasite can sometimes be found in biopsies of the rectosigmoid mucosa. The administration of praziquantel arrested the course of the illness, but all but one of our patients was left disabled.

Myelitis of Noninfectious Inflammatory Type (Multiple Sclerosis and Acute and Subacute Transverse Myelitis) (See Chap. 36)

The spinal cord disorders that make up this category take the form of a leukomyelitis based on either demyelination or necrosis of portions of the spinal cord. The critical factor in their pathogenesis appears to be a disordered immune response, in some cases, as a response to an infection, and in others such as multiple sclerosis an idiopathic immune disorder. Varied clinical syndromes are produced, and the basic disease is classified in textbooks under headings such as *acute transverse myelitis*, *postinfectious myelitis*, *postvaccinal myelitis*, *acute MS*, *neuromyelitis optica*, and *necrotizing myelitis*. While each of these conditions may affect other parts of the nervous system (most often the optic nerves and brain), often the only manifestations are spinal. The aforementioned myelopaths are characterized by various degrees of inflammatory destruction, usually with lymphocytes congregating around venules

in the cord, but they are sufficiently distinct to justify their separate classification. Nonetheless, transitional cases sharing the clinical and pathologic attributes of more than one disease are encountered in any large clinical practice and pathologic collection.

Postinfectious and Postvaccinal Myelitides

The characteristic features of these diseases are their temporal relationship following a viral infection or vaccination with the delayed development of neurologic signs over the period of a few days, and a monophasic course, i.e., a single attack with variable degrees of recovery and no recurrence. These processes may involve the brain as well as the spinal cord, in which case the process is properly designated as *acute disseminated encephalomyelitis* (ADEM). On the basis of the clinical features of disseminated postinfectious encephalomyelitis and the animal model of experimental allergic encephalomyelitis (EAE), postinfectious myelitis is presumed to be immunologic in nature, reflecting an attack that is more or less confined to spinal cord myelin as described in more detail in Chap. 36.

The usual history in these cases is of weakness and numbness of the feet and legs (less often of the hands and arms), which typically develop over a few days, and for the sensory symptoms to ascend from the feet to the trunk. Paresthesias in the feet and legs, which simulate a polyneuropathy, are common early symptoms. Sphincteric disturbances and backache are also common in the first days but as often arise later. A slight asymmetry of the symptoms and signs, a sensory level on the trunk, or a Babinski sign clearly marks the disease as a myelopathy and serves to distinguish it from a rapidly progressive polyneuropathy such as the Guillain-Barré

syndrome. Back pain of varying degree and headache and stiff neck may or may not be present. In about half of cases the patient can identify a recent infectious illness, usually a mundane upper respiratory syndrome, but the fever has usually abated when the neurologic symptoms begin. The illness evolves over several days, sometimes a single day or on the other extreme, over 1 or 2 weeks. Despite the term *transverse myelitis*, fewer than half of cases demonstrate a truly "transverse" involvement of the cord; more often there is an incomplete corticospinal and spinothalamic syndrome affecting one side more than the other. As discussed further on, it is usually not possible to distinguish an acute episode of postinfectious myelitis from the first attack of multiple sclerosis, but a well-defined preceding infection with certain organisms favors the former process. The latency between infection and myelitis is an uncertain matter but there are well-documented instances in which the febrile episode blends into the neurologic syndrome and others in which the latency has been 2 weeks; considerably longer intervals make the association suspect.

Almost invariably, the CSF contains lymphocytes and other mononuclear cells in the range of 10 to 50/mm³ (sometimes higher), with slightly raised protein and normal glucose content. However, there may be only 3 or 4 cells/mm³, or none, making the inflammatory aspect less clear. Oligoclonal bands are usually absent. In most instances that have come under our care, the MRI has shown slight T2 signal abnormalities and minimal gadolinium enhancement extending over 2 or 3 spinal segments. Although the cord may be swollen in these regions (Fig. 44-4), several of our patients with mild and partial myelitis have had normal MRI studies.

Figure 44-4. T2-weighted MRI of acute postinfectious myelitis in the sagittal (A) and axial (B) planes. There is abnormal T2 hyperintensity within the dorsal spinal cord and the cord is mildly enlarged. Mild enhancement following gadolinium infusion was noted (not shown).

Clinical variants of this syndrome are frequent in our experience; including an almost pure paresthetic illness with posterior column dysfunction and the converse; a symmetrical paraparesis with analgesia below a level on the trunk but without involvement of deep sensation (a syndrome more typically associated with infarction in the territory of the anterior spinal artery); a syndrome of variable sensory loss involving the leg and groin on one side or both; a purely lumbosacral or sacral myelopathy (conus syndrome with saddle analgesia and sphincter disturbances); and a partial Brown-Séquard syndrome.

In the past, postinfectious myelitis was most often observed in relation to the common exanthems (rubella, rubeola, varicella). The neurologic signs appeared as the rash was fading, often with a slight recrudescence of fever. Practically all human viruses have at one time or another been found to have preceded acute myelitis; however, the DNA viruses such as Epstein-Barr and cytomegalovirus are most common, and hepatitis B, varicella, and enteroviruses have been detected from time to time. *Mycoplasma* is almost unique in being a bacterial trigger of the disease, but as noted earlier, there is some uncertainty regarding its ability to cause direct infection rather than a postinfectious immune reaction. Our interpretation of the existing information still favors a postinfectious etiology. In most instances of postinfectious myelitis, the connection to a preceding infection is presumed but cannot be proved. Only the associations with EBV, CMV, and *Mycoplasma* seem fairly certain based on the regularity of their occurrence, but it may simply reflect the relative ease with which a recent infection can be documented by serologic tests. The list of antecedent infections is otherwise much the same as for the Guillain-Barré syndrome with the notable difference of *Campylobacter jejuni*, which has not led to myelitis and is a frequent precedent to acute polyneuropathy. It can be reasonably assumed that, for example, pharyngitis, respiratory infection, and conjunctivitis, with or without fever, was a likely trigger for myelitis and the finding of abnormal liver function tests or severe pharyngitis with cervical adenopathy usually indicates EBV or, less often, CMV infection.

More difficult to understand are the large number of cases of myelitis, including autopsy-proven ones, in which the disease develops without an apparent antecedent infection. There is understandable uncertainty in such cases as to whether the illness is the opening phase of multiple sclerosis of the type described below under "Acute Demyelinating Myelitis of Multiple Sclerosis." In the numerous cases of transverse myelitis under our care, fewer than half have shown other signs of MS after 10 to 20 years (this is a far lower incidence than disseminated multiple sclerosis following a bout of optic neuritis). There is also an isolated form of *relapsing myelitis*, sometimes but not always triggered by an infection that does not manifest lesions elsewhere in the neuraxis and therefore has an ambiguous relationship to MS. Further discussion of acute transverse myelitis in relation to other demyelinating diseases can be found below and in Chap. 36.

The *pathologic changes* in postinfectious myelitis take the form of numerous subpial and perivenular zones of

demyelination, with perivascular and meningeal infiltrations of lymphocytes and other mononuclear cells, and para-adventitial pleomorphic histiocytes and microglia. Taken in isolation, these pathologic changes cannot be distinguished from those of MS.

Treatment Once symptoms begin, it is not clear if any treatment is of consistent value. One's first impulse, assuming the mechanism to be autoimmune, is to administer high doses of corticosteroids, a practice we have followed but without conviction. Perhaps it is advisable to do so, but there is as yet no evidence that this alters the course of the illness. We have also used plasma exchange or intravenous immune globulin in several patients with uncertain results, although this approach was seemingly helpful in a few patients who had an explosive clinical onset.

The prognosis of this illness is better than the initial symptoms might suggest. Invariably, the myelitic disease improves, sometimes to a surprising degree, but there are examples in which the sequelae have been severe and permanent. Pain in the midthoracic region or an abrupt, severe onset usually indicates a poor prognosis (Ropper and Poskanzer). The authors have several times given a good prognosis for long-term recovery and assurance that no relapse will occur, only to witness a recrudescence of other symptoms at a later date, indicating that the original illness was probably multiple sclerosis.

Acute Demyelinating Myelitis of Multiple Sclerosis (Chap. 36)

The lesions of acute MS share many of the features of the postinfectious type as noted above. However, the clinical manifestations of the former tend to evolve more slowly, over a period of 1 to 3 weeks or even longer. Also, a relation to antecedent infections is not often seen in MS. Only the occurrence of subsequent attacks or additional lesions revealed by MRI or evoked potentials indicates that the basic illness is one of chronic recurrent demyelination.

The most typical of clinical expression of demyelinating myelitis is with numbness that spreads over one or both sides of the body from the sacral segments to the feet, anterior thighs, and up over the trunk, with coincident but variable and usually asymmetric weakness and then paralysis of the legs. As this process becomes complete, the bladder is also affected. The sensorimotor disturbance may extend to involve the arms, and a sensory level can be demonstrated on the upper parts of the trunk. The CSF may show a mild lymphocytosis, as in the postinfectious variety, but it is as often normal. Oligoclonal bands may be absent with the first attack. Bakshi and colleagues have suggested that in myelitis as a result of MS, the changes seen on MRI occupy only a few adjacent spinal segments in comparison to the postinfectious lesions, which have a longer vertical extent, but this has not been a consistent distinction in our experience. As a general rule, acute spinal MS is relatively painless and without fever, and the patient usually improves, with variable residual signs. The differential diagnosis of demyelinating myelitis is considered more fully in Chap. 36.

Treatment Corticosteroids, as outlined for the treatment of MS in Chap. 36, may lead to a regression of symptoms, sometimes with relapse when the medication is discontinued (after 1 to 2 weeks). Other patients, however, show no apparent response, and a proportion of cases have even continued to worsen while the medication was being given. Plasma exchange and intravenous immune globulin have reportedly been beneficial in individual cases, particularly in those with an explosive onset (see later). The results in our patients have been too variable to interpret.

Neuromyelitis Optica, Acute and Subacute Necrotizing Myelitis, and Devic Disease

(See discussion in Chap. 36)

In every large center, examples of this disorder are found among the many patients who present with a subacute paraplegia or quadriplegia, sensory loss, and sphincter paralysis. The neurologic signs may erupt so precipitously that a vascular lesion is assumed. In most other cases, the disease evolves at a slower and usually stepwise pace, over several months or years. Necrotizing myelopathy is distinguished from the more common types of transverse myelitis by a persistent and profound flaccidity of the legs (or arms if the lesion is cervical), areflexia, and atonicity of the bladder—all reflecting a widespread necrosis that involves both the gray and white matter of the spinal cord over a considerable vertical extent. This clinical picture is unexpected for a spinal cord lesion and, therefore, is often mistakenly attributed to spinal shock or to a completely different process such as Guillain-Barré syndrome.

This combination of spinal cord necrosis and optic neuritis corresponds to the syndrome described by Devic in 1894 and named by him *neuromyelitis optica* (Devic disease). Nearly all neurologists agree that a similar clinical syndrome involving the optic nerve and spinal cord (usually without necrosis) may also be caused by postinfectious encephalomyelitis or by MS, however, the finding by Lennon and colleagues of a specific serum IgG antibody in half of cases of Devic disease was a notable advance. The antibody is directed against the aquaporin channel in capillaries of the brainstem and cerebellum and its role in the pathogenesis of the disease partially resolves the decades old uncertainty regarding a distinction between Devic disease and forms of multiple sclerosis, in which the antibody is not present.

In both the isolated necrotizing myelopathy and in Devic disease, a few or up to several hundred mononuclear cells per cubic millimeter and increased protein may be found in the CSF but oligoclonal banding is usually absent. Some cases show only an elevated protein concentration. More so than with postinfectious transverse myelitis, the MRI reveals extensive signal changes and gadolinium enhancement, usually occupying several contiguous spinal segments; called a “longitudinally extensive” lesion (Fig. 44-5). Imaging studies performed weeks or more later show atrophy of the involved segments of cord. Persistent swelling of the affected region is more suggestive of spinal cord tumor or another type of inflammation,

Figure 44-5. MRI of necrotic myelopathy in a patient with neuromyelitis optica. Note the long extent of the lesion and thinning of the cord as the acute illness subsides.

but the permissible duration of cord swelling may extend for weeks. The electromyogram (EMG) often shows denervation of several contiguous myotomes, reflecting damage to the gray matter of those segments.

In cases coming to postmortem examination at variable times after the onset of symptoms, the lesion has proved to be a necrotizing myelitis with widespread loss of spinal cord tissue. The pattern of tissue destruction appears, at least in part, infarctive, i.e., not respecting the borders of gray and white matter. However, areas of residual inflammation and demyelination are often detected at the edges of the destructive lesions. Older lesions leave the spinal cord cavitated or collapsed over a vertical extent of 5 to 20 cm, with conical extensions of necrosis into the gray matter above and below the area of transverse damage. Probably many of these cases would now be categorized as part of the neuromyelitis family with aquaporin autoantibodies.

Subacute Necrotic Myelopathy and Foix-Alajouanine Myelopathy

Under the title “Subacute Necrotic Myelitis,” Foix and Alajouanine, and later Greenfield and Turner, and later, Hughes, described a disorder mainly of adult men characterized by amyotrophic paraplegia that ran a progressive course over several months. The defining feature, one that still gives rise to lively polemical discussions, is severe necrosis of both gray and white matter in the

lumbosacral region and a marked increase in the number of small vessels, their walls thickened, cellular, and fibrotic (“angiodysplastic”), yet without vascular occlusion. The veins are also thickened and surrounded by lymphocytes, mononuclear cells, and macrophages.

These findings have been difficult to interpret and their relationship to the group of arteriovenous malformations and fistulas, discussed later, has been unclear but we are inclined to the view of Antoni and others who were impressed with the prominence of large arteries and veins and have reinterpreted this pathologic process as an arteriovenous malformation. In many other cases of necrotic myelopathy that are not associated with a true vascular malformation, the vascular changes simply reflect a neovascular response to necrosis or may be examples of neuromyelitis optica.

A similar syndrome is produced by a rare idiopathic necrotizing vasculitis that is confined to the spinal cord (Caccamo et al). In these cases, there is a persistent and marked pleocytosis and some clinical stabilization with corticosteroids. One of our young male patients with this type of subacute necrotizing myelitis, responsive to corticosteroids, had mononuclear cells in the spinal fluid persistently over a year and died as a result of fulminant inflammatory cerebral hemorrhages. There were multiple occlusions of small vessels surrounding the spinal cord and a *vasculitis*. Polyarteritis nodosa and necrotizing arteritis only rarely involve the spinal cord. Schistosomiasis, as mentioned earlier, may also produce a necrotizing myelitis of the lumbosacral region.

Myelitis (Myelopathy) With Connective Tissue Disease

A rapidly evolving or subacute myelopathy occurs in association with systemic lupus erythematosus. The process is presumed to arise from a microvasculitis or an autoantibody. Propper and Bucknall presented such a case and reviewed 44 others in which patients with lupus developed a transverse myelitis over a period of days. There was back pain at the level of sensory loss (the cases we have seen have been painless), and pleocytosis and elevation of CSF protein were characteristic. The MRI revealed segmental swelling of the spinal cord. Postmortem examinations of similar cases have disclosed widespread vasculopathy of small vessels with variable inflammation and myelomalacia, and, rarely, a vacuolar myelopathy.

Some but not all cases also have circulating antiphospholipid antibody; the relationship of these antibodies to the myelopathy and to microvascular occlusion is uncertain (see also “Antiphospholipid Antibody Syndrome” in Chap. 34 and further discussion in Chap. 36). The incidence of lupus myelopathy is not known, but one such case is admitted to our service, in a hospital with an active rheumatology division, about every year.

Sjögren Syndrome Myelopathy

In addition to a well-described posterior root ganglionopathy and sensory neuritis, an inflammatory myelitis is associated with Sjögren syndrome. In most instances, the patient has had overt symptoms of Sjögren disease

including, the sicca complex, and in others, the association has been established through serologic testing or by the finding of inflammatory infiltration of minor salivary glands (obtained by biopsy). In many reported cases, the myelopathy has simulated the myelitis of MS, even to the extent of including episodes of optic neuritis as in the cases described by Williams and colleagues and by de Seze and coworkers. The myelitis has been in different cases acute, chronic, or relapsing and displayed MRI changes in the cord that would otherwise be considered to be postinfectious or demyelinating myelitis. The spinal fluid formula has also varied but generally does not contain oligoclonal bands. Treatment with prednisone and cyclophosphamide or methotrexate has been suggested and was seemingly successful in several of our patients.

The authors cannot comment authoritatively on this entity. There is little pathologic material on which to judge the association, but the presence of other inflammatory lesions of the central and peripheral nervous system in Sjögren disease makes the existence of myelitis plausible. Antibody tests (anti-SS-A [Ro] and SS-B [La]) and possibly a biopsy of the minor salivary glands (at the junction of mucosa and epidermis of the lower lip) are justified in patients with unusual myelopathies or in those with sicca symptoms; however, screening in this manner of all cases that otherwise suggest MS or postinfectious myelitis may be excessive. This subject is also reviewed in Chap. 36, in relation to multiple sclerosis.

There is also the rare occurrence of nondescript myelitis with scleroderma as mentioned above (systemic sclerosis). The authors of most reports acknowledge the difficulty in distinguishing between the myelopathies of various connective tissue diseases. There may be some response to corticosteroids and other immunosuppressive medications. Myopathy and neuropathy, particularly trigeminal neuritis, are more common manifestations of scleroderma.

Paraneoplastic Myelitis (See also Chap. 31)

A subacute necrotic myelitis developing in conjunction with bronchogenic carcinoma was first brought to notice by Mancall and Rosales in 1964. Several dozen cases have since been recorded in association with lymphomas and carcinomas, but the disease must be rare. Actually, in cancer patients, intramedullary metastasis, quite infrequent to begin with, is more common as a cause of intrinsic myelopathy and, of course, a compressive lesion is far more frequent than either of these conditions.

The clinical syndrome consists of a progressive painless loss of motor and then sensory function, usually with sphincter disorder, over weeks. Imaging studies demonstrate an area of T2 signal change in the cord, occupying one or several contiguous segments, similar to neuromyelitis optica (Devic disease); some have slight enhancement with gadolinium or rarely, imaging may be normal. This is in distinction to the nodular enhancing appearance of an intramedullary metastasis or of extradural metastatic disease with cord compression.

The CSF may contain a few mononuclear cells and a slightly increased protein, or it may be normal. The lesions are essentially of necrotic type and respect neither

gray nor white matter, but the latter is more affected. There is little or no evidence of an infective-inflammatory or ischemic lesion, for the blood vessels, apart from a modest cuffing with mononuclear cells, are normal. No tumor cells are visible in the CSF, meninges, or spinal cord tissue, and no virus has been isolated. Unlike the situation in most of the paraneoplastic neurologic disorders, there are no diagnostic markers by way of specific antineural antibodies. In particular, this myelopathy does not seem to be a component of the anti-Hu-associated encephalitis-neuropathy spectrum.

In some cases of paraneoplastic myelopathy, the pathologic changes have been more chronic, confined to the posterior and lateral columns, and associated with a diffuse loss of cerebellar Purkinje cells. This latter syndrome may have a special association with ovarian carcinoma but has been observed with carcinoma of other types and with Hodgkin disease as discussed in Chap. 31. Most of the reported cases of these types have ended fatally. Steroids and plasma exchanges have been of no clear value. Treatment of the underlying systemic tumor or immunosuppression has also failed in most cases to alter the myelopathy according to Flanagan and colleagues. A rare variety of anterior horn cell destruction that resembles motor neuron diseases is known to occur with certain lymphomas; it is also discussed with the paraneoplastic syndromes in Chap. 31.

Subacute Spinal Neuronitis (Propriospinal Myoclonus)

Two distinct entities seem to be encompassed under this name, both rare; a progressive myelopathy and a regional disorder, mainly of the abdominal muscles. Whitely and colleagues drew attention to the process characterized clinically by tonic rigidity and intermittent myoclonic jerking of the trunk and limb muscles and by painful spasms of these muscles evoked by sensory or emotional stimuli. Their cases were progressive and eventually involved the limbs.

In the few well-studied cases of this type, the brunt of the pathologic process has fallen on the cervical portion of the spinal cord. Widespread loss of internuncial neurons with relative sparing of the anterior horn cells, reactive gliosis and microglial proliferation, conspicuous lymphocytic cuffing of small blood vessels, and scanty meningeal inflammation have been the main findings. Involvement of the white matter is less marked. The pathophysiology of the rigidity in these cases is presumed to be because of the impaired function (or destruction) of Renshaw cells, with the release of tonic reflexes (Penry et al). The painful spasms and dysesthesias relate in some way to neuronal lesions in the posterior horns of the spinal cord and dorsal root ganglia. Whitely and Lhermitte and their coworkers proposed that these cases probably represent an obscure form of viral myelitis.

The cases we have observed have been of the type that remained confined to several contiguous spinal segments, usually the upper abdomen and lower thorax as described by Brown and colleagues. Some patients report a premonitory sensation before the abdominal jerking, or there is

worsening with the supine position. Whether these represent the same disease as the one noted above is unclear but the segmental, abdominal variety is now a firmly established entity, albeit also idiopathic, as described in a series by Roze et al and discussed under "Spinal or Segmental Myoclonus" in Chap. 6. The CSF may be normal or show a mild lymphocytosis and increase in protein content.

Myoclonic jerking of the trunk and limbs in a focal or segmental distribution is probably a result of neuronal damage of this same type that is limited to a few segments of the spinal cord. Clonazepam, various antiepileptic and antispasticity drugs in combination may partially suppress the myoclonus, and local injection of botulinum toxin has improved the symptoms in some. A similar syndrome in a few cases has followed vertebral or spinal artery angiography (see later). A paraneoplastic variety usually associated with breast cancer has been proposed, as in the case described by Roobol and colleagues, but its nature has not been fully elucidated.

VASCULAR DISEASES OF THE SPINAL CORD

In comparison with the brain, the spinal cord is an uncommon site of vascular disease. Blackwood, in a review of 3,737 necropsies at the National Hospital for Nervous Diseases, London, during the period 1903 to 1958, found only 9 cases of spinal cord infarction, but in general hospitals, the incidence (judged on clinical grounds in our hospital) is higher. The spinal arteries tend not to be susceptible to atherosclerosis, and emboli rarely lodge there. Of all the vascular disorders of the spinal cord, infarction as a result of aortic disease, dural fistula, bleeding, and arteriovenous malformation are the only ones that are encountered with any regularity, but even taken together, they are infrequent in comparison to demyelinating myelitis or compression of the cord by tumor. In current practice, most cases of infarction have developed in relation to operations on the aorta, usually the thoracic portion, where the vessel must be clamped for some period. The dural arteriovenous fistulas that cause spinal cord swelling are being recognized increasingly as their clinical syndromes are exposed and vascular imaging of small spinal arteries becomes more sophisticated. They have probably overtaken in frequency cord infarction in this category of disease. An understanding of these disorders requires knowledge of the blood supply of the spinal cord.

Vascular Anatomy of the Spinal Cord

The blood supply of the spinal cord is derived from a series of segmental vessels arising from the aorta and from branches of the subclavians and internal iliac arteries. The most important branches of the subclavian are the vertebral arteries, small branches of which give rise to the rostral origin of the anterior spinal artery and to smaller posterolateral spinal arteries that together constitute the major blood supply to the cervical cord. The thoracic and lumbar cord is nourished by segmental

arteries arising from the aorta and internal iliac arteries. Segmental branches of the lateral sacral arteries supply the sacral cord.

A typical segmental artery divides into an anterior and a posterior ramus (Fig. 44-6). Each posterior ramus gives rise to a spinal artery, which enters the vertebral foramen, pierces the dura, and supplies the spinal ganglion and roots through its anterior and posterior radicular branches. Most anterior radicular arteries are small and some never reach the spinal cord, but a variable number (4 to 9), arising at irregular intervals, are much larger and supply most of the blood to the spinal cord. Tributaries of the radicular arteries supply blood to the vertebral bodies and surrounding ligaments. The venous drainage is into the posterior veins forming the spinal plexus. Their importance relates to the pathogenesis of fibrocartilaginous embolism (see further on).

Lazorthes, in his thorough review of the circulation of the spinal cord, divides the radiculomedullary arteries

into three groups: (1) upper or cervicothoracic, which are derived from the anterior spinal arteries and branches of the thyrocervical and costovertebral arteries; (2) intermediate or middle thoracic (T3 to T8 cord segments), usually from a single T7 radicular artery; and (3) lower or thoracolumbar, from a large T10 or L1 anterior radicular artery, better known as the *artery of Adamkiewicz*. This artery supplies the lower two-thirds of the cord, but in any individual the precise area supplied by this or any other anterior radiculomedullary artery varies greatly and one cannot predict what portion or proportion of cord will be infarcted if one of these vessels is occluded. The junction between the vertebral spinal and aortic circulations typically lies at the T2-T3 spinal segment, but most ischemic lesions lie well below this level.

The anterior medullary arteries form the single anterior spinal artery, which runs the full length of the cord in its anterior sulcus and gives off direct penetrating branches via the central (sulcocommisural) arteries. These penetrating branches supply most of the anterior gray columns and the ventral portions of the dorsal gray columns of neurons (see Fig. 44-6). The peripheral rim of white matter of the anterior two-thirds of the cord is supplied from a pial radial network, which also originates from the anterior median spinal artery. Thus, the branches of the anterior median spinal artery supply roughly the ventral two-thirds of the spinal cord. Infarction of the region supplied by this artery give rise to an anterior spinal cord syndrome that consists of loss of pain and temperature and paralysis below the level of the lesion, but with sparing of proprioception and vibration sense that correspond to transection of the spinothalamic and cortico-spinal tracts but not of the posterior columns.

The posterior medullary arteries form the paired posterior spinal arteries that supply the dorsal third of the cord by means of direct penetrating vessels and a plexus of pial vessels (similar to that of the ventral cord, with which it anastomoses freely). Within the cord substance, then, there is a "watershed" area of capillaries where the penetrating branches of the anterior spinal artery meet the penetrating branches of the posterior spinal arteries and the branches of the circumferential pial network. All spinal segments, because of the variable size of collateral arteries, do not have the same abundance of circulatory protection.

Normally there are 8 to 12 anterior medullary veins and a greater number of posterior medullary veins arranged fairly close to one another at every segmental level. They drain into radicular veins. In addition, a network of valveless veins extends along the vertebral column from the pelvic venous plexuses to the intracranial venous sinuses without passing through the lungs (Batson plexus) and is considered a route for metastatic disease from the pelvis.

Figure 44-6. Anterior view of the spinal cord with its segmental blood supply from the aorta. (Reproduced with permission from Prasad S, Price RS, Kranick SM et al: Clinical reasoning: A 59-year-old woman with acute paraplegia. *Neurology* 69:E41, 2007.)

Infarction of the Spinal Cord

Ischemic infarction of the spinal cord usually involves the territory of the anterior spinal artery, i.e., a variable vertical extent of the ventral two-thirds of the spinal cord. Infarctions in this territory are relatively uncommon as

already mentioned, representing 1.2 percent of all strokes (Sandson and Friedman). The resulting clinical abnormalities are generally referred to as the *anterior spinal artery syndrome*, described by Spiller in 1909. Atherosclerosis and thrombotic occlusion of the anterior spinal artery is quite uncommon, as noted, and infarction in the territory of this artery is more often secondary to disease of the extravertebral collateral artery or to disease of the aorta, either advanced atherosclerosis, a dissecting aneurysm, or intraoperative surgical occlusion—which compromises the important segmental spinal arteries at their origins. An ischemic myelopathy has been reported in cocaine users, preceded sometimes by episodes of cord dysfunction resembling transient ischemic attacks. Cardiac and aortic surgery, which requires clamping of the aorta for more than 30 min, and aortic arteriography may also be complicated by infarction in the territory of the anterior spinal artery; more often in these circumstances damage to central neuronal elements is greater than that to anterior and lateral funiculi, as described below.

Rarely, polyarteritis nodosa may cause occlusion of a spinal medullary artery. Systemic cholesterol embolism arising from a severely atheromatous aorta may have the same effect. This latter type of embolism is prone to occur after surgical procedures, angioplasty, or cardiopulmonary resuscitation. For unexplained reasons, the spinal cord infarction sometimes follows one of the aforementioned procedures by up to 3 weeks, as emphasized in Dahlberg's series of cases. In almost all such patients, other evidence of widespread embolism can be expected. Infarction may also result from systemic hypotension, the most vulnerable part being of the thoracic segments of the cord. One of our patients had cord infarction during a bout of diabetic coma.

Among the most curious causes of cervical cord infarctions is *dissection of the extracranial vertebral arteries*, either unilateral or bilateral. The resultant ischemia in the territories of the anterior spinal arteries causes anterior and central cervical cord ischemia. In two cases of this nature that have been brought to our attention, there were an asymmetric brachial diplegia and a suspended sensory loss, preceded by intense radicular and neck pain. The patients reported by Weidauer and colleagues are representative, and there are numerous other case reports although the cause of the vertebral artery dissections has not always been clear. A few patients have vertigo at the onset, directing attention to the vertebral artery damage. We have also encountered instances of myelomalacia in adolescents and young adults in whom no aortic or spinal arterial disease could be demonstrated. Possibly, some of these were because of embolization of disc material (nucleus pulposus) into the local vasculature (see further on).

A quite different progressive ischemic necrosis of the cord can occur in the neighborhood of an arteriovenous malformation or dural fistula and is considered later in this chapter (see also the subacute necrotic myelitis of Foix and Alajouanine, described earlier).

Despite the elucidation of these causes of spinal cord infarction, a large group in any series has no identifiable cause; for example, an etiology could be established in

only 7 of 27 consecutive cases in the series from Novy and colleagues. The clinical manifestations of spinal arterial occlusion will, of course, vary with the level and portions of the cord that are infarcted, but common to practically all cases of infarction in the territory of the anterior spinal artery is pain in the neck or back and the development of paralysis and loss of pain and thermal sensations below the level of the lesion, accompanied by paralysis of sphincteric function. Except in high cervical lesions, the sensory changes are dissociated, i.e., pain and temperature sensations are lost (because of interruption of the spinothalamic tracts), but vibration and position sense are unimpaired (a result of sparing of posterior columns).

Rarely, infarction is preceded by *spinal transient ischemic attacks* as has been emphasized in cases related to cocaine use. The symptoms may develop instantaneously or, more often in our experience, over an hour or two; in any case, more rapidly than in the inflammatory myelitides. Radicular pain corresponding to the upper level of the lesion is sometimes a complaint. Paralysis is usually bilateral, occasionally unilateral, and rarely complete. Also reported is a bibrachial paralysis as a fragment of the anterior spinal artery syndrome, as mentioned earlier. In cases that cause a complete transverse myelopathy, the limbs are initially flaccid and areflexic, as in spinal shock from traumatic lesions, followed after several weeks by the development of spasticity and the return of a degree of voluntary bladder control (unless sacral segments have been infarcted). Many patients regain a substantial degree of motor function, mainly in the first month but extending over a year (see Sandson and Friedman; Cheshire et al; Novy et al).

Infarction in the territory of the posterior spinal arteries is uncommon and the corresponding syndrome is not stereotyped; only 2 of 27 cases from the series by Novy and colleagues had this pattern. It may occur with surgery or trauma of the spine or rarely with vertebral artery dissections.

Some, but not all, spinal cord infarctions are detected by MRI. After a few days, there are obvious lesions on the T2 sequences, presumably reflecting edema that extends over several levels. There may be slight enhancement after infusion of gadolinium. It is notable, however, that the MRI taken in the first hours or day is often normal. The reason for the delay in the appearance of the imaging findings is not known. In the chronic stages, the infarcted region collapses and has an attenuated signal on MRI. Whether diffusion weighted sequences can dependably demonstrate these infarctions is not clear.

Dissecting aneurysm of the aorta, which is characterized by intense interscapular and/or chest pain (occasionally it is painless), widening of the aorta, and signs of impaired circulation to the legs or arms and various organs, gives rise to a number of myelopathic syndromes. The neurologic picture was first described by Kalischeri in 1914 and the aortic lesion leading to dissection, according to Erdheim, was a medionecrosis. The spinal syndromes of aortic dissection according to Weisman and Adams are (1) paralysis of the sphincters and both legs with sensory loss below T6; (2) ischemic infarction of the cord confined

to the gray matter, in which case there is an abrupt onset of muscle weakness or myoclonus and spasms in the legs but no pain or sensory loss; (3) obstruction of the origin of a common carotid artery with hemiplegia; and, less commonly, (4) obstruction of a brachial artery with a sensorimotor neuropathy of the limb.

With regard to *aortic aneurysm surgery*, paraplegia is uncommon after procedures performed on the infrarenal segment but occurs as frequently as 5 to 10 percent following repair of thoracoabdominal aneurysms. Again emphasized here is the not easily explained observation that up to a quarter of these myelopathies do not appear for several days postoperatively (8 days in one of our patients). The article by Lintott and colleagues may be consulted for further details.

In the past, aortography was sometimes complicated by an acute myelopathy; we had observed a number of such cases and Killen and Foster reviewed 43 examples of this accident. The most striking examples, fortunately rare, are now the result of complications of vertebral angiography, resulting in high cervical infarction, similar in most ways to the aforementioned spinal infarction from extracranial dissection of the vertebral artery. The onset of sensorimotor paralysis is immediate, and the effects are often permanent. The syndrome of painful segmental spasms, spinal myoclonus, and rigidity, mentioned earlier, has also been observed under these conditions. It was presumed that vascular spasm and occlusion resulted in infarct necrosis. The frequency of this complication was greatly reduced by the introduction of less toxic contrast media.

Treatment Whether the acute effects of spinal infarction can be modified by high-dose corticosteroids, agents that increase blood flow, or anticoagulation is not known. There are case reports of improvement in paraplegia following aortic dissection by the use of CSF drainage, for example, as in the cases reported by Blacker and colleagues and by Killen and associates, but other factors may have contributed. Many surgical services insert a spinal drain prior to aortic procedures in order to reduce spinal fluid pressure, ostensibly reducing the incidence of cord infarction. There may be gradual improvement after spinal cord infarction, as Robertson and colleagues have reported in perhaps the largest series available, but most patients remain with substantial difficulties.

Surfer's Myelopathy

This unusual nontraumatic athletic problem has been described by Thompson and colleagues from Hawaii. It mainly affects novice surfers who were prone for prolonged times on the surfboard and then engaged in vigorous movements, followed by assuming a standing position. Within an hour of surfing, there was characteristic severe upper lumbar or thoracic pain after, followed by progressive paraparesis or paraplegia, and urinary retention. In several reports, MRI showed signal changes in a long extent of the thoracic spinal cord and when the proper imaging sequences have been performed, some cases have restricted diffusion in the affected region. On the basis of the latter finding and preservation of proprioception some patients (implicating ischemia of

the anterior portion of the spinal cord), a vascular mechanism has been proposed. In the series reported by Chang and colleagues, improvement was inconsistent.

Hemorrhage of the Spinal Cord (Hematomyelia) and Canal

Hemorrhage into the spinal cord is rare compared with the frequency of cerebral hemorrhage. The apoplectic onset of symptoms that involve spinal tracts (motor, sensory, or both), associated with blood and xanthochromia in the spinal fluid are the identifying features of *hematomyelia*. Aside from trauma, hematomyelia is usually traceable to a vascular malformation or a bleeding disease and particularly to the administration of anticoagulants. Actually, most vascular malformations of the spinal cord do not cause hemorrhage, but instead produce a progressive, presumably ischemic myelopathy as described later and mentioned in the earlier section on the Foix-Alajouanine type of subacute necrotic myelopathy.

The same causes (anticoagulation, blood dyscrasia with coagulopathy, and arteriovenous malformation [AVM]) may underlie bleeding into the epidural or subdural space and give rise to a rapidly evolving compressive myelopathy. In some cases, as in those of Leech and coworkers, one cannot ascertain the source of the bleeding, even at autopsy. Epidural or subdural bleeding, like epidural abscess, represents a neurologic emergency and calls for immediate radiologic localization and, in most cases, surgical evacuation.

Advances in the techniques of selective spinal angiography and microsurgery have permitted the visualization and treatment of vascular lesions that cause bleeding with a precision not imaginable a few decades ago. These procedures make it possible to distinguish among the several types of vascular malformations, arteriovenous fistulas, and vascular tumors, such as hemangioblastomas, and to localize them accurately to the spinal cord, epidural or subdural space, or vertebral bodies. This subject is discussed further on.

Vascular Malformations and Fistulas of the Spinal Cord and Dura

These lesions cause both ischemic and hemorrhagic lesions. Some are true arteriovenous malformations (AVMs), implying a congenital connection between the two sides of the circulation and others are more limited fistulas in the dura, probably mostly acquired for various reasons. The distinction is in the size of the nidus of communication between an artery and a vein and the size and location of feeding and draining vessels. The classification of spinal AVMs is confusing, in part because the enlarged draining veins by which the lesions were formerly identified are probably secondary features. A more useful categorization reflects the appearance and location of the malformation: (1) arteriovenous malformations that are strictly intramedullary or that also involve the meninges and surrounding structures, such as the vertebral bodies, to a limited extent; (2) a variety of intradural perimedullary fistulas that lie on the pial and subpial

surface of the cord (these probably conform most closely to the lesion described by Foix and Alajouanine discussed in the earlier section “Subacute Necrotic Myelopathy and Foix-Alajouanine Myelopathy”); and (3) dural fistulas. There is insufficient pathologic material to determine whether these represent distinct pathologic entities or simply differing degrees and configurations of a common developmental process but, as mentioned, the last of these types may be acquired from local venous occlusions and the other types do not originate in this way. Once recognized, treatment of a spinal cord malformation of any type may be an urgent matter, especially in cases with rapid clinical deterioration and impending paralysis.

Dural Arteriovenous Fistula The entity is addressed first because it has emerged as the most common type, at least in our practices. Fistulas within the dura that overlie the spinal cord are capable of causing a myelopathy, sometimes several segments distant from the vascular lesion. Most are situated in the region of the low thoracic cord or the conus and have a limited venous draining system. Some are in a dural root sleeve and drain into the normal perimedullary coronal venous plexus. Men seem to be affected disproportionately.

The presenting clinical features in our patients have included slowly progressive bilateral but asymmetric leg weakness with variable sensory loss. According to Jellema and colleagues, who studied 80 patients with spinal dural fistulas, the most common initial symptoms were gait imbalance, numbness, and paresthesias. As the process progressed, the majority developed urinary problems, leg weakness, and numbness in the legs and buttocks. The degree of leg weakness varied greatly and back pain in their series was infrequent and has not been a consistent feature in the patients under our care.

The myelopathy may have a subacute or saltatory evolution, presumably from fluctuating venous congestion within the cord. A claudicatory syndrome has also been reported. Characteristically, activities that increase venous pressure (Valsalva maneuver, exercise) transiently amplify the symptoms or produce irreversible, stepwise worsening. One remarkable such case involved a baritone opera singer whose legs gave way repeatedly while singing (Khurana et al). A few of our patients have reported transient symptoms upon standing. Many cases occur, however, without a stepwise progression or elicitable worsening. As mentioned, many reported cases have been painless, although most of our patients have had a moderate spinal ache or sciatica. In contrast to the larger parenchymal arteriovenous lesions, these bleed only rarely. The spinal fluid is normal or shows a slight elevation of protein.

The disease can be inferred from the MRI appearance of a characteristic swelling of one or a few adjacent segments of the cord that represents venous congestion and edema as discussed further on.

Intradural AVM The true AVM, previously referred to as *angioma racemosum venosum* or *dorsal extradural arteriovenous malformation*, is typically located on the dorsal surface of the lower half of the spinal cord and occurs most often in middle-aged and elderly men

(23 of 25 of Logue’s patients were male). However, this lesion may occur at any age and at any location in the cord and may be quite widespread. In a few cases has there been an overlying dermatomal nevus.

The clinical picture was well described by Wyburn-Mason. Acute cramp-like, lancinating pain, sometimes in a sciatic distribution, is often a prominent early feature. It may occur in a series of episodes over a period of several days or weeks; sometimes it is worse in recumbency. Almost always there is weakness or paralysis of one or both legs and numbness and paresthesias in the same distribution with a highly variable duration of evolution; an abrupt apoplectic onset is known or the neurologic signs may appear over months, most cases conforming to the middle of these extremes. Wasting and weakness of the legs may introduce the disease in some instances, with uneven progression, sometimes in a series of abrupt episodes. Severe disability of gait is usually present within 6 months, and half of the patients described by Aminoff and Logue were chair-bound within 3 years; the average survival in the past was 5 to 6 years, but the disorder has rarely been fatal in our patients. These lesions only infrequently give rise to intramedullary or subarachnoid hemorrhage. The spinal fluid shows high protein but little or no cellular reaction.

When viewed directly, the dorsal surface of the lower cord may be covered with a tangle of veins, some involving roots and penetrating the surface of the cord. The progression of symptoms is presumably a result of chronic venous hypertension and secondary intramedullary ischemic changes, and the abrupt episodes of worsening are attributed to the thrombosis of vessels, all on uncertain grounds because angiographic studies sometimes show only a single or a few such dilated draining vessels. Furthermore, there is insufficient pathologic material to determine whether some of the more prominent venous anomalies represent true venous angiomas (probably they do not).

Intradural Perimedullary and Subpial AVM The pial fistulous arteriovenous communication that involves the superficial aspect of the cord to a variable extent is the least frequent in this category but probably of a similar nature to the dural type; it may be related (or identical) to the vascular lesion in the earlier discussed Foix-Alajouanine process. In contrast to dorsal arteriovenous malformations, these fistulas tend to involve the lower thoracic and upper lumbar segments or the anterior parts of the cervical enlargement. The patients are often younger and the sexes are equally affected. The clinical syndrome may take the form of slow spinal cord compression, sometimes with a sudden exacerbation, or the initial symptoms may be apoplectic in nature, either because of thrombosis of a vessel or of a hemorrhage from an associated draining vein that dilates to aneurysmal size and bleeds into the subarachnoid space or cord (hematomyelia and subarachnoid hemorrhage); the latter complication occurred in 7 of 30 cases reported by Wyburn-Mason.

Diagnosis These lesions—dural or parenchymal—may be apparent on MRI or CT myelography by the presence of one or more enlarged and serpiginous draining vessels in the subarachnoid space; just as often, they

are not visualized by these methods (Jones et al). For this reason, the possibility should come to mind that an otherwise unexplained myelopathy with signs of congestion of the cord on MRI may be the result of a vascular malformation. However, several studies, such as the one by Toossi and colleagues, have suggested that the absence of both T2 hyperintensity and flow voids on MRI makes the presence of a dural fistula unlikely and spares the patient from the need for angiography.

Imaging features that have been emphasized with dural fistulas include enlargement of the spinal cord at the level of the lesion and T2 bright signal of the swollen cord over several segments, but these are not invariable. Infrequently, the draining surface vessels are evident on MRI (Fig. 44-7A). Because of the slow blood flow within the vascular lesion, the affected region may have a hypointense T1 signal. Hurst and Grossman have commented on the presence of peripherally located regions of T2 hypointense signal changes. Many of these changes are reversed by surgical or endovascular interventions that ablate the malformation. There is no enhancement although, with increasingly improved MRI techniques, more fistulas are becoming apparent. Some remarkable ones appear as a multiple small enhancing areas that are like hairs standing on end, coating the cord over several levels.

The diagnosis is usually established through selective angiography, which shows the fistula in the dura overlying the cord or on the surface of the cord itself but the most conspicuous finding is often the associated early draining vein (Fig. 44-7B). Demonstration of the fistula requires the injection of feeding vessels at numerous levels above and below the suspected lesion, because the main artery of origin is often some distance away from the malformation. The small angiodysplastic vessels of the Foix-Alajouanine lesion may not be opacified with angiography. In rare instances, the fistula or high-flow arteriovenous malformation lies well outside the cord, for example, in the kidney, and gives rise to a myelopathy, presumably by raising venous pressures within the cord.

Other Rare Vascular Anomalies of the Cord In the *Klippel-Trenaunay-Weber syndrome*, a sometimes extensive vascular malformation of the spinal cord is associated with a cutaneous vascular nevus overlying the AVM or in a limb supplied by the affected cord level; when the malformation lies in the low cervical region, there may be enlargement of finger, hand, or arm (the hemangiectatic hypertrophy of Parkes Weber; neurofibromatosis is another cause of limb enlargement). Spinal segmental and tract lesions may occur at any age, but the patients we have observed were young adults. Vascular occlusion

Figure 44-7. Dural arteriovenous fistula of the cord. **A.** Sagittal T2-weighted MRI of the lower spinal cord of a 50-year-old man with progressive myelopathy. Cord edema (T2 hyperintensity at the conus medullaris) and multiple vascular flow voids surrounding the spinal cord and extending up to the mid-thoracic vertebral levels are seen, both the result of the arterio-venous fistula. **B.** Angiographic injection of the left T12 radicular artery from the patient whose MRI is shown in **A**, demonstrating abnormal early filling of veins surrounding the spinal cord, confirming the presence of an arterio-venous fistula. The fistula was repaired and the patient's symptoms partially improved.

or hemorrhage was responsible for the myelopathy. Some of these vascular lesions have been treated by defining and ligating their feeding vessels. In a few reported cases it has been possible to extirpate the entire lesion, especially if it occupied the surface of the cord.

Other rare vascular anomalies of the spinal cord include *aneurysm of a spinal artery with coarctation of the aorta* and *telangiectasia of the cord*, which may or may not be associated with the hereditary hemorrhagic type of Osler-Rendu-Weber. Over the years, the authors have had under their care patients with the latter disease who developed acute hemorrhagic lesions of the spinal cord. We have also observed several *cavernous hemangiomas of the spinal cord*. In two of our patients, an angiographically negative solitary cavernous angioma was the source of an acute partial transverse myelopathy. The lesions were clearly demonstrable only in the T2-weighted MR images. McCormick and associates have reported similar cases. Characteristically, the angiomas cause partial syndromes and are followed by considerable recovery of function just as when they occur in the brain. There may or may not be blood in the CSF. Rarely, the same disease is responsible for one or more hemorrhagic lesions of the brain. The association of cavernous angiomas with arteriovenous fistulas of the lung is a rare finding, and the latter may be a source of brain abscess. In *coarctation of the aorta*, the circulation to the lower part of the spinal cord may be deficient, with resultant paresis of the legs, sensory loss, and sphincteric impairment. Or there may be intracranial subarachnoid hemorrhage from a ruptured saccular aneurysm, an associated condition in a small number of cases.

Treatment The rate of progression of the myelopathy from these various lesions varies greatly. In some cases, as already noted, it may become a matter of some urgency to reverse the venous congestion and avoid infarction of the cord. Other lesions require a more measured approach. By occluding the feeding artery of a spinal AVM or fistula, which is often single, and thereby eliminating the excess pressure in veins, the course of disease can be arrested and any pain reduced (Symon et al). In most of our patients, there has been postoperative improvement in the neurologic deficit over a few weeks or months. In cases of the larger racemose AVMs, stripping the enlarged veins along the dorsal cord is no longer considered necessary and may be dangerous. Increasingly, one resorts to obliteration of a fistula or a reduction of the AVM by the use of endovascular techniques and various types of embolic particles. The procedure is long and painstaking, for the operator must identify and embolize all the feeding vessels of the malformation; general anesthesia is required in most cases.

This approach has certain drawbacks; recanalization occurs months later in many instances, as does distal occlusion of the venous drainage system with worsening of the myelopathy. For these reasons, surgical ligation of the arterial supply is still preferred as the initial procedure for larger AVMs. Some surgeons advise a staged approach in which the size of the malformation is first reduced by endovascular techniques, thereby making the surgery less complicated. Intradural fistulas are usually treated

by endovascular methods but they can be excised if visualized intraoperatively. Interventional techniques have also been used to advantage in the intramedullary malformations, either as the sole treatment or in combination with surgery. Focused radiation has been tried but the results have been difficult to evaluate.

Fibrocartilaginous Embolism

Naiman and coworkers described the case of an adolescent boy who died of sudden paralysis after a fall in a seated position. Postmortem examination revealed extensive myelomalacia as a result of occlusions of numerous spinal vessels by emboli of nucleus pulposus material. The clinical picture is essentially one of spinal apoplexy; after spinal trauma of even mild degree the patient experiences the abrupt onset of pain in the back or neck, accompanied by the signs of a transverse cord lesion affecting all sensory, motor, and sphincteric functions and evolving over a period of a few minutes to an hour or more. Occasionally, the syndrome spares the posterior columns, thus simulating an anterior spinal artery occlusion. The CSF is normal. As with other types of cord infarction, the changes may not appear on MRI for a day or more.

In some of the reported instances there was said to have been no excessive activity or spinal trauma preceding the spinal cord symptoms. However, this has not been true of our patients, most of whom had been participating in some strenuous activity, but often earlier in the day rather than at the time of the paraplegia. Others had fallen and injured themselves on preceding days; a direct blow to the back during contact athletic sports was the antecedent event in several others and is the easiest-to-understand cause.

At autopsy, numerous small arteries and veins within the spinal cord are occluded by fibrocartilage, with necrosis of the spinal cord over 1 or 2 segments. A ruptured disc of the usual type is usually not found in these patients, but high-resolution radiographs have exposed a discontinuity of the cortical bone of the vertebral body adjacent to a collapsed disc and herniation of disc tissue into a vertebral body in a few instances (Tosi et al). The explanation suggested by Yogananden and colleagues is that the high intravertebral pressure forces nucleus pulposus material into venules and arteries of the marrow of the vertebral body, and thence into the adjacent radicular vessels. This mechanism has probably been overlooked in some otherwise unexplained cases of acute ischemic myelopathy.

Caisson Disease (Decompression Sickness, "Bends")

This extraordinary myelopathy, which is well known to the scuba diving community, is observed in persons who are subjected to high underwater pressure and then ascend too rapidly. It affects mainly the upper thoracic spinal cord as a result of nitrogen bubbles that form and are trapped in spinal vessels. There may be little or no involvement of the brain. Haymaker, who has provided the most complete

account of the neuropathologic changes, observed ischemic lesions mainly in the white matter of the upper thoracic cord; the posterior columns were more affected than lateral and anterior ones. We have encountered instances in which an almost complete transverse myelopathy was evident soon after the patient resurfaced but the syndrome then improved, leaving the patient with an asymmetrical and incomplete albeit permanent residual deficit. The smallest degree of damage is manifest as a minor myelopathy that affects the anterior or the posterior funiculi, leaving either spasticity or numbness of the legs. Immediate treatment consists of recompression in a hyperbaric chamber; later treatment is symptomatic, with antispasticity drugs and physical therapy.

Spinal Subdural Hemorrhage

This is an unusual process but we have reported cases that presented with excruciating thoracic back pain of such severity as to cause a bizarre, almost psychotic, reaction (Swann et al). The neck becomes slightly stiff and there may be a headache, suggesting subarachnoid hemorrhage. However, signs of a myelopathy do not appear, indicating that the bleeding is confined to the pliable subdural spaces surrounding the cord, thereby allowing the blood to spread over several segments.

Lumbar puncture yields a distinctive dark yellow-brown spinal fluid that resembles, to us, used motor oil. The color is imparted by methemoglobin and reflects the presence of an adjacent, decomposing walled-off clot. Usually there are also red blood cells in the CSF, suggesting seepage into the subarachnoid space from the adjacent collection. MRI or CT myelography shows a subdural collection, with characteristically smooth borders. When drained operatively, this is found to be clotted blood. Usually, no vascular malformation is demonstrable and the cause remains obscure. Trauma or anticoagulation underlies a few cases but many are spontaneous. The symptoms resolve in 1 or 2 weeks after removal of the subdural hematoma. Small collections may be managed without surgery, in which case corticosteroids may be helpful in reducing the pain.

The syndrome of spinal subarachnoid hemorrhage has been mentioned earlier and is also covered in Chap. 34 under "Other Causes of Intracranial Bleeding and Multiple Cerebral Hemorrhages."

SYNDROME OF SUBACUTE OR CHRONIC SPINAL PARAPARESIS WITH OR WITHOUT ATAXIA

The gradual development of weakness of the legs is the common manifestation of many diseases of the spinal cord. A syndrome of this type, including ataxia of gait beginning insidiously in late childhood or adolescence and progressing steadily, is usually indicative of hereditary spinocerebellar degeneration (Friedreich ataxia) or one of its variants (see Chap. 39). In early adult life, MS is the most frequent cause and AIDS myelopathy is

being increasingly recognized; syphilitic meningomyelitis, formerly of great importance, is now quite uncommon. In middle and late adult life, cervical spondylosis, subacute combined degeneration of the cord (vitamin B₁₂ deficiency), combined system degeneration of the nonpernicious anemia type, some associated with low levels of serum copper, radiation myelopathy, tropical spastic paraplegia, spinal arachnoiditis, and thoracic spinal tumor, particularly meningioma, are the important diagnostic considerations for the slowly progressive cord syndrome. In most forms of subacute and chronic spinal cord disease, spastic paraparesis is more prominent than posterior column ataxia, Friedreich ataxia and the myelopathy caused by vitamin B₁₂ deficiency being notable exceptions.

Spinal Multiple Sclerosis

(See earlier under "Acute Demyelinating Myelitis of Multiple Sclerosis" and also Chap. 36 for a discussion of multiple sclerosis.)

Ataxic paraparesis is among the most common manifestations of MS. Asymmetrical involvement of the limbs and signs of cerebral, optic nerve, brainstem, and cerebellar involvement usually provide confirmatory diagnostic evidence. Nevertheless, purely spinal involvement may occur, no lesions being found outside the spinal cord even at autopsy. A frequent problem in diagnosis is posed by the older woman who was not known to have had MS in earlier life, previous episodes having been absent, asymptomatic, or forgotten. A secondary progressive stage of spinal multiple sclerosis is the consequence of recurrent demyelinating attacks. There is another group, however, in which slowly advancing neurologic deterioration represents the primary manifestation of the disease. The National Hospital Research Group examined 20 cases of the secondary progressive type of spinal MS and 20 of the primary type by gadolinium-enhanced MRI of the spinal cord and brain and found new lesions in only 3 of each group (Kidd et al). They suggest that the progression correlates better with progressive atrophy of the spinal cord than with recurrent demyelinating lesions.

This clinical state must be differentiated from cervical disc disease, spondylosis, and tumor. The main aids in diagnosis are the CSF findings (minor pleocytosis and oligoclonal IgG abnormalities), present in 70 to 90 percent of cases, the demonstration by MRI of other unsuspected white matter lesions in the spinal cord and brain.

Cervical Spondylosis With Myelopathy (Spondylitic Myelopathy) (See also Chap. 11)

It has been stated, correctly in our opinion, that this is the most frequently observed myelopathy in general practice. It is a degenerative disease of the spine involving the lower and midcervical vertebrae that narrows the spinal canal and intervertebral foramina and causes progressive injury of the spinal cord, roots, or both.

Historical Note Key, in 1838, probably gave the first description of a spondylotic bar, or ossified protrusion into the spinal canal. In 2 cases of compressive myelopathy with

paraplegia, he found "a projection of the inter-vertebral substance and posterior ligament of the spine, which was thickened and presented as a firm ridge that had lessened the diameter of the canal by nearly a third." The ligament, where it passes over the posterior surface of the intervertebral substance, was found to be "ossified." In 1892, Horsley performed a cervical laminectomy on such a patient, removing a "transverse ridge of bone" compressing the spinal cord at the level of the sixth cervical vertebra. Thereafter, operations were performed in many cases of this sort, and the tissues removed at operation were repeatedly misidentified as benign cartilaginous tumors or "chondromata." In 1928, Stookey described the pathologic effects upon the spinal cord and roots of these "ventral extradural chondromas." Peet and Echols, in 1934, were probably the first to suggest that the so-called chondromata represented protrusions of disc material. But this idea never gained wide credence until the publication, in the same year, of the classic article on the ruptured intervertebral disc by Mixter and Barr. Although their names are associated with the lumbar disc syndrome, 4 of their original 19 cases were instances of cervical disc disease. It was C.S. Kubik who identified the extruded material as nucleus pulposus from surgical specimens obtained by Mixter and Barr's.

Also of importance is Gowers' account, in 1892, of *vertebral exostoses*, in which he described osteophytes that protrude from the posterior surfaces of the vertebral bodies and encroach upon the spinal canal, causing slow compression of the cord as well as bony overgrowth in the intervertebral foramina, giving rise to radicular pain. Gowers correctly predicted that these lesions would offer a more promising field for the surgeon than would other kinds of vertebral tumors.

For some reason, there was little awareness of the frequency and importance of spondylotic myelopathy for many years after these early observations had been made. All the interest was in the acute ruptured disc. Finally, it was Russell Brain who, in 1948, put cervical spondylosis on the neurologic map, so to speak. He drew a distinction between acute rupture and protrusion of the cervical disc (often traumatic and more likely to compress the nerve roots than the spinal cord) and chronic spinal cord and root compression consequent to disc degeneration and associated osteophytic outgrowths (*hard disc*), as well as changes in the surrounding joints and ligaments. In 1957, Payne and Spillane documented the importance of a developmentally smaller-than-normal spinal canal in the genesis of myelopathy in patients with cervical spondylosis. These reports were followed by a spate of articles on the subject (see Wilkinson). Rowland's review of the natural history of cervical spondylosis and the results of surgical therapy is a useful modern reference, as is that by Uttley and Monro.

Symptomatology

The characteristic syndrome consists of combinations of the following in varying degrees: (1) painful, stiff neck or pain in the neck, shoulders, and upper arms (brachialgia) that may be aching or radicular (stabs of sharp and radiating pain evoked by movement), asymmetric or unilateral;

(2) numbness and paresthesias of the hands; and (3) spastic leg weakness with Babinski signs, unsteadiness of gait, and a Romberg sign. The numbness and paresthesias are occasionally the earliest symptoms and typically involve the distal limbs, especially the hands. Variations of these symptoms are elaborated below. Each of the components may occur separately, or they may occur in combination and various sequences.

With reference to the most common of these symptoms, the neck and shoulder pain, in any sizable group of patients older than 50 years of age, approximately 40 percent will be found at times to have some clinical abnormality of the neck, usually crepitus or pain, with restriction of lateral flexion and rotation (less often of extension). Pallis and colleagues, in a survey of 50 patients, all of them older than 50 years of age and none with neurologic complaints, found that 75 percent showed radiologic evidence of narrowing of the cervical spinal canal as a result of osteophytosis of the posterior vertebral bodies or of narrowing of the intervertebral foramina because of osteoarthropathy at the apophyseal joints; thickening of the ligaments (both the ligamentum flavum posteriorly and the posterior longitudinal ligament anteriorly) adds to the narrowing of the canal. However, only half of the patients with radiologic abnormalities showed physical signs of root or cord involvement such as changes in the tendon reflexes in the arms, briskness of reflexes and impairment of vibratory sense in the legs, and sometimes Babinski signs. The occasional finding of a Babinski sign in older individuals who had never had a stroke or complained of neurologic symptoms is often explained by an otherwise invident cervical osteophyte (Savitsky and Madonick).

The pain is usually centered at the base of the neck or higher, often radiating to an area above the scapula. When brachialgia is also present, it takes several forms: a sharp pain in the pre- or postaxial border of the limb, extending to the elbow, wrist, or fingers; or a persistent dull ache in the forearm or wrist, sometimes with a burning sensation. Discomfort may be elicited by coughing, Valsalva maneuver, or neck extension, or neck flexion may induce electrical feelings down the spine (Lhermitte symptom). Rarely, the pain is referred subinternally.

As to the sensory features (which may occasionally be absent), numbness, tingling, and prickling of the hands and soles of the feet and around the ankles are the most frequent complaints. Some patients complain of numbness or paresthesias, most often in one or two digits, a part of the palm, or a longitudinal band along the forearm. Slight clumsiness or weakness of a hand is another complaint. A feeling as if "wearing gloves," "swollen," or the hands "coated with glue" are common descriptions. Several of our patients have complained of paresthesias in the distal limbs and trunk for years before there was any indication of motor involvement. In advanced cases, there may be a vague sensory level at or just above the clavicles. Impaired vibratory sensation and diminished position sense in the toes and feet (all indicative of a lesion of the posterior columns), as well as the Romberg sign, are the most conspicuous sensory

findings. This imparts a “tabetic” unsteadiness to the gait. Sensory defects tend to be asymmetrical. (It is noteworthy that symmetric sensory symptoms and signs of identical type are seen with subacute combined degeneration as a result of vitamin B₁₂ deficiency.) Rarely, the sensorimotor pattern takes the form of a Brown-Séquard syndrome. Less frequently, paresthesias and dysesthesias in the lower extremities and trunk may be the principal symptoms; even less often there are sensory complaints on the face, ostensibly corresponding to compression of the trigeminal sensory tract in the upper cervical cord.

The third part of the typical syndrome, spastic legs from a compressive myelopathy, most often manifests as a complaint of weakness of a leg or of getting up stairs and slight unsteadiness of gait. The entire leg or the quadriceps feels stiff and heavy and gives out quickly after exercise. Mobility of the ankle may be reduced, and the advancing toe of the shoe scrapes the floor. On examination, slight hypertonicity of the legs is usually more evident than weakness, and the tendon reflexes are increased (ankle jerks may not share in this change in the elderly). Although the patient may believe that only one leg is affected, it is commonly found that both plantar reflexes are extensor, the one on the side of the stiffer leg being more clearly so. Less often, both legs are equally affected. As the compression continues, walking becomes unsteady because of the addition of sensory ataxia.

The biceps and brachioradial reflexes on one or both sides may be depressed, sometimes in association with an increase in the triceps and finger reflexes. The hand or forearm muscles may undergo slight atrophy; in a few cases, the atrophy of hand muscles is severe. In such cases, the spondylotic compression, as judged by MRI or CT myelography, may be confined to the high cervical cord, well above the levels of the motor neurons that innervate these muscles. In patients with sensory loss, pain and thermal sensation often appear to be affected more than tactile sense. An unexpected Babinski sign has already been mentioned and a few fasciculations may be seen, especially in proximal arm muscles. Another unusual feature in advanced stages of cervical cord compression is the appearance of *mirror movements* of the hands, in which effortful attempts to make refined movements of the fingers of one hand, causes the opposite hand to move similarly.

As the myelopathy progresses, sometimes intermittently, both legs become weaker and more spastic. Sphincteric control may then be altered; slight hesitancy or precipitancy of micturition are the usual complaints; frank incontinence is infrequent. In the more advanced form of this condition, walking requires the aid of a cane or canes or a walker; in some cases, all locomotion ultimately becomes impossible, especially in the elderly patient. Abrupt worsening, even paraplegia or quadriplegia, may follow forceful traumatic flexion or extension injuries of the neck, as indicated later.

Pathologic Changes

The fundamental spinal lesion is generated initially by a fraying of the annulus fibrosus with extrusion of disc

material into the spinal canal. The disc becomes covered with fibrous tissue or partly calcified, thereby forming a transverse osteophytic “spondylitic bar” or there may be simply central bulging of the annulus without extrusion of nuclear material. The latter, unlike ruptured discs that occur mainly at the C5-C6 or C6-C7 interspace, often involve higher interspaces and may occur at several adjacent levels. The dura may be thickened and adherent to the posterior longitudinal ligament at affected levels. The underlying pia-arachnoid is also thickened and the adjacent ligamentous hypertrophy contributes to compression of the cord or the nerve roots. This series of pathologic changes is often ascribed to a type of hypertrophic osteoarthritis. However, osteophyte formation and ridging are so frequently observed in patients who have no other signs of arthritic disease that this explanation is surely not totally correct. Subclinical trauma in persons who are structurally susceptible to spondylosis is more likely to be the cause of bar formation, in the authors’ opinion.

When a cervical nerve root is compressed by lateral osteophytic overgrowth, the dural sleeve is thickened and truncated and the root fibers are damaged. Usually the fifth, sixth, or seventh cervical roots are affected in this way, both the anterior and posterior, or only the anterior, on one or both sides. A small neuroma may rarely appear proximal to the site of anterior root compression.

The dura is ridged and the underlying spinal cord is flattened. The root lesions may lead to secondary wedge-shaped areas of degeneration in the lateral parts of the posterior columns at higher levels. The most marked changes in the spinal cord are at the level(s) of compression. There are zones of demyelination or focal necrosis at the points of attachment of the dentate ligaments (which tether the spinal cord to the dura) and areas of rarefaction in the posterior and lateral columns, as well as loss of nerve cells. Ventral gray matter lesions, often asymmetrical, are attributed by Hughes to ischemia.

Pathogenesis

The vulnerability of the cervical spine to degenerative change has no ready explanation. Most likely it is related in some way to the high degree of mobility of the lower cervical vertebrae, which is accentuated by their location next to the relatively immobile thoracic spine.

The mechanism of spinal cord injury would seem to be one of simple compression and ischemia. When the spinal canal is developmentally narrow in its anteroposterior dimension at one or several points, the space available for the spinal cord becomes insufficient. A small canal certainly makes an individual more subject to the compressive effects of spondylosis. The range acquired of narrowing of the canal that produces symptomatic cervical spondylosis is generally from 7 to 12 mm (normal canal diameter: 17 to 18 mm). Consequently, one must consider several additional mechanisms by which the cord might be damaged. The effects of the natural motions of the spinal cord during flexion and extension of the neck are probably important in this respect. Adams and Logue confirmed the observation of O’Connell that,

during full flexion and extension of the neck, the cervical cord and dura move up and down. The spinal cord is literally dragged over protruding osteophytes and hypertrophied ligaments; conceivably it is this type of intermittent trauma that causes progressive injury.

It has also been shown that the spinal cord, displaced posteriorly by osteophytes, is compressed by the infolding of the posterolateral ligamentum flavum each time the neck is extended (Stoltmann and Blackwood). Segmental ischemic necrosis resulting from intermittent compression of spinal arteries or from compression of the anterior spinal artery has also been postulated. Most neuropathologists favor the idea of intermittent cord compression between osteophytes anteriorly and ligamentum flavum posteriorly, with an added vascular element accounting for the scattered lesions deep in the cord. Trauma from sudden extreme extension, as in a fall, severe whiplash injury, or chiropractic manipulation, or from a lesser degree of retraction of the head during myelography, tooth extraction, or a tonsillectomy may be operative in individual cases, particularly in patients with congenitally narrow canals. The lateral extension of the osteophyte and hypertrophy of the adjacent facet joint together compress the nerve root as it is entering its spinal foramen. Sometimes these are the main changes and cause only a radiculopathy, as discussed in Chap. 11.

Diagnosis

When pain and stiffness in the neck, brachialgia, either in the form of aching or a more distinctive radicular pain, and sensorimotor-reflex changes in the arms are combined with signs of myelopathy, there is little difficulty in diagnosis. When the neck and arm changes are inconspicuous or absent, the diagnosis becomes more difficult. The myelopathy must then be distinguished from the late, progressive form of spinal multiple sclerosis. Because posterior vertebral osteophytes and other bony alterations are frequent in the sixth and seventh decades of life, the question that must be answered in any given case is whether the vertebral changes are adequately severe to cause the neurologic abnormality. The finding of some degree of sensorimotor or reflex change corresponding only to the level of the spinal abnormalities is a point that always favors spondylotic myelopathy. A lack of such corresponding changes and the presence of oligoclonal bands and signs of lesions in the optic nerves and brain indicate demyelinating myelopathy.

The detailed findings on both MRI and CT myelography become critical in such cases (Fig. 44-8). The MRI may overestimate the degree of cord compression by an osteophyte, but clear deformation of the cord into the shape of a kidney bean and obliteration of the surrounding CSF spaces in the transverse image support the diagnosis of spondylotic compression. To confidently attribute neurologic symptoms to spondylosis there should be considerable encroachment on and obliteration of the circumferential CSF space at that level, not simply an impingement or slight deformation of the normal oval shape of the cord. Signal changes within the body of the cord underlying or within a half segment of the compression are seen in advanced

Figure 44-8. Sagittal T2 MRI in a patient with symptomatic cervical spondylosis. The spinal cord is severely compressed at the C5-C6 intervertebral disc space. Faint abnormal T2 hyperintensity of the spinal cord can be seen at the point of compression. Following surgical decompression, the patients myelopathic symptoms partially improved.

cases and usually indicate a degree of irreversibility of at least the sensory symptoms. Curiously, these signal changes may be one or two levels above or below the site of main compression. However, serious symptoms may occur even without changes in the intrinsic MRI signal. Contrast myelography with the patient supine and lateral views taken during flexion and extension of the neck are useful diagnostic procedures in uncertain cases.

It has been stated that spondylotic myelopathy may simulate amyotrophic lateral sclerosis (amyotrophy of arms and spastic weakness of the legs). This has seldom been a diagnostic problem. Although brachial and shoulder fasciculations with muscle atrophy may be combined with hyperreflexia in spondylosis, the widespread denervation and progressive course of ALS are not in evidence. We have observed only a few patients with spondylotic myelopathy who exhibited an absolutely pure motor syndrome, i.e., one in which there was no cervical or brachial pain and no sensory symptoms in the arms or impairment of vibratory or position sense in the legs. Likewise, a pure spastic paraparesis is more likely to be a manifestation of MS, hereditary spastic paraplegia, motor neuron disease (primary lateral sclerosis type), HTLV-I myelopathy, or the carrier state of adrenoleukodystrophy or other intrinsic myelopathy.

When imbalance, both perceived by the patient and observed in tests of walking, is a major symptom, spondylosis must be differentiated from a number of acquired large-fiber polyneuropathies, particularly inflammatory or immune types and the more benign sensory neuropathy of the aged (see discussion of this entity in Chap. 46). Loss of tactile sensation in the feet and loss of tendon reflexes are characteristic of the latter; examination of the tendon reflexes distinguishes neuropathy from myelopathy. Subacute combined degeneration of the spinal cord because of vitamin B₁₂ deficiency or low serum copper, AIDS and HTLV-I myelopathy, ossification of the posterior longitudinal ligament, and spinal cord tumor (discussed further on) are usually listed among the conditions that might be confused with spondylotic myelopathy. The gait abnormality produced by spondylotic myelopathy may also be mistaken for that of normal-pressure hydrocephalus; a marked increase of imbalance with removal of visual cues (Romberg sign) is a feature of spondylosis but not of hydrocephalus, and the short-stepped and magnetic quality of walking that is characteristic of hydrocephalus is not seen in cervical myelopathy (see Chap. 31 for discussion of NPH). Incontinence occurs only in advanced cases of spondylotic myelopathy but usually follows soon after gait deterioration in hydrocephalus.

The special problems of spondylotic radiculopathy, which may accompany or occur independently of the myelopathy, are discussed in Chap. 11.

Treatment

The slow, intermittently progressive course of cervical myelopathy with long periods of relatively unchanging symptomatology makes it difficult to evaluate the effects of treatment. Assuming that the prevailing view of the mechanism of cord and root compression is correct, the use of a soft collar to restrict anteroposterior motions of the neck seems reasonable. This form of immobilization may be sufficient to reduce discomfort in the neck and arms; only exceptionally in our experience, however, has arm and shoulder pain alone been sufficiently severe and persistent to require surgical decompression unless there is in addition a laterally protruded disc or osteophytic constriction of a root foramen. Many patients have been dissatisfied with the results of this passive approach and are unable to wear a collar for prolonged periods.

If osteophytes have narrowed the spinal canal at several interspaces, a posterior decompressive laminectomy with severance of the dentate ligaments helps to prevent further injury. The results of such a procedure in relieving symptoms are fairly satisfactory (Epstein and Epstein); in fully two-thirds of the patients, improvement in the function of the legs occurs, and in most of the others, progression of the myelopathy is halted. The operation carries some risk; rarely, an acute quadriplegia—presumably a result of manipulation of the spinal cord and damage to spinal arteries—has followed the surgical procedure. When only one or two interspaces are the site of osteophytic compression, their removal by an anterior approach (anterior cervical discectomy, or “ACD”) has given better results

and carries less risk. Braakman has reviewed the surgical methods and their relative advantages.

Even with modern surgical techniques, most series indicate that once symptomatic, the outcome varies and that a significant proportion of patients, even after adequate decompression and initial improvement, have persistent symptoms or undergo some degree of later functional deterioration (see also Chap. 11). This creates a conundrum for the physician in advising the patient about the correct time to undertake surgical decompression. Nonetheless, certain clinical observations pertain and may be used as guides to treatment. Any degree of spasticity, sphincter disturbance, or loss of sensation in the hands will not improve, and indeed usually worsens over months, without surgery. Hand weakness and muscular atrophy that is the result of radicular compression will improve with decompression of the appropriate root by one of several surgical approaches, but weakness that is from central cord damage requires decompression to halt the process and probably should not be delayed more than a few weeks once it is apparent that this is the problem. Usually, such patients have MRI signal changes within the substance of the cervical cord in apposition to an osteophytic bar.

Lumbar Stenosis (See Chap. 11)

This is another spondylotic abnormality seen with particular frequency in older individuals, especially men. Usually it declares itself by numbness and weakness of the legs, sometime with poor control of sphincters. Many texts state that there may be little or no pain or only a spinal ache that fluctuates from day to day but in our experience the majority of patients have constant backache and sciatica. A notable feature is the induction or aggravation of the neurologic symptoms upon standing and walking (neurologic claudication). This topic is discussed in “Lumbar Stenosis” in Chap. 11, which should be consulted for a detailed discussion.

Ankylosing Spondylitis

This condition of the spine is a result of inflammation at the sites of ligamentous insertions into bone that leads to an intense calcification. The sacroiliac joints and lumbar spine are most affected, as discussed in Chap. 11, but as the disease advances, the entire spine becomes fused and rigid. The biomechanics of the rigid spine make it susceptible to fracture. The most common complication is a spinal stenosis and cauda equina syndrome. Bartleson and associates described 14 patients (and referred to 30 others in the medical literature) who, years after the onset of spondylitis, developed sensory, motor, reflex, and sphincteric disorders referable to L4, L5, and the sacral roots. Surprisingly, the spinal canal was not narrowed but instead the caudal sac was actually dilated. Confavreux and coworkers presented evidence that enlargement of the lumbar dural sac is caused by a defect in resorption of the CSF. There are usually arachnoidal diverticula on the posterior root sleeves, but no other explanation can be given for the radicular symptoms and signs. Surgical decompression has not benefited most patients, nor has corticosteroid therapy.

This condition occasionally occurs at higher levels and gives rise to a myelopathy. Our experience includes several cases with symptoms related to the cervical roots.

The most hazardous complication of ankylosing spondylitis is compression of the cord from seemingly minor trauma that has resulted in fracture-dislocation of the cervical (or lumbar) vertebrae. Fox and colleagues treated 31 such patients in a 5-year period; the majority of unstable fractures that required surgical fixation were in the cervical region, and several patients had fracture-dislocations at two levels. The instability at the upper spinal levels may be difficult to detect radiologically, and caution should be observed in allowing patients to resume full activity after a neck injury if the cervical spine is involved by ankylosing spondylitis. Careful flexion and extension radiograph views usually, but not always, demonstrate the instability.

As mentioned briefly earlier, multiple arachnoid cysts in the thoracic or lumbar region are associated with ankylosing spondylitis (and with *Marfan syndrome*).

Rheumatoid Arthritis of the Spine

The spinal changes of rheumatoid arthritis differ somewhat from those of ankylosing spondylitis although the latter too may be a cause of atlantoaxial dislocation (see further on under "Anomalies at the Craniocervical Junction"). The ligaments that attach the odontoid to the atlas and to the skull and the joint tissue are weakened by the destructive inflammatory process. The subsequent dislocation of the atlas on the axis may remain mobile or become fixed and give rise to an intermittent or persistent paraparesis or quadriparesis. Similar effects may result from a forward subluxation of C4 on C5 (see Nakano et al). Atlantoaxial dislocation is known to be a cause of collapse and sudden death. If the upper cervical cord is compressed, the odontoid process must be removed and C1-C2 decompressed and stabilized. Other levels of the spine are less frequently affected.

Ossification of the Posterior Longitudinal Ligament (OPLL)

Compressive cervical myelopathy caused by this process occurs almost exclusively in patients of Japanese extraction and has been demonstrated to us as an almost mundane finding by colleagues in Hawaii. The clinical signs are much the same as those of cervical spondylosis, but the radiologic appearance of cancellous bone along a segment of the posterior longitudinal ligament is unique. The ligamentous calcification can be seen on plain films, CT scan, and MRI and may be mistaken for spondylitic change. The ossified areas may enlarge enough to form islands of bone marrow. Laminoplasty with enlargement of the spinal canal has been successful.

Cervical Dural Sac Myelopathy (Hirayama Disease)

This unusual myelopathy has usually been considered in discussions of the motor neuron disorders because of its characteristic features of chronic wasting of one or both hands and forearms without sensory changes or long tract signs. It appears, however, that the damage in this

disease is from intermittent compression of the lower cervical cord and gradual deterioration of the motor neurons in the anterior grey matter. Hirayama pointed out that in the young men who were affected, the mechanism of cord damage is a buckling of the dorsal dural sac and an intermittent anterior displacement and ligamentous compression of the cord during flexion of the neck.

The muscles innervated by C7, C8, and T1, encompassing mainly the hand and forearm, are affected on one side or bilaterally, but asymmetrically. There are few or no fasciculations and no sensory changes; the painless loss of power and muscle bulk proceeds smoothly over several years, giving the impression of a degenerative condition. MRI or CT myelogram performed with the neck flexed, as described by Hirayama and Tokumaru, shows the cervical cord to be atrophic with signal changes in the anterior parts of the cord and confirms the diagnosis of compression by the buckled dura. We have examined several such patients and can corroborate their claim from observation of MRI with the patient placed in a flexed-neck position. Presumably, this configuration causes ischemia of the anterior gray matter, but this has not been proved. Others have reported the syndrome in the absence of this structural configuration (Willeit et al). Two of our young male patients had long swan-like necks. What is most important about this process is the degree of recovery afforded by ligamentous sectioning and by similar surgical approaches that accomplish decompression of the lower cervical cord.

Paget Disease of the Spine (Osteitis Deformans)

Enlargement of the vertebral bodies, pedicles, and laminae in Paget disease may result in narrowing of the spinal canal. The clinical picture is one of cord compression. The plasma alkaline phosphatase concentration is high, and the typical bone changes are seen in radiographs. Usually, several adjacent vertebrae of the thoracic spine are affected but other parts of the skeleton are also involved (see later), which facilitates diagnosis. Posterior surgical decompression leaving the pedicles intact is indicated if there is sufficient stability of the vertebral bodies to prevent collapse. Medical management includes the use of nonsteroidal antiinflammatory drugs for persistent pain; calcitonin to reduce pain and plasma levels of alkaline phosphatase; and cytotoxic drugs such as plicamycin and etidronate disodium to reduce bone resorption.

Other Spinal Abnormalities With Myelopathy

The spinal cord is obviously vulnerable to any vertebral maldevelopment or disease that encroaches upon the spinal canal or compresses its nutrient arteries. Some well-known abnormalities are listed here.

Congenital Anomalies at the Craniocervical Junction

Of these, congenital *fusion of the atlas and foramen magnum* is the most common. McCrae, who described the radiologic features of more than 100 patients with bony abnormalities at the craniocervical junction, found this partial or complete bony union of the atlas and occipital bone in

28 cases. He also noted that whenever the anteroposterior diameter of the canal behind the odontoid process was less than 19 mm, there were signs of spinal cord compression. Fusion of the second and third cervical vertebrae is a common associated anomaly but does not seem to be of clinical significance. There is considerable crossover with the foreshortened neck of the Klippel-Feil syndrome mentioned below.

Abnormalities of the Odontoid Process These were found in 17 cases of McCrae's series. There may be complete separation of the odontoid from the axis or chronic *atlantoaxial dislocation* (atlas displaced anteriorly in relation to the axis). These abnormalities may be congenital or the result of injury and are known causes of acute or chronic spinal cord compression and stiffness of the neck.

In all the congenital anomalies of the foramen magnum and the upper cervical spine there is a high incidence of syringomyelia. McCrae found that 38 percent of all patients with syringomyelia and syringobulbia showed such bony anomalies, but this is considerably higher than in our experience. All patients whose symptoms might be explained by a lesion in the cervicocranial region (particularly patients in whom MS and foramen magnum tumor are suspected) require careful radiologic examination.

In mucopolysaccharidosis IV, or the Morquio syndrome (Chap. 37), a typical feature is the absence or severe hypoplasia of the odontoid process. This abnormality, combined with laxity or redundancy of the surrounding ligaments, results in atlantoaxial subluxation and compression of the spinal cord. Affected children refuse to walk or develop spastic weakness of the limbs. Early in life they excrete an excess of keratan sulfate, but this may no longer be detectable in adult life. In certain of the mucopolysaccharidoses, we have also seen a true pachymeningopathy with great thickening of the dura in the basal cisterns and high cervical region with spinal cord compression. Surgical decompression and spinal immobilization have been curative.

Achondroplasia This dominantly inherited form of dwarfism is caused by a mutation in one of the fibroblastic growth factors, which causes a failure of conversion of fetal cartilage to bone at the growth plate. It occasionally results in great thickening of the vertebral bodies, neural arches, laminae, and pedicles because of increased periosteal bone formation. The spinal canal is narrowed in the thoracolumbar region, often with kyphosis, leading sometimes to a progressive spinal cord or cauda equina syndrome. Another complication, which results from a small foramen magnum, is hydrocephalus (or markedly widened subarachnoid spaces). In young children, a syndrome of central apnea and spasticity of the legs is characteristic. These complications may require ventricular shunting. Narrowing of the lumbar canal tends to present later in life.

Platybasia and Basilar Invagination *Platybasia* refers to a flattening of the base of the skull (the angle formed by intersection of the plane of the clivus and the plane of the anterior fossa is greater than 135 degrees). *Basilar impression* or *invagination* has a somewhat different meaning, namely, an upward bulging of the occipital

condyles; if the condyles, which bear the thrust of the spine, are displaced above the plane of the foramen magnum, basilar invagination is present. Each of these abnormalities may be congenital or acquired (as in Paget disease); frequently they are combined. They give rise to a characteristic shortness of the neck and a combination of cerebellar and spinal signs. A normal-pressure hydrocephalus may also develop.

In the *Klippel-Feil syndrome* there is fusion of the upper cervical vertebrae or of the atlas to the occiput. The anomaly is easily identified by substantial foreshortening of the neck. Affected individuals are susceptible to compression of the cervical cord after minor trauma. Many such patients demonstrate mirror movements of their hands, comparable to those described earlier in cervical spondylosis.

Tethered Cord This developmental anomaly is discussed more fully and illustrated in Chap. 38. A progressive cauda equina syndrome with prominent urinary difficulties and varying degrees of spasticity are the usual presentations.

Syphilitic Meningomyelitis

Here, as in multiple sclerosis, the degree of ataxia and spastic weakness is variable. A few patients have an almost pure state of spastic weakness of the legs, requiring differentiation from motor system disease and familial spastic paraplegia. Such a syndrome, formerly called Erb spastic paraplegia and attributed to meningovascular syphilis, is now recognized as being nonspecific and more often caused by demyelinating disease. In a minority of chronic syphilitic patients, sensory ataxia and other posterior column signs predominate. Ventral roots are involved in the chronic meningeal inflammation, giving rise to signs of segmental amyotrophy—hence the term *syphilitic amyotrophy* of the upper extremities with spastic paraplegia. Confirmation of this now infrequent diagnosis depends on finding a lymphocytic pleocytosis, an elevated protein and gamma globulin, and a positive serologic reaction in the CSF. Other aspects of this disease and treatment are discussed under "Spinal Syphilis" in Chap. 32. *Tabes dorsalis* is, of course, another important form of syphilitic myelitis.

Subacute Combined Degeneration of the Spinal Cord (See Chap. 41)

This form of nutritional spinal cord disease is caused by vitamin B₁₂ deficiency and is fully described in Chap. 41. Almost invariably it begins with bilateral symptoms and signs of posterior column involvement in the hands (paresthesias and reduced touch, pressure, and joint sensibility), which, if untreated, is followed within a matter of several weeks or months by progressive spastic paraparesis because of involvement of the corticospinal tracts to which a vague sensory level on the trunk may be added. Particular importance attaches to the fact that this is a treatable disease and that the degree of reversibility is dependent upon the duration of symptoms before specific treatment is begun.

Copper Deficiency Myelopathy (Combined System Disease of Nonpernicious Anemia Type)

This refers to a metabolic disease of the spinal cord caused by low copper, affecting the posterior and lateral columns, in this sense, also a combined system degeneration. The clinical syndrome and potential causes were elegantly elaborated by Kumar and colleagues. A homologous disease exists as “swayback” in lambs. A deficiency of vitamin B₁₂ is not causative, but may coexist in some cases, probably on the basis of a shared inadequacy of dietary intake. Women are more often affected than men. Imbalance is the most common presenting complaint. Posterior column signs and gait ataxia tend to predominate but a degree of spasticity is usually conjoined and there may be Babinski signs and reduced ankle reflexes. The problem is typically one of impaired absorption of copper, for example, after gastric bypass or bowel surgery, which together account for half of cases. Of importance in causation in some patients is excess zinc intake in the form of health supplements, coin swallowing, and denture creams (see Nations et al).

There is an associated hypocupremic anemia with ringed sideroblasts and leukopenia with vacuolated myeloid precursors in the marrow that may be mistaken for a myelodysplastic process. The idiopathic variety has certain similarities to the disorder of copper mobilization in Menkes disease, but the disordered enzyme responsible in the latter has been normal. As reported by others, in a recent case on our service without explanation for the discovered copper deficiency, MRI of the cervical cord revealed distinctive signal changes in both the posterior and lateral columns identical to those of B₁₂ deficiency, and these were no longer present after copper treatment. The majority of affected patients have abnormal somatosensory evoked potentials with delays in central conduction.

Treatment Oral copper supplementation, 2 mg/d for at least several months, seems effective in most patients, but some do not improve and the appropriate duration of treatment is unknown. Some patients relapse after an initial improvement even with continued administration or when copper supplementation is stopped. The gluconate, sulfate, or chloride preparations of copper may be used, although there has been concern about the bioavailability of the first-named compound. Intravenous therapy as a way of initially replenishing copper stores has been introduced but the need for such treatment is uncertain. Zinc supplements must, of course, be discontinued, as they lower copper levels.

There remains a group of subacute ataxic-spastic myelopathies that are not caused by multiple sclerosis or by B₁₂ or copper deficiency. Progressive spastic or spastic-ataxic paraparesis of a chronic, irreversible type may also develop in conjunction with chronic, decompensated liver disease; with AIDS; in cases of adrenoleukodystrophy, particularly in the symptomatic female heterozygote; in tropical spastic paraplegia (HTLV-I); radiation myelopathy; and adhesive spinal arachnoiditis, which is discussed immediately below.

Spinal Arachnoiditis (Chronic Adhesive Arachnoiditis) (See Chap. 11)

This is now a relatively uncommon spinal cord disorder that was introduced in relation to the subject of low back pain in Chap. 11. It is characterized by a combination of painful root and spinal cord symptoms that may mimic intraspinal tumor. There is opacification and thickening of the arachnoidal membranes and adhesions between the arachnoid and dura—the result of proliferation of connective tissue. The subarachnoid space is unevenly obliterated. In this sense, the term *arachnoiditis* is not entirely appropriate, although it seems likely that the connective tissue overgrowth is a reaction to an antecedent arachnoidal inflammation. Some forms of arachnoiditis were traced to syphilis or to a subacute, therapeutically resistant meningitis of another type. Most others in the past followed the introduction of a variety of substances, most no longer used, into the subarachnoid space for diagnostic or therapeutic purposes or following spinal anesthesia, soon afterward or after an interval of weeks, months, or even years. This complication was eventually traced to a detergent that had contaminated vials of procaine.

More pernicious, however, is a delayed meningo-myelopathy that developed within a few months or years of the inciting event, causing a spastic paralysis, sensory loss, and incontinence of sphincters. There are also cases on record in which an epidural or similar catheter has accidentally penetrated the cord and caused a traumatic partial myelopathy as mentioned earlier. Still seen regularly is a restricted form of arachnoiditis that complicates a series of operations for lumbar discs or the spinal injection of methylene blue. Less convincing are cases attributed to closed spinal injuries. In many cases, no provocative factor can be recognized. A familial form was reported by Duke and Hashimoto, but we have had no experience with it.

Clinical Manifestations Symptoms may occur in close temporal relation to an acute arachnoidal inflammation or may be delayed for weeks, months, or even years as indicated above. The most common mode of onset is with pain in the distribution of one or more sensory nerve roots, first on one side, then on both, in the lumbosacral regions. The pain has a burning, stinging, or aching quality and is persistent. Abnormalities of tendon reflexes are common, but weakness and atrophy, the results of damage to anterior roots, are less frequent. In thoracic lesions, symptoms of root involvement may antedate those of cord compression by months or years. Sooner or later, however, there is involvement of the spinal cord, manifest by a slowly progressive spastic ataxia with sphincter disturbances.

The localized lumbar arachnoiditis associated with repeated disc surgery (the common variety seen in pain clinics) is characterized by back and/or leg pain with other inconstant signs of radiculopathy (loss of tendon reflexes, weakness, and variable degrees of sensory loss), usually bilateral.

The CSF is abnormal during the acute stage in practically all cases that ultimately result in adhesive arachnoiditis. In some there is a moderate lymphocytic

pleocytosis, occurring soon after the inciting event. In the localized lumbar arachnoiditis, referred to earlier, the CSF may be normal or show only a slight increase in protein content. The prominent finding with imaging is a partial or complete obliteration of the spinal subarachnoid space. The loculated myelographic appearance of arachnoiditis is characteristic (patchy dispersion of the column of dye and a “candle-guttering” appearance that was most evident with oil-based contrast media); MRI reveals a loss of the normal ring of CSF or localized loculations of CSF (see Fig. 11-5).

Treatment In the early stages of arachnoiditis, corticosteroids have been given to control the inflammatory reaction and to prevent progress of the disease, but their value is questionable. Surgery may be effective in the case of localized “cyst” formation and cord compression. Severe radicular pain can be effectively relieved by posterior rhizotomy, but there is a strong tendency for the pain to return after an interval of several months or a year or two so that this approach has been all but abandoned. For chronic adhesive lumbar arachnoiditis in which diffuse back and limb pain is the most distressing symptom, there is little effective surgical or medical treatment, although relief has reportedly been provided in isolated instances by painstaking microsurgical dissection of the lumbar roots. In some cases, the loculations return. Administration of corticosteroids, systemic and epidural, has not been consistently beneficial but may be tried. Immune-suppressant medication such as azathioprine or interferons have been tried but not studied systematically. Transcutaneous stimulator treatment and gabapentin have also been used with inconsistent results.

Herniation of the Cord Through a Dural Tear

Violent trauma to the spinal canal or skull such as a fall or blow to the back can cause arachnoidal and dural tears. The associated neural injury dominates the picture and the dural tear may require repair so as to minimize the development of meningitis. More difficult to understand is the occurrence of spinal cord herniation through a spontaneous rent in the adjacent dura with no preceding injury. In view of the fact that we have encountered five such instances in a decade, without trauma having occurred, it is probably not rare.

In the typical case, a vertically oriented tear of limited extent occurs in the ventral dura overlying the mid- or high-thoracic region, and a segment of the spinal cord protrudes through it into the epidural space. The result is a painless, subacute, and incomplete spinal cord syndrome, which reaches a plateau and leaves the patient with an asymmetrical spastic paraparesis and variable sensory loss. There are reports of a Brown-Séquard hemi-cord syndrome and variations of it as described in the small series by Watters and colleagues. Orthostatic headache of low-CSF pressure is not usually part of the syndrome. MRI or CT myelopathy demonstrates the protruded segment of the cord where it buckles through the dura. Presumably the herniation creates a sufficient degree of local ischemia or mechanical disturbance to account for the myelopathic symptoms. Surgical restoration of the cord to its proper

position and repair of the tear, have resulted in partial or complete return of neurologic function (Vallee et al).

As to the cause of this condition, a congenital duplication of the dura membranes combined with herniation through the inner layer has been observed in some cases at operation. The abnormal configuration of the membrane has been proposed as a cause of the propensity for the fibers to separate and create an aperture.

Intraspinal Tumors

Compression of the spinal cord by a metastatic tumor in the vertebral column is a common occurrence in many types of cancers. Primary tumors of the spinal cord are considerably less frequent. In the Mayo Clinic series of 8,784 primary tumors of the CNS, only 15 percent were intraspinal (Sloof et al). In contradistinction to brain tumors, the majority of intraspinal ones is benign and produces effects mainly by compression of the spinal cord rather than by invasion. Thus, a proportion of intraspinal tumors are amenable to surgical removal, and their early recognition, before irreversible neurologic changes have occurred, becomes a matter of utmost importance.

General Considerations (See also Chap. 31)

Neoplasms and other space-occupying lesions within the spinal canal can be divided into two groups: (1) those that arise within the substance of the spinal cord, either as a primary neural neoplasm or as a metastasis, and invade and destroy tracts and central gray structures (*intramedullary*) and (2) those arising outside the spinal cord (*extramedullary*), either from vertebral bodies and epidural tissues (*extradural*) or in the leptomeninges or roots (*intradural*). In a general hospital, the relative frequency of spinal tumors in these different locations is approximately 5 percent intramedullary, 40 percent intradural–extramedullary, and 55 percent extradural, the majority of the latter being metastatic cancers, as already mentioned. This percentage of extradural lesions is higher than that encountered in more specialized neurosurgical services (e.g., Elsberg’s figures of 7, 64, and 29 percent, respectively), probably because the latter do not include as many patients with extradural lymphomas, metastatic carcinomas, and the like, as are seen in general hospitals.

Intraspinal Tumors The most common *primary extramedullary* tumors are the neurofibromas and meningiomas, which together constitute approximately half of all intraspinal neoplasms. They are more often intradural than extradural. Neurofibromas have a predilection for the lumbar and thoracic region, whereas meningiomas are more evenly distributed over the vertical extent of the cord (Fig. 44-9). The other primary extramedullary tumors are sarcomas, vascular tumors, chordomas, and epidermoid and similar tumors, in that order of frequency.

Primary intramedullary tumors of the spinal cord have the same cellular origins as those arising in the brain (Chap. 31), although the proportions of particular cell types differ. Ependymomas, some of which arise from the filum terminale, make up 60 percent of the spinal cord cases and astrocytomas make up approximately

Figure 44-9. Sagittal (*left*) and axial (*right*) gadolinium-enhanced T1-weighted MRI of an intraspinal meningioma that displaced and compressed the spinal cord, causing incontinence and leg weakness. As in intracranial meningiomas, homogenous contrast enhancement and a dural attachment are seen.

25 percent. The astrocytoma is the most common intramedullary tumor if one excludes tumors arising in the filum terminale (Fig. 44-10). Oligodendrogliomas are much less common. The remainder (approximately 15 percent) consists of a diverse group of nongliomatous tumors: lipomas, epidermoids, dermoids, teratomas, hemangiomas, hemangioblastomas, chordomas, schwannomas, and intraspinal metastatic carcinomas. The cavernous hemangioma may be a source of spontaneous hematomyelia. As indicated further on, there is a frequent association between intramedullary tumors (both gliomatous and nongliomatous) and syringomyelia. The basis of this relationship remains obscure.

Spinal ependymomas arise from ependymal lining of the central canal of the spinal cord. The myxopapillary type originates from clusters of ependymal cells in the filum terminale. The myxopapillary ependymoma that originates in the filum terminale causes a special syndrome referable to both lumbar roots (cauda equina) and conus. As commented in Chap. 31, a combination of asymmetric or bilateral sciatic or anterior thigh pain, sphincter difficulty, and upper motor neuron signs is typical. These spinal tumors occur in adults as often as in children, quite different from intracranial ependymomas, which are mainly childhood tumors. Although they are considered to be benign, intraspinal spread can occur and local recurrence after resection occurs in 10 percent of cases, even decades after surgery as described by Rezaei and colleagues. Treatment is with surgical removal and selective

radiation if there has not been gross total removal and long-term survival is the rule. The main differential diagnosis is a spinal schwannoma (neurofibroma).

Intramedullary growths invade as well as compress and distort fasciculi in the spinal cord white matter. As the cord enlarges from the tumor growing within it or is compressed by a tumor from without, the free space around the cord is eventually consumed, and the CSF below the lesion becomes isolated or loculated from the remainder of the circulating fluid above the lesion. This is marked by Froin syndrome (xanthochromia and clotting of CSF from greatly elevated protein content) and an interruption of flow of contrast medium in the subarachnoid space. The most informative diagnostic procedure is an MRI, which demonstrates both the intramedullary extent of the tumor and the effect on the surrounding subarachnoid space.

Secondary spinal cord tumors can also be subdivided into intramedullary and extramedullary types. *Extradural metastases (carcinoma, lymphoma, myeloma)* are the most common of all spinal tumors. They account for the largest group of patients who develop symptoms of myelopathy while being cared for in hospital and are therefore likely to be encountered in the course of neurologic consultations. Extradural metastases arise from hematogenous deposits or extend from tumors of the vertebral bodies or from a paraspinal tumor extending via the intervertebral foramina (Fig. 44-11). Secondary extradural tumor growths are far more often extradural than intradural.

Figure 44-11. Sagittal T1-weighted MRI showing multiple spinal metastases from carcinoma of the lung. The metastases exhibit low signal intensity due to tumor replacement of bone marrow, which is normally T1 hyperintense.

The intradural type takes the form of a meningeal carcinomatosis or lymphomatosis and the rare primary melanoma of the meninges, which are considered in Chap. 31.

Intramedullary metastases are not as rare as is generally believed. In a retrospective autopsy study of 627 patients with systemic cancer, Costigan and Winkelmann found 153 cases with central nervous system (CNS) metastases, in 13 of which the metastases were located within the cord. In 9 of the 13 cases, the metastasis was deep in the cord, unassociated with leptomeningeal carcinomatosis; in 4 cases, the neoplasm seemed to extend from the pia. Bronchogenic carcinoma was the main source. Diagnosis is difficult but is aided greatly by MRI with gadolinium infusion; there is generally extensive contiguous edema (Fig. 44-12). Differentiation is from meningeal carcinomatosis, radiation myelopathy, and paraneoplastic necrotizing myelopathy, which is the least common of these entities. Treatment is usually ineffective unless radiation therapy is begun before paraplegia supervenes (Winkelmann et al).

Symptomatology

Patients with spinal cord tumors are likely to present with one of three clinical syndromes: (1) a sensorimotor spinal tract syndrome, (2) a painful radicular-spinal cord syndrome, or (3) least often, an intramedullary syringomyelic syndrome. The sensory features of these syndromes are depicted in Fig. 9-7.

Figure 44-12. Sagittal T2 MRI of an intramedullary metastasis from breast cancer. The expansile lesion is at the T2 vertebral level (arrow) and the adjacent edema extends superiorly and inferiorly over a great length of the spinal cord.

Pain and stiffness of the back may antedate signs of spinal cord disease or dominate the clinical picture in some cases of extramedullary tumor. The back pain is usually worse when the patient lies down or may become worse after several hours in the recumbent position and be improved by sitting up. *In children*, severe back pain associated with spasm of paravertebral muscles is often prominent initially; scoliosis and spastic weakness of the legs come later. Because of this somewhat unusual clinical presentation and the rarity of intraspinal lesions in childhood, spinal cord tumors in this age group may be overlooked.

Sensorimotor Spinal Tract Syndrome The clinical picture is related predominantly to compression and less often to invasion and destruction of spinal cord tracts. The signs of compression consist of a combination of (1) an asymmetrical spastic weakness of the legs with thoracolumbar lesions and of the arms and legs with cervical lesions, (2) a sensory level on the trunk below which perception of pain and temperature is reduced or lost, (3) posterior column signs, and (4) a spastic bladder under weak voluntary control. The onset of the compressive symptoms is usually gradual and the course progressive over a period of weeks and months, frequently with back pain. With extradural tumors, paralysis usually develops over a period of days to several weeks, but the tempo of progression may be more rapid or more leisurely. The initial disturbance may be of motor or sensory function and the distribution may be asymmetrical. High cervical or foramen magnum lesions produce special clinical syndromes, as described in Chap. 3 and below. With thoracic lesions, one leg usually becomes weak and stiff before the other one. Subjective sensory symptoms of the dorsal column type (tingling paresthesias) assume similar distributions. Pain and thermal senses are more likely to be affected than tactile, vibration, and position senses. Nevertheless, the posterior columns are frequently involved as the process progresses. Initially, the sensory disturbance is contralateral to the maximum motor weakness, but a sharply defined Brown-Séquard hemicord syndrome is rarely observed. The bladder and bowel usually become paralyzed coincident with paralysis of the legs. If the compression is relieved, there is recovery from these sensory and motor symptoms, often in the reverse order of their appearance; the first part affected is the last to recover, and sensory symptoms tend to disappear before motor ones.

Radicular-Spinal Cord Syndrome Here the syndrome of spinal cord compression is combined with radicular pain, i.e., pain in the distribution of a sensory nerve root. The discomfort is described as knife-like or as a dull ache with superimposed sharp stabs of pain, which radiate in a distal direction, i.e., away from the spine, and are intensified by coughing, sneezing, or straining. Segmental sensory changes (paresthesias, impaired perception of pinprick and touch) or motor disturbances (cramp, atrophy, fascicular twitching, and loss of tendon reflexes) and an ache in the spine, in addition to the radicular pain, are the usual manifestations. Tenderness of the spinous processes over the tumor is found by percussion in about half the patients. The segmental changes, particularly the

sensory radicular ones, often precede the signs of spinal cord compression by months if the lesion is benign.

Intramedullary Syringomyelic Syndrome No single symptom is unique to the *intramedullary tumors*. Some degree of pain, sometimes minor, is common and is almost invariably present with tumors of the filum terminale. Ependymomas and astrocytomas, the two most common intramedullary tumors, usually give rise to a mixed sensorimotor tract syndrome. When the intramedullary tumor involves the central gray matter, a central cord, or *syringomyelic syndrome* may result. The main features are segmental or dissociated sensory loss, amyotrophy, early incontinence, and late corticospinal weakness. Sacral sparing of sensation may be found as described in Chap. 9 on the sensory syndromes but is of less value in distinguishing intramedullary from extramedullary lesions. A dissociation of thermal pain and tactile sensory loss over several contiguous segments on the trunk is a more dependable sign of an intramedullary lesion. Rarely, an extramedullary tumor may give rise to a syringomyelic sensory syndrome, possibly by causing vascular insufficiency in the central portion of the cord.

Special Spinal Syndromes Unusual clinical syndromes may be found in patients with *tumors in the region of the foramen magnum*, as discussed in Chap. 3. They produce quadriplegia with pain in the back of the head and stiff neck, weakness and atrophy of the hands and dorsal neck muscles, marked imbalance, and variable sensory changes or, if they spread intracranially, there may be signs of cerebellar and lower cranial nerve involvement. Slowly growing tumors in this region, such as meningiomas, characteristically produce an "around the clock" progression of weakness beginning in one limb and proceeding to the adjacent one in a clockwise or counterclockwise direction. Lesions at the level of the lowermost thoracic and the first lumbar vertebrae may result in mixed cauda equina and spinal cord symptoms. A Babinski sign indicates that the spinal cord is involved above the fifth lumbar segment.

Lesions of the cauda equina alone, always difficult to separate from those of the lumbosacral plexuses and multiple nerves, are usually attended in the early stages by sciatic and other root pain and lumbar ache, which are variously combined with a bilaterally asymmetrical, atrophic, areflexic paralysis, radicular sensory loss, and sphincteric disorder. These must be distinguished from *lesions of the conus medullaris* (lower sacral segments of the spinal cord), in which there are early disturbances of the bladder and bowel (urinary retention and constipation), back pain, symmetrical hypesthesia or anesthesia over the sacral dermatomes, a lax anal sphincter with loss of anal and bulbocavernosus reflexes, impotence, and sometimes weakness of leg muscles. Sensory abnormalities may precede motor and reflex changes by many months. Very rarely, for unclear reasons, tumors of the thoracolumbar cord (intramedullary, as a rule) are associated with markedly elevated spinal fluid protein and hydrocephalus; these respond to shunting and removal of the spinal tumor (Feldman et al). Less often, these tumors are associated with a pseudotumor cerebri syndrome.

Differential Diagnosis

Several problems arise in the diagnosis of spinal cord tumors in addition to several previously mentioned. In the early stages, neoplastic compression or invasion of the cord must be distinguished from other diseases that cause pain over certain segments of the body, e.g., diseases affecting the gall-bladder, pancreas, kidney, stomach and intestinal tract, pleura. Localization of the pain to a dermatome; its intensification by sneezing, coughing, and straining, and sometimes by recumbency; and the finding of segmental sensory changes and minor alterations of motor, reflex, or sensory function in the legs will usually provide the clues to the presence of a spinal cord–radicular lesion. MRI will settle the diagnosis in most instances. The pain of tumor or blood clot in the retroperitoneal space may cause an orthostatic and nocturnal back pain that is similar to that of spinal tumor.

There is then the problem of locating the segmental level of the lesion. At first, the sensory and motor deficits may be most pronounced in those parts of the body farthest removed from the lesion, i.e., in the feet or lumbosacral segments. Later the levels of the sensory and motor deficits ascend, but they may still be at a level several segments below the lesion. In determining the level of the lesion, the location of back pain, root pain, and atrophic paralysis are of greater help than the upper level of hypoalgesia.

Once vertebral and segmental levels of the lesion are settled, there remains the necessity of determining whether the lesion is extradural, intradural–extramedullary, or intramedullary and whether it is neoplastic. If there is a visible or palpable spinal deformity or radiographic evidence of vertebral destruction, one may confidently assume an extradural localization. Even without these changes, one still suspects an extradural lesion if root pain developed early and is bilateral, if pain and aching in the spine are prominent and percussion tenderness is marked, if motor symptoms below the lesion preceded sensory ones, and if sphincter disturbances were late. However, to distinguish between intradural–extramedullary lesions and intramedullary lesions on clinical grounds alone is often difficult. The findings of segmental amyotrophy and sensory loss of dissociated type (loss of pain and temperature and preservation of tactile sensation) point to an intramedullary lesion.

Extradural tumors, both primary and secondary, must be differentiated from cervical spondylosis, tuberculous granuloma, sarcoidosis, arteriovenous malformations of the cord, spinal dural fistulas, and certain chronic pyogenic or fungal granulomatous lesions, as well as from lipomas in patients receiving corticosteroids for prolonged periods and from the necrotizing myelopathy associated with occult tumors or occurring independently of them. A number of rarer conditions of the vertebral bodies such as bone cysts, chondromas, eosinophilic granuloma, chordomas and giant cell tumors must also be considered; these are summarized by Ropper and coworkers (2011). In the thoracic region, a ruptured disc or eventration of the cord through a dural tear is always a possibility. In the region of the lower back, i.e., over the

cauda equina, one must also distinguish between tumor and protruded inter-vertebral disc. Here, an extradural tumor may produce mainly sciatic and low back pain with little or no motor, sensory, reflex, or sphincter disturbances. With intradural–extramedullary lesions, the important diagnostic considerations are meningioma, neurofibroma, meningeal carcinomatosis, cholesteatoma, and teratomatous cyst, a meningomyelitic process, or adhesive arachnoiditis. Intramedullary lesions are usually gliomas, ependymomas, or vascular malformations or, in the context of a known carcinoma, intramedullary metastases. The definition of vascular malformations by means of selective spinal angiography was discussed in an earlier section. Normal protein in the CSF and negative MRI effectively exclude an intramedullary tumor.

Treatment

The main consideration in the management of epidural metastases is the need for early diagnosis, at a stage when only back pain is present and before neurologic symptoms and signs have appeared. Once these signs appear, especially sphincter disturbances, the results of treatment are less successful but may still result in good limb and bladder function. Epidural growths of carcinoma and lymphoma are best managed by administration of high to moderate doses of corticosteroids and radiation of the region of tumor. This may be supplemented by endocrine therapy (for carcinoma of breast and prostate), and of antineoplastic drugs (for certain lymphomas and myelomas. Pain relief is sometimes difficult to attain and requires narcotics. Only infrequently is operation necessary as a first resort. Gilbert and associates presented evidence that patients who receive high-dose corticosteroids (16 to 60 mg of dexamethasone) and fractionated radiation (500 cGy on each of the first 3 days and then spaced radiation up to 3,000 cGy) do as well as those who have surgical decompression.

However, laminectomy and decompression are necessary to prevent irreversible compressive effects and infarction of the cord for rapidly growing tumors that have caused recent and severe loss of function below the level of compression. Cases that have been allowed to progress should be operated on if paraplegia has occurred within one or perhaps two days or less and the overall state of the patient's cancer makes survival likely for at least several weeks. If the maximal safe radiation dosage had previously been applied to the spinal column, or the diagnosis can only be made from tissue obtained from the site of spinal compression, surgical palliation is also usually undertaken.

Intradural–extramedullary tumors should generally be removed if this can be accomplished safely, and this applies to benign extradural tumors that are symptomatic as well. Laminectomy, decompression, excision in isolated cases, and radiotherapy constitute the treatment of intramedullary gliomas. Such patients may improve and lead useful lives for a decade or longer. Constantin and colleagues, based on a large experience with intramedullary lesions, mainly gliomas in children and young

adults, recommend a radical excision of the tumor, but this approach has not been subjected to a trial.

Other Causes of Spinal Cord Compression

Epidural fat deposition (*epidural lipomatosis*) with spinal cord compression occurs in Cushing disease and after the long-term use of corticosteroids, but also in the absence of these disorders. The clinical picture may suggest discogenic disease (Lipson et al). Copious amounts of normal adipose tissue are found at laminectomy and removal of this tissue is curative. Lowering the dose of steroid and caloric restriction may help mobilize the fat and relieve the symptoms. An intra-spinal lipoma is also a component of the developmentally tethered cord, but in this process the essential problem is a conus medullaris myelopathy from stretching of the cord, rather than compression (see Chap. 38 and Thomas and Miller.)

Arachnoid diverticula—intra- or extradural outpouchings from the posterior nerve root—are rare causes of a radicular-spinal cord syndrome, first described by Bechterew in 1893. They tend to occur in the thoracic or lumbosacral regions. The symptoms, in order of decreasing frequency, are pain, radicular weakness and sensory disorder, gait disorder, and sphincteric disturbances, as described by Cilluffo et al. The frequent association of arachnoid diverticula with osteoporosis, ankylosing spondylitis, and arachnoiditis makes it difficult to interpret the role of the diverticula themselves. Surgical obliteration of the pouches has yielded unpredictable results. They have attained clinical importance more often as the source of spontaneous CSF leaks and a low-pressure syndrome (see Chap. 30).

Spinal cord compression with paraplegia may be caused by *extramedullary hematopoiesis* in cases of myeloclerosis, thalassemia, cyanotic heart disease, myelogenous leukemia, sideropenic anemia, and polycythemia vera. A similar phenomenon occurs with ossification of the posterior longitudinal ligament, as described earlier.

Solitary *osteochondromas* of vertebral bodies and *multiple exostoses* of hereditary type are other reported causes of spinal cord compression. In the case reported by Buur and Morch, the clinical syndrome was one of pure spastic paraparesis of several months' progression.

Lathyrism (See also Chap. 43)

From the interesting historical review of Dastur, one learns that this disease was known to Hippocrates, Pliny, and Galen in Europe, to Avicenna in the Middle East, and to the ancient Hindus. The term *lathyrism* was applied by Cantani, in Italy, because of its recognized relationship to the consumption of *Lathyrus sativus* (chickling vetch, vetch pea, or grass pea).

The disease is still common in some parts of India and Africa. In these districts, during periods of famine when wheat and other grains are in short supply, the diet may for months consist of flour made of the grass pea. In individuals so exposed, a gradual weakening of the legs accompanied by spasticity and cramps occurs. Paresthesias, numbness, formication in the legs, and fre-

quency and urgency of micturition, erectile dysfunction, and sphincteric spasms are added. The upper extremities may exhibit coarse tremors and involuntary movements. These symptoms, once established, are more or less permanent but not progressive, and most of the patients live out their natural life span.

Only two reports on the neuropathology of lathyrism were known to Dastur, one by Buzzard and Greenfield in England, the other by Filiminoff in Russia. Both of their patients had been in a stationary paraplegic state for years. Greenfield noted a loss of ascending and descending tracts in the spinal cord, particularly the corticospinal and direct spinocerebellar tracts. Filiminoff observed a loss of myelinated fibers in the lateral and posterior columns. Unlike the cases of Spencer and colleagues, there had been a loss of pain and thermal sensation in the upper extremities. The larger Betz cells had disappeared, while anterior horn cells were unaffected. Gliosis and thickening of blood vessels was seen in the degenerated tracts.

The toxic nature of this disease, long suspected, was confirmed by Spencer and colleagues. They extracted a neuroexcitatory amino acid, beta-*N*-oxalylaminoalanine (BOAA), from grass peas and were able to induce corticospinal dysfunction in monkeys by giving this substance with a nutritious diet. Subsequently, Hugon and coworkers produced a primate model of lathyrism by feeding monkeys a diet of *L. sativus* in addition to an alcoholic extract of this legume. These findings tend to negate the importance of several other factors that had been thought to be causative, namely, malnutrition, ergot contamination, and toxins derived from *Vicia sativa*, the common vetch that grows alongside the lathyrus species.

The African acute spastic paraplegia called *konzo* has a similar toxic pathogenesis; it is caused by cyanide-like compounds in flour made from cassava.

Dysraphic Syndromes (Spina Bifida) and Tethered Cord

These are described in Chap. 38 but should be considered in cases of chronic and progressive syndromes of the cauda equina and conus medullaris.

Familial Spastic Paraplegia (See Chap. 39)

There are several familial forms of progressive spastic paraplegia, some beginning in childhood, others in adult life. The pattern of inheritance in almost all our adult cases has been autosomal dominant. A lack of sensory symptoms and signs and sparing of sphincteric function until late in the illness are important diagnostic features. A number of adult cases are "complicated" in the sense that the spastic paraplegia is associated with cerebellar ataxia or dementia. By contrast, *primary lateral sclerosis*, a sporadic form of degenerative disease of the motor system, is characterized by a pure spastic paraplegia and bulbar spastic palsy either initially or with progression, the result of changes that are confined to the corticospinal pathways. These disorders are discussed extensively with the heredodegenerative diseases in Chap. 39, and the myelopathy associated with adrenoleukodystrophy, in Chap. 37.

SYRINGOMYELIC SYNDROME OF SEGMENTAL SENSORY DISSOCIATION WITH BRACHIAL AMYOTROPHY

This syndrome is most often attributable to developmental syringomyelia, i.e., a central cavitation of the spinal cord of undetermined cause, but a similar clinical syndrome may be observed in association with other pathologic states such as intramedullary cord tumors, traumatic myelopathy, postradiation myelopathy, infarction (myelomalacia), bleeding (hematomyelia), and, rarely, with extramedullary tumors, cervical spondylosis, spinal arachnoiditis, and cervical necrotizing myelitis.

Syringomyelia (Syrinx) (See also Chap. 38)

Syringomyelia (from the Greek *syrix*, "pipe" or "tube") is defined as a chronic progressive degenerative or developmental disorder of the spinal cord, characterized clinically by painless weakness and wasting of the hands and arms (brachial amyotrophy) and segmental sensory loss of dissociated type (loss of thermal and painful sensation with sparing of tactile, joint position, and vibratory sense, as described later). The cause is a cavitation of the central parts of the spinal cord, usually in the cervical region, but extending upward in some cases into the medulla and pons (syringobulbia) or downward into the thoracic and even into the lumbar segments. Frequently, there are associated developmental abnormalities of the vertebral column (thoracic scoliosis, fusion of vertebrae, or Klippel-Feil anomaly), of the base of the skull (platybasia and basilar invagination), and there is a special relationship to developmental deformations of the cerebellum and brainstem (particularly type I Chiari malformation). A large proportion of cases of developmental syringomyelia have type I Chiari malformation, consisting of a descent of cerebellar tonsils below the foramen magnum as discussed in Chap. 38. There is also a group of less frequent but well-described syringomyelias that derives from the acquired processes mentioned earlier such as intramedullary tumor (astrocytoma, hemangioblastoma, ependymoma) and from preceding traumatic or hemorrhagic necrosis of the spinal cord.

Wider experience with the pathology of developmental syringomyelia has led to the following classification, modified from Barnett and colleagues that unfortunately creates some confusion because it simulates the Roman numeral classification of the Chiari malformations, with which it is sometimes allied:

- Type I. Syringomyelia with obstruction of the foramen magnum and dilatation of the central canal (developmental type)
 - A. With type I Chiari malformation
 - B. With other obstructive lesions of the foramen magnum, usually bony anomalies
- Type II. Syringomyelia without obstruction of the foramen magnum (idiopathic developmental type)
- Type III. Syringomyelia with other diseases of the spinal cord (acquired types)

- A. Spinal cord tumors (usually intramedullary, especially hemangioblastoma)
- B. Traumatic myelopathy
- C. Spinal arachnoiditis and pachymeningitis
- D. Secondary myelomalacia from cord compression (tumor, spondylosis), infarction, hematomyelia

Type IV. Pure hydromyelia (developmental dilatation of the central canal), with or without hydrocephalus

Historical Note Although pathologic cavitation of the spinal cord was recognized as early as the sixteenth century, the term *syringomyelia* was first used to describe this process in 1827 by Ollivier d'Angers (cited by Ballantine et al). Later, following recognition of the central canal as a normal structure, it was assumed by Virchow (1863) and by Leyden (1876) that cavitation of the spinal cord had its origin in an abnormal expansion of the central canal, and they renamed the process *hydromyelia*. Cavities in the central portions of the spinal cord, unconnected with the central canal, were recognized by Hallopeau (1870); Simon suggested in 1875 that the term *syringomyelia* be reserved for such cavities and that the term *hydromyelia* be restricted to simple dilatation of the central canal. Thus, a century ago, the stage was set for an argument about pathogenesis that has not been settled to the present day.

Clinical Features

The clinical picture varies in the four pathologic types previously listed, the differences depending not only on the extent of the syrinx but also on the associated pathologic changes, particularly those related to the Chiari malformation. In the type I developmental syrinx (idiopathic, Chiari-associated developmental syringomyelia), symptoms usually begin in early adult life (20 to 40 years). Males and females are equally affected. Rarely, some abnormality is noted at birth, but usually the first symptom appears in late childhood or adolescence. The onset is usually insidious and the course irregularly progressive. In many instances, the symptoms or signs are discovered accidentally, for example, as a result of painless burn or atrophy of the hand, and the patient cannot say when the disease began. Rarely, there is an almost apoplectic onset or worsening; there are cases on record of an aggravation of old symptoms or the appearance of new symptoms after a violent strain or paroxysm of coughing. Trauma is a less certain precipitant. Once the disease is recognized, some patients remain much the same for years, even decades, but more often there is intermittent progression to the point of being chair-bound within 5 to 20 years. This extremely variable course makes it difficult to evaluate therapy.

The precise clinical picture at any given point in the evolution of the disease depends on the cross-sectional and longitudinal extent of the syrinx, but certain clinical features are so common that the diagnosis can hardly be

made without them. These traditionally cited elements are: (1) *segmental weakness and atrophy of the hands and arms*, (2) *loss of some or all tendon reflexes in the arms*, and (3) *segmental anesthesia of a dissociated type* (loss of pain and thermal sense and preservation of the sense of touch) over the neck, shoulders, and arms. The last of these leads to one of the most characteristic features of syringomyelia: *painless injuries and burns of the hands*. Finally, there are in cases of extensive cavitation weakness and ataxia of the legs from involvement of the corticospinal tracts (possibly at their decussation) and posterior columns in the cervical region.

Kyphoscoliosis is added in many of the cases and in nearly one-quarter of them there is an overt cervicooccipital malformation (short neck, low hairline, odd posture of the head and neck, fused or missing cervical vertebrae, i.e., Klippel-Feil abnormality).

The particular muscle groups that are affected on the two sides may vary. Exceptionally, motor function is spared, and the segmental dissociated sensory loss and/or pain are the only marks of the disease. In a few of the cases, especially those with the Chiari malformation, the reflexes in the arms are preserved or even hyperactive, as might be expected with upper rather than lower motor neuron involvement. Or the shoulder muscles may be atrophic and the hands spastic. In the lower extremities the weakness, if present, is of a spastic (corticospinal) type.

The characteristic segmental sensory dissociation is usually bilateral but a unilateral pattern affecting only one hand and arm is not unknown, and this is true of the amyotrophy as well. The sensory loss is distributed in a "cape" or hemicafe pattern, often extending to back of the head or the face and onto the trunk. Although tactile sensation is usually preserved, there are cases in which it is impaired, usually in the region of the densest analgesia over the trunk or hand. Exceptionally there is no sensory loss in the presence of amyotrophy, and cases have been recorded in which only a hydrocephalus and hydromyelia were present with spastic paraparesis. If tactile sensation is affected in the arms, joint position and vibratory sense tend also to be impaired. In the lower extremities and over the abdomen there may be some loss of pain and thermal sensation proximally, but more often there is a loss of vibratory and position sense, which is indicative of a posterior column lesion and is the basis of ataxia. A Horner syndrome may result from ipsilateral involvement of the intermediolateral cell column at the C8, T1, and T2 levels.

Pain has been a symptom in about half of our patients with developmental types of syringomyelia. The pain is usually unilateral or more marked on one side of the neck, shoulder, and arm; it is of a burning, aching quality, mostly in or at the border of areas of sensory impairment. In a few patients, it involves the face or trunk. An aching pain at the base of the skull or posterior cervical region that is intensified by coughing, sneezing, or stooping (brief exertional pain) is often present, but, as Logue and Edwards point out, pain of this type may be a feature of Chiari malformation without syringomyelia

and in that case is probably attributable to compression or stretching of cervical roots.

Syringobulbia is the lower brainstem equivalent of syringomyelia. Usually the two coexist and the brainstem cavity is simply an extension of one in the upper cord, but occasionally the bulbar manifestations precede the spinal ones or, rarely, occur independently. The glial cleft or cavity is located most often in the lateral tegmentum of the medulla, but it may extend into the pons and, rarely, even higher. The symptoms and signs are characteristically unilateral and consist of nystagmus, analgesia, and thermoanesthesia of the face (numbness); wasting and weakness of the tongue (dysarthria); and palatal and vocal cord paralysis (dysphagia and hoarseness). Diplopia, episodic vertigo, trigeminal pain or facial sensory loss, and persistent hiccup are less common symptoms. For understandable reasons, the diagnosis of brainstem MS is often raised. The clinical and pathologic features of syringobulbia have been described in great detail by Jonesco-Sisesti.

When a Chiari malformation is associated with syringomyelia and syringobulbia, it may be difficult to separate the effects of the two disorders. A typical example is shown in Fig. 38-4. Clinical features that favor the predominance of Chiari malformation are nystagmus, cerebellar ataxia, exertional head and neck pain, prominent corticospinal and sensory tract involvement in the lower extremities, hydrocephalus, and craniocervical malformations. In syringomyelia without a Chiari malformation but with some other type of obstructive lesion at the foramen magnum, the clinical picture is much the same, and the nature of the foramen magnum lesion can be determined only by MRI or surgical exploration.

The association of syringomyelia with an intramedullary tumor (type III) should be suspected when there is a disassociated sensorimotor abnormality extending over many segments of the body. With von Hippel-Lindau disease, the diagnosis hinges on the finding of the characteristic hereditary hemangioblastoma in the syrinx and retinal and cerebellar vascular malformations. In the posttraumatic cases, necrosis of the spinal cord that has been stable for months or years begins to cause pain and spreading sensory or motor loss, recognizable only in segments above the original lesion (Schurch et al). This occurred in approximately 3 percent of the traumatic myelopathy cases of Rossier and coworkers, more often in quadriplegics than in paraplegics. The posttraumatic syrinx is not as well defined anatomically as the usual forms of syringomyelia but consists instead of several contiguous areas of glia-lined myelomalacia with differing degrees of cavitation. In some instances of progressive spinal cord symptoms occurring several years after spinal surgery, the lesion has proved to be one of arachnoiditis and cord atrophy and not a syrinx (Avrahami et al).

Hydromyelia

This refers to a dilatation of the central canal that is distinct from developmental syringomyelia. The relationship between hydromyelia and syringomyelia has been

the source of endless debate, in part the result of the lack of a coherent pathophysiologic explanation for either process. At least one hypothesis for the origin of syringomyelia includes an initial dilatation of the central canal (see later). Our impression is that a relatively nonprogressive, well-defined, cylindrical enlargement of the central canal over a few thoracic segments is a frequent enough occurrence in the absence of clinical changes that it represents an independent entity. In the few cases of symptomatic hydromyelia that have come to our attention, there had usually been a long-standing congenital hydrocephalus complicated years later by progressive weakness and atrophy of the shoulders and the muscles of the arms and hands. More often, there is no associated obstruction at the upper cord and no hydrocephalus for which reason it is our impression that most cases are benign and relatively nonprogressive. Proof of the existence of pure hydromyelia in the past has been based on necropsy demonstration of an enormously widened central canal, with or without hydrocephalus. Now, hydromyelia is easily diagnosable by MRI and numerous asymptomatic cases are being discovered, causing unnecessary concern and neurologic consultation.

Pathogenesis

Experimental work in animals has indicated that there is a normal flow of CSF from the spinal subarachnoid space through perivascular spaces to the parenchyma of the cord and possibly into the central canal. It has been suggested that impediments to flow might explain dilatation of the central canal, or the creation of a parallel or attached syrinx cavity.

One theory of the pathogenesis of developmental syringomyelia, of which Gardner was the main advocate, is that the normal flow of CSF from the central canal to the fourth ventricle and its outlets is prevented by an obstruction of the foramina of Luschka and Magendie. As a result, a pulse wave of CSF pressure that is generated by systolic pulsations of the choroid plexuses is transmitted into the cord from the fourth ventricle through the central canal. According to this theory, the syrinx consists essentially of a greatly dilated central canal with a diverticulum that ramifies from the central canal and dissects along gray matter and adjacent fiber tracts. The frequency with which syringomyelia is linked to malformations at the craniocervical junction, i.e., to Chiari and other lesions that could interfere with normal flow of CSF, lends credence to this theory.

There are many instances, however, in which Gardner's hydrodynamic theory could not explain syringomyelia. In some cases, for example, the foramina of Luschka and Magendie are found to be patent, and other abnormalities of the posterior fossa or foramen magnum that block CSF flow are not in evidence. Furthermore, in many cases, including several we have inspected, serial histologic sections have failed to demonstrate a connection between the fourth ventricle and the syrinx in the spinal cord or of a widening of the central canal above the syrinx (see also Hughes). Gardner's theory has been questioned on other grounds. Ball and

Dayan calculated the pulse-pressure wave transmitted into the cord to be of such low amplitude as to be unlikely to produce a syrinx. In their view, the CSF around the cervical cord, under increased pressure during strain or physical effort because of subarachnoid obstruction at the craniocervical junction, tracks into the spinal cord along the Virchow-Robin spaces or other subpial channels. Over a prolonged period, abetted perhaps by traumatic lesions, small pools of fluid coalesce to form a syrinx. In their view, originally the syrinx forms independently of the central canal, but eventually the two may become connected, allowing secondary enlargement of the canal (hydromyelia ex vacuo). The findings of Heiss and colleagues lend support to this theory. They found that progression of syringomyelia is produced by the compressive effect of the cerebellar tonsils, which partially occlude the subarachnoid space at the foramen magnum and create pressure waves that compress the spinal cord from without and not from within; the pressure waves propagate syrinx fluid caudally with each heartbeat. This hardly exhausts the list of hypotheses that have been offered over the years but none of them has been confirmed.

The authors favor the type of hydrodynamic mechanism as postulated originally by Gordon Holmes and elaborated by Ball and Dayan. In this view, a relationship exists between basal cranial, cervical spine, the cerebellospinal Chiari malformation, syringomyelia, and disturbed hydrodynamics of perispinal CSF. Logue and Edwards documented several cases of syringomyelia in which the foramen magnum was obstructed by a lesion other than a Chiari formation, e.g., by dural cyst, localized arachnoiditis, atlantoaxial fusion, simple cerebellar cyst, and basilar invagination (see Williams for a review of the numerous hypotheses of causation).

Irrespective of its mode of origin, the syrinx first occupies the central gray matter of the cervical portion of the spinal cord, usually independent of the central canal but sometimes extending into it. It interrupts the crossing pain and temperature fibers in the anterior commissure at several successive cord segments. As the cavity enlarges, it extends symmetrically or asymmetrically into the posterior and anterior horns and eventually into the lateral and posterior funiculi of the cord. It may enlarge the spinal cord. The cavity is lined with astrocytic glia and a few thick-walled blood vessels, and the fluid in the cavity is clear and in our patients, has had relatively low protein content, like intracranial CSF.

The cavitation nearly always arises in the cervical portion of the cord and can only reach the thoracic and lumbar portions by its extension from the cervical region, sometimes by a small, flat and thin, eccentrically placed. Either a cavity or a glial septum may extend asymmetrically into the medulla, usually in the vicinity of the descending tract of the fifth cranial nerve to create a syringobulbia.

Diagnosis

The clinical picture of syringomyelia is so characteristic that diagnosis is seldom in doubt. Now one can obtain

Figure 44-13. Sagittal T2-weighted MRI showing a developmental syringomyelia without Chiari malformation. The cervical spinal cord is greatly expanded but there were only signs of spinothalamic sensory loss over the arms.

spectacular demonstrations of the syrinx, either traumatic or developmental (Fig. 44-13), Chiari malformations, and other foramen magnum lesions by MRI of the sagittal planes of the brain and spinal cord (see Fig. 38-4). Also, hours after a CT myelogram, contrast material fills the syrinx and the central canal directly, possibly by diffusion from the surface of the cord.

Certain rare polyneuropathies (amyloid, Tangier disease, and Fabry disease) that preferentially affect small fibers in the nerves of the upper extremities can reproduce the dissociated sensory loss that is characteristic of a syrinx ("pseudosyringomyelic" deficit), but motor abnormalities are not prominent in these neuropathic cases. These diseases are discussed in Chap. 46.

Treatment

The only therapy of lasting value for type I syringomyelia (related to Chiari malformation) is surgical decompression of the foramen magnum and upper cervical canal. Headache and neck pain are helped most; ataxia and nystagmus tend to persist, but these are related to the Chiari process. The cavity tends to cease enlarging. Radiation therapy, which was formerly recommended, is of no benefit. The operation advised by Gardner, of plugging the connection between the fourth ventricle and the central canal of the cervical cord, has been abandoned.

There were complications of this operative procedure, and the results were no better than those obtained from simple decompression. The decompression operation also carries some risk, especially if there is an attempt to excise the tonsillar projections of the cerebellum. In the series of Logue and Edwards, comprising 56 cases of type I syringomyelia, the occipitocervical pain was relieved by decompression in most patients, but the shoulder-arm pain usually persisted. Upper motor neuron weakness of the legs and sensory ataxia were often improved, whereas the segmental sensory and motor manifestations of the syringomyelia were not. Hankinson, in the past, had reported good results from decompression in 75 percent of type I cases of syringomyelia. In the retrospective review of 141 adult patients by Stevens and colleagues, good surgical outcome was achieved in 50 percent of those with minor degrees of descent of the cerebellar tonsils, but in only 12 percent of those with major cerebellar ectopia. A distended syrinx also led to a more favorable outcome. Whether the long-term course of these diseases is altered has not been determined. Other surgical series of Chiari-syrinx are discussed and cited in Chap. 38.

Syringotomy or shunting of the cavity has been performed in type I and some of the type II (idiopathic) cases, but the results have been unpredictable. Love and Olafson, who performed this procedure in 40 patients of both types (mainly type II), stated that 30 percent had an excellent outcome. Schurch and coworkers obtained improvement of pain and motor weakness in five of their seven cases by stabilization of the spine and syringotomy with placement of a T-tube within the syrinx. In a more recent and comprehensive study of 73 patients with a developmental syrinx operated by Sgouros and Williams (1995), one-half remained clinically stable for a 10-year period; 15 percent had serious complications from the surgery, however. Our experience with this procedure has not persuaded us of its lasting value; most of these patients, even those who reported some improvement originally, soon relapsed to their preoperative state, and the disease then progressed in the usual way. An enlarged cervical cord with progressive clinical worsening may nonetheless justify an attempt to shunt the cavity. Other comments are found in Chap. 38.

Surgery for the *posttraumatic* cases has given only slightly more favorable results. With incomplete myelopathy, syringotomy relieved the pain in all 10 patients of Shannon and associates. Where they found the myelopathy to be complete, the cord was transected and the upper stump excised. Sgouros and Williams (1996) studied 57 such patients and recommend decompressive laminectomy and reconstruction of the subarachnoid space as the most effective of the several procedures used in the management of traumatic cavities. An extensive review of surgical approaches to syringomyelia can be found in the article by Brodbelt and Stoodley, who tentatively recommend lysis of arachnoidal adhesions as preferable to shunting or filleting of the cord, but acknowledge that the current state of treatment is unsatisfactory.

In the cases of syringomyelia with tumor, in which the cyst fluid may be high in protein and viscid (unlike the low-protein fluid of the usual syrinx), the tumor should be excised if possible. This has been done successfully with hemangioblastomas of the posterior columns and occasionally with ependymomas.

The infrequent case of symptomatic purely hydro-myelic may benefit from ventriculoperitoneal shunts of hydrocephalus, and a few excellent results are reported. This procedure has also been attempted in type I developmental cases, with unimpressive results unless there is an associated hydrocephalus. Draining the central canal by amputation of the tip of the sacral cord has been unsuccessful and can be harmful. Most patients with hydromyelia do not require treatment.

CONCLUDING REMARKS ON DISEASES OF THE SPINAL CORD

It is always well to remind oneself that of the more than 30 diseases of the spinal cord, effective means of treatment are available for many of the common ones: spondylosis, extramedullary spinal cord tumors, epidural abscess, hematoma and granuloma (tuberculous, fungal, sarcoidosis), myelitis, syringomyelia, and subacute combined degeneration and other forms of nutritional myelopathy. Many of the inflammatory myelopathies respond well to immune-modulating measures. The physician's major responsibility is to determine whether the patient has one of these treatable diseases.

Electrophysiologic and Laboratory Aids in the Diagnosis of Neuromuscular Disease

The clinical suspicion of neuromuscular disease, disclosed by any of the symptoms or syndromes in the succeeding chapters, finds ready confirmation in the laboratory. The intelligent selection of ancillary examinations requires knowledge of the biochemistry and physiology of nerve action potentials, neuromuscular transmission, and muscle fiber contraction. These basic subjects, with the relevant anatomy, serve as an introduction to the descriptions of the laboratory methods and the subject matter of the chapters on the diseases of muscle and nerve that follow.

ELECTROLYTES AND NEUROMUSCULAR ACTIVITY

Since the early studies of Hodgkin (1951) and of Hodgkin and Huxley (1952), tomes have been written on the subject of the conduction of electrical impulses in neural tissues. Such conduction in nerve and muscle depends first on the maintenance of a fluid internal environment that is distinctly different from the external or interstitial medium. The main intracellular constituents are potassium (K), magnesium (Mg), and phosphorus (P), whereas those outside the cell are sodium (Na), calcium (Ca), and chloride (Cl). In both nerve and muscle the intracellular concentrations of these ions are held within a narrow range by both passive electrical and active chemical forces, which maintain the membranes in an electrochemical equilibrium termed the resting membrane potential. These forces are the result of selective permeability of the membranes to various ions and to the continuous expulsion of intracellular Na through specific channels by a pump mechanism (the sodium pump). The function of the sodium pump is dependent on the enzyme Na-K-ATPase (adenosine triphosphatase), which is localized in the membranes.

This resting membrane potential is the result of the differential concentrations of K and Na. The interior of the cell is some 30 times richer in K than the extracellular fluid, and the concentration of Na is 10 to 12 times greater in the extracellular fluid. In the resting state, the chemical forces that promote diffusion of K ions out of the cell (down their concentration gradient) are counterbalanced by electrical forces, the internal negativity, that opposes further diffusion

of K to the exterior of the cell. The situation of Na ions in the equilibrium state is the opposite; they tend to diffuse into the cell, both because of their concentration gradient and because of the relative negativity inside the cell. Because the membrane at rest is less permeable to Na than to K, the amount of K leaving the cell exceeds the amount of Na entering the cell, thus creating the difference in electrical charge across the membrane. This discrepancy creates an electrical potential across the membrane such that, in the resting state, the intracellular compartment is 70 to 90 mV negative relative to the extracellular space (the resting membrane potential). The actions of the Na:K pump and the presence of impermeant, negatively charged intracellular proteins, contribute to maintaining this negative potential.

From this resting potential, any electrical discharge of neural and muscular tissue is predicated on the special property of excitable membranes; namely, the permeability of the cell to Na is linked to the electrical potential across the membrane by voltage-gated (i.e., voltage sensitive or voltage triggered) ion channels. Any depolarization of the membrane by a slight electrical or chemical change, creates an increased permeability to Na through the sodium channels and a consequent inward movement of sodium. Subsequently, K moves outward and repolarizes the membrane and thereby reduces its permeability to Na. If a greater degree of depolarization occurs, a situation arises in which the outward movement of K is unable to stabilize the membrane potential. The membrane then becomes even more depolarized and progressively more permeable to Na, and an "explosive," or regenerative Na current develops in which Na rushes down its chemical and electrical gradients into the cell. With the elevation in Na permeability, the Na ions continue to depolarize the intracellular compartment to about +40 mV (the Nernst equilibrium potential for Na). It is this depolarization of the intracellular compartment, lasting a few milliseconds, that constitutes the action potential.

However, an equilibrium at this level is not established because there is a rapid (within 5 ms) fall in membrane Na permeability back to baseline levels. This fall in Na permeability occurs because the depolarization inactivates Na conductance. The transient depolarization at the same time activates an increase in membrane permeability to K. The combined effects of the resulting

efflux of K and a diminishing influx of Na repolarizes the membrane back to its resting level. During a brief period immediately after repolarization, the nerve and muscle fibers are refractory, at first absolutely then relatively, to another depolarizing stimulus. The duration of the refractory period is determined largely by the duration of the inactivation of the Na channel.

Conduction, or propagation, of the action potential along nerve or muscle, occurs as the current created by depolarization of a small segment of membrane flows into the contiguous membrane, which, in turn, becomes depolarized. When the depolarization reaches the threshold for development of an action potential, a new zone of increased Na permeability is created. In this manner, the action potential spreads in an “all-or-none” fashion, down the length of the nerve or muscle membrane. The action potentials in individual nerve fibers are too small and brief to be detected by conventional nerve conduction techniques, but a summated volley of all the fibers within a nerve is large enough to be recorded, and it is this electrical potential and the one it produces in the muscle that it innervates that is utilized to study nerve function.

As nerve impulses pass centrifugally from the axon into its terminal branches, transmission may “break down,” especially if impulses arrive too frequently at branch points; they then fail to reach the neuromuscular junction of these fibers; or there may be failure of conduction at the neuromuscular junction, which is the characteristic feature of myasthenia gravis.

In large motor and sensory nerves, contiguous spread of action potentials along a fiber eventually decays over long distances. Conduction is aided by the structure and configuration of the myelin sheaths surrounding the axon. The sodium channels, which generate the action potential, are concentrated at short exposed segments of the axon, the nodes of Ranvier, lying between longer segments of myelinated axon, the internodes. In contrast, the internodes covered by myelin remain electrically insulated. This creates “flux lines” that converge on the nodes and allows current to be regenerated at each gap in the myelin. The speed of electrical conduction, which jumps in a “saltatory” fashion from node to node, is many times faster than conduction through an unmyelinated axon. The largest-diameter fibers have the thickest myelin sheaths and longest internodal distances, conferring on them the fastest conduction times.

Conventional laboratory studies of nerve conduction generally measure the speed of these fastest-conducting fibers. This dependence of nerve conduction on large, heavily myelinated fibers explains a number of electrophysiologic abnormalities that are a consequence of nerve disease. One common result, is a mild slowing of nerve conduction because of a dependence on the remaining smaller diameter, slower conducting axons. When myelin destruction is the prominent feature of a neuropathy (*demyelinating neuropathy*), conduction velocity is greatly slowed because of delays in regenerating the sodium current at nodes of Ranvier, or there may be total block of electrical conduction. An

intermediate state of partial demyelination slows and desynchronizes the electrical volley, leading to temporal dispersion of the action potentials that reach the muscle. The cumulative effect of any of these changes is to reduce the number of nerve fibers that are capable of conducting an electrical volley, leading to a graduated reduction in the amplitude of the muscle action potential over longer segments of nerve. This reduction in amplitude of the compound motor action potential (CMAP) as the stimulating electrode is moved proximally is termed *conduction block* (discussed under “Studies of Nerve Conduction” further on). Blocked conduction of this restricted nature is a reliable marker of an acquired demyelinating neuropathy; of all the electrophysiologic changes, it also corresponds most closely to the degree of muscle weakness (see further on).

In contrast to these effects of demyelination of peripheral nerve, loss of axon fibers (*axonal neuropathy*) results in a reduction of the amplitude of summed electrical activity of the action potential in muscles uniformly all along the nerve, and to atrophic denervation of muscle as described further on.

THE NEUROMUSCULAR JUNCTION (MOTOR ENDPLATE)

This is the interface between the finely branched nerve fiber and the muscle fiber, where the electrical activity of the motor nerve is translated into muscle action (Fig. 45-1). The nerve fiber contacts the muscle membrane in a trough-like junctional space of 50 nm—the *synaptic cleft*—between the axolemma and sarcolemma (see Fig. 49-1). Within the nerve terminal, a relatively fixed number of packets, or quanta, of acetylcholine (ACh), each packet containing about 10,000 molecules, are liberated through an exocytotic process that is triggered by the arrival of axonal action potentials. Arrival of the electrical impulse opens calcium channels in the presynaptic neural membrane, which serves to bind packets of ACh to the membrane and govern their release. Molecules of ACh diffuse into the synaptic cleft and attach to receptor sites on the postsynaptic membrane. Each impulse triggers the release of approximately 20 to 50 quanta of ACh and produces a depolarization of sufficient size to initiate an action potential in the postsynaptic muscle membrane through the same mechanism of a regenerative sodium current described earlier. Botulinum toxin interferes with exocytosis of ACh at the release site by cleaving “synaptic protein 25.” There is also a nonquantal release of ACh through continuous leakage. This appears to play a role in the trophic influence of nerve on muscle.

The ACh molecule binds to the postsynaptic ACh receptor, a complex of 5 proteins that constitute the postsynaptic ion channel. Binding of ACh by this receptor causes a conformational change in the receptor that leads to a local increase in the conductance of Na and K and other small ions. This produces a depolarization known as the *endplate potential*. Small (miniature) endplate potentials (MEPPs) are continuously formed

Figure 45-1. Motor endplate showing relationship between various structures in nerve and muscle. Last segment of myelin, with Schwann nucleus (S), terminates abruptly, leaving axis cylinder covered by sheaths of Schwann and Henle. Endplate nuclei (EP) of muscle fiber lie embedded in sarcoplasm and have same staining reactions as sarcolemmal nuclei (M). Ramifications of axis cylinder (telodendria) lie in grooves or pouches in granular sarcoplasm, each lined by spiny “subneuronal apparatus” of Couteaux, which is continuous with membranous sarcolemma and also Schwann membrane. Nucleus (S) of sheath of Schwann commonly lies near point of branching of axon. Sheath of Henle has small nuclei (H) and fuses with endomysial sheath of muscle fiber.

and regenerated as the membranes repolarize, much as in the process of passive decay previously described. These potentials are too small to be recorded by routine electromyography (EMG) testing or to trigger an action potential, although fortuitous needle placement adjacent to a synapse may detect them.

The bound ACh is hydrolyzed by cholinesterase, a glycoprotein enzyme that exists in free form in the neuromuscular junction clefts. Its main function is to terminate the action potential and permit the sequential activation of muscle. The postsynaptic membrane, once depolarized, is refractory to another action potential until it is repolarized.

The calcium that entered the presynaptic nerve terminal is sequestered and then extruded, and the choline from the hydrolyzed ACh enters the nerve terminal, where it is resynthesized to ACh near the release sites.

The analysis of a rapid series of electrically of voluntarily elicited muscle contractions is used to test the function of the neuromuscular junction by stressing conduction across the junction. In general, a decrement in the amplitude of serial muscle action potentials is typical of postsynaptic failure, and an increment in the amplitude from a train of stimuli is a reflection of presynaptic failure.

Myasthenia gravis is the principal disease affecting the neuromuscular junction and represents a failure of postsynaptic function (see Chap. 49). In this process, the fundamental defect is not a deficiency of ACh or its release, but rather a failure of ACh to attach to the postsynaptic receptor, as a result of blockade by an antibody at the receptor site or of destruction of the membrane by antibody attack. There are several quite different synaptic disorders caused by botulism, aminoglycoside antibiotics, and the antibodies of the Lambert-Eaton myasthenic syndrome, which impede presynaptic release of ACh.

A number of pharmacologic agents also interfere with neuromuscular transmission by combining with

the cholinergic (nicotinic) receptor on the postsynaptic membrane, thereby competitively blocking the transmitter action of ACh. The curariform drugs, derived from curare and termed *nondepolarizing neuromuscular blockers* because they do not alter the postsynaptic membrane potential are the main examples. Other drugs, notably succinylcholine and decamethonium, cause neuromuscular blockage by producing direct depolarization of the endplate and adjacent sarcoplasmic membrane (*depolarizing neuromuscular blockers*). Agents that inactivate cholinesterase have the opposite effect, i.e., they enhance the action of ACh. The ones in clinical use for the treatment of myasthenia gravis are the carbamates neostigmine, physostigmine, and pyridostigmine, the effects of which are reversible. The organophosphates are irreversible blockers of cholinesterase function, for which reason they are feared weapons of chemical warfare. Because the potent cholinergic antagonist atropine is active only at muscarinic sites, it has no effect at the neuromuscular junction.

BIOCHEMISTRY OF MUSCLE CONTRACTION

The sarcolemma, the transverse tubules, and the sarcoplasmic reticulum each play a role in the control of the activity of muscle fibers. Figure 45-2 illustrates the structural components involved in excitation, contraction, and relaxation of muscle. Following nerve stimulation, an action potential is transmitted by the sarcolemma from the motor endplate region to both ends of the muscle fiber. Depolarization spreads quickly to the interior of the fiber along the walls of the transverse tubules, probably by a conducted action potential. The transverse tubules and the terminal cisternae of the sarcoplasmic reticulum come into close proximity at points referred to as *triads*. Here, depolarization of the transverse tubules alters the conformation of a voltage-sensitive calcium channel in the transverse tubule membrane. This causes a large

Figure 45-2. Schematic of the major subcellular components of a myofibril. The transverse (*T*) system, which is an invagination of the plasma membrane of the cell, surrounds the myofibril midway between the *Z* lines and the center of the *A* bands; the *T* system is approximated to, but apparently not continuous with, dilated elements (terminal cisternae) of the sarcoplasmic reticulum on either side. Thus, each sarcomere (the repeating *Z*-line-to-*Z*-line unit) contains two “triads,” each composed of a pair of terminal cisternae on each side of the *T* tubule. (From Peter, by permission.)

protein (the ryanodine receptor) in the membrane of the adjacent sarcoplasmic reticulum (SR) to open an internal calcium pore, allowing stored calcium to exit the SR and flood into the cytoplasm. The released calcium binds to the regulatory protein *troponin*, thereby removing the inhibition exerted by the troponin–tropomyosin system upon the contractile protein *actin*. This allows an interaction to occur between the actin molecules of the thin filaments and the cross-bridges of the myosin molecules in the thick filaments and enables myosin ATPase to split adenosine triphosphate (ATP) at a rapid rate, thereby providing the energy for contraction. This chemical change allows the filaments to slide past each other, thereby shortening the muscle fiber. Relaxation occurs as a result of active (energy-dependent) Ca reuptake by the sarcoplasmic reticulum.

The pyrophosphate bonds of ATP, which supply the energy for muscle contraction, must be replenished constantly by a reaction that involves interchanges with the muscle phosphagen creatine diphosphate, where high-energy phosphate bonds are stored. These interactions, in both contraction and relaxation, require the action of creatine kinase (CK).

Myoglobin, another important muscle protein, functions in the transfer of oxygen, and a series of oxidative enzymes are involved in this exchange. The intracellular Ca, as noted earlier, is released by the muscle action potential and must be reaccumulated within the cisternae of the sarcoplasmic reticulum before actin and myosin filaments can slide back past one another in relaxation. This reuptake of Ca requires the expenditure of considerable energy. When there is defective generation of ATP, for example, from an enzyme deficiency, the muscle remains shortened, as in the *contracture* of phosphorylase deficiency (McArdle disease) or of phosphofructose kinase deficiency. The same sort of shortening contracture occurs under normal conditions in some of the “catch muscles” of certain mollusks and is the basis of rigor mortis in mammals.

Many glycolytic and other enzymes (transaminases, aldolase, CK) are utilized in the metabolic activity of muscle, particularly under relatively anaerobic conditions. Muscle fibers differ from one another in their relative content of oxidative and glycolytic enzymes; the latter determine the capacity of the

muscle fiber to sustain anaerobic metabolism during periods of contraction with inadequate blood flow. Muscle cells rich in oxidative enzymes (type 1 fibers) contain more mitochondria and larger amounts of myoglobin (therefore appearing red), have slower rates of contraction and relaxation, fire more tonically, and are less fatigable than muscle fibers poor in oxidative enzymes. The latter (type 2 fibers) fire in bursts and are used in quick phasic, rather than sustained, reactions. The amount of myosin ATPase activity, which governs the speed of contraction, is low in oxidative-rich fibers and high in glycolytic-rich fibers. The myosin ATPase stain at pH 9.4 has been used to differentiate these two types of fibers in microscopic sections. Type 1 fibers have a low content of myosin ATPase, and type 2 (phosphorylative-rich) fibers have a high content of this enzyme; hence type 1 fibers stain lightly and type 2 darkly (the reverse reaction occurs at pH 4.6). All the fibers within one motor unit are of the same type, a feature that is used to advantage to identify the reinnervation of muscle fibers by a single motor neuron after adjacent neurons have died and denervated their constituent muscle fibers (fiber-type grouping).

The chemical energy required to maintain the various activities of the muscle cell is derived mainly from the metabolism of carbohydrate (blood glucose, muscle glycogen) and from fatty acids (plasma-free fatty acids, esterified fatty acids, and ketone bodies). There is a lesser contribution to energy from branched-chain and other amino acids, but their activity increases during prolonged exercise.

The most readily available source of muscular energy is glycogen, which is synthesized and stored in muscle cells. It provides more than 90 percent of the energy needs of muscle under conditions of high work intensity and during the early stages of submaximal exercise. Blood glucose and free fatty acids supplement intracellular glycogen as exercise proceeds. The free fatty acids are obtained from endogenous triglycerides (found mostly in type 1 fibers), from the triglycerides released by circulating lipoproteins, and from the lipolysis of adipose tissue. Most of the energy needs of resting muscle are provided by fatty acids.

The enzymatic reactions involved in the transport of these substrates into muscle cells and their intracellular synthesis and degradation during anaerobic and aerobic cell conditions have been thoroughly investigated and most of the participating enzymes have been identified. This subject is too extensive to be presented in a textbook of neurology, but enough is known about these matters to state that there are diseases that impair the contractile functions of muscle without destroying the fiber. In particular, specific enzymatic deficiencies alter carbohydrate utilization (myophosphorylase, debrancher enzyme, phosphofructokinase, and phosphoglyceromutase deficiencies), fatty acid utilization (carnitine and carnitine palmitoyl transferase deficiencies), pyruvate metabolism, and cytochrome oxidase activity (in the mitochondrial muscle diseases). These diseases are discussed in later chapters.

PHYSIOLOGY OF MUSCLE CONTRACTION

The contraction of a muscle fiber may be viewed as a series of electrochemical events that culminate in a mechanical effect. The mechanical change far outlasts the electrical one and extends through the period when the muscle fiber is refractory to another action potential. When a second muscle action potential arrives after the refractory phase of the previous action potential, but before the muscle has relaxed, the contraction will be prolonged. Thus, at frequencies of anterior horn cell firing of more than 100 per second, twitches fuse into a sustained voluntary contraction or *fused tetanus*. In most sustained contractions, there is incomplete tetanus, attained by firing rates of 40 to 50 per second. In this fashion, the mechanical contractions of individual muscle fibers are smoothed into a continuous process, even though the electrical potentials present as a series of depolarizations, separated by intervals during which the muscle membrane resumes its resting polarized state.

As pointed out in Chap. 3, the physiology of muscle activity is best considered in terms of motor units, i.e., the group of muscle fibers innervated by a single anterior horn cell. The strength of muscle contraction is in turn a function of the number and rates of firing of many adjacent motor units. The smoothness of contraction depends on the integrated and sequential enlistment of motor units of increasing size. The electrical signal of this summated contraction, the compound motor action potential, or CMAP, as recorded at the skin surface overlying a muscle is the main feature of the surface EMG and serves as the basis for quantifying the size of the motor nerve potential in the nerve conduction examinations.

The CMAP can be visualized on the screen of an oscilloscope or a computer and its onset used to measure the speed of motor nerve conduction (conduction velocity) as well as the summated amplitudes produced by all the innervating nerve fibers. It can also be converted into an audible noise. Further study involves the insertion into the muscle of a coaxial needle, which samples several motor units in the vicinity of the electrode. When elicited by a sustained voluntary contraction, the flurry of electrical activity from many muscle fibers at different distances from the electrodes is referred to as an *interference pattern* (see further on, under "Studies of Nerve Conduction" and "Needle Examination of Muscle [Electromyography]").

Various biochemical changes may cause not only an impairment of muscular activity (paresis, paralysis) but also excessive irritability, tetany, spasm, and cramp. In these instances, spontaneous discharges may occur from instability of axon polarization; hence a single nerve impulse may initiate a train of action potentials in nerve and muscle, as in the tetany of hypocalcemia. The common cramps of calf and foot muscles (painful, sustained contractions with motor unit discharges at frequencies up to 200 per second) may be a result of increased excitability (or unstable polarization) of the

motor axons. Quinine, procainamide, diphenhydramine, and warmth reduce the irritability of nerve and muscle fiber membranes, as do a number of antiepileptic drugs that act by blocking sodium channels, thereby limiting spontaneous membrane discharges.

The muscle fiber, which is wholly dependent on the nerve for its stimulus to contract, may be physiologically activated or paralyzed in a number of ways that are explained by the principles described above. The main disturbances of nerve, muscle, and neuromuscular function occur when the motor nerve cell or its axon is injured or inexcitable, in which case the muscle cannot be stimulated; or, the nerve cell in the anterior horn of the spinal cord may be disinhibited, permitting the discharge of continuous action potentials, as in tetanus and the "stiff man" syndrome (see Chap. 48); the nerve fiber may fail to conduct impulses (demyelinating neuropathies) or the number of fibers may be inadequate to produce a fused and sustained contraction (axonal neuropathies); the distal axon may not distribute the nerve impulse simultaneously to all parts of the motor unit; ACh may not be released at the presynaptic region of the neuromuscular junction (as occurs in botulism and in the Eaton-Lambert syndrome) or, once released, ACh may not be inactivated by cholinesterase (physostigmine, organophosphates); the receptor zone on the postsynaptic membrane may be destroyed or blocked by antibodies or pharmacologic agents (myasthenia gravis or curariform drugs); and, finally, the metabolic or contractile elements of the muscle may not react or, once contracted, may not relax. One type of this last category is due to genetically determined abnormalities of voltage-gated ion channels, the "channelopathies," that are the subject of Chap. 50.

Similarly, there may be an unstable polarization of the nerve fibers, as in tetany and in dehydration with salt depletion, or hyperirritability of the motor unit, as in amyotrophic lateral sclerosis. The threshold of mechanical activation or electrical reactivation of the sarcolemmal membrane may be reduced, as occurs in myotonia, or impairment of an energy mechanism within the fiber may slow the contractile process, as in hypothyroidism; or a deficiency of phosphorylase, which deprives muscle of its carbohydrate energy source, may prevent relaxation, as in the contracture of McArdle disease. Lesions of the most peripheral branches of nerves, which allow nerve regeneration, may give rise to continuous activity of motor units. This is expressed clinically as a rippling of muscle, or *myokymia*.

In recent years, special techniques have made it possible to study each of the proteins and channels involved in neuromuscular transmission and the excitation-contraction-relaxation of muscle fibers. The amino acid composition of these proteins has also been determined. This information is being increasingly applied to the analysis of genetic diseases of muscle in the normal state and under conditions of disease. Pertinent comments and references to this subject are found in the chapters that follow.

EFFECTS ON MUSCLE OF SERUM ELECTROLYTES

Diffuse muscle weakness or muscle twitching, spasms, and cramps should always raise the question of uremia or an abnormality in serum electrolytes. These disorders reflect the concentrations of electrolytes in the intra- and extracellular fluids. If the plasma concentration of K falls below 2.5 mEq/L or rises above 7 mEq/L, weakness of extremity and trunk muscles results; below 2 mEq/L or above 9 mEq/L, there is almost always flaccid paralysis of these muscles and later, of the respiratory ones as well; only the extraocular and other cranial muscles are spared. In addition, the tendon reflexes are diminished or absent. The normal reaction of muscle to direct percussion is also reduced or abolished, suggesting impairment of transmission along the sarcolemmal membranes themselves. *Hypocalcemia of 7 mg/dL or less* (as in rickets or hypoparathyroidism) or relative reduction in the proportion of ionized calcium (as in hyperventilation) causes increased muscle irritability and spontaneous discharge of sensory and motor nerve fibers (i.e., tetany) and sometimes convulsions from similar effects upon cerebral neurons; frequent repetitive and prolonged spontaneous discharges grouped in couplets or triplets appear in the EMG. *Hypercalcemia with Ca levels above 12 mg/dL* (as occurs in vitamin D intoxication, hyperparathyroidism, carcinomatosis, sarcoidosis, and multiple myeloma) causes weakness perhaps on a central basis, and lethargy. Extreme *hypophosphatemia*, observed most often with intravenous hyperalimentation or bone tumor, can cause acute areflexic paralysis with nerve conduction abnormalities. *Reduction in the plasma concentration of magnesium* also results in tremor, muscle weakness, tetanic muscle spasms, and convulsions; a considerable *increase in magnesium levels* leads to muscle weakness and depression of central nervous function. The weakness of muscle in hypermagnesemia may also be partly a result of reduced release of ACh at the motor endplate.

The electrocardiogram (ECG) also becomes abnormal with many of these systemic electrolyte derangements as a result of alterations of the intracellular levels of electrolytes in the myocardium; ECG patterns are most sensitive to extreme changes in serum K levels.

CHANGES IN SERUM LEVELS OF ENZYMES ORIGINATING IN MUSCLE CELLS

In all diseases that cause extensive damage to striated muscle fibers, intracellular enzymes leak out of the fibers and enter the blood. Those measured routinely are the transaminases, lactic acid dehydrogenase, aldolase, and, especially, CK. The concentration of CK in serum has proved to be the most consistent and most sensitive measure of skeletal muscle damage. Because high concentrations of this enzyme are found in heart muscle and brain,

raised serum values may be a result of myocardial or cerebral infarction, as well as of the necrotizing diseases of striated muscle (polymyositis, muscle trauma, muscle infarction, and the more rapidly advancing muscular dystrophies). For serum CK levels to be interpretable, one has to be certain that the enzyme released into the serum is not derived from heart or brain. This can be determined by the quantitation of serum isoenzymes of CK, referred to as MB, MM, and BB (M, muscle; B, brain); their measurement provides a means for the detection of damage to myocardium (MB), skeletal muscle (MM), and nervous tissue (BB), respectively.

The MM form of CK is found in highest concentration in striated muscle, but these muscles also contain 5 to 6 percent MB isoform. Myocardial tissue contains 17 to 59 percent MB; hence, the diagnosis of myocardial infarction requires that the CK-MB fraction be greater than 6 percent (or that troponin, which is overrepresented in heart muscle, be elevated in the serum). Embryonic and regenerating muscle contains more CK-MB than mature normal muscle. In patients with destructive lesions of striated muscle, serum values of CK often exceed 1,000 U/L and may reach 50,000 U or more (the upper limit of normal varies from 65 to 300 U/L, depending on the method of measurement). It is notable that in some black men the level may normally be in the range of 500 U/L in the absence of muscle or nerve disease (see below). The serum of the healthy adult contains only the MM isoenzyme, but in healthy children, as much as 25 percent of serum CK may be derived from the MB fraction.

As interesting is the rise in serum enzyme concentration in some children with progressive muscular dystrophy before there is enough destruction of fibers for the disease to be clinically manifest, at least as judged by the relatively crude test of muscle strength. Moreover, the unaffected female carrier of Duchenne dystrophy may be identified by an elevated serum level of CK; these changes reflect a "leaky" membrane that allows the transgression of the large enzyme molecules. Alterations of serum enzyme levels are, however, nonspecific as they occur in all types of disease that damage the muscle fiber. Moreover, in the more slowly evolving types of dystrophy, the serum levels of CK may be normal.

It would be expected that enzyme values would be normal in paralysis due to denervation with secondary muscular atrophy, but elevations are sometimes observed in patients with progressive spinal muscular atrophy and amyotrophic lateral sclerosis, particularly if there is relatively rapid progression of the disease. Even vigorous exercise or surgical operations involving muscle elevate CK, sometimes with the MB fraction exceeding 6 percent.

Idiopathic "HyperCKemia" In some normal individuals, CK may be persistently elevated without evidence of muscle or other disease. There is a particularly high incidence of this finding, albeit of mild degree, in African American men. An unexplained alteration of the sarcolemma with elevated serum CK occurs in hypothyroidism and in alcoholism. Toxic myopathies, for example, the type caused by the cholesterol-lowering drugs (statins), are another common cause of elevation in CK in current practice. Among the causes of persistently

elevated CK are numerous underlying genetically determined muscle defects, usually one of the varieties of abnormal dystrophin or another membrane protein. Detailed examination may reveal slight proximal weakness and perhaps minimal calf enlargement characteristic of the mildest forms of Becker dystrophy. Closely related is the finding of CK elevations that occur in females who are asymptomatic carriers of Duchenne or Becker dystrophies. These diseases are described in Chap. 48.

Several nondystrophic muscle diseases also present as elevated CK levels in the blood, including polymyositis and dermatomyositis, carnitine palmitoyl transferase deficiency, some of the mitochondrial myopathies, McArdle disease, central core disease, multicore disease, and some forms of inclusion body myopathy. Finally, the rapid denervation of muscle that accompanies some cases of ALS may cause CK elevation.

If other sources of persistently elevated CK levels have been excluded, particularly those caused by exercise, trauma, and by drug-induced muscle damage, it is appropriate to follow the patient over time so that mild weakness may be detected, or to perform a biopsy to resolve the issue of an inflammatory myopathy or a mild muscular dystrophy. Because treatment would likely be withheld until weakness or pain arises, in idiopathic cases of raised enzyme levels, it seems prudent to delay biopsy unless the enzyme levels are massively elevated.

An isolated elevation of aldolase, the serum enzyme other than CK that is derived predominantly from skeletal muscle, generally has less clinical significance. Measurement in the serum of various transaminases or lactate dehydrogenase is not particularly useful for the diagnosis of muscle disease because of the ubiquitous distribution of these enzymes in many mammalian tissues. Nevertheless, the neurologist should be aware that unexplained elevations in all of the muscle-derived enzymes (CK, lactate dehydrogenase [LDH], serum glutamic-oxaloacetic transaminase [SGOT], aldolase) can be caused by inevent muscle trauma and by many other processes that damage the muscle membrane. As mentioned, cardiac muscle-specific enzyme, troponin, is not expressed in skeletal muscle and therefore is not found in the serum in cases of muscle disease, except in unusual circumstances in which regenerating muscle fibers in muscular dystrophies may transiently express the enzyme (the T, but the I, isotype) as noted in the series reported by Jaffe and colleagues. More often, elevations or troponin in these muscular diseases reflects a parallel myocardial disorder that accompanies several varieties of dystrophy.

MYOGLOBINURIA

The red pigment myoglobin, responsible for much of the color of muscle, is an iron-protein compound present in the sarcoplasm of striated skeletal and cardiac fibers. Of the heme compounds, approximately 25 percent are in muscle and the remainder are in red blood corpuscles

and other cells. Destruction of striated muscle, regardless of the cause liberates myoglobin, and because of its relatively small size, the molecule filters through the glomeruli and appears in the urine, imparting to it a burgundy-red color. Because of the low renal threshold for myoglobin, excretion of the pigment is so rapid that the serum remains uncolored. In contrast, the high renal threshold for hemoglobin colors both the serum and the urine if there is destruction of red blood corpuscles. Myoglobinuria should thus be suspected when the urine is deep red and the serum is normal in color. It is estimated that 200 g of muscle must be destroyed to color the urine visibly (Rowland).

As with hemoglobinuria, the guaiac and benzidine tests performed on urine are positive if myoglobin is present. However, the colored urine does not fluoresce, as it does in porphyria. On spectroscopic analysis, myoglobin shows an absorption band at 581 nm but the most sensitive method for measuring myoglobin in the urine and serum is by radioimmunoassay. Some years ago, the measurement of creatine and creatinine in blood and urine was a standard method of estimating damage to striated muscle. This technique is now seldom used, having been replaced by the measurement of CK and its isoenzymes. However, measurement of urine creatinine in large-volume samples of urine that have been collected for other testing assures that an adequate amount of renal excretion is being captured in the sample.

ENDOCRINE MYOPATHIES

In a number of disorders of the endocrine glands, muscle weakness may be a prominent feature, and occasionally may be the chief complaint. These diseases are discussed in detail in Chap. 48 but it should be noted here that such metabolic causes of muscle weakness, acute or chronic, may occur in the absence of changes in serum electrolytes or enzymes. Specific hormone assays are then necessary for diagnosis. This is particularly true of patients with thyrotoxicosis or Cushing disease, and of those receiving prolonged corticosteroid therapy. In thyrotoxicosis, muscle weakness may appear without the signs of Graves disease.

ELECTRODIAGNOSIS OF NEUROMUSCULAR DISEASE (NERVE CONDUCTION AND ELECTROMYOGRAPHY)

It was long ago discovered that muscle would contract when a pulse of electric current was applied to the skin, near the point of entrance of the muscular nerve (*the motor point*). The electrical pulse required is brief, less than a millisecond, and is most effectively induced by rapidly alternating (faradic) current. *If there has been muscle denervation*, an electrical pulse of several milliseconds induced by a constant electrical (galvanic) stimulus is required to produce the same response. This change, in

which the galvanic stimulus remains effective after the faradic one has failed, was the basis of the “Erb reaction” of degeneration, and varying degrees of this change were formerly plotted in the form of strength-duration curves. For decades, this was the standard electrical method for evaluating denervation of muscle. Although still valid, it was replaced by nerve conduction studies and by the needle electrode examination. The latter test, based on the sherringtonian concept of the “motor unit” described in Chap. 3, is accomplished by the insertion into muscle of needle electrodes to measure spontaneous and voluntarily evoked muscle fiber activity. The terms *electromyography* and *electromyogram* were used originally to describe the needle electrode examination but are now a common shorthand designation for the entire electrodiagnostic evaluation, including the *nerve conduction studies*.

Studies of Nerve Conduction

The main laboratory technique for the study of peripheral nerve function involves the transcutaneous stimulation of motor or sensory nerves and recording of the elicited action potentials in the muscle (CMAP) and the sensory nerve action potential (SNAP). The results of these *motor and sensory nerve conduction studies*, expressed as amplitudes, conduction velocities, and distal latencies, yield certain quantitative information and additional qualitative observations regarding the waveform and dispersion of electrical neural and muscular impulses.

Hodes and coworkers, in 1948, were the first to describe nerve conduction studies in patients, and the techniques used currently are not much changed. An accessible nerve is stimulated through the skin by surface electrodes, using a stimulus that is large enough to recruit (cause a discharge in) all the available nerve fibers. The resulting action potential is recorded by electrodes on the skin (1) over the muscle distally in the case of motor fibers stimulated in a mixed or motor nerve (CMAP), (2) over the nerve more distally, using antidromic techniques for sensory nerve conduction studies (this has technical advantages over orthodromic techniques), and (3) over the nerve more proximally for mixed (sensory and motor) nerve conduction studies (Fig. 45-3). These techniques are the ones used most often in clinical work. An alternative but much more demanding technique uses “near-nerve” needle electrodes to record action potentials as they course through the nerve. The main characteristics of the conventional nerve conduction studies are described below.

Distal (Terminal) Latencies, Conduction Times, and Conduction Velocities

The conduction times from the most distal stimulating electrode to the recording site over a muscle, in milliseconds, as determined by the latency from the stimulus artifact to the onset and to the peak of the CMAP, are termed the *distal* (or terminal) and *peak* motor latencies, respectively (see Fig. 45-3). The former is the one used more often as a reflection of conduction time in routine work. A stimulus may then be applied to the nerve at a second

Figure 45-3. The median nerve is stimulated percutaneously (1) at the wrist and (2) in the antecubital fossa with the resultant compound muscle action potential recorded as the potential difference between a surface electrode over the thenar eminence (arrow) and a reference electrode (Ref.) more distally. Sweep 1' on the display depicts the stimulus artifact followed by the compound muscle action potential. The distal latency, A', is the time from the stimulus artifact to the take-off phase of the compound muscle action potential and corresponds to conduction over distance A. The same is true for sweep 2', where stimulation is at 2 and the time from the artifact to the response is A' + B'. The maximum motor conduction velocity over segment B is calculated by dividing distance B by the time B'.

site more proximally (or if recording electrodes can be placed more proximally in the case of sensory fibers), and a conduction time can be measured over a longer segment of nerve. When the distance (in millimeters) between the two sites of stimulation is divided by the difference in conduction times (in milliseconds), one obtains a *conduction velocity* (in meters per second), which describes the maximal velocity of propagation of the action potentials in the largest-diameter and fastest-conducting nerve fibers. These velocities in normal subjects vary from a minimum of 40 or 45 m/s to a maximum of 65 to 75 m/s, depending upon which nerve is studied (e.g., slower in the legs than in the arms; Table 45-1). Values are lower in infants, reaching the adult range by the age of 2 to 4 years, and declining again slightly with advancing age. Conduction velocity also is diminished with exposure to cold, a potentially important factor if these recordings are taken when the patient's skin is cool; consequently, measurement of skin temperature is routinely done prior to performing the nerve conduction tests.

Normal values have been established for distal latencies from the usual sites of stimulation on various mixed nerves to the appropriate muscles. Stimulating the median nerve at the wrist, for example (see electrode 1 and segment A in Fig. 45-3), has a latency for motor

conduction through the carpal tunnel to the median-innervated thenar muscles of less than approximately 4.5 ms in healthy adults. Similar normal values have been compiled for orthodromic and antidromic sensory conduction velocities and for distal latencies in all the main peripheral nerves (see Table 45-1).

Disease processes that preferentially injure the fastest-conducting, large-diameter fibers in peripheral nerves reduce the maximal conduction velocity because the remaining thinner fibers conduct more slowly. In most neuropathies, all of the axons are affected either by a fairly uniform "dying-back" phenomenon or by wallerian degeneration as described in Chap. 46, and nerve conduction velocities are then less informative. This is true, for example, in typical alcoholic-nutritional, carcinomatous, uremic, diabetic, and other metabolic neuropathies, in which conduction velocities range from the low-normal range to mildly slowed. In these "axonal neuropathies," the motor and sensory nerve amplitudes are diminished.

By contrast, demyelinating neuropathies of the acute (Guillain-Barré) and chronic types, such as chronic inflammatory, metachromatic leukodystrophy, and the common type of Charcot-Marie-Tooth disease, show marked slowing of conduction and, in the case of the acquired demyelinating diseases, there is also dispersion of the motor action potential and a highly characteristic conduction block (see later).

Amplitude of the Compound Muscle Action Potential

In addition to the study of distal latency and conduction velocity, the amplitude of the evoked muscle action potential (CMAP) yields valuable information about peripheral nerve function. These amplitudes are a semi-quantitative measure of the number of nerve fibers that respond to a maximal stimulus (and of the innervated volume of muscle). Demyelinative lesions affecting the large, fast-conducting fibers are detected by the finding of differential slowing among various caliber fibers that causes a dispersal of the CMAP response. Reduction in motor and sensory amplitudes is a more specific and sensitive indicator of axonal loss than is slowing of conduction velocity or prolongation of distal latencies. Conversely, prolonged distal latencies and slowed motor conduction velocities, as well as conduction blocks and dispersed responses (described below), are the hallmarks of demyelinate lesions. Table 45-1 shows the range of normal amplitudes for the CMAPs that are elicited by stimulation of the main motor nerves.

It is usually possible to obtain a reliable motor conduction study as long as some functioning nerve fibers remain intact. The conduction velocities then reflect the status of the surviving axons, and the velocity may be normal or nearly so despite widespread axonal degeneration. This is most apparent following incomplete transection of a nerve; the maximal motor conduction velocity may be normal in the few remaining fibers, although the muscle involved is almost paralyzed and the compound muscle potential recorded from it is very low.

Table 45-1

NORMAL VALUES FOR REPRESENTATIVE NERVE CONDUCTION VALUES AT VARIOUS SITES OF STIMULATION (MEAN VALUES \pm 2 SD FOR ADULTS 16 TO 65 YEARS OF AGE)

Motor Nerve Conduction Studies								
NERVE	DISTAL STIMULATION SITE	OTHER STIMULATION SITES	RECORDING SITE	ONSET LATENCY (ms)	AMP (mv)	CV (M/S)	DISTANCE (cm)	F-WAVE LATENCY (ms)
Median	Wrist	Elbow	APB	<4.2	>4.4	>49	6–8	<31
Ulnar	Wrist	BG, AG	ADM	<3.4	>6.0	>49	5.5–7.5	<32
Radial	Forearm	Elbow, SG	EIP	<5.2	>4.0	>50	10	NA
Peroneal	Ankle	BFH, AFH	EDB	<5.8	>2.0	>42	6–11	<58
Peroneal	BFH	AFH	TA	<3.0	>5.0	>42	10	NA
Tibial	Ankle	PF	AH	<6.5	>3.0	>41	6–8	<59 ^a

Sensory Nerve Conduction Studies ^b							
NERVE	DISTANCE STIMULATION SITES	RECORDING SITE	ONSET LATENCY (ms)	PEAK LATENCY (ms)	AMP (μ v)	CV (M/S)	DISTANCE (cm)
Median	Wrist	Dig2	<2.5	<3.5	>20	>52	13
Ulnar	Wrist	Dig5	<2.1	<3.0	>15	>52	11
Radial	Forearm	Wrist	<1.9	<2.8	>20	>48	10
Sural	Calf	Ankle	<3.2	<4.4	>6	>42	14

ADM, adductor digiti minimi; AFH, above fibular head; AG, above ulnar groove; AH, abductor hallucis; APB, abductor pollicis brevis; BFH, below fibular head; BG, below ulnar groove; EDB, extensor digitalis brevis; EIP, extensor indicis proprius; PF, popliteal fossa; SG, spiral groove; TA, anterior tibialis.

^aTibial H reflexes: latency <35 ms; side-to-side difference <1.4 ms.

^bSensory studies are performed antidromically; amplitudes are measured from baseline to negative peak of nerve potential.

Sensory Nerve Action Potentials

When motor fibers in a mixed nerve are stimulated, an amplified CMAP of many hundreds of microvolts can easily be recorded from electrodes on the skin over the muscle. However, when one attempts to measure sensory potentials, where activity must be recorded from nerve fibers themselves, the “amplification” provided by many motor units is not available and electronic amplification is required. Sensory potentials are sometimes very small or absent even when powerful computer-averaging techniques are used, and sensory conduction measurements may then be difficult to determine. Table 45-1 gives the range of normal values for sensory nerve action potential amplitudes and velocities.

Conduction Block

By stimulating a motor nerve at multiple sites along its course, it is possible to demonstrate segments in which conduction is partially “blocked” or is differentially slowed. From such data one infers the presence of a multifocal demyelinating process in motor nerves. This contrasts with the findings in certain of the inherited and metabolic demyelinating neuropathies, in which all parts of the nerve fiber are altered to more or less the same degree, i.e., there is uniform slowing and reduction in amplitude and no conduction block.

As a technical matter, conduction block is demonstrated by a reduction in the amplitude of the CMAP elicited from the proximal site along the motor nerve, compared

to stimulation at a distal site. Generally, a 40 percent reduction in amplitude over a short distance of nerve, or 50 percent over a longer distance, qualifies as a block, one possible exception being along the tibial nerve, in which there is some degree of physiologic dispersion (it is also difficult to stimulate all the motor nerve fibers of this nerve in obese patients); therefore a slight drop in amplitude over the length of the nerve is normally expected. It is important to be sure that any reduction in amplitude along the course of the nerve is not solely a result of dispersion of the waveform. The presence of a conduction block can also be inferred from the finding of poor recruitment of muscle action potentials and the concurrent absence of active denervation (see further on). The finding of conduction block is a main feature of a number of acquired immune demyelinating neuropathies including Guillain-Barré syndrome, chronic inflammatory demyelinating neuropathy, and multifocal conduction block associated with the G_{M1} antibody, which are discussed in Chap. 46.

Focal conduction block may be caused simply by nerve compression at certain common sites (fibular head, across the elbow, flexor retinaculum at the wrist, etc.) rather than to an intrinsic disease of the peripheral nerves. *Focal compression of nerve*, as occurs in these entrapment syndromes, produces localized slowing or blocks in conduction, perhaps because of segmental demyelination, only at the site of compression. The demonstration of such localized changes of conduction affords ready confirmation of nerve entrapment; for example, if the

distal latency of the median nerve (see *A*, Fig. 45-3) exceeds 4.5 ms while that of the ulnar nerve remains normal, compression of the median nerve in the carpal tunnel is likely. Similar focal slowing or partial block of conduction may be recorded from the ulnar nerve at the elbow and from the peroneal nerve at the fibular head.

Electrodiagnostic Studies of Nerve Roots and Spinal Segments (Late Responses, Blink Responses, Evoked Responses)

H Reflex

Information about the conduction of impulses through the proximal segments of a nerve is provided by the study of the H reflex and the F wave. In 1918, Hoffmann, after whom the H reflex was named, showed that submaximal stimulation of mixed motor-sensory nerves, insufficient to produce a direct motor response, nonetheless induces a muscle contraction (H wave) after a latency that is far longer than that of the direct motor response. This reflex is based on the activation of afferent fibers from muscle spindles (the same axons that conduct the afferent volley of the tendon reflex), and the long delay reflects the cumulative time required for the impulses to reach the spinal cord via the sensory fibers, synapse with anterior horn cells, and to be transmitted along motor fibers to the muscle (see Fig. 3-1). Thus the H reflex is the electrical representation of the tendon reflex circuit and is a useful measure because the impulse traverses both the posterior and anterior spinal roots. The H reflex is particularly helpful in the diagnosis of S1 radiculopathy and of polyradiculopathies. Its status generally parallels that of the clinically elicited Achilles reflex. However, it is difficult to obtain an H reflex from nerves other than the tibial. Stimuli of increasing frequency but low intensity cause a progressive depression and finally obliteration of H waves. The latter phenomenon has been used to study spasticity, rigidity, and cerebellar ataxia, in which there are differences in the frequency-depression curves of H waves. In parallel with the Achilles tendon reflex, the H-reflex is transiently obliterated in spinal shock (see Chap. 44).

F Response (Wave)

The F response, so named because it was initially elicited in the feet, was first described by Magladery and McDougal in 1950. It is evoked by a supramaximal stimulus of a mixed motor-sensory nerve. After a latency that is longer than for the direct motor response (latencies of 28 to 32 ms in arms, 40 to 59 ms in legs), a second small muscle action potential is recorded. This F wave is the result of the impulses that travel antidromically in motor fibers to the anterior horn cells, a small number of which are activated and produce an orthodromic response that is recorded in a distal muscle. The F response is a more reliable test than the H wave of proximal motor nerve and root conduction in that the F wave traverses only the ventral root and can be elicited from a number of muscles. The combination of a normal F response and an absent H reflex is found in diseases of sensory nerves and roots. Both of these "late responses" find their main use as corroborative tests that

are interpreted in the context of the entire nerve conduction examination (see Willbourn). As with the H reflex, the F wave may be absent in the state of spinal shock (see Chap. 44). Table 45-1 gives the normal F wave response latencies.

Blink Responses

This special nerve conduction test is not in frequent clinical use but it serves a purpose in the diagnosis of certain demyelinating neuropathies and in any process that affects the trigeminal or facial nerve. The supraorbital (or infraorbital) nerve is stimulated transcutaneously and the reflex closure of both orbicularis oculi muscles is recorded with surface electrodes. Two CMAP bursts are observed: the first (R1) appears ipsilaterally 10 ms after the stimulus and the second (R2), ipsilaterally at 30 ms and contralaterally up to 5 ms later. The amplitudes of the responses vary considerably and are not in themselves clinically important. The first response is not visible as a muscular contraction but may serve some preparatory function by shortening the blink reflex delay. R1 is mediated by an oligosynaptic pontine circuit consisting of one to three neurons located in the vicinity of the main sensory nucleus; R2 uses a broader and less-well-defined reflex pathway in the pons. It has been established that R1 and R2 are generated by the same facial motor neurons.

The elicitation of blink reflexes establishes the integrity of the afferent trigeminal nerve, the efferent facial nerve, and the interneurons in the pons (R1) and caudal medulla (related to the bilateral R2 response). The test may also be helpful in identifying a demyelinating neuropathy when the facial and oropharyngeal muscles are affected and those of the limbs are relatively spared, thereby leaving conventional nerve studies normal. In such cases, the blink responses are delayed ipsilaterally and contralaterally as a result of conduction block in the proximal facial nerve. Direct facial nerve stimulation often fails to demonstrate this block because only the distal segment of the nerve is amenable to study. Although the blink responses are rarely necessary for diagnosis, most patients with hereditary neuropathy have blink response abnormalities. In Bell's palsy there is a delay or absence of R1 and R2 responses only on the affected side. Large acoustic neuromas (vestibular schwannomas) may interfere with the afferent trigeminal portion of the pathway and give rise to abnormal responses on the affected side. Diseases of the brainstem have yielded inconsistent responses. It is noteworthy that the test is normal in patients with trigeminal neuralgia.

Segmental Motor, Cranial, and Somatosensory Evoked Potentials (See also Chap. 2)

These techniques find use in diseases that affect the spinal roots and in studying central pathways.

By applying a magnetic stimulus, which induces an electrical impulse, or by a directly delivered electrical stimulus over the lower cervical or lumbar spine, it is possible to activate the motor (anterior) roots and to measure the time required to elicit a muscle contraction (see review by Cros and Chiappa). These root stimulation tests can be quite uncomfortable for the patient as a result of the contraction of muscles surrounding the stimulation site.

Transcranial magnetic stimulation of the cerebral cortex permits measurement of the latency of muscle contraction after excitation of motor neurons in the cortex. Thus, the integrity of the entire corticospinal system, from the cortical motor neurons through spinal tracts, anterior horn cells, and the peripheral motor nerve can be determined. By combining this technique with the above-described root stimulation, it becomes possible to measure central and peripheral motor conduction times. These forms of motor testing have their main use in the study of multiple sclerosis, amyotrophic lateral sclerosis (ALS), and related disorders.

As described in Chap. 2, by applying repetitive electrical stimuli to a peripheral nerve, the sensory evoked responses can be recorded from sites along the nerve and plexus as well as in central pathways (the thalamus and somatosensory cortex). These somatosensory evoked potential tests find their main use in the diagnosis of multiple sclerosis and in disorders of the sensory nerve roots as discussed in Chaps. 2 and 36. Discussion of magnetic stimulation, collision techniques, and quantitative EMG, among other topics, can be found in several monographs, such as the ones by Kimura, by Aminoff, and by Brown and Bolton.

Repetitive Motor Nerve Stimulation

(See also Chap. 49)

This test of the neuromuscular junction is based on Jolly's observation in 1895 that in myasthenia gravis the strength of muscular contractions progressively declines in response to a train of stimuli. By adjusting the amplitude of a stimulus over a nerve to the supramaximal range, a maximal CMAP may be obtained for each stimulus. With repeated stimuli, each response will have the same waveform and amplitude until normal fatigue supervenes. In a healthy individual, a muscular response follows each stimulus with rates of stimulation up to 25 per second for periods of 60 s or more before a decrement of the CMAP appears. In certain disorders, notably myasthenia gravis, a train of 4 to 10 stimuli at rates of 2 to 5 per second (optimally 2 to 3 per second), the amplitude of the motor potentials decreases and then, after four or five further stimuli, may increase slightly (Fig. 45-4A). A progressive reduction in amplitude is most likely to be found in proximal muscles, but these are not easily stimulated for which reason the locations most commonly used for clinical testing are the accessory nerve in the posterior triangle of the neck (trapezius), the ulnar nerve (hypothenar muscle), the median nerve at the wrist (thenar muscle), and the facial nerve (orbicularis oculi muscle). A decrement of 10 percent or more denotes a failure of a proportion of the neuromuscular junctions.

The sensitivity of the procedure is improved by first exercising the tested muscle for 30 to 60 s; a form of posttetanic potentiation. (The full procedure consists of testing the muscle with a train of stimuli before and immediately after exercise [or maximal voluntary contraction] and at 30-s intervals for several minutes. The posttetanic potentiation partially compensates for the depletion of ACh during slow rates of stimulation;

this is followed by a decrease in the excitability of the neuromuscular junction during the approximately 2 to 4 min after exercise.) The induced failure of neuromuscular transmission in myasthenia is similar to the one produced by curare and other nondepolarizing neuromuscular blocking agents, and both cases can be partially corrected with anticholinesterase drugs such as neostigmine and edrophonium. Similar but lesser decremental responses may occur in poliomyelitis, ALS, and certain other diseases of the motor unit or motor nerve, particularly those resulting in the growth of reinnervating nerve twigs.

The Lambert-Eaton myasthenic syndrome, often associated with oat cell carcinoma of the lung, as discussed in Chap. 49, is characterized by a presynaptic blockage of acetylcholine release and produces the opposite defect of neuromuscular transmission to the one recorded in myasthenia gravis. During tetanic stimulation (20- to 50-per-second repetitive stimulation of nerve), the muscle action potentials, which are small or practically absent with the first stimulus, increase in voltage with each successive response until a more nearly normal amplitude is attained (see Fig. 45-4B). Exercising the muscle for 10 s before stimulation will cause a similar posttetanic facilitation in patients with the Lambert-Eaton syndrome (200-fold increases are not uncommon). A less important decremental response to slow stimulation may occur, but it is difficult to discern because of the greatly diminished amplitude of the initial responses. Neostigmine has little effect on this phenomenon, but it is reversed by guanidine and 3,4-diaminopyridine, which stimulate the presynaptic release of ACh. The effects of botulinum toxin and of aminoglycoside antibiotics are similar, i.e., being active at the presynaptic membrane, they produce an incremental response at high rates of stimulation.

The single-fiber EMG, discussed in a later section, is an even more sensitive method of detecting failure of the neuromuscular junction.

Figure 45-4. Compound action potentials evoked in hypothenar muscles by electrical stimulation of the ulnar nerve at the wrist. *A.* Patient with myasthenia gravis—typical pattern of decrement in first four responses followed by slight increment. At this rate of stimulation (4 per second), the decrement in response does not continue to zero. *B.* Patient with Lambert-Eaton syndrome and oat cell carcinoma—typical marked increase toward normal amplitude with rapid repetitive stimulation (20 per second). Horizontal calibration: 250 ms.

Needle Examination of Muscle (Electromyography)

This technique requires the use of monopolar or concentric bipolar needle electrodes, which are inserted into the body of the muscle to record the electrical activity generated by contraction. With concentric electrodes, the tip of the wire that runs in the hollow of the needle is in proximity to many muscle fibers belonging to several different overlapping motor units; this is the active recording electrode. The shaft of the needle, in contact over most of its length with intercellular fluid and many other muscle fibers, serves as the reference electrode. Monopolar electrodes use the uninsulated needle tip as the active electrode, while the reference electrode may be another monopolar needle electrode placed elsewhere in subcutaneous tissue or a surface electrode on the skin overlying the muscle. Patients almost invariably find this portion of the test uncomfortable and should be prepared by a description of the procedure. Rapid and brief needle insertion by the skilled examiner makes the test more tolerable.

As the electrical impulse travels along the surface of the muscle toward the recording electrode, a positive potential is recorded on the oscilloscope, i.e., the recorded signal is deflected downward by convention (at A in Fig. 45-5). When the depolarized zone moves under the recording electrode, it becomes relatively negative and the beam is deflected upward (at B). As the depolarized zone continues to move along the sarcolemma, away from the recording electrode, the current begins to flow outward through the membrane toward the distant depolarized region, and the recording electrode becomes relatively positive again (at C). There is then a return to the

Figure 45-5. The shaded area represents the zone of the action potential, which is negative to all other points on the fiber surface. It is shown at three points in its course (from left to right) along the fiber. At each point, the correspondingly lettered portion of the triphasic muscle action potential displayed on the display screen reflects the potential difference between the active (vertical arrow) and reference (Ref.) electrodes. Polarity in this and subsequent figures is negative upward as depicted. The time calibration is on the screen.

resting isopotential position. The net result is a triphasic action potential, as in Fig. 45-5. This configuration is typical of the firing of a single fiber.

The electrical activity of various muscles is recorded both at rest and during active contraction by the patient. As indicated earlier, muscle fibers do not normally discharge until activated together in motor unit activity. This involves the almost simultaneous contraction of all the muscle fibers innervated by a single anterior horn cell. Although the typical configuration of a motor unit potential (MUP) is triphasic, up to 10 percent of normal MUPs consist of four or more phases (*polyphasic potentials*); however, an excess of polyphasic potentials beyond this is pathologic.

Normal muscle in the resting state should be electrically silent; the small tension spoken of as muscle tone has no EMG equivalent. There are, however, two closely related types of normal spontaneous activities and another that is induced by the insertion of the needle itself. One is a low-amplitude, 10- to 20- μ V monophasic (negative) potential of very brief (0.5 to 1 ms) duration. These represent single or synchronized miniature end plate potentials (MEPPs) because of the small number of ACh quanta that are being released all the time. They are normally sparse but are most evident when the recording needle electrode is placed near a motor endplate ("endplate noise"). Fortuitous placement of the needle electrode very close to or in contact with the endplate gives rise to a second type of normal spontaneous activity. That is characterized by irregularly discharging high-frequency (50- to 100-Hz) biphasic spike discharges, 100 to 300 μ V in amplitude (i.e., large enough to cause an isolated muscle action potential). These potentials have been termed *endplate spikes* and represent discharges of single muscle fibers excited by spontaneous activity in nerve terminals. They must be distinguished from fibrillation potentials (see later). Finally, insertion of the needle electrode into the muscle injures and mechanically stimulates a number of fibers, causing a burst of potentials of short duration (300 ms). This is referred to as normal *insertional activity*, but the extent of this activity is greatly raised in certain pathologic states as noted below.

When a muscle is voluntarily contracted, the action potentials of motor units begin to appear. One can observe a pattern of force build up by watching the progressive recruitment of MUPs; the initial ones, representing smaller motor units, firing at rates of 5 to 10 per second. With increased force of contraction, there is recruitment of larger, previously inactive motor units as well as an increased rate of firing (40 to 50 per second; Fig. 45-6A). Because individual MUPs can no longer be distinguished during maximal voluntary contraction, this activity is referred to as a *complete interference pattern* (Fig. 45-6A, right). This is seen not only as a summated signal pattern but is also heard as a mixed high-frequency clicking when the electrical activity is made audible. As muscles relax, an increasing number of units drop out. If a muscle is weakened by denervation or if electrical conduction is blocked, there obviously will be fewer MUPs, but the firing rate is still rapid (*reduced recruitment*; see

Figure 45-6. Patterns of motor unit recruitment. *A.* Normal. With each increment of voluntary effort, more and larger units are brought into play until, with full effort at the extreme right, a complete “interference pattern” is seen in which single units are no longer recognizable. *B.* After denervation, only a single motor unit is recorded despite maximal effort. It is seen to fire repetitively. *C.* With myopathic diseases, a normal number of units are recruited on minimal effort, though the amplitude of the pattern is reduced. Calibrations: 50 ms (horizontal) and 1 mV in *A* and *B*; 200 μ V in *C* (vertical).

Fig. 45-6*B*). In contrast, with poor voluntary effort and with upper motor neuron lesions, the MUPs fire in decreased numbers, at slower rates, and often in an irregular pattern (termed *poor activation*).

In the usual EMG examination, a plan for the study is made based on detailed knowledge of muscular innervation and focusing on the regions affected by weakness. In some patients, as in those with motor neuron diseases or polymyositis, a wider sampling of muscles is required to detect changes in asymptomatic regions.

The Abnormal Electromyogram

Clinically important deviations from the normal EMG include (1) increased or decreased activity upon insertion of the needle; (2) the occurrence of abnormal “spontaneous” activity during the relaxed state (fibrillation potentials, positive sharp waves, fasciculation potentials, cramp potentials, myotonic discharges, myokymic potentials); (3) abnormalities in the amplitude, duration, and shape of single MUPs; (4) a decrease in the number of MUPs and changes in their firing pattern; (5) variation in amplitude and number of phases of MUPs during voluntary contraction; and (6) the demonstration of special phenomena, such as electrical silence during shortening of the muscle (physiologic contracture and states of continuous muscle fiber activity).

Insertional Activity At the moment the needle is inserted into muscle, there is a brief burst of action potentials that ceases once the needle is stable, provided that it is not in a position to irritate a nerve terminal. Increased insertional activity is seen in most instances of denervation as well as in many forms of primary muscle disease and in disorders that dispose to muscle cramps. In cases of advanced denervation or myopathy, in which muscle fibers have been largely replaced by connective tissue and fat, insertional activity may be decreased

and there is a palpable increase in the mechanical resistance to the insertion of the needle.

Abnormal “Spontaneous” Activity With the muscle at rest, spontaneous activity of single muscle fibers and of motor units, known respectively as *fibrillation potentials* and *fasciculation potentials*, is abnormal. The two phenomena are often confused. *Fibrillation* is the spontaneous contraction of a *single muscle fiber*. It occurs when the muscle fiber has lost its nerve supply and is ordinarily not visible through the skin (but may be visible in the tongue). *Fasciculation* represents the spontaneous firing of an entire motor unit, causing contraction of a group of muscle fibers, and may be visible through the skin. The irregular firing of a number of motor units, seen as a rippling of the skin, is called *myokymia*.

Fibrillation Potentials Destruction of a motor neuron or interruption of its axon causes the distal part of the axon to degenerate, a process that takes several days or more. The muscle fibers formerly innervated by the branches of the dead axon—that is, the motor unit—are thereby disconnected from the nervous system. By mechanisms that are still obscure, the chemosensitive region of the sarcolemma at the motor endplate “spreads” after denervation to involve the entire surface of the muscle fiber. Then, 10 to 25 days after death of the axon, the denervated fibers develop spontaneous activity; each fiber contracts at its own rate and without relation to the activity of neighboring fibers. This spontaneous activity is associated with a random conglomeration of brief di- or triphasic fibrillation potentials (Fig. 45-7*A*) having a duration of 1 to 5 ms and rarely exceeding 300 μ V in amplitude. When brief spontaneous fibrillation potentials of this sort are observed firing regularly at two or three different locations (outside the endplate zone) of a resting muscle, one may conclude that the fibers are denervated. Usually, fibrillation potentials discharge at an almost regular rate. In some early lesions (less than

6 to 8 weeks), irregularly firing fibrillation potentials may be observed.

Diseases such as poliomyelitis, which damage spinal motor neurons, or injuries of the peripheral nerves or anterior spinal roots, frequently produce only partial denervation of the involved muscles. In such muscles, one electrode placement may record fibrillation potentials at rest from denervated fibers and normal potentials during voluntary contraction from nearby healthy fibers. Fibrillation potentials continue until the muscle fiber is reinnervated by progressive proximal-distal regeneration of the interrupted nerve fiber or by the outgrowth of new axons from nearby healthy nerve fibers (collateral sprouting), or until the atrophied fibers degenerate and are replaced by connective tissue, a process that may take many years. In addition, fibrillation potentials may take the form of positive sharp waves, i.e., spontaneous, initially positive diphasic potentials of longer duration and slightly greater amplitude than the spikes of fibrillation potentials (see Fig. 45-7A).

Fibrillation potentials, while characteristic of neurogenic denervation, are not altogether specific; for example, they are seen in muscle diseases such as polymyositis and inclusion body myopathy which presumably damage the muscle fiber and make its membrane electrically unstable.

Fasciculation Potentials As stated earlier, a fasciculation is the spontaneous or involuntary contraction of a motor unit or part of a motor unit. Such contractions may cause a visible dimpling or twitching under the skin, although ordinarily they are of insufficient force to move a joint. Large distal fasciculations can briefly displace a finger or toe. They occur irregularly and infrequently, and prolonged inspection of the skin overlying a muscle may be necessary to detect them. The accompanying electrical form of an individual fasciculation potential is relatively constant. Typically, a fasciculation potential will have 3 to 5 phases (i.e., they are “polyphasic” as described later, in contrast to normal biphasic muscle activity), a duration of 5 to 15 ms (longer than normal but somewhat less in the facial muscles), and an amplitude of several millivolts (see Fig. 45-7B). Fasciculation potentials are evidence of motor nerve fiber irritability. Thus, the combination of fibrillations and fasciculations indicates active denervation combined with more chronic reinnervation of muscle.

The precise source of fasciculation is still contested. Forster and colleagues challenged the original belief that the discharge originated in anterior horn cells by demonstrating that fasciculations persisted after nerve block in ALS and ceased only with the appearance of fibrillation potentials, signifying wallerian (axonal) degeneration. These observations favored a distal site of generation. Other physiologic and pharmacologic evidence pointed to the first segment of the motor axon, or to the distal axon, or even to the motor point (the site of insertion of the nerve into muscle), involving elements of the postsynaptic muscle membrane (particularly in the case of benign fasciculations) as the source of the spontaneous electrical activity. It seems that several regions of the axon are capable of spontaneous impulse generation, depending on the underlying disease. Most of

Figure 45-7. A. Fibrillations and positive sharp waves. This spontaneous activity was recorded from a totally denervated muscle—no motor unit potentials were produced by attempts at voluntary contraction. The fibrillations (above arrow) are 1 to 2 ms in duration, 100 to 300 mV in amplitude, and largely negative (upward) in polarity following an initial positive deflection. A typical positive sharp wave is seen above the star. B. Fasciculation. This spontaneous motor unit potential was recorded from a patient with amyotrophic lateral sclerosis. It has a serrated configuration and it fired once every second or two. Calibrations: 5 ms (horizontal) and 200 mV in A; 1 μ V in B (vertical).

the diseases that produce fasciculations involve the anterior horn cell or the motor root, but more distal sites in the motor axon are spontaneously active in cases of nerve compression and polyneuropathy.

Occasional fasciculation potentials, particularly in the calves, hands, and periocular or paranasal muscles, occur in many normal persons. They can be almost constant for days or weeks on end, or even for years in some individuals, without weakness or wasting; therefore they need not be taken as evidence of disease (“benign fasciculations”). Certain quantitative features of fasciculations, such as brief duration and a consistent pattern and location of firing, favor benign over pathologic discharges. Shivering induced by low temperature and twitchings associated with low serum calcium levels are other forms of fasciculatory activity.

Fasciculation potentials occur with great frequency in chronic, slowly advancing, destructive diseases of the anterior horn cells, such as ALS and progressive spinal muscular atrophy. In these diseases, both voluntary MUPs and fasciculation potentials may be of long duration (more than 15 ms) and of increased amplitude, indicating chronic denervation and reinnervation. They are seen often in the early stages of poliomyelitis but only occasionally in the chronic phase of the disease, perhaps because the affected cells die rapidly. When anterior horn cells degenerate once again in older individuals who had had poliomyelitis (postpolio syndrome), fasciculations may return. Occasionally, they are seen in one muscle as a result of a compressive anterior root lesion, such as those caused by a protruded intervertebral disc. Large numbers of axons may be affected in this case, with the result that the fasciculations (or even cramps) may be even more prominent than with disease of anterior horn cells but they are restricted to the territory of innervation of the root or nerve. Fasciculation potentials in lesser numbers are also observed with chronic nerve entrapments, e.g., ulnar neuropathy at the elbow and other peripheral

nerve lesions and some polyneuropathies. In all these cases, the damaged neuron or its axon seems to leave intact axons in a state of hyperirritability. The blocking of axon conduction by local anesthesia does not abolish fasciculations, but curare-like drugs do so.

Other Types of Spontaneous and Elicited Electrical Activity (See Chaps. 48 and 50) These various phenomena, including some discussed above, can be classified according to their generating source. The muscle fibers themselves are the source of fibrillations, positive sharp waves, and complex repetitive discharges (CRDs). The motor axons produce fasciculation potentials, myokymic discharges, neuromyotonia, and cramp syndromes; and the central nervous system is the source of complex ensembles of continuous motor activity such as occur in the stiff man syndrome.

The common phenomenon of complex repetitive discharges, referred to in the past as bizarre high-frequency discharges, consists of repetitive spontaneous potentials created by numerous single muscle fibers that fire in near synchrony; there is often an erratic configuration and abrupt starting and stopping of the discharges. They are seen in some myopathies, in hypothyroidism, and in certain denervating disorders, and are a mark of chronicity (lesions more than 6 months old). High-frequency coupling of action potentials into doublets, triplets, or higher multiples of single units, indicating instability in repolarization of the nerve fiber to a muscle, occurs in tetany and in the early stages of myokymia.

Myokymia is a persistent quivering and rippling of muscles at rest (colloquially called "live flesh"). The EMG picture is distinctive. The spontaneously firing MUPs are called *myokymic potentials*, or *discharges* and consist of groups of repetitive discharging units, each firing at its own rate, quasirhythmically, usually several times per second, followed by a briefer period of silence. The small motor unit discharges may occur singly or as doublets, triplets, or multiples.

The site of generation of this activity has been contested, possibly because it may arise from several sites along the motor nerve. The discharge corresponds to an alteration in the calcium concentration in the microenvironment of the axon. Spontaneous discharges arising in large myelinated fibers have been implicated in the genesis of myokymia; indeed, demyelinating polyneuropathies are among the conditions that give rise to this phenomenon. Myokymia is also caused by peripheral nerve hyperexcitability because of both K channel mutations and antibodies against the channels. This activity may be blocked by lidocaine infusion around the peripheral nerve and may be diminished by carbamazepine or phenytoin. Central forms of myokymia also occur, as in multiple sclerosis; the mechanism is similar to the peripheral form, namely irritation or demyelination of the motor nerve, but in its fascicular (central) course.

Focal and *segmental myokymias* differ in small ways from the generalized form of myokymia with regard to the timing and duration of the discharges. The focal types refer mainly to facial myokymia, seen most often

in multiple sclerosis, Guillain-Barré syndrome, large cerebellopontine angle tumors, or compression of the facial nerve by a small aberrant blood vessel, but it may follow any peripheral nerve injury and regeneration. The EMG patterns are complex, either high-frequency (30- to 100-Hz) recurrent bursts or brief lower-frequency bursts. Segmental myokymia is a common occurrence in demyelination and in radiation injuries of the brachial plexus. The EMG bursts tend to be longer and less frequent than in generalized myokymia, and the interburst frequency is highly variable. The origin of these discharges is probably in the distal peripheral nerve, where activity of afferent fibers, possibly via ephaptic transmission, irregularly excites distal motor terminals. *Segmental myokymia* refers to similar activity in the distribution of one or more adjacent motor roots again, usually related in some way to demyelination. This activity persists during sleep and general anesthesia.

The phenomenon of generalized *myotonia*, or neuromyotonia denotes a failure of voluntary relaxation of muscle because of sustained firing of the muscle membrane (see Chaps. 48 and 50), is characterized by high-frequency repetitive discharges generally having a positive sharp waveform. These myotonic discharges wax and wane in amplitude and frequency, producing a "dive-bomber" sound on the audio monitor. The discharges can be elicited mechanically by percussion of the muscle or movement of the needle electrode and are also seen following voluntary contraction or electrical stimulation of the muscle via its motor nerve. The MUPs may appear normal during voluntary contraction, but they are not followed by the silence that normally occurs on relaxation; instead, there is a "prolonged afterdischarge" consisting of long trains of fibrillation-like potentials that may take as long as several minutes to subside (Fig. 45-8A). These EMG findings can be seen with any myotonic disorder. If the muscle is activated repeatedly at short intervals, the late discharge becomes briefer and briefer and eventually disappears (see Fig. 45-8B), as the patient becomes able to relax the exercised muscle ("warmup" effect).

In *paradoxical myotonia* the myotonia worsens after each of a succession of voluntary contractions. This is the converse of what happens in myotonia congenita (Thomsen disease). As shown by single-fiber EMG studies, myotonia is generated by single muscle fibers and the mechanism of the membrane instability, at least in some forms, seems to involve changes in the chloride conductance. These disorders are discussed in subsequent chapters.

The *cramp-like contracture* of McArdle disease and phosphofructokinase deficiency is associated with electrical silence of contracting muscle. This feature is an important part of the definition of true physiologic muscle contracture (as distinguished from chronic shortening of a muscle and its tendon which, strictly speaking, is a pseudocontracture).

In the *syndrome of continuous muscle fiber activity* or *Isaacs syndrome* (see Chap. 50), which is a generalized form of myokymia, the EMG discloses high-frequency (up to 300-Hz) repetitive discharges of varying waveforms.

Figure 45-8. A. Myotonia congenita (Thomsen disease). The five lines are a continuous record of activity in the biceps brachii following a tap on the tendon. The initial response is within normal limits, but it is followed by a prolonged burst of rapid activity, gradually subsiding over a period of many seconds or minutes. B. Same electrode placement as in A. Response to the fifth of a series of tendon taps. “Warmup” has occurred, and the characteristic prolonged myotonic activity is no longer evident. (See Chap. 48 for a description of the disease.)

In the *stiff man syndrome*, painful muscle spasms and stiffness are generated by a spinal mechanism; the EMG potentials resemble normal motor units but are abnormal by virtue of continuous firing at rest (see Chap. 50).

Abnormalities in Amplitude, Duration, and Shape of Motor Unit Potentials

Figures 45-9 (schematically) and 45-10 depict the ways in which disease processes affect the motor unit and the appearance of the MUP in the EMG.

Motor Unit Potentials in Denervation Early in the course of denervation, many motor units with functional connections to the spinal cord are unaffected, and although the number of MUPs appearing during contraction is reduced, the configurations of the remaining ones are quite normal. In time, the remaining MUPs often increase in size and in electrical amplitude, perhaps two to three times normal, and become longer in duration and sometimes *polyphasic* (more than four phases).

Such large and sometimes *giant polyphasic potentials* (see Figs. 45-9C and 45-10B) arise from motor units containing more than the usual number of muscle fibers that are spread out over a greatly enlarged territory within the muscle. Presumably, new nerve twigs have sprouted from nodal points and terminals of undamaged axons and have reinnervated previously denervated muscle fibers, thus adding them to their own motor units. Soon after reinnervation, the MUPs generated will be low in amplitude, extremely prolonged, and polyphasic, findings that constitute a transitional configuration of early reinnervation. These amplitudes disappear as the motor unit is reestablished. Increased amplitude is usually associated with very chronic, proximal axon

Figure 45-9. The colored muscle fibers are functional members of one motor unit, whose axon enters from the upper left and branches terminally to innervate the appropriate muscle fibers. The action potential produced by each motor unit is seen in the upper right: its duration is measured between the two vertical lines. The normal-appearing but uncolored fibers belong to other motor units. A. Hypothetical situation, with five muscle fibers in the active unit. B. In this myopathic unit, only two fibers remain active; the other three (shrunken) were affected by one of the primary muscle diseases. C. Four fibers that originally belonged to other motor units and had been denervated are now reinnervated by terminal sprouting from an undamaged axon. Both the motor unit and its action potential are now larger than normal. Note that only under these abnormal circumstances do fibers in the same unit lie next to one another.

loss, for example, with remote poliomyelitis and chronic radiculopathy. These MUPs are to be differentiated from (1) polyphasic potentials of normal duration, which, as has been mentioned, make up as much as 10 percent of the total number of MUPs in normal muscle, and (2) polyphasic MUPs of short duration and low amplitude, which are characteristic of most myopathies and of myasthenia gravis and other disorders of neuromuscular transmission.

The Motor Unit Potential in Myopathy As Fig. 45-9B shows, diseases such as polymyositis, the muscular dystrophies, and other myopathies that

Figure 45-10. Single voluntary motor unit potentials. *A.* Normal. *B.* Prolonged polyphasic potential seen with reinnervation. *C.* “Giant unit”—normally shaped but of much greater amplitude than normal. *D.* Brief, low-amplitude “myopathic” units. Calibrations: 5 ms (horizontal) and 1 mV in *A* and *B*; 5 mV in *C*; 100 mV in *D* (vertical).

randomly destroy muscle fibers or render them nonfunctional, and obviously reduce the population of muscle fibers per motor unit. Therefore, when such a unit is activated, its potential is of lower voltage and shorter duration than normal, and it may also appear polyphasic as the compound MUP becomes fragmented into its constituent single-fiber potentials. Slowing of the propagated muscle fiber action potential in affected muscle fibers also contributes to the changes in the “myopathic” MUP. When most of the muscle fibers are affected, the MUPs are very small and of short duration and are recruited out of proportion to the tension generated, so-called *early recruitment*. Both types of alterations produce a characteristic high-pitched crackling sound from the audio monitor that has been likened to rain falling on a tin roof. They occur in all forms of chronic myopathies. Identical MUP changes are seen occasionally with other processes that cause disintegration of the motor unit, for example, early Guillain-Barré syndrome (because of conduction block along some of the terminal nerve fibers), and rarely with disorders of neuromuscular transmission (myasthenia gravis, other myasthenic syndromes), but they are most characteristic of primary muscle disease.

As mentioned earlier, fibrillation potentials, while typical of denervation, are sometimes seen in the myositides, and the rapidly progressive muscular dystrophies, perhaps because the muscle membrane has been made unstable; in the past the finding was attributed to isolation of a segment of the fiber from its nerve supply. In myasthenia gravis, where transmission of impulse fails at the neuromuscular junction, a single MUP may vary in amplitude during sustained weak contraction and some fibers cease to function. Electromyographic recordings of single muscle fibers belonging to the same motor unit disclose varying interpotential intervals on successive discharges; this phenomenon is called “jitter” and increases to the point of actual block, with deficits in neuromuscular transmission within a motor unit (see below and Chap. 50).

Abnormalities of the Interference Pattern Diseases that reduce the population of functional motor neurons or axons within the peripheral nerve decrease the number of motor units that can be recruited in the affected muscles. The decreased number of motor units available for activation produces a low-amplitude interference pattern with only a few remaining units firing at a moderate to rapid rate. A severe reduction in the interference pattern may result in the recruitment of only a single unit (see Fig. 45-6B). Structural damage to nerve, as well as demyelinating block, can produce this pattern of reduced recruitment; indeed, a reduced recruitment pattern coupled with the absence of denervation indicates a conduction block.

If muscle power is reduced in diseases such as polymyositis or muscular dystrophy, in which individual muscle fibers are affected, there may be little or no reduction in the number of motor units available for recruitment until the process is far advanced and entire MUPs have been lost as a result of random loss of all their constituent muscle fibers. Nonetheless, each motor unit will consist of fewer muscle fibers than normal, so more motor units must be activated to reach a certain degree of force. A modest effort can thus produce a full interference pattern despite marked weakness (increased recruitment). Because fewer muscle fibers are firing, the amplitude of the pattern will be reduced from normal. This type of full, highly complex interference pattern of less-than-usual amplitude in the face of dramatic weakness is the hallmark of myopathy (see Fig. 45-6C).

Motor Unit Quantification

This experimental technique, developed by McComas and colleagues estimates the size of motor units and is thus exquisitely sensitive to changes of denervation and reinnervation. It is carried out by applying a weak stimulus to a motor nerve or motor point and increasing it gradually as the evoked muscle response is recorded. Each quantal increase in the compound-evoked response is presumed to be caused by the addition of a single motor unit. In reinnervated muscles, the additional units are reduced in number and are abnormally large. The technique is used mainly for the investigation of motor neuron disorders. When a normal number and configuration of motor units is found, it has been helpful in distinguishing benign fasciculations from those of serious diseases.

Single-Fiber Electromyography

This is a special technique for the recording of single-muscle-fiber action potentials that has found utility in measuring muscle fiber density and in detecting so-called jitter in disease of the neuromuscular function, particularly myasthenia gravis. *Fiber density* is an index of the number and distribution of muscle fibers within a motor unit. *Jitter* is the variability of the interpotential interval of successive discharges of two single muscle fibers belonging to the same motor unit. This phenomenon is largely a result of the very slight variability of delay at the branch points in the distal axon and by synaptic delay at the neuromuscular junction, especially in myasthenia

gravis where it has found its main clinical use. Fiber density and jitter may, however, also be increased in neuropathic disorders that cause denervation with reinnervation. Both are usually normal or only slightly increased in myopathic disorders.

Testing for jitter is carried out by having the patient voluntarily contract a muscle to the slightest degree possible so as to activate only one motor unit (requiring a great deal of cooperation by the patient) or by stimulating an intramuscular nerve twig (requiring great patience on the part of the examiner). The EMG needle is advanced until two muscle fibers from the same motor unit are recorded. If the oscilloscope sweep is triggered by the firing of the first fiber, a fluctuating latency of the second fiber potential can be seen on the screen as a movement (jitter) of the second peak. The degree of jitter can be quantitated by measuring the interval between the activation of the two muscle fibers (the result of slightly differing lengths of the terminal axons) from which a mean interpeak interval is determined. Approximately 20 fiber pairs are sampled, and an average of the mean consecutive intervals can be derived. In a muscle such as the extensor digitorum communis, the average variation should be no more than 34 ms. The acceptable average is lower for large proximal muscles. Also, in disease of the neuromuscular junction, one muscle fiber in a pair may fail to fire intermittently as a result of a blocking of conduction. Further details of this technique and its clinical applications are discussed by Stålberg and Trontelj.

Imaging of Muscle and Nerve

Imaging techniques—CT, MRI, and ultrasonography—enable one to measure muscle volume and to recognize qualitative changes in muscle structure (see review of DeVisser and Reimers). Such methods are finding some clinical and research use in the diagnosis of disorders of muscle and in gauging the effects of treatment. CT scans of dystrophic muscle show foci of decreased attenuation, representing masses of fat cells. The fatty masses spread gradually from multiple foci and eventually replace muscle fibers. The original shape of the muscle is retained; indeed, an enlarged weak muscle containing mostly fat confirms the clinical impression of pseudohypertrophy. In denervative atrophy, the muscles are obviously small and contain multiple punctate areas of decreased attenuation, which represent interstitial fat. Eventually, large portions of chronically denervated muscle may be replaced by fat. Blood, blood products, and calcium deposits are expressed by increased attenuation in CT. This may be helpful in the diagnosis of muscle trauma, myositis ossificans, and dermato- and polymyositis.

Fat and bone marrow have a high signal intensity in MR images, whereas fascia, ligaments, and cortical bone lack signal intensity. In T1-weighted images, normal muscle has a low signal and dystrophic muscle, a slightly increased signal; in T2-weighted images, dystrophic muscle has a slightly enhanced signal. Given its sensitivity to these dystrophic changes in muscle, MRI is particularly effective in determining the distribution

of muscle involvement in a dystrophy. Transverse MR sections, for example, can help distinguish the topographic patterns of such disorders as the proximally predominant Becker dystrophy and the distally predominant Miyoshi myopathy, or subtle subtypes of Emery-Dreifuss dystrophy (Mercuri et al). Spectroscopic MRI in metabolically determined myopathies has the capacity to quantitate levels of selected biochemical constituents of muscle, including intracellular pH and levels of metabolic intermediates such as phosphocreatine. This technique is particularly effective in demonstrating subnormal generation of intracellular acidosis after a limb is exercised in disorders of glycogenolysis and of glycolysis. Some individuals with mitochondrial disease of muscle will demonstrate rapid depletion of energy supplies and profound delays in recovery that can be quantified and used as an end point for treatments.

New magnetic resonance techniques are also being developed that allow the imaging of nerves. This may be an aid in assessing traumatic nerve injury and in demonstrating neuromas, hypertrophy or atrophy of a nerve trunk, as well as neural tumors.

BIOPSIES OF MUSCLE AND NERVE

Muscle Biopsy

Muscle biopsy can be of great diagnostic value, but both surgical and microscopic techniques must be exacting. The muscle chosen for study should be accessible; there should be evidence that it has been affected but not totally destroyed by the disease in question; and it should not have been the site of a recent injection or EMG study, since the trauma of the needles produces focal necrotizing and inflammatory lesions. Muscle biopsy is helpful in distinguishing the following basic disorders in patients with neuromuscular disease.

1. *Denervation atrophy*. Reduction in the size of muscle fibers with an accompanying enlargement of intact motor units (because of collateral reinnervation) and degenerative changes in some fibers are the main changes of denervation atrophy. *Group atrophy* denotes enlarged motor units where all the fibers in the group are reduced to the same size; this is typical of progressive denervation. Normally, the fibers of each motor unit are not clustered, so that when grouping occurs it means that some fibers of a denervated unit have been adopted by an adjacent intact motor unit. This change typifies axonal neuropathies and many spinal cord diseases that affect the anterior horn cell. A related change is particularly well shown in histochemical stains for ATPase, phosphorylase, and oxidases, where the normal mosaic pattern of fiber types is altered. The use of these stains reveals *fiber type grouping*, the most specific histologic evidence of denervation and reinnervation. Here, muscle fibers of similar histochemical type form groups of 15 or more fibers as a result of reinnervation by a single motor neuron. The diagnosis of denervation atrophy

can usually be made from the clinical and EMG examinations; seldom is biopsy necessary for this purpose, but it is still used in cases of possible ALS, for example, where the diagnosis remains uncertain after other testing.

2. *Segmental necrosis of muscle fibers with myophagia and various manifestations of regeneration.* These are the typical changes in idiopathic polymyositis (in combination with infiltrates of inflammatory cells), and infective polymyositis (e.g., in the presence of *Trichinella* or *Toxoplasma*). These changes may also be observed in more limited form in Duchenne and other rapidly progressive muscular dystrophies.
3. *Inflammation and vasculitis.* Lymphocytic infiltration of the endomysium is most characteristic of polymyositis and in dermatomyositis it is predominantly perivascular and perimysial. The lymphocytic infiltrate may be florid in these processes but, as often, it is less intense and scattered. Inclusion body myopathy is characterized by inflammation but has additional diagnostic features. Lesser degrees of inflammation are common in the myopathies associated with Sjögren syndrome, mixed connective tissue disease, and scleroderma. Numerous other processes, including the infections mentioned earlier and some dystrophies (especially the fascioscapulohumeral type)—may be associated with an inflammatory reaction. There is usually acute myofibrillar destruction in regions of maximal lymphocytic infiltration.
4. *Vasculitis.* The muscle is a site of inflammatory vascular destruction in systemic diseases such as polyarteritis nodosa, and for this reason it is often useful to obtain a small sample of muscle adjacent to a nerve biopsy. The finding of a granulomatous myopathy may indicate the presence of systemic sarcoidosis.
5. *Alterations in the protein and histochemical composition of muscle fibers* are shown by special stains for enzymes, glycogen, and structural proteins that are implicated in disease. It has become possible to detect the absence or deficiency of specific structural proteins of the muscle membrane that define each of the muscular dystrophies: dystrophin, sarcoglycan, laminin, dysferlin, and others as discussed in Chap. 48. These tests require rapid freezing (in a cryostat) rather than formalin fixation. Also, a number of enzymatic deficiencies and intrafiber glycogen storage that lead to weakness and muscle fatigue may be detected by appropriate histochemical staining (see Chap. 48).
6. *Unusual changes of muscle fibers.* Included here are sarcoplasmic masses and disorganized ring or serpentine collections of myofibrils and myofilaments (*Ringbinden*) in myotonic dystrophy; glycogen masses in glycogen storage diseases, rods (nemaline), central cores, aggregates of lipid bodies, and other cytoplasmic changes in certain congenital myopathies; and nuclear and cytoplasmic inclusions that characterize but are not isolated to inclusion-body myositis. Application of histochemical methods and electron microscopy are the important techniques in the diagnosis of these disorders. These are discussed in relation to each of these specified diseases in the following chapters.

7. *Abnormalities of mitochondria.* Several distinctive abnormalities are readily visualized in muscle biopsies and are virtually diagnostic of an entire class of mitochondrial diseases. Light microscopy of frozen sections of muscle stained with the Gomori trichrome stain show the main feature, so-called ragged red fibers, which are accumulations of subsarcolemmal mitochondria.

8. *Disorders of the neuromuscular junctions.* Here, an abnormality may be revealed by performing the demanding procedure of motor point biopsy (to include the motor endplate), and the use of electron microscopy and special staining techniques for nerve terminals, cholinesterase, and the outlining of acetylcholine receptors. Myasthenia gravis, botulism, Lambert-Eaton syndrome, and myasthenic syndrome with motor endplate cholinesterase deficiency fall into this category. Biopsy is rarely necessary for the diagnosis of these disorders, but it has added considerably to our understanding of them.

As a rule, the muscle biopsy procedure requires no more than a small cleanly excised block of muscle, 1.0 to 2.0 cm, which is prevented from contracting by a clamp or by tying at full length to a tongue depressor. As an alternative to the standard surgical technique, percutaneous needle biopsies are now being done routinely in neuromuscular clinics and may be adequate for the diagnosis of certain muscle dystrophies and for their study over time and for a number of other muscle diseases and denervation atrophy. Unfortunately, the erratic distribution of lesions in many of the common disorders of muscle lessens the diagnostic yield of all types of biopsies, but in general the needle biopsy is less satisfactory than an open biopsy. The study of the muscle biopsy requires special care in removal, transport, and fixation techniques. These are discussed in detail by Engel (1994b).

Nerve Biopsy

Nerve biopsies are processed for study by conventional histologic methods and by thin-section phase and electron microscopy. These methods, sometimes supplemented by study of teased fiber preparations and immunologic studies, can provide valuable histopathologic data. With ordinary microscopy and staining, one may find evidence of focal inflammation, demyelination, axon destruction, vasculitis, amyloidosis, leprosy, or sarcoidosis. As mentioned in reference to certain guidelines cited below, these procedures are most valuable in the diagnosis of inflammatory, vasculitic, and amyloid neuropathies. In children, the nerve biopsy may reveal the histologic features of metachromatic or globoid leukodystrophy, giant axonopathy, or neuroaxonal dystrophy. However, nerve biopsy is relatively unhelpful in most other polyneuropathies and should be used prudently because the procedure is not without complications, including the occasional occurrence of wound infections, painful stump neuromas, persistent dysesthesias of the lateral foot or heel, and thrombophlebitis. Guidelines given by England and associates from a review of the literature up to 2009, has suggested that nerve biopsy is useful in cases

of mononeuropathy multiplex, suspected amyloidosis, and unusual forms of chronic inflammatory demyelinating neuropathy, all the subjects of discussion in Chap. 46, but not clearly useful in nondescript distal peripheral sensorimotor neuropathies.

Representative of the results of nerve biopsies in a neuromuscular clinic is a prospective study of 50 consecutive cases of sural nerve samples reported by Gabriel and colleagues in which nerve biopsy served only to confirm the clinical diagnosis in 70 percent of cases and altered the clinical diagnosis in only 14 percent. Nevertheless, in some instances of idiopathic polyneuropathy that are not clarified by clinical and electrophysiologic testing, and particularly if a treatable chronic inflammatory polyneuropathy is suspected, many neuromuscular experts resort to sural nerve biopsy as a final diagnostic step. Although the sural nerve is typically chosen for biopsy, the superficial peroneal nerve and the adjacent peroneus brevis muscle gives a higher yield in cases of vasculitis (see Collins et al).

In diseases that involve only the motor nerves, it is sometimes useful to sample a fascicle of the superficial radial nerve or the nerve to the extensor digitorum brevis, which may be taken with the muscle itself and leaves little or no clinical deficit. Chronic inflammatory neuropathy and vasculitic neuropathy may be disclosed by this selective biopsy technique when the sural nerve is unaffected. In selected circumstances we have undertaken biopsy of small radicles of upper lumbar roots (L1 or L2) to establish the diagnosis of an infiltrative lymphoma. Little deficit occurs from the removal of

nerves from these sites if the procedure is done by an experienced surgeon.

Additional techniques that are used in the study of muscle biopsies and specific pathologic findings that characterize the many individual diseases, of both muscle and peripheral nerve, are discussed in the chapters that follow.

Other Laboratory Tests in the Study of Muscle and Nerve Disease

None of the diagnostic procedures previously described may be taken as an infallible diagnostic index of a specific disease of muscle or nerve. Each procedure is subject to technical error and the findings to misinterpretation. A biopsy specimen may be taken from an unaffected muscle or portion of an affected muscle, and such an error causes the sample to be normal in the face of obvious clinical evidence of disease. This is particularly true of the inflammatory myopathies that affect muscle in heterogeneous and spotty manner.

Rough excision and improper fixation and staining produce artifacts that may be misinterpreted as marks of disease when, in fact, the muscle (and nerve) is microscopically normal. Similarly, EMG study may fail to record fibrillations in obviously denervated muscle, particularly in slowly progressive disorders. Also, in some of the muscles of the feet, fibrillations and fasciculations may be found in normal asymptomatic older individuals (Falck and Alaranta). As in the study of all disease, laboratory data have significance only if evaluated in the light of the clinical findings.

Diseases of the Peripheral Nerves

In this single chapter, an attempt is made to provide an overview of the very large and difficult subject of peripheral nerve disease. Because the structure and function of the peripheral nervous system are relatively simple, one might suppose that our knowledge of its diseases would be fairly complete. Such is not the case. For example, when a group of patients with chronic polyneuropathy were investigated intensively in a highly specialized center for the study of peripheral nerve diseases several decades ago, a suitable explanation for their condition could not be found in 24 percent (Dyck et al, 1981) and even more discouraging figures prevail in our clinics today. Moreover, the physiologic basis of many neuropathic symptoms continues to be elusive and in several of the neuropathies the pathologic changes have not been fully determined.

There has, however, been a surge of interest in diseases of the peripheral nervous system (PNS), which promises to change this state of affairs. Rapidly advancing techniques in the fields of immunology and molecular genetics are now clarifying entire categories of neuropathic disease. Also, in recent years, effective forms of treatment for several peripheral neuropathies have been introduced, making accurate diagnosis imperative. For these reasons, clinicians now find the peripheral neuropathies among the most challenging and gratifying categories of neurologic disease.

GENERAL CONSIDERATIONS

It is important to have a clear concept of the extent of the PNS and the mechanisms by which it is affected by disease. The PNS includes all neural structures lying outside the pial membrane of the spinal cord and brainstem with the exception of the optic nerves and olfactory bulbs, which are special extensions of the brain. The nerves within the spinal canal and attached to the ventral and dorsal surfaces of the cord are the *spinal roots*; those attached to the ventrolateral surface of the brainstem are the *cranial nerve roots*, or cranial nerves.

The dorsal, or posterior (afferent, or sensory), spinal roots consist of central axonal processes of the sensory and cranial ganglia. On reaching the spinal cord and brainstem, the roots extend for variable distances into the

dorsal horns and posterior columns of the cord and into the spinal trigeminal and other tracts in the medulla and pons before synapsing with secondary sensory neurons, as described in Chaps. 8 and 9 that are devoted to the neurology of pain and sensation. The peripheral axons of the dorsal root ganglion cells are the sensory nerve fibers. They terminate as freely branching or specialized corpuscular endings—i.e., the sensory receptors—in the skin, joints, and other tissues. The sensory nerve fibers vary greatly in size and in the thickness of their myelin covering; based on these dimensions, they are classified as type A, B, or C, as discussed in Chap. 8.

The ventral, or anterior (efferent, or motor), roots are composed of the emerging axons of anterior and lateral horn cells and motor nuclei of the brainstem. Large, heavily myelinated fibers terminate on muscle fibers and smaller unmyelinated ones terminate in sympathetic or parasympathetic ganglia. From these autonomic ganglia issue the axons that terminate in smooth muscle, heart muscle and conducting system, and glands. Traversing the subarachnoid space, where they lack well-formed epineurial sheaths, the cranial and spinal roots (both sensory and motor) are bathed in and are susceptible to substances in the cerebrospinal fluid (CSF), the lumbosacral roots having the longest exposure (Fig. 46-1).

The vast extent of the peripheral ramifications of cranial and spinal nerves is noteworthy, as are their thick protective and supporting sheaths of perineurium and epineurium that are endowed with a vascular supply through longitudinal arrays of richly anastomosing nutrient arterial branches. The perineurium comprises the connective tissue sheaths that surround and separate each bundle of nerve fibers (fascicles) of varying size, each fascicle containing several hundred axons. The sheath that binds and surrounds all the fascicles of the nerve is the epineurium. As the nerve root approaches the cord, the epineurium blends with the dura (see Fig. 46-1). The fine connective tissue covering of individual nerve fibers is the endoneurium. Longitudinally oriented and widely anastomotic endoneurial vessels also nourish the nerve fibers and are susceptible to disease.

The nerves traverse narrow foramina (intervertebral and cranial) and a few pass through tight channels peripherally in the limbs (e.g., the median nerve between the carpal ligament and tendon sheaths of flexor forearm

Figure 46-1. Diagram showing the relationships of the peripheral nerve sheaths to the meningeal coverings of the spinal cord. The epineurium (EP) is in direct continuity with the dura mater (DM). The endoneurium (EN) remains unchanged from the peripheral nerve and spinal root to the junction with the spinal cord. At the subarachnoid angle (SA), the greater portion of the perineurium (P) passes outward between the dura mater and the arachnoid (A), but a few layers appear to continue over the nerve root as part of the root sheath (RS). At the subarachnoid angle, the arachnoid is reflected over the roots and becomes continuous with the outer layers of the root sheath. At the junction with the spinal cord, the outer layers of the root sheath become continuous with the pia mater (PM). (From Haller FR, Low FM: The fine structure of the peripheral nerve root sheath in the subarachnoid space in the rat and other laboratory animals. *Am J Anat* 131:1, 1971, by permission.)

muscles that make up the carpal tunnel; the ulnar nerve in the cubital tunnel). These anatomic features explain the sites of susceptibility of certain nerves to compression and entrapment and also to ischemic damage.

The axons themselves contain a complex internal microtubular apparatus for maintaining the integrity of their membranes and for transporting substances such as neurotransmitters over long distances between the nerve cell body and the distant reaches of the nerve fiber. As discussed in Chap. 45, the long axons of sensory nerves can properly be considered to be dendrites but we use the term “axon” in this and other chapters to denote all the neuronal processes of peripheral nerves. Nerve fibers (axons) are coated with short segments of myelin of variable length (250 to 1,000 μm), each of which is enveloped by a Schwann cell and its membrane that constitute the myelin sheath. In fact, the PNS may be accurately defined as the part of the nervous system that is invested by the cytoplasm and membranes of Schwann cells. Each myelin segment and Schwann cell has a symbiotic relationship to the axon but is morphologically independent. The structure of the axonal membrane in the gaps between segments of the myelin sheaths (nodes of Ranvier) is specialized, containing a high concentration of sodium channels and permitting the saltatory electrical conduction of nerve impulses as described in Chap. 45. Unmyelinated fibers, more numerous in peripheral nerves than myelinated ones, also arise from cells in dorsal root and autonomic ganglia. Small bundles of these naked (unmyelinated) axons are enveloped by a single Schwann cell; delicate tongues of Schwann cell cytoplasm partition these bundles and separate individual axons. Each sensory nerve fiber terminates in a specialized ending which

is designed to be especially sensitive to certain natural stimuli as discussed in Chaps. 8 and 9.

Pathogenic Mechanisms in Peripheral Nerve Disease

The features described previously enable one to conceptualize the possible avenues by which disease may affect the peripheral nerves. Pathologic processes may be directed at any one of the several groups of nerve cells whose axons constitute the nerves, i.e., the cells of the anterior or lateral horns of the spinal cord, the dorsal root ganglia, or the sympathetic and parasympathetic ganglia. Each of these cell types exhibits specific vulnerabilities to disease, and if destroyed—as, for example, the motor nerve cells in poliomyelitis—there is secondary degeneration of the axons and myelin sheaths of the peripheral fibers of these cells. Neuropathic symptoms are also induced by alterations of function and structure of the ventral and dorsal columns of the spinal cord, which contain the fibers of exit and entry of anterior horn and dorsal root ganglion cells, respectively. The myelin of these centrally located fibers is constituted differently from that of the peripheral nerves, being enveloped by oligodendrocytes rather than Schwann cells and the nerve fibers are supported by astrocytes rather than fibroblasts.

Because of the intimate relation of the nerve roots to the CSF and to specialized arachnoidal cells (the arachnoidal villi), a pathologic process in the CSF or leptomeninges may damage the exposed spinal roots. Diseases of the connective tissues affect the peripheral nerves that lie within their sheaths. Diffuse or localized arterial diseases may injure nerves by occluding their nutrient arteries. In a large category of immune-mediated neuropathies,

the damage is the result of a cellular or humoral attack on various components of myelin. A subset of these is characterized by the binding of circulating antibodies to the specialized regions at the nodes of Ranvier, causing a block of electrical conduction. A complement-dependent humoral immune reaction against the radicular or peripheral axon is also known. Toxic or immunologic agents that selectively damage the Schwann cells or their membranes cause demyelination of peripheral nerves, leaving axons relatively intact, or a toxin may specifically affect axons and dendrites by poisoning their cell bodies, the axolemma, or the lengthy and complex axonal transport apparatus.

Finally, one might correctly suppose that axons of the motor or sensory nerves, sympathetic fibers of varying diameter and length, or the end organs to which they are attached would each have its own particular liability to disease. At present we can cite only a few examples of diseases that cause disease through these mechanisms exclusively: e.g., diphtheria, in which the bacterial toxin acts directly on the membranes of the Schwann cells near the dorsal root ganglia and adjacent parts of motor and sensory nerves (the most vascular parts of the peripheral nerve); polyarteritis nodosa, which causes occlusion of vasa nervorum, resulting in multifocal nerve infarction; tabes dorsalis, in which there is a treponemal meningoradiculitis of the posterior roots (mainly of the lumbosacral segments); doxorubicin toxicity, wherein protein synthesis of dorsal root ganglion cells is blocked with subsequent neuronal destruction; poisoning by arsenic,

which combines with the axoplasm of the largest sensory and motor nerves via sulfhydryl bonds; and vincristine toxicity, which damages the microtubular transport system. Analogous anatomic pathways are probably implicated in other diseases by mechanisms that remain to be discovered.

Among the genetically determined neuropathies, the altered gene products are now known in some cases to lead to defective myelination, which greatly slows conduction along nerves. In other genetic diseases it is known that structural components of the axon are disrupted, leading to axonal degeneration and impaired electrical conduction.

Pathologic Reactions of Peripheral Nerve

Several distinct histopathologic changes are recognized in the peripheral nerve, although they are not disease-specific and they may be present in varying combinations in any given case. The three main ones are *segmental demyelination*, *wallerian degeneration*, and *axonal degeneration* (diagrammatically illustrated in Fig. 46-2).

The myelin sheath is the most susceptible element of the nerve fiber, for it may break down as part of a primary process involving the Schwann cells or of the myelin itself, or it may be damaged secondarily as a consequence of disease affecting its axon. Focal degeneration of the myelin sheath with sparing of the axon is called *segmental demyelination*. The characteristic change of segmental demyelination is the disappearance of the sheath over

Figure 46-2. Diagram of the basic pathologic processes affecting peripheral nerves. In wallerian degeneration, there is degeneration of the axis cylinder and myelin distal to the site of axonal interruption (arrow) and central chromatolysis. In segmental demyelination, the axon is spared. In axonal degeneration, there is a distal degeneration of myelin and the axis cylinder as a result of neuronal disease. Both wallerian and axonal degeneration cause muscle atrophy. Further details are found in the text. (Courtesy of Dr. Arthur Asbury)

segments of variable length, bounded on each end by one side of a node of Ranvier and an adjacent preserved segment of myelin. This exposes long segments of the axon to the interstitial environment. Myelin may also degenerate from axonal disease in a general process that may occur either proximal or distal to the site of axonal interruption.

Common to many lesions of the peripheral nerve is *wallerian degeneration*, a reaction of both the axon and myelin *distal* to the site of disruption of an axon. Wallerian degeneration might be described as “dying forward,” a process in which the nerve degenerates from the point of axonal damage outward. In contrast, when the axon degenerates as part of a “dying-back” phenomenon in a more generalized metabolically determined polyneuropathy, it is termed *axonal degeneration*. Here, the axon is affected progressively from the distal-most site to the proximal, with dissolution of myelin that occurs roughly in parallel with the axonal change. One possible explanation for this process is that the primary damage is to the neuronal cell body, which fails in its function of synthesizing proteins and delivering them to the distal parts of the axon. Certain toxic and metabolic processes affect axons uniformly along their length or impair anterograde axonal transport to the periphery; the functional impairment is then proportional to the size and length of the blocked axons.

Destruction of a proximal spinal motor root results in a gradual dissolution of the distal motor nerve and its myelin sheath (a form of wallerian degeneration). The neuronal motor cell body that gives rise to the motor fiber undergoes characteristic retrograde morphologic changes described below but does not die. Similar destruction of the dorsal spinal root produces secondary wallerian degeneration of the posterior columns of the spinal cord, but not of the peripheral sensory nerve because the dorsal root ganglion cell maintains the integrity of the distal axon. In other words, destruction of axons results within several days in wallerian degeneration of the myelin distal to the point of injury but not transgressing the neuronal cell body. The myelin breaks down into blocks or ovoids in which lie fragments of axons (digestion chambers of Cajal). The myelin fragments are then converted, through the action of macrophages, into neutral fats and cholesterol esters and carried by these cells to the bloodstream.

Certain diseases affect the neuron primarily rather than the axon and cause either a motor or sensory *neuronopathy*. In the former case, the anterior horn cell is affected by a disease process (motor neuron disease, or motor neuronopathy) and in the latter, the sensory ganglion cell (ganglionopathy) is destroyed. A type of wallerian distal degeneration of the respective nerve fibers follows.

Some of these pathologic reactions are more easily understood if one considers certain features of cytoskeletal structure and function of nerve cells and their axons. The axon contains longitudinally oriented neurofilaments and microtubules, which are separated but interconnected by cross-bridges. Their main function involves the transport of substances from nerve cell body to axon terminal (anterograde transport) and from the distal axon back to the cell body (retrograde transport). Thus, when

the axon is severed, organelles cannot be transmitted to the distal axon for the purpose of renewing membrane and neurotransmitter systems. By means of retrograde axonal transport, the cell bodies receive signals to increase their metabolic activity and to produce growth factors and other materials needed for axonal regeneration. In an incompletely defined way, the axon also creates a local environment that allows the Schwann cell to maintain the integrity of the adjacent myelin sheath. Loss of this trophic influence leads to dissolution of the myelin sheath, but not of the Schwann cell itself.

There are also highly characteristic histopathologic changes in the nerve cell body termed *chromatolysis* as a secondary consequence of axonal interruption. These retrograde changes consist of swelling of the cell cytoplasm and marginalization and dissolution of the Nissl substance. The important point again is that despite the destructive changes in the nerve fibers, the nerve cells, while altered in histologic appearance, are left intact with preservation of the apparatus required for recovery.

In segmental demyelination, recovery of function may be rapid because the intact but denuded axon needs only become remyelinated. The newly formed internodal segments are initially thinner than normal and of variable length. By contrast, recovery is much slower with wallerian or axonal degeneration, often requiring months to a year or more because the axon must first regenerate and then reinnervate the muscle, sensory organ, or blood vessel before function returns. When the regenerating axon first becomes myelinated, the internodal myelin segments are short, the length of one normal internode being replaced by three or four shorter new ones. Recurrent demyelination and remyelination lead to “onion bulb” formations and enlargement of nerves, the result of proliferating Schwann cells and fibroblasts that encircle the axon and its thin myelin sheath. If nerve cells are destroyed, no recovery of function is possible except by collateral regeneration of axons from intact nerve cells. Interruption of a nerve fiber by severing or by crude destruction usually prevents continuity from being reestablished. Regenerating axon filaments take aberrant courses and, with fibroblastic scar formation, they may form a disorganized clump of tissue termed *pseudoneuroma*.

These relatively few pathologic reactions do not, in themselves, differentiate the many dozens of diseases of the peripheral nerves, but when they are considered in relation to the selective effects on various types and sizes of fibers, the topography of the lesions, and the time course of the process, they furnish criteria for fairly accurate diagnosis. Moreover, the identification of these basic reactions is of great value in the inspection of pathologic material obtained from biopsy or autopsy.

There are additional special pathologic changes, not specifically neural in nature that characterize certain diseases of the peripheral nervous system. These involve inflammatory or vascular changes or deposition of material in the interstitium of the nerve. For example, acute demyelinating polyneuritis of the Guillain-Barré type is characterized by endoneurial infiltrations of lymphocytes

and other mononuclear cells in the nerves, roots, and sensory and sympathetic ganglia. Deposition of amyloid in the endoneurial connective tissue and walls of vessels affecting the nerve fibers are the distinctive features of inherited and acquired amyloid polyneuropathy. Diphtheritic polyneuropathy is typified by the demyelinating character of the nerve fiber change, the location of this change in and around the roots and sensory ganglia, the subacute course, and the lack of inflammatory reaction. A number of neuropathies are characterized by the deposition of antibodies and complement on the myelin sheath or on elements of the axon. These changes can be demonstrated by immunohistopathologic techniques. Many other polyneuropathies (paraneoplastic, nutritional, porphyric, arsenical, and uremic) are topographically symmetrical and represent forms of axonal degeneration but cannot be easily distinguished from one another on histopathologic grounds.

Concerning the pathology of the *mononeuropathies*, our knowledge is somewhat more complete. Compression of nerve or nerve roots, local or segmental ischemia, stretch, and laceration of nerves are understandable mechanisms and their pathologic changes can be reproduced experimentally. Tumor infiltration and importantly, vasculitis with ischemic infarction of nerve account for a proportion of cases. Of infections and granulomas localized to single nerves, leprosy, sarcoid, and herpes zoster represent identifiable disease states. For most of the acute mononeuropathies that are a result of transient compression, the pathologic changes have yet to be fully defined, as they are usually reversible states that provide no opportunity for complete pathologic examination. Experimental models of nerve compression indicate disruption of tubular transport and local demyelination. The common symptoms of compression such as paresthesias are explained, as discussed further on, by exposure of sodium channels along denuded axons and spontaneous and ectopic electrical discharges.

SYMPTOMATOLOGY OF PERIPHERAL NERVE DISEASE

There are a number of motor, sensory, reflex, autonomic, and trophic symptoms and signs that are typical of peripheral nerve disease. Grouping them into syndromes based on their temporal and topographic features has proved to be of great value in clinical diagnosis. Although motor, sensory, reflex, and trophic changes are taken together to determine specific diagnosis, each element of the neuropathic diseases is first given in detail further on.

Impairment of Motor Function

It is not surprising that weakness in various patterns and degrees is a feature of almost all neuropathies. The degree of weakness is proportional to the number of axons or motor neurons affected. *Polyneuropathies* that are the result of axonal damage are characterized foremost by a relatively symmetric distribution of weakness that is, moreover, distal because the pathologic changes begin in

the far distal parts of the largest and longest nerves and advance along the affected fibers toward their nerve cell bodies (dying-back neuropathy, or "distal axonopathy"). The muscles of the feet and legs are typically affected earlier and more severely than those of the hands and forearms. In milder forms of axonal disease, only the feet and lower legs are involved. Truncal and cranial muscles are usually the last to yield, and then only in severe cases. This represents the "length-dependent" pattern that is typical of axonal degeneration. The nutritional, metabolic, and toxic neuropathies assume this predominantly distal "axonal" pattern. An exception is porphyria, an axonal process in which there may be mainly proximal weakness. By contrast, in *demyelinating polyneuropathies*, the multifocal nature of lesions and blockage of electrical conduction often leads to weakness of proximal limb and facial muscles before or at the same time as distal parts are affected.

Another pattern of neuropathic weakness is one in which all the muscles of the limbs, trunk, and neck are involved almost simultaneously, often including respiratory paralysis, therefore making it impossible to determine if the axons or myelin, or both, have been damaged. The best characterized of these processes is the Guillain-Barré syndrome (GBS). Less common causes of *generalized paralysis* include diphtheria, tick paralysis, and certain toxic polyneuropathies. Fatalities, when they occur, are usually a result of respiratory failure.

A predominantly *bibrachial paralysis* is an unusual presentation of neuropathic disease but may occur in the inflammatory-demyelinating polyneuropathies, as well as in Sjögren syndrome, chronic immune or paraneoplastic neuropathies, lead neuropathy, Tangier disease, and in a familial type of brachial neuritis. (A more frequent cause of bibrachial palsy is disease of the motor neurons themselves namely, motor system disease, or a lesion placed centrally in the cervical cord that damages these same neurons.) *Paraparesis* is not typical of the generalized polyneuropathies, but it is observed with infections and inflammations of the cauda equina, as occurs with Lyme disease, cytomegalovirus, herpes simplex, and with neoplastic infiltration of the nerve roots. Bifacial and other cranial nerve paralyzes are likely to occur in GBS, neoplastic invasion, with connective tissue diseases, HIV and herpes virus infection, sarcoidosis, Lyme disease, or one of the rare metabolic neuropathies (Refsum, Bassen-Kornzweig, Tangier, and Riley-Day). These are discussed in Chap. 47 on diseases of the cranial nerves and in respective chapters on infections and metabolic diseases of the nervous system.

Atrophy of weak or paralyzed muscles is characteristic of chronic disease of the motor neuron or motor axon and conversely, demyelinating neuropathies relatively spare muscle bulk because of the absence of denervation. Atrophy proceeds slowly over several weeks and months, the degree being proportional to the number of damaged motor nerve fibers. The maximum degree of denervation atrophy after an acute injury to the axons occurs in 90 to 120 days and reduces muscle volume by 75 to 80 percent. Atrophy may also be a consequence of disuse; it occurs over many weeks but in itself does not reduce muscle

volume by more than 25 to 30 percent. In chronic axonal neuropathies, the degrees of paralysis and atrophy tend to correspond. As mentioned previously, atrophy does not coincide with weakness in acute paralysis caused by the demyelinating neuropathies in which the nerve fiber is relatively less affected than is the myelin. Ultimately in muscle atrophy, there is degeneration and loss of the denervated muscle fibers. This process begins in 6 to 12 months; in 3 to 4 years, most of the denervated fibers will have degenerated. If reinnervation takes place within a year or so, motor function and muscle volume may be restored.

Tendon Reflexes

As a rule, neuropathies are associated with a reduction or loss of tendon reflexes. Most often, this is the result of an interruption of the afferent (sensory) portion of the monosynaptic reflex arc. The reflexes may be diminished if muscular function is impaired, but this occurs mainly in the case of extreme atrophy, in which there are too few muscle fibers to manifest a contraction. There are, of course, many other processes that reduce the tendon reflexes, but it is the neuropathies with which loss of reflexes is most closely associated. An exception is the group of *small-fiber neuropathies*, in which tendon reflexes may be retained, even with marked loss of perception of painful stimuli. This discrepancy is attributable to the dependence of the afferent component of the tendon reflex arc on the large, heavily myelinated fibers that originate in muscle spindles. Conversely, in neuropathies that affect the largest diameter, heavily myelinated fibers, the tendon reflexes are diminished early and disproportionately to weakness. Slowing of conduction in sensory fibers may also abolish the reflex by dispersing the afferent volley of impulses initiated by the tendon tap. There is generally a concordance between areflexia and a loss of proprioceptive and joint-position senses; i.e., the large nerve fibers from spindle afferents are of the same type and size as those mediating these forms of sensation. Furthermore, loss of sensory functions that are dependent on these large fibers in the presence of preserved reflexes implicates the central projections of the sensory ganglion cells i.e., a lesion in the posterior columns of the spinal cord that does not interrupt the afferent tendon reflex arc. Regional loss of a reflex is usually a sign of a radiculopathy.

Sensory Loss (See also "Sensory Syndromes" in Chap. 9)

Most polyneuropathies cause impairment of both motor and sensory functions, but one is often affected more than the other. In the toxic and metabolic neuropathies, sensory loss usually exceeds weakness. These differences are emphasized in the descriptions of individual peripheral nerve diseases in later parts of the chapter.

In the axonal polyneuropathies, sensation is affected symmetrically in the distal segments of the limbs and more in the legs than in the arms, owing to the length-dependent nature of most diseases that affect peripheral nerves. In most types, all sensory modalities (touch-pressure, pain and temperature, vibratory and joint

position senses) are impaired or eventually lost, although one modality is affected disproportionately to the others, or pain and temperature sensation (small afferent fibers) may be impaired more than joint position and vibration (larger fibers). As an axonal neuropathy worsens, there is spread of sensory loss from the distal to more proximal parts of the limbs and eventually, to the anterior abdomen, thorax, and the face. An "escutcheon" pattern of sensory loss over the abdomen and thorax in severe axonal neuropathy may be mistaken for the sensory level of a spinal cord lesion. Another characteristic form of sensory loss affects the trunk, scalp, and face; this is the pattern of a sensory ganglionopathy that is the result of simultaneous dysfunction of all parts of the sensory nerve.

Most often, *universal sensory loss* is attributable to an acquired disease affecting the sensory ganglia (sensory neuronopathy); a paraneoplastic process, certain toxic or immune diseases are usually responsible (e.g., Sjögren disease, scleroderma).

Paresthesias, Pain, and Dysesthesias

These symptoms were described in Chaps. 8 and 9. Sensory symptoms tend to be especially marked in the hands and feet. "Pins and needles," "falling asleep," "stabbing," "tingling," "prickling," "electrical," and "Novocain-like" are the adjectives chosen by patients to describe these positive sensory experiences. In some neuropathies, paresthesias and numbness are the only symptoms and objective sensory loss is lacking or minimal. Certain neuropathies characteristically cause pain, which is described as burning, aching, sharp and cutting, or crushing and at times may resemble the lightning pains of tabes dorsalis. Perversion of sensation (allodynia) is also commonplace in some polyneuropathies—e.g., tingling, burning, stabbing pain, or just an uncomfortable dysesthesia is induced by tactile stimuli. Under these conditions a stimulus induces not only an aberrant sensation but also one that radiates to adjacent areas and persists after the stimulus is withdrawn. As remarked in Chap. 9, the reactions of a patient with allodynia may seem to indicate hypersensitivity ("hyperesthesia"), but more often the sensory threshold is actually raised and it is the sensory experience or response that is exaggerated (*hyperpathia*).

Painful paresthesias and dysesthesias are particularly common in diabetic, alcoholic-nutritional, and amyloid neuropathies. Mainly they affect the feet ("burning feet") and less often the hands. In herpes zoster, they are confined to dermatomal regions of the body. A particularly intense form of burning pain typifies the *causalgia* of a partial nerve lesion (usually traumatic) of the ulnar, median, posterior tibial, peroneal, or occasionally some other nerve (see Chap. 8 and further on in this chapter).

The mechanism of thermal and painful dysesthesias is not fully understood. It has been theorized that a loss of large touch-pressure fibers disinhibits the pain-receiving nerve cells in the posterior horns of the spinal cord. An argument against this explanation is the lack of pain in Friedreich ataxia, in which the larger neurons degenerate, and also in certain purely sensory polyneuropathies, where only the perception of tactile stimuli (large fibers)

is lost. A more likely explanation, supported by micro-neurographic recordings, is that dysesthetic pain results from ectopic discharges arising at many sites along surviving intact or regenerating nerve fibers or their terminal receptors. It has been postulated, on uncertain grounds, that the deep, aching neuropathic pain of sciatica or brachial neuritis (nerve trunk pain) arises from irritation of the normal endings (*nervi nervorum*) in the sheaths of the nerve trunks themselves (Asbury and Fields). These considerations are discussed in Chap. 8.

Sensory Ataxia and Tremor

Proprioceptive deafferentation with retention of a reasonable degree of motor function may give rise to ataxia of gait and of limb movement as discussed in Chap. 9. Dysfunction of the spinocerebellar fibers of the peripheral nerves is probably the source of the ataxia. Some of the most severe ataxias of this type occur with sensory ganglionopathy, as commented further on.

Ataxia without weakness is also characteristic of *tabes dorsalis*, a purely posterior root disease, but this syndrome is duplicated by diabetic polyneuropathy, which may affect posterior roots (diabetic pseudotabes) and by a variant of GBS (termed Fisher syndrome). The ataxia is indistinguishable from that caused by cerebellar diseases, but other features of cerebellar dysfunction such as dysarthria and nystagmus are lacking. Characteristic of the sensory-ataxic gait are brusque, flinging, slapping movements of the legs. Loss of proprioception may also give rise to small wavering, fluctuating movements of the outstretched fingers—called *pseudoathetotic*, or “dancing fingers.”

An action tremor of fast-frequency type may also appear during certain phases of a polyneuropathy; Shahani and coworkers had the impression that it is a result of loss of input from the muscle-spindle afferents. Corticosteroid therapy enhances this fast tremor. A particularly severe form of slower action tremor is combined with clumsiness of movement in the neuropathies caused by the autoimmune, anti-myelin-associated glycoprotein (anti-MAG) polyneuropathy and in some cases of chronic inflammatory demyelinating polyneuropathy (CIDP). The tremor may be so coarse as to resemble the intention tremor of cerebellar disease and all movements are rendered useless. However, a tremor at rest is not found in these afferent-sensory neuropathies. The neuropathic type of tremor is also discussed in Chap. 6.

Deformity and Trophic Changes

In a few of the chronic polyneuropathies, the feet, hands, and even the spine may become progressively deformed. This is most likely to occur when the disease begins during childhood. Austin pointed out that foot deformity is found in 30 percent of patients with hereditary polyneuropathy, and spine curvature is found in 20 percent. In early life, the feet are pulled into a position of talipes equinus (plantar deviation) because of disproportionate weakness of the pretibial and peroneal muscles and the unopposed action of the calf muscles. Weakness of the intrinsic foot muscles during the period of life when the bones are

forming allows the long extensors of the toes to dorsiflex the proximal phalanges and the long flexors to shorten the foot, heighten the arch, and flex the distal phalanges. The result is the *claw foot*—*le pied en griffe*—or *pes cavus* (high arches) when the process is less severe. These changes in the structure of the foot are valuable diagnostic indicators that a neuromuscular disease originated in early childhood or during intrauterine development. A congenital claw hand has a similar implication. Unequal weakening of the paravertebral muscles on the two sides of the spine during early development leads to kyphoscoliosis.

Denervation atrophy of muscle can be considered the main trophic disturbance resulting from interruption of the motor nerves. However, there are numerous other changes. Analgesia of distal limb parts makes them susceptible to burns, pressure sores, and other forms of injury that are easily infected and heal poorly. In an anesthetic and immobile limb, the skin becomes tight and shiny, the nails curved and ridged, and the subcutaneous tissue thickened (“trophic changes”). Hair growth is diminished in denervated areas. If the autonomic fibers are also interrupted, the limb becomes warm and pink. Repeated injuries and chronic subcutaneous and osteomyelitic infections result in a painless loss of digits and the formation of plantar ulcers (*mal perforant du pied*). These are prominent features of the recessive form of hereditary sensory neuropathy and we have observed them in dominant forms as well. In *tabes dorsalis* and syringomyelia as well as certain familial and other chronic polyneuropathies analgesic joints, when chronically traumatized, may first become deformed and then actually disintegrate in a process called Charcot arthropathy (“Charcot joint”).

Apart from analgesia, a critical factor in these trophic changes may be aberrant neural regulation of the distal vasculature, which interferes with normal tissue responses to trauma and infection. Ali and colleagues have related the ulcer formation to loss of C fibers, which mediate both pain and autonomic reflexes. However, paralyzed limbs, even in hysteria, if left dependent, are often cold, swollen, and pale or blue. These are probably secondary effects of immobilization, as pointed out long ago by Lewis and Pickering. Erythema and edema, burning pain, and cold sensations surely can be evoked by peripheral nerve irritation, particularly of C and A- δ fibers as discussed in Chap. 8.

Autonomic Dysfunction

Anhidrosis and orthostatic hypotension, two of the most frequent manifestations of autonomic failure, predominate in certain types of polyneuropathies. They occur frequently in amyloidosis and in other small-fiber polyneuropathies, especially diabetic, and in several congenital types. These are also the main features of an acute autonomic polyneuropathy called *pandysautonomia* (Young et al; Adams et al; Low et al) and can be prominent in some cases of GBS. The neuropathic dysautonomic conditions are described in detail in Chap. 26 and later in this chapter.

Other manifestations of autonomic paralysis are small or medium-sized unreactive pupils that are unusually sensitive to certain drugs (see Chap. 14); lack of sweat,

tears, and saliva; erectile dysfunction; weak bowel and bladder sphincters with urinary retention or overflow incontinence; and weakness and dilation of the esophagus and colon. As a result of vagal and other parasympathetic dysfunction, the normal variability of heart rate with respiration (sinus arrhythmia) is lost and there may be paralytic ileus or dyscoordinated peristalsis, as well as achlorhydria and hyponatremia. Some of these abnormalities are found in diabetic and amyloid polyneuropathy. They correspond to degeneration of small unmyelinated autonomic fibers in the peripheral nerves.

In any neuropathy involving sensory nerves, there is loss of autonomic function in the same zones as sensory loss. *This is not true of radicular diseases* because the autonomic fibers join the spinal nerves from the sympathetic chain and parasympathetic ganglia more distally. Changes in sweating and cutaneous blood flow may be demonstrated by a number of special tests described in Chap. 26.

Fasciculations, Cramps, and Spasms (See also Chap. 48)

Fasciculations and cramps are not prominent features in most polyneuropathies and in this respect there is a difference from diseases of the anterior horn cells where they are important features. There are exceptions, however. Chronic spinal motor root compression leads to fasciculations or painful spasms in the innervated muscles. Occasionally one observes a state of mild motor polyneuropathy that, upon recovery, leaves the muscles in a state variably referred to as myokymia, continuous muscular activity, and neuromyotonia as discussed in Chaps. 45 and 50. The affected muscles ripple and quiver and occasionally cramp. Use of the muscles increases this activity and there is a reduction in their contractile efficiency, which the patient senses as a stiffness and heaviness. In some instances this apparently constitutes the entire neuropathic syndrome and may be relieved by carbamazepine or phenytoin.

Other closely related phenomena are spasms or involuntary movements of the toes and feet. The latter, when the sole manifestation of disease, was referred to by Spillane and colleagues as the syndrome of *painful legs and moving toes*. It has been attributed by Nathan to ectopic discharges in sensory roots, ganglia, or nerves, evoking both pain and organized movements. This is but one of many causes of the nocturnal restless leg syndrome, but it does not explain the more common type of idiopathic restless leg nocturnal syndrome described in Chap. 19. Other possible mechanisms for cramps and spasms are ephaptic cross-transmission between adjacent axons denuded of myelin, segmental hyperactivity from deafferentation, and neuronal sprouting during reinnervation. Infrequently, the muscle activity induces odd postures or slow writhing movements that Jankovic and van der Linden have likened to dystonia. The pathophysiology of these asynchronous activities of motor neurons is not known. Stimulation of a motor nerve in these cases, instead of causing a brief burst of action potentials in the muscle, results in a prolonged or dispersed

series of potentials lasting several hundred milliseconds. Evidently, branched axons involved in collateral innervation have unstable polarization that may last for years.

APPROACH TO THE PATIENT WITH PERIPHERAL NEUROPATHY

The clinician is faced initially with several problems that can be solved sequentially when dealing with this group of diseases: (1) establishing the existence of disease of the peripheral nervous system and differentiating it from a process of the central nervous system, neuromuscular junction or the muscles; (2) distinguishing by clinical examination which of the main topographic syndromes it being displayed; (3) determining by examination and nerve conduction studies) if the problem is predominantly of a motor or sensory or autonomic in nature or is of mixed type and whether the myelin sheath, the axon, or cell body (motor or sensory neurons) is the target of disease; and (4) assessing if the neuropathy is acquired or hereditary in nature. When taken together, these features limit the likely etiologic diagnoses from a vast list of possibilities.

Topographic and Clinical Patterns of Neuropathy (Table 46-1)

At the outset it must be determined whether the neurologic findings correspond to one of the following syndromic patterns:

1. Polyneuropathy
2. Radiculopathy or polyradiculopathy
3. Neuronopathy—motor or sensory
4. Mononeuropathy
5. Multiple mononeuropathies (mononeuropathy multiplex)
6. Plexopathy (involvement of multiple nerves in a plexus)

A discussion of these patterns is given in Chap. 9, but the main facts are repeated here.

In *polyneuropathy*, a generalized process affecting the peripheral nerves, weakness is relatively symmetrical from the beginning and progresses bilaterally; reflexes are lost in affected parts but particularly at the ankles; sensory complaints and loss of sensation are most pronounced distally, and in the feet before the hands in most cases.

Polyradiculopathy, a disease of multiple spinal roots, differs from polyneuropathy in that the neurologic signs are asymmetrical, with an erratic distribution that may, for example, be proximal in one limb and distal in another. Weakness and zones of sensory loss correspond to involvement of one or more spinal or cranial roots. Pain in the sensory distribution of the roots is a common feature. The common *single radiculopathy*, most often the result of root compression by disease of the spinal column, is identified by pain, sensory, motor, and reflex change solely in the distribution of one nerve root. The distinction from mononeuropathy (see later) is not always apparent and one must resort to a reference or to memorized knowledge of the motor and sensory innervation patterns

Table 46-1

ACTIONS OF THE PRINCIPAL MUSCLES AND THEIR NERVE ROOT SUPPLY

ACTION TESTED	ROOTS*	NERVES	MUSCLES
Cranial			
Closure of eyes, pursing of lips, exposure of teeth	Cranial 7	Facial	Orbicularis oculi Orbicularis oris
Elevation of eyelids, movement of eyes	Cranial 3, 4, 6	Oculomotor, trochlear, abducens	Levator palpebrae, extraocular
Closing and opening of jaw	Cranial 5	Motor trigeminal	Masseters Pterygoids
Protrusion of tongue	Cranial 12	Hypoglossal	Lingual
Phonation and swallowing	Cranial 9, 10	Glossopharyngeal, vagus	Palatal, laryngeal, and pharyngeal
Elevation of shoulders, anteroflexion and turning of head	Cranial 11 and upper cervical	Spinal accessory	Trapezius, sternomastoid
Brachial			
Adduction of extended arm	C5, C6	Brachial plexus	Pectoralis major
Fixation of scapula	C5, C6, C7	Brachial plexus	Serratus anterior
Initiation of abduction of arm	C5, C6	Brachial plexus	Supraspinatus
External rotation of flexed arm	C5, C6	Brachial plexus	Infraspinatus
Abduction and elevation of arm up to 90°	C5, C6	Axillary nerve	Deltoid
Flexion of supinated forearm	C5, C6	Musculocutaneous	Biceps, brachialis
Extension of forearm	C6, C7, C8	Radial	Triceps
Extension (radial) of wrist	C6	Radial	Extensor carpi radialis longus
Flexion of semipronated arm	C5, C6	Radial	Brachioradialis
Adduction of flexed arm	C6, C7, C8	Brachial plexus	Latissimus dorsi
Supination of forearm	C6, C7	Posterior interosseous	Supinator
Extension of proximal phalanges	C7, C8	Posterior interosseous	Extensor digitorum
Extension of wrist (ulnar side)	C7, C8	Posterior interosseous	Extensor carpi ulnaris
Extension of proximal phalanx of index finger	C7, C8	Posterior interosseous	Extensor indicis
Abduction of thumb	C7, C8	Posterior interosseous	Abductor pollicis longus and brevis
Extension of thumb	C7, C8	Posterior interosseous	Extensor pollicis longus and brevis
Pronation of forearm	C6, C7	Median nerve	Pronator teres
Radial flexion of wrist	C6, C7	Median nerve	Flexor carpi radialis
Flexion of middle phalanges	C7, C8, T1	Median nerve	Flexor digitorum superficialis
Flexion of proximal phalanx of thumb	C8, T1	Median nerve	Flexor pollicis brevis
Opposition of thumb against fifth finger	C8, T1	Median nerve	Opponens pollicis
Extension of middle phalanges of index and middle fingers	C8, T1	Median nerve	First, second lumbricals
Flexion of terminal phalanx of thumb	C8, T1	Anterior interosseous nerve	Flexor pollicis longus
Flexion of terminal phalanx of second and third fingers	C8, T1	Anterior interosseous nerve	Flexor digitorum profundus
Flexion of distal phalanges of ring and little fingers	C7, C8	Ulnar	Flexor digitorum profundus
Adduction and opposition of fifth finger	C8, T1	Ulnar	Hypothenar
Extension of middle phalanges of ring and little fingers	C8, T1	Ulnar	Third, fourth lumbricals
Adduction of thumb against second finger	C8, T1	Ulnar	Adductor pollicis
Flexion of proximal phalanx of thumb	C8, T1	Ulnar	Flexor pollicis brevis
Abduction and adduction of fingers	C8, T1	Ulnar	Interossei

Table 46-1

ACTIONS OF THE PRINCIPAL MUSCLES AND THEIR NERVE ROOT SUPPLY (CONTINUED)

ACTION TESTED	ROOTS*	NERVES	MUSCLES
Crural			
Hip flexion from semiflexed position	L1, L2, L3	Femoral	Iliopsoas
Hip flexion from externally rotated position	L2, L3	Femoral	Sartorius
Extension of knee	L2, L3, L4	Femoral	Quadriceps femoris
Adduction of thigh	L2, L3, L4	Obturator	Adductor longus, magnus, brevis
Abduction and internal rotation of thigh	L4, L5, S1	Superior gluteal	Gluteus medius
Extension of thigh	L5, S1, S2	Inferior gluteal	Gluteus maximus
Flexion of knee	L5, S1, S2	Sciatic	Biceps femoris Semitendinosus Semimembranosus
Dorsiflexion of foot (medial)	L4, L5	Peroneal (deep)	Anterior tibial
Dorsiflexion of toes (proximal and distal phalanges)	L5, S1	Peroneal (deep)	Extensor digitorum longus and brevis
Dorsiflexion of great toe	L5, S1	Peroneal (deep)	Extensor hallucis longus
Eversion of foot	L5, S1	Peroneal (superficial)	Peroneus longus and brevis
Plantar flexion of foot	S1, S2	Tibial	Gastrocnemius, soleus
Inversion of foot	L4, L5	Tibial	Tibialis posterior
Flexion of toes (distal phalanges)	L5, S1, S2	Tibial	Flexor digitorum longus
Flexion of toes (middle phalanges)	S1, S2	Tibial	Flexor digitorum brevis
Flexion of great toe (proximal phalanx)	S1, S2	Tibial	Flexor hallucis brevis
Flexion of great toe (distal phalanx)	L5, S1, S2	Tibial	Flexor hallucis longus
Contraction of anal sphincter	S2, S3, S4	Pudendal	Perineal muscles

*Predominant root(s) supplying a particular muscle are indicated in bold italic type.

of roots and nerves as given in Figs. 9-1, 9-2, and 9-3 and on the overleaves. Most helpful is the limitation of sensory loss to one of the dermatomes, but it so happens that there is overlap between adjacent dermatomes and such a pattern is not easily discerned.

Mononeuropathy is the most circumscribed form of peripheral nerve disease. It is reflected by weakness and sensory loss in the territory of a single peripheral nerve. Specific features serve to differentiate mononeuropathy from a radiculopathy—for example, weakness in dorsiflexion and eversion of the foot is referable either to the peroneal nerve or to the L5 nerve root; however, if there is weakness of inversion of the foot, innervated by the tibial nerve, the fault must be with the L5 root, not with the peroneal nerve. Conversely, if inversion is spared in a foot drop, the lesion is in the peroneal nerve. The distribution of sensory loss also aids in distinguishing the two processes; for example, in the aforementioned case the region of sensory change corresponding to the L5 root extends almost up to the knee on the anterior surface of the foreleg whereas it ends a limited distance above the ankle in the case of a peroneal nerve lesion (see the sensory maps in Figs. 9-1, 9-2, and 9-3).

At times, particularly in advanced stages, the accumulation of multiple mononeuropathies, termed *mononeuropathy multiplex*, may be difficult to differentiate from polyneuropathy as discussed further on.

Plexopathies (brachial or lumbosacral) create the most confusing patterns of motor and sensory involvement; only one limb is affected, but the motor, sensory, and reflex loss does not conform to a pattern of several adjacent nerve roots or nerves. Knowledge of the innervation of the involved muscles at the level of the plexus usually clarifies the situation.

In *sensory neuropathy*, the ganglion cells rather than the peripheral sensory nerves are predominantly affected. This gives rise to symptoms and signs of sensory loss in both a proximal and distal distribution, including the scalp, thorax, abdomen, and buttocks as well as the extremities; sensory ataxia is a common accompaniment. There is no weakness, but movements may be awkward as a result of a sensory ataxia. *Motor neuropathy* is essentially the obverse condition, a disorder of the anterior horn causing weakness, fasciculations, and atrophy in a widespread distribution and, therefore, not properly included as a process of the peripheral nerves.

The apparent complexity of peripheral nerve disease is greatly simplified by recognizing that, of the multitude of diseases, each manifests itself by one or another of above-described topographic and sensory-motor patterns for which reason *the pattern of neuropathy sets limits on the etiologic possibilities*.

In the analysis of a *polyneuropathy*, it is of further value to determine whether the process is predominantly motor with less sensory involvement or the converse, or purely sensory, motor, or mainly autonomic. The *time course* of the disease also informs diagnosis. An acute onset (i.e., rapid evolution) is nearly always an inflammatory, immunologic, toxic, or vascular polyneuropathy. The other extreme, a polyneuropathy evolving over many years, is indicative of a hereditary or, rarely, a metabolic disease. Most of the toxic, nutritional, and systemic diseases of nerve develop subacutely over several weeks and months. In addition to the patient's report of the progress of symptoms, signs such as muscle atrophy signify a process of relatively long-standing, at least several months in duration.

The etiologic diagnosis of polyneuropathy is next guided by deducing whether the myelin sheath or the axon is primarily involved (i.e., *demyelinating* or *axonal neuropathy*). The neurologic examination alone may be sufficient to make this distinction, but greater precision is attained from nerve conduction studies and needle examination of muscles (EMG). The latter test also helps separate primary disorders of muscle (myopathies) and neurogenic denervation of muscle or neuromuscular block (myasthenia). The electrical examinations of nerve and muscle described in Chap. 45 greatly reduce the number of possible diagnoses. These EMG and nerve conduction abnormalities may be so characteristic as

to virtually define a neuropathy, e.g., chronic demyelinating motor neuropathy with multifocal conduction block.

Other useful laboratory procedures are (1) biochemical tests to identify metabolic, nutritional, or toxic states; (2) CSF examination (increase in protein and in cells that indicate radicular or meningeal involvement); (3) nerve, and occasionally accompanying muscle biopsy (the latter aids in the diagnosis of vasculitic causes of neuropathy); (4) measurement of immunoglobulins and antineural antibodies that relate to immune-mediated neuropathies; and (5) genetic testing for several of the inherited neuropathies. These are discussed in the context of each of the main diseases of nerve and in the later parts of Chap. 45.

Once having established that the patient has a disease of the peripheral nerves and having ascertained its clinical and electrophysiologic pattern and time course, one is usually able to determine its cause. This is accomplished most readily by allocating the case in question to one of the categories listed in Table 46-2, which classifies the peripheral nerve diseases syndromically according to their mode of evolution and clinical presentation. Our use of the terms *acute*, *subacute*, and *chronic* neuropathy must be explained. By *acute*, we mean evolution in terms of days, and by *subacute*, evolution in terms of weeks. *Chronic* is divided into two groups: one in which the neuropathy has progressed for a period of several months

Table 46-2

THE PRINCIPAL NEUROPATHIC SYNDROMES AND THEIR CAUSES

- I. Syndrome of acute motor paralysis with variable disturbance of sensory and autonomic function
 - A. Guillain-Barré syndrome (GBS; acute inflammatory demyelinating polyneuropathy [AIDP]); see also Table 46-3
 - B. Acute axonal form of GBS (AMAN)
 - C. Acute sensory neuropathy and neuronopathy syndrome
 - D. Diphtheritic polyneuropathy
 - E. Porphyric polyneuropathy
 - F. Certain toxic polyneuropathies (thallium, triorthocresyl phosphate)
 - G. Rarely, paraneoplastic
 - H. Acute pandysautonomic neuropathy
 - I. Tick paralysis
 - J. Critical illness polyneuropathy
- II. Syndrome of subacute sensorimotor paralysis
 - A. Symmetrical polyneuropathies
 1. Deficiency states: alcoholism (beriberi), pellagra, vitamin B₁₂ deficiency, chronic gastrointestinal disease (see Chap. 41)
 2. Poisoning with heavy metals and solvents: arsenic, lead, mercury, thallium, methyl *n*-butyl ketone, *n*-hexane, methyl bromide, ethylene oxide, organophosphates (TOCP, etc.), acrylamide (see Chap. 43)
 3. Drug toxicity: isoniazid, ethionamide, hydralazine, nitrofurantoin and related nitrofurazones, disulfiram, carbon disulfide, vincristine, cisplatin, paclitaxel, chloramphenicol, phenytoin, pyridoxine, amitriptyline, dapsone, stilbamidine, trichloroethylene, thalidomide, cloquinoxol, amidarone, adulterated agents such as L-tryptophan
 4. Uremic polyneuropathy (see Chap. 40)
 5. Subacute inflammatory polyneuropathy
 6. Paraneoplastic polyneuropathy
 7. HIV
 - B. Asymmetrical neuropathies (mononeuropathy multiplex)
 1. Diabetes
 2. Polyarteritis nodosa and other inflammatory angiopathic neuropathies (Churg-Strauss, hypereosinophilic, rheumatoid, lupus, Wegener granulomatosis, isolated peripheral nervous system vasculitis); see also Table 46-3
 3. Mixed cryoglobulinemia

(Continued)

Table 46-2

THE PRINCIPAL NEUROPATHIC SYNDROMES AND THEIR CAUSES (CONTINUED)

4. Sjögren-sicca syndrome
5. Sarcoidosis
6. Ischemic neuropathy with peripheral vascular disease
7. Lyme disease
8. HIV
9. Diabetes
10. Multifocal motor neuropathy (MMN)
11. Multifocal conduction block (MADSAM)
- C. Unusual sensory neuropathies
 1. Wartenberg migrant sensory neuropathy
 2. Sensory perineuritis
- D. Meningeal based nerve root disease (polyradiculopathy)
 1. Neoplastic infiltration
 2. Granulomatous and infectious infiltration: Lyme, sarcoidosis
 3. Spinal diseases: osteoarthritic spondylitis
 4. Idiopathic polyradiculopathy
- III. Syndrome of early chronic sensorimotor polyneuropathy
 - A. Paraneoplastic: carcinoma, lymphoma, myeloma, and other malignancies
 - B. Chronic inflammatory demyelinating polyneuropathy (CIDP)
 - C. Paraproteinemias
 - D. Uremia (occasionally subacute)
 - E. Nutritional beriberi (usually subacute)
 - F. Diabetes
 - G. Connective tissue diseases
 - H. Amyloidosis
 - I. Leprosy
 - J. Hypothyroidism
 - K. Benign sensory form in the elderly
- IV. Syndrome of more chronic (late) polyneuropathy, genetically determined forms (see Table 46-6)
 - A. Inherited polyneuropathies of predominantly sensory type
 1. Dominant mutilating sensory neuropathy in adults
 2. Recessive mutilating sensory neuropathy of childhood
 3. Congenital insensitivity to pain
 4. Other inherited sensory neuropathies, including those associated with spinocerebellar degenerations, Riley-Day syndrome, and the universal anesthesia syndrome
 - B. Inherited polyneuropathies of mixed sensorimotor types
 1. Peroneal muscular atrophy (Charcot-Marie-Tooth; CMT types 1 [demyelinating] and 2 [axonal] and CMTX [X-linked])
 2. Hypertrophic polyneuropathy of Dejerine-Sottas, adult and childhood forms (CMT3)
 3. Roussy-Lévy polyneuropathy
 4. Polyneuropathy with optic atrophy, spastic paraplegia, spinocerebellar degeneration, or dementia
 5. Hereditary liability to pressure palsy (HNPP)
 - C. Inherited polyneuropathies with a recognized metabolic disorder (see Chap. 37)
 1. Refsum disease
 2. Metachromatic leukodystrophy
 3. Globoid-body leukodystrophy (Krabbe disease)
 4. Adrenoleukodystrophy
 5. Amyloid polyneuropathy
 6. Porphyric polyneuropathy
 7. Anderson-Fabry disease
 8. Abetalipoproteinemia (Bassen-Kornzweig)
 9. Tangier disease
- V. Neuropathy associated with mitochondrial diseases (see Chap. 37)
- VI. Syndrome of recurrent or relapsing polyneuropathy
 - A. Porphyria
 - B. Chronic inflammatory demyelinating polyneuropathy
 - C. Certain forms of mononeuritis multiplex
 - D. Beriberi or intoxications
 - E. Refsum disease
 - F. Tangier disease
 - G. Repeated toxic exposures
- VII. Syndrome of mononeuropathy or plexopathy
 - A. Brachial plexus neuropathies
 - B. Brachial mononeuropathies

Table 46-2

THE PRINCIPAL NEUROPATHIC SYNDROMES AND THEIR CAUSES (CONTINUED)

- D. Lumbosacral plexopathies
- E. Crural mononeuropathies
- F. Migrant sensory neuropathy
- G. Entrapment neuropathies

to a few years and another in which progression is over many years, most of which prove to have a genetic cause. It can be restated that these temporal properties are, with the topographic pattern, the main determinants in the categorization of neuropathy.

Diseases of the peripheral nerves are considered in a more comprehensive fashion in the two-volume *Peripheral Neuropathy*, edited by Dyck and colleagues and in the text by Amato and Russell cited in the references. Also recommended are more concise monographs by Schaumburg and associates and by Asbury and Thomas, and the atlas on the pathology of peripheral nerve by King.

SYNDROME OF ACUTE MOTOR PARALYSIS WITH VARIABLE DISTURBANCE OF SENSORY AND AUTONOMIC FUNCTION

A number of differences separate the polyneuropathies in this category: (1) acute inflammatory demyelinating or axonal polyneuropathy (GBS), (2) vasculitic polyneuropathies, (3) porphyria, (4) certain toxic polyneuropathies, and (5) acute sensory and autonomic polyneuropathies. Of these various acute polyneuropathic diseases, the Guillain-Barré demyelinating syndrome, because of its frequency and gravity, is most demanding of the physician's attention.

Guillain-Barré Syndrome (Landry-Guillain-Barré-Strohl Syndrome, Acute Inflammatory Demyelinating Polyneuropathy, AIDP)

This is the most common cause of acute or subacute generalized paralysis in practice. (During certain past epochs it was exceeded in frequency by polio.) GBS occurs in all parts of the world and in all seasons, affecting children and adults of all ages and both sexes. A mild respiratory or gastrointestinal infection or immunization precedes the neuropathic symptoms by 1 to 3 weeks in approximately 60 percent of cases. Typical is a nondescript upper respiratory infection, but almost every known febrile infection and immunization has at one time or another been reported to precede GBS (some probably coincidentally). In recent years, it has been appreciated from serologic studies that the enteric organism *Campylobacter jejuni* is the most frequent identifiable antecedent infection, but it accounts for only a relatively limited proportion of cases. Other common antecedent

events or associated illnesses include viral exanths in children and numerous other viral illnesses in adults and children, particularly the large viruses of the herpes family (cytomegalovirus [CMV], Epstein-Barr virus [EBV], HIV), and less often, bacterial infections other than *Campylobacter* (*Mycoplasma pneumoniae*, Lyme disease). There are less certain associations with lymphoma (particularly Hodgkin disease) and with the systemic autoimmune diseases.

Historical Background

The earliest description of an afebrile generalized paralysis is probably that of Wardrop and Ollivier, in 1834. Important landmarks were Landry's report (1859) of an acute, ascending, predominantly motor paralysis with respiratory failure leading to death among peasants on his land; Osler's (1892) description of "febrile polyneuritis"; and the account by Guillain, Barré, and Strohl (1916) of a benign polyneuritis with albuminocytologic dissociation in the CSF (increase in protein without cells). The first comprehensive account of the pathology of GBS was that of Haymaker and Kernohan (1949), who stressed that edema of the nerve roots was an important change in the early stages of the disease. Subsequently, Asbury and colleagues (1969) established that the essential lesion, from the beginning of the disease, was perivascular mononuclear inflammatory infiltration of the roots and nerves. More recently, it has been found that complement deposition on the myelin surface may be the earliest immunologic event. For details of the historical and other aspects of this disease, see the monographs by Ropper and colleagues (1991) and by Hughes (1990).

Incidence

The incidence rate of GBS has varied between 0.4 and 1.7 cases per 100,000 persons per year; the median taken from several studies is 1.1 and may be most dependable. It is generally a nonseasonal and nonepidemic disease, but outbreaks have been recorded in rural China following exposure of children to *C. jejuni* through chicken feces deposited in rice paddies. Women appear to be slightly more susceptible. The age range in our series has been 8 months to 81 years, with attack rates highest in persons 50 to 74 years of age. Cases are known in infants and in the very aged.

In addition to a seasonal increase in incidence after natural influenza outbreaks, the administration of the A/New Jersey (swine) influenza vaccine, given in the United States in late 1976, brought attention to a slight increase in the incidence of GBS and several, but

not most subsequent influenza vaccination programs have been associated with a marginal increase in cases. Representative was the widely publicized worldwide H1N1 vaccination program that was studied in Quebec, where the calculated risk of developing GBS after vaccination was in the range 2 cases per 1 million doses of vaccine, barely above the baseline rate and appearing mostly in individuals over 50 years (De Wals et al). GBS appears in temporal relationship to almost all other vaccinations, but the association in these instances may be idiosyncratic and infrequent. Trauma and surgical operations may precede the neuropathy, but a causal association to them also remains uncertain.

Symptomatology

The typical case is readily identified. Paresthesias and slight numbness in the toes and fingers are the earliest symptoms; only infrequently are they absent throughout the illness. The major clinical manifestation is weakness that evolves more or less symmetrically over a period of several days to a week or two, or somewhat longer. The proximal as well as distal muscles of the limbs are involved, usually the lower extremities before the upper (thus the older term *Landry ascending paralysis*); the trunk, intercostal, neck, and cranial muscles may be affected later. Weakness progresses in approximately 5 percent of patients to total motor paralysis with respiratory failure within a few days. In severe cases, the ocular motor nerves are paralyzed and even the pupils may be unreactive.

More than half of the patients complain of pain and an aching discomfort in the muscles, mainly those of the hips, thighs, and back. These symptoms precede weakness and may be mistaken for lumbar disc disease, back strain, and orthopedic diseases. A few patients describe burning in the fingers and toes, and if this appears as an early symptom, it may become a persistent problem. Sensory loss is variable during the first days and may initially be barely detectable so that the typical case has the character of a predominantly motor neuropathy. By the end of a week, vibration and joint position sense in the toes and fingers are usually reduced; when such loss is present, deep sensibility (touch-pressure-vibration) tends to be more affected than superficial (pain-temperature).

Reduced and then absent tendon reflexes are consistent findings. Only the ankle reflexes may be lost during the first week of illness. At an early stage, the arm muscles are usually stronger than the leg muscles, and in a few cases, they are spared almost entirely. Facial diplegia occurs in more than half, sometimes bilaterally at the same time or sequentially over days. Other cranial nerve palsies, if they occur, usually come later, after the arms and face are affected; they are the initial signs in a variant pattern of disease as described further on. At the onset, there is no fever, and if lymphadenopathy or splenomegaly occurs, they are related to a preceding viral infection.

Disturbances of autonomic function include sinus tachycardia and, less often, bradycardia, facial flushing, fluctuating hypertension and hypotension, loss of sweating,

or episodic profuse diaphoresis; one or more are common in minor form and infrequently do they become pronounced or persist for more than a week. Urinary retention occurs in approximately 15 percent of patients soon after the onset of weakness, but catheterization is seldom required for more than a few days. Numerous medical complications follow in severe cases as a result of immobilization and respiratory failure, as discussed further on under "Treatment."

The archetypical illness described in the preceding paragraphs is typically a result of the widespread inflammatory-demyelinating process within peripheral nerves. This is contrasted with an axonal form of GBS described just below.

Acute Axonal Form of Guillain-Barré Syndrome

Attention was drawn by Feasby and colleagues (1986) to an acute areflexic polyneuropathy clinically similar to typical GBS but characterized pathologically by widespread and severe axonal degeneration. In their initial report they described 5 patients with a rapid evolution of polyneuropathy and slow and poor recovery. Unlike the common form of demyelinating GBS, muscle atrophy became apparent relatively early in the axonal form (within weeks). The defining feature was the presence of numerous electrically inexcitable motor nerves and signs of extensive denervation. This finding could also signify a distal demyelinating block from which complete recovery is possible (Triggs et al). Nevertheless, most cases of abrupt and severe denervating paralysis, particularly if postinfectious, are caused by the axonal form of GBS (Ropper, 1986b).

Postmortem examinations have disclosed severe axonal degeneration in nerves and roots with minimal inflammatory changes and little demyelination, even early in the disease. Based on the deposits of complement and the presence of macrophages in the periaxonal space, a humoral antibody directed against some component of the axolemma was postulated by Griffin and associates (1995). Visser and colleagues reported similar findings in a series of acute motor polyneuropathies. The outbreaks of motor neuropathy that occur seasonally in rural China have many of the same characteristics. These cases appear to be triggered largely by *C. jejuni* infections. Some, but not all, sporadic instances of acute axonal GBS have been preceded by the same infection. It is noteworthy that infection with the same bacteria can also induce a typical demyelinating form of GBS.

A proportion of axonal cases, perhaps up to one-fifth, are associated with circulating antibodies to the G_{M1} ganglioside of peripheral nerve, and some of these reflect recently preceding infection with *C. jejuni*. The acronyms AMAN (acute motor) and AMSAN (acute motor-sensory axonal neuropathy) are equivalents to axonal GBS. Another variant of this illness, of which we have seen several instances, has been an acute multifocal neuropathy with electrophysiologic motor conduction block that leaves the reflexes unaltered and has high titers of anti-G_{M1} antibody (Capasso et al). Most experience with the generalized axonal form of GBS indicates that recovery is prolonged and incomplete.

Table 46-3

VARIANTS OF GUILLAIN-BARRÉ SYNDROME

Regional

Fisher syndrome of ophthalmoplegia, ataxia, and areflexia
 Cervico-brachial-pharyngeal weakness, often with ptosis
 Oculopharyngeal weakness
 Predominant paraparesis
 Bilateral facial or abducens weakness with distal paresthesias
 Ophthalmoplegia with GQ₁b autoantibodies

System specific

Generalized ataxia without dysarthria or nystagmus
 Pure sensory
 Pure motor
 Pandysautonomia
 Axonal (AMAN)

Variants of Guillain-Barré Syndrome

(Table 46-3)

Portions of the clinical picture of GBS appear in isolated or abortive form and are a source of diagnostic confusion. Whereas in most patients the paralysis ascends from legs to trunk, to arms, and then to cranial regions, and reaches a peak of severity within 10 to 14 days, the *pharyngeal-cervical-brachial* muscles may be affected first or constitute the entire illness, causing difficulty in swallowing with neck and proximal arm weakness (Ropper, 1986a). Ptosis, often with ophthalmoplegia, may be added. The differential diagnosis then includes myasthenia gravis, diphtheria, and botulism and a lesion affecting the central portion of the cervical spinal cord and lower brainstem.

A syndrome comprising virtual or *complete ophthalmoplegia with ataxia* and areflexia represents a variant of GBS described by Fisher (and is called *Fisher syndrome*). A *purely ophthalmoplegic* form also exists; it may be coupled with the pharyngeal-cervical-brachial pattern mentioned earlier. Ophthalmoplegia, whether occurring alone or with weakness or ataxia of other parts, is almost uniformly associated with a specific antineural antibody, anti-GQ₁b. The ophthalmoplegic pattern raises the diagnostic possibilities of myasthenia gravis, botulism, diphtheria, tick paralysis, and basilar artery occlusion. Bilateral but asymmetrical facial and abducens weakness coupled with distal paresthesias or with proximal leg weakness is other variants in our experience (Ropper, 1994). The tendon reflexes may be absent only at the ankles or at the knees. Lyme disease and sarcoidosis are then considerations in diagnosis. Whether bifacial palsy alone represents a variant of GBS is uncertain, but almost every case in our experience has had an alternative explanation.

Paraparetic, ataxic, and purely motor or purely sensory forms of the illness have also been observed. Less difficulty attends the correct diagnosis of GBS if paresthesias in the acral extremities, progressive reduction or loss of reflexes, and relative symmetry of weakness appear after several days. The laboratory tests, particularly nerve conduction studies that affirm the diagnosis of typical GBS, give similar but generally milder abnormalities if

they are carefully sought in all these variant forms. In a few patients, the weakness continues to evolve for 3 to 4 weeks or longer. From this group, a chronic form of demyelinating neuropathy (CIDP) may emerge and an intermediate group that progresses for 4 to 8 weeks and then improves can be identified (see further on).

Laboratory Findings

The most important laboratory aids are the electrodiagnostic studies and CSF examination. The CSF is under normal pressure and is acellular or contains only a few lymphocytes in all but 10 percent of patients; in the latter group, 10 to 50 cells (rarely more) per cubic millimeter, predominantly lymphocytes, may be found. The number of cells then decreases in a matter of 2 to 3 days; persistent pleocytosis suggests an alternative or additional process producing aseptic meningitis such as neoplastic infiltration, HIV, sarcoidosis, or Lyme infection. We have been unable to relate pleocytosis in the spinal fluid with any of the clinical features of GBS or to the severity of illness. The protein content is usually normal during the first few days of illness, but then it rises, reaching a peak in 4 to 6 weeks and persisting at a variably elevated level for many weeks. The increase in CSF protein is probably a reflection of widespread inflammatory disease of the nerve roots, but high values have had no clinical or prognostic significance in our material, apart from a few exceptional cases of pseudotumor cerebri (Ropper and Marmarou). In a few patients (fewer than 10 percent), the CSF protein values remain normal throughout the illness. From our experience, there is a higher proportion of patients with normal or only slightly elevated protein values among those with Fisher syndrome and other restricted or axonal forms of GBS.

Abnormalities of nerve conduction are early and dependable diagnostic indicators of GBS. In cases with a typical clinical and EMG/NCS presentation, one can probably dispense with the CSF analysis as a confirmatory test. The most frequent early electrodiagnostic findings are a reduction in the amplitude of muscle action potentials, slowed conduction velocity, and conduction block in motor nerves, singly or in combination (see Chap. 45). Prolonged distal latencies and reduced distal amplitudes (reflecting distal conduction block) and prolonged or absent F responses (indicating involvement of proximal parts of motor nerves and roots) are other important diagnostic findings, all reflecting focal areas of demyelination. The H reflex is almost always much delayed, or more often absent, but this does little more than confirm the loss of ankle reflexes. Although a limited electrodiagnostic examination may be normal early in the illness, a thorough study, which includes measurement of late responses, invariably shows disordered conduction in an affected limb within days of the first symptom. Features that indicate widespread axonal damage portend a poor and protracted recovery in both young and old patients as discussed above.

The clinical, CSF, and electrodiagnostic criteria for GBS were assessed by Asbury and Cornblath and are discussed in detail in the monograph by Ropper and colleagues.

Many patients with acute GBS have shown gadolinium enhancement of the cauda equina roots on magnetic resonance imaging (21 of 24 patients in our study) and this may serve as a useful test in complicated cases (Gorson et al, 1996).

Beyond the close association between autoantibodies to GQ 1b and Fisher syndrome or other variants that include ophthalmoplegia as mentioned previously other anti-ganglioside antibodies have become of interest in GBS. The acute motor axonal variety has a tendency to be associated with antibodies to GM1 or GD1a and the pharyngeal-cervical-brachial syndrome, to GT1a. Much of this work comes from the laboratory of Yuki, and his review article with Hartung is recommended for further explanations of potential autoimmune mechanisms.

Abnormalities of liver function occur in fewer than 10 percent of patients, probably reflecting a recent or ongoing viral hepatitis, usually as a result of CMV or EBV infections (rarely one of the hepatitis viruses). T-wave and other electrocardiographic changes of minor degree are reported frequently but tend to be evanescent. The sedimentation rate is normal unless there is an additional process of infectious, neoplastic, or autoimmune nature, any of which can occasionally coexist with GBS. Hyponatremia occurs in a proportion of cases after the first week, but particularly in ventilated patients. This is usually attributable to the syndrome of inappropriate antidiuretic hormone secretion (SIADH), but a natriuretic type also occurs, from an excess of atrial natriuretic factor (Wijdicks et al). Transient diabetes insipidus is a rare and unexplained complication. With regard to proteinuria due to glomerulonephritis reported by several groups in cases of GBS, we have found it infrequently.

Pathologic Findings

These have had a relatively consistent pattern and form. Even when the disease is fatal within a few days, most cases show endoneural perivascular (mainly perivenous) lymphocytic infiltrates. Later, there is segmental demyelination and a variable degree of wallerian degeneration. The cellular infiltrates are scattered throughout the cranial nerves, ventral and dorsal spinal roots, dorsal root ganglia, and along the entire length of the peripheral nerves. Swelling of nerve roots at the site of their dural exit has been emphasized by some authors and theorized to cause root damage.

Variations of this pattern have been observed, each perhaps representing a different immunopathology. For example, there may be widespread demyelination changes and only a paucity of perivascular lymphocytes (Ropper and Adelman). In patients whose electrophysiologic tests display severe axonal damage early in the illness as discussed earlier the pathologic findings corroborate the predominantly axonal nature of the disease with secondary myelin damage and usually little inflammatory response. An occasional case has shown an inflammatory process with primary axonal damage rather than demyelination (Honovar et al).

Pathogenesis and Etiology

Most evidence supports a cell-mediated immunologic reaction directed at peripheral nerves. Waksman and Adams demonstrated that experimentally induced peripheral nerve disease (experimental allergic neuritis [EAN]), clinically and pathologically indistinguishable from GBS, develops in animals 2 weeks after immunization with peripheral nerve homogenates. Brostoff and colleagues suggested that the antigen in this reaction is a basic protein, designated P2, found only in peripheral nerve myelin. Subsequent investigations by these authors indicated that the neurotoxic factor might be a specific peptide in the P2 protein. However, it has become evident that there is no dominant antigen-antibody reaction in GBS and it is likely that any number of myelin and axonal elements may be involved in inciting the immune reaction. Figure 46-3 diagrammatically illustrates the pathologic steps in this proposed reaction. As noted further on, complement also seems to be a necessary factor in the initial attack on myelin.

Although the transmission of EAN by T cells sensitized to myelin is strong evidence of their role in GBS, antimyelin antibodies are probably involved in the initial part in the disease. The serum from patients with GBS damages myelin in tissue cultures and induces a characteristic ("vesicular") form of myelin destruction. Subepineural injection of serum from GBS patients into the sciatic nerve of rats leads to local demyelination and electrical conduction block. The studies by Koski and associates of complement-dependent myelin damage by immunoglobulin (Ig) M antimyelin antibodies in GBS provided evidence that antimyelin antibodies are able to initiate myelin destruction even through T cells and that macrophages are the ultimate effectors of the damage. Indeed, the very earliest change that could be detected by Hafer-Macko and colleagues was the deposition of complement on the inner layer of myelin.

As mentioned earlier, circulating autoantibodies directed at components of nerve ganglioside are detected but only inconsistently in patients with GBS, the most important being anti-GQ_{1b}, which is found in almost all patients with ophthalmoplegia. Approximately one-fifth of patients have anti-G_{M1} antibodies early in their course, corresponding in most instances to a predominantly motor presentation and to axonal damage, the highest titers being associated with cases that follow *Campylobacter* infections. Antibodies directed against GD_{1a} or GT_{1b} are associated in some cases with the pharyngeal-brachial-cervical variant. Thus it would seem that casting GBS exclusively as a humoral or as a cellular immune process is an oversimplification.

An unanswered question is what incites the immune reaction isolated to peripheral nerves in humans. All attempts to identify a virus or microbial agent within nerves have failed and it is likely that a variety of agents—viral, bacterial (particularly *C. jejuni*), certain vaccines, and perhaps neural injury itself—are each capable, in susceptible individuals, of precipitating an immune response against components of autologous peripheral nerve. The occurrence of GBS in patients with AIDS or with EBV or CMV infections simply indicates that these agents too

Figure 46-3. Diagram of probable cellular events in acute inflammatory polyneuropathy (Guillain-Barré syndrome). *A.* Lymphocytes attach to the walls of endoneurial vessels and migrate through the vessel wall, enlarging and transforming as they do so. At this stage no nerve damage has occurred. *B.* More lymphocytes have migrated into the surrounding tissue. The first effect on the nerve is breakdown of myelin, the axon being spared (segmental demyelination). This change appears to be mediated by the mononuclear exudate, but the mechanism is uncertain. *C.* The lesion is more intense, polymorphonuclear leukocytes being present as well as lymphocytes. There is interruption of the axon in addition to myelin sheath damage; as a result, the muscle undergoes denervation atrophy and the nerve cell body shows central chromatolysis. If the axonal damage is distal, the nerve will survive, and regeneration and clinical recovery are likely. If, as in *D*, axonal interruption has occurred proximally because of a particularly intense root or proximal nerve lesion, the nerve cell body may die and undergo dissolution. In this situation, there is no regeneration, only the possibility of collateral reinnervation of muscle from surviving motor fibers. (From Asbury et al [1969], by permission.)

induce such an autoimmune response without implicating a direct viral infection of nerve. The observation that only one of many individuals who are infected with a particular pathogen go on to develop GBS suggests that host factors are significant (there is, however, little consistency of human leukocyte antigen [HLA] types in GBS patients). Whether the aforementioned antibodies against

various gangliosides of peripheral nerve are pathogenically active is also uncertain.

Several animal diseases—namely coonhound paralysis of dogs, Marek disease of chickens (a viral neuritis), and cauda equina neuritis of horses—resemble GBS superficially but do not share its main clinical or pathologic features.

Differential Diagnosis

GBS is not only the most frequent acute generalized polyneuropathy seen in general hospitals but also the most rapidly evolving and potentially fatal form. Any polyneuropathy that brings the patient to the brink of death or to respiratory failure within a few days will usually be of this variety. Most cases, however, are of the more limited variety with paresthesias, limb weakness, and areflexia. Several other conditions must be considered. The immediate problem is to differentiate GBS from acute spinal cord disease marked by sensorimotor paralysis with a defined spinal level and prominent sphincter disturbances. There may be diagnostic difficulty in the case of an acute lesion of the cord in which tendon reflexes are initially lost (spinal shock), or with necrotizing myelopathy, where a permanent loss of tendon reflexes follows extensive destruction of spinal gray matter. Early and transient urinary retention occurs in a proportion of patients with GBS and causes diagnostic confusion with spinal disease. Several features are useful in distinguishing GBS from a cervical myelopathy: in GBS, the facial and respiratory muscles are usually involved if there is generalized paralysis; the fingertips should be paresthetic once sensory symptoms have ascended to the level of the midcalves; marked sensory loss proximal to the hands or feet or only of the trunk is unusual early in the illness; and tendon reflexes are almost invariably lost in limbs that are too weak to resist gravity. Of course, careful testing of sensation on the trunk and limbs will expose the cause of paralysis as spinal in origin.

Tick paralysis, a disease of children in the United States but affecting both children and adults in Australia and elsewhere, may be nearly impossible to distinguish from GBS unless one finds the tick (see Chap. 43). In addition to an ascending generalized paralysis, both may cause ataxia and may paralyze eye movements, but sensory loss is not usually a feature of tick paralysis and the CSF protein is normal. Episodes of painful paralytic porphyria also bear a superficial resemblance to GBS. Predominant motor features in comparison to sensory ones is the major characteristic of GBS, for which reason the differential diagnosis also includes poliomyelitis, caused by the West Nile virus and by enteroviruses other than the polio agent. In these infectious cases, the illness is marked by fever, meningoencephalitic symptoms, early pleocytosis in the spinal fluid, and purely motor and usually asymmetrical areflexic paralysis, all unusual in GBS.

Several times we were misled by cases of carcinomatous meningitis with polyradiculopathy that caused a painless, subacute, and fairly symmetric but mainly distal weakness, similar to GBS. An irregular distribution of weakness between proximal and distal parts, the absence of facial weakness, and the appearance of symptoms sequentially in one limb after another suggest the presence of this type of neoplastic polyradiculopathy. Sciatica may occur as an early feature with either process but radicular pain in the arms is unusual in GBS. Examination of the spinal fluid usually settles the matter.

Another problem arises in distinguishing generalized GBS with ophthalmoparesis or the Fisher variant from basilar artery thrombosis. The presence of reactive pupils, areflexia, and F-wave abnormalities in GBS, and of lively reflexes and Babinski signs in the case of brainstem infarction, dependably separate the disorders. Ptosis and oculomotor weakness in GBS causes confusion with myasthenia gravis, but there are no sensory symptoms and the tendon reflexes are unimpaired in the latter disease. The mandibular muscles remain relatively strong in GBS, whereas the exercised jaw hangs open in myasthenia. Botulism also simulates this cranial variant of GBS, but pupillary reflexes are lost early in botulism (pupillary paralysis occurs mainly in advanced cases of GBS) and there is usually a bradycardia, which is unusual for GBS. Ingestion of shellfish or reef fish contaminated with saxitoxin, ciguatera, or tetrodotoxin (ciguatera, neurotoxic shellfish poisoning) is another cause of facial-brachial paresthesias, weakness, tachypnea, and iridoplegia lasting up to a few days—symptoms that resemble the cranial nerve variants of GBS.

A number of neuromuscular disorders in critically ill patients with systemic medical conditions are difficult to distinguish from GBS. These include the polyneuropathy of critical illness (see further on in the chapter); an accelerated neuropathy of renal failure that is seen mainly in diabetic patients receiving peritoneal dialysis (both discussed further on); acute hypophosphatemia induced by hyperalimentation; polymyopathy produced by the administration of high-dose corticosteroids; and the prolonged effects of neuromuscular blocking drugs, resulting in the accumulation of their metabolites in patients under conditions of renal failure and acidosis.

Treatment

General Medical Care In severe cases, respiratory assistance and assiduous nursing are paramount, because the disease remits naturally and the outlook for recovery is favorable in the majority of patients. About one-quarter of our patients have required mechanical ventilation. Because a patient's condition may deteriorate unpredictably and rapidly in the first days of illness, virtually all but the mildest cases should be admitted to the hospital for observation of respiratory, autonomic, and motor function. The comments that follow are applicable to most other forms of acute and subacute neuromuscular respiratory failure, including myasthenia gravis and high spinal cord injury.

Measurement of maximal inspiratory force and expiratory vital capacity suffices for the bedside estimation of diaphragmatic strength and respiratory function. The trend of these measurements is a guide to the likelihood of respiratory failure. As had been observed in poliomyelitis, the strength of the neck muscles and trapezii, which share the same segmental innervation as the diaphragm, tends to parallel diaphragmatic power. A rough estimate of breathing capacity may be obtained by having the patient count quickly on one deep breath. The ability to reach 20 generally corresponds to a vital capacity of greater than 1.5 L. If a downward trend in

these measurements is recognized and the vital capacity diminishes to below about 10 mL/kg, endotracheal intubation and mechanical ventilation are usually necessary (see further on). However, a fairly severe impairment of ventilation may occur before the first sign of dyspnea appears and before there is elevation of arterial carbon dioxide content. Incipient respiratory failure may be evident by tachypnea and a decrease in arterial oxygen tension (P_{O_2} , less than 85 mm Hg) reflecting pulmonary atelectasis. When respiratory failure arises gradually as the patient weakens over days, there is slight tachycardia, diaphoresis, restlessness, and tachypnea. Attempts to forestall intubation and positive-pressure ventilation by using negative-pressure cuirass-type devices have been unsatisfactory in our experience. Patients with oropharyngeal weakness require intubation even earlier so as to prevent aspiration, but full mechanical ventilation is not always necessary at the same time. Patients in these circumstances should obviously be admitted to an intensive care unit staffed by personnel skilled in maintaining ventilation and airway patency.

The other major aspects of the treatment in severely affected patients involve the management of *autonomic instability* and the prevention of the many *general medical problems* that attend any immobilizing critical illness. Hypotension from *dysautonomia*, which occurs in approximately 10 percent of paralyzed patients and a smaller proportion with lesser degrees of weakness, is treated by intravenous infusions of saline and by the use of vasopressor agents for brief periods. Extremes of hypertension are managed by short-acting and titratable antihypertensive medications, such as intravenous labetalol. The choice and dosing of an antihypertensive drug is important, as episodes of hypertension may be rapidly succeeded by precipitous declines in pressure. Severe autonomic problems are difficult to anticipate, but provocative maneuvers such as ocular pressure to elicit heart block are used in some units to identify patients at risk.

In patients who are bedbound, prevention of electrolyte imbalances, gastrointestinal hemorrhage, and particularly pulmonary embolism (by the use of subcutaneous heparin or pneumatic compression boots) requires careful attention. Adynamic ileus is a problem in some cases, manifest by abdominal pain coincident with nasogastric tube feeding and by bloating; it may lead to bowel perforation even if feeding is discontinued. As mentioned, a number of patients become hyponatremic, usually from SIADH but occasionally from a natriuresis, and the drop in sodium is exaggerated by positive-pressure mechanical ventilation. The distinction between the two conditions that cause hyponatremia determines the course of treatment: fluid restriction in the case of SIADH or salt replacement in the case of sodium loss. Many patients have bizarre waking dreams or hallucinations after weeks of immobilization (oneiric hallucinations). A dependable mode of communication should be established by the nursing staff, preferably before the patient is intubated. A Plexiglas or opaque board with letters and phrases is useful for this purpose.

Failure to effectively clear the tracheobronchial airways and the need for prolonged mechanical ventilation are the usual indications for tracheostomy. In most cases, this procedure can be postponed until the third week of intubation. However, patients who become rapidly quadriplegic and ventilator-dependent benefit from tracheostomy earlier. Once tracheostomy is performed, careful tracheal toilet and treatment of pulmonary and urinary tract infections by the use of appropriate antibiotics are required; prophylactic antibiotic treatment is not recommended. With tracheostomy and intensive care, the mortality from the disease can be reduced to approximately 3 percent (Ropper and Kehne; see further on under "Prognosis").

The decisions to wean and then discontinue respiratory aid and to remove the endotracheal or tracheostomy tube are based on the degree and timing of recovery of respiratory function. The weaning process generally begins when the vital capacity reaches approximately 10 mL/kg and comfortable breathing can be sustained for a few minutes. The relative merits of the numerous methods of delivering positive-pressure volume-cycled ventilation and its gradual withdrawal are not covered here, but there is little to favor one over the other and the reader is referred to the monograph *Neurological and Neurosurgical Intensive Care* by Ropper and colleagues.

Physical therapy (passive movement and positioning of limbs to prevent pressure palsies and, later, mild resistance exercises) can begin once they can be comfortably undertaken.

Plasma Exchange and Immune Globulin Specific treatment of the presumed immune disorder that underlies GBS includes plasma exchange and IVIg. Our practice has been to observe patients who are still able to walk unaided rather than institute treatment immediately. If the patient becomes unable to walk, shows a reduction in vital capacity, or signs of oropharyngeal weakness, plasma exchange or IVIg is instituted promptly. This typically occurs at the fifth to tenth day after the appearance of the first symptoms, but may be as early as 1 day or as late as 3 weeks.

Three large randomized trials comprising more than 500 patients have established the efficacy of *plasma exchange* administered during the evolving phase of GBS. In patients who are treated within 2 weeks of onset, there is an approximate halving of the period of hospitalization, of the duration of mechanical ventilation, and of the time required to achieve independent ambulation. However, in the largest trial, if the first plasma exchange was delayed for 2 weeks or longer after the onset of the disease, the procedure was of little value. Nonetheless, if a patient continues to progress in the third or fourth week of illness, it is probably still appropriate to institute the exchanges. The most important predictors of responsiveness to plasma exchange treatment are the same as for the overall prognosis, namely the patient's age (responders are younger) and the preservation of motor compound muscle action potential amplitudes prior to instituting treatment (McKhann et al). One study has found that the condition of patients was better at 6 and 12 months after

treatment as compared to untreated patients; other studies have been equivocal on this point and demonstrated mainly accelerated improvement.

The advised regimen of plasma exchange removes a total of 200 to 250 mL/kg of plasma in 4 to 6 treatments on alternate days, or over a shorter period if there is no coagulopathy. The replacement fluid is saline combined with 5 percent albumin. The need for large-bore venous access usually requires the insertion of a double-lumen subclavian or internal jugular catheters and this may be the main source of complications (pneumothorax, infection, hemorrhage). In some patients, treatment can be instituted, and sometimes the entire course completed, through the antecubital veins. During and after the procedure, hypotension, hypoprothrombinemia with bleeding and cardiac arrhythmias may occur. Some units measure the level of fibrinogen, which is greatly reduced by exchanges, before the next exchange to gauge to the risk of potential hemorrhage. Reactions to the citrate that is used to prevent blood from clotting in the plasma exchange machine are common but can be obviated by the cautious addition of calcium to the intravenous return line. Hepatitis and AIDS are not risks if plasma is replaced with albumin and saline rather than with pooled plasma.

As effective as plasma exchange is, IVIg (0.4 g/kg per day for 5 consecutive days) is both easier to administer and probably safer because there is no need for large intravenous access. The results of the first trial conducted by van der Meché and colleagues were corroborated in an international study led by Hughes, in which we participated (see Plasma Exchange/Sandoglobulin Guillain-Barré Syndrome Trial Group). That trial compared plasma exchange to IVIg and also evaluated their use sequentially. There was a tenuous trend toward a better outcome in patients who received plasma exchange and results were perhaps slightly better in a group who were treated with plasma exchange followed immediately by 5 days of immune globulin infusions; in both instances, however, the differences failed to attain statistical significance and the three modes of treatment were said to be equivalent. Renal failure, proteinuria, and aseptic meningitis, manifested most often by severe headache, are infrequent complications of IVIg. The only serious reactions we have encountered have been in a very few patients who congenitally lacked IgA and in whom pooled gamma globulin caused anaphylaxis, and a few cases of inflammatory local venous thrombosis in the region of the infusion site. The pharmacokinetics of IVIg are highly variable among individuals and some groups have found an association between a high rate of clearance of agent and poorer clinical outcome (see Kuitwaard and colleagues). This group has suggested that patients who show only a small increment in serum IgG levels might benefit from higher doses or a second course of IVIg.

After the use of either plasma exchange or IVIg, 5 to 10 percent of patients who initially improve will have a relapse that becomes apparent several days or up to 3 weeks after completion of treatment. If there had been a response to the initial therapy, the same treatment may be

repeated or the alternative treatment may be tried; either can be successful. A few such patients relapse repeatedly and have the course of chronic inflammatory demyelinating polyneuropathy (see further on). In some patients under our care, this form of the disease stabilized after several months in response to the administration of corticosteroids, with very gradual tapering of the dose over several months, or in combination with repeated courses of IVIg or plasma exchanges.

The clinical improvement that follows the administration of IVIg or plasma exchange usually cannot be readily discerned in an individual patient; i.e., it is apparent only by comparing large groups of treated and untreated patients. For this reason it is not possible to judge that a patient who fails to improve or who worsens through the period of treatment has derived no benefit from therapy. The question nevertheless arises regarding further plasma exchanges or continued infusion of immune globulin in cases of continued worsening or lack of improvement. Further complicating the matter are the limited expectations for early improvement in cases of axonal GBS. Our advice has been to repeat either of the two immune treatments if a patient is clearly declining, particularly if there is evidence of demyelinating neuropathy on the NCS, and if the illness is not much longer than 4 weeks in duration. Performing plasma exchanges after the use of IVIg does not make sense to us (but this notion has not been tested); therefore, we either follow a series of exchanges with IVIg or, more often, repeat a course of IVIg as suggested by Farcas and colleagues.

The value of corticosteroids alone in the treatment of GBS has been disputed for decades. Many clinicians were persuaded of their benefit; however, two randomized controlled trials, one with conventional-dose prednisolone and the other with high-dose methylprednisolone, have failed to demonstrate beneficial effect (Hughes et al, 1991). Although corticosteroids can no longer be recommended as routine treatment for acute GBS, we have observed a few instances in which the administration of intravenous high-dose corticosteroids seemingly halted the progress of an acute case.

Prognosis

As already indicated, approximately 3 to 5 percent of patients do not survive the illness, even in the best equipped hospitals. In the early stages, death is most often a result of cardiac arrest, sometimes related to dysautonomia, adult respiratory distress syndrome, pneumo- or hemothorax, or some type of accidental machine failure. Later in the illness, pulmonary embolism and infectious complications of prolonged immobilization and respiratory failure are the main causes of death.

The majority of patients recover with mild motor deficits or sensory complaints in the feet or legs. In approximately 10 percent, however, the residual disability is pronounced; this occurs in those with the most severe and rapidly evolving form of the disease, when there has been evidence of widespread axonal damage and in those requiring early and prolonged mechanical

ventilatory assistance. A fairly consistent predictor of residual weakness and muscle atrophy is the finding of greatly reduced amplitudes of muscle action potentials and widespread denervation, both indicative of axonal damage.

In patients with respiratory failure, the average period of machine-assisted respiration has been 22 days and the period of hospitalization approximately 50 days (these were twice as long prior to the introduction of plasma exchange and IVIg). As a rule, older adults recover more slowly than younger ones and children and have more residual weakness.

The most common remaining difficulties are weakness of the lower leg muscles, numbness of the feet and toes, and mild bifacial weakness. A few patients are left with sensory ataxia that tends to be severe and quite disabling. Distal neuropathic pain and persistent autonomic problems occur but are also infrequent. All manner of other late symptoms are attributed with little evidence to the illness and should be addressed on their own merits—fatigue and asthenia, muscle cramps, dizziness, pain, and breathlessness. Depression has not been frequent.

The speed of recovery varies, but its pace is steady. Often, it occurs within a few weeks or months; however, if axons have been damaged, their regeneration may require 6 to 18 months or longer. In our experience, little improvement can be expected in disabilities that have lasted 2 or more years.

Some 5 to 10 percent of patients encounter one or more recurrences of the acute polyneuropathy. An illness that in the beginning appeared to be an acute inflammatory polyradiculoneuropathy may fail to stabilize and continue to progress steadily, or there may be an incomplete remission followed by a chronic, fluctuating, slowly progressive neuropathy. These more chronic forms of inflammatory neuropathy are described in a later section of this chapter.

Critical Illness Polyneuropathy

An acute or subacute symmetrical polyneuropathy is a frequent development in critically ill and septic patients, particularly in those with failure of multiple organs (Zochodne et al). This neuropathy causes difficulty in weaning a patient from the ventilator, even as the underlying critical illness comes under control. The neuropathic process, predominantly of motor type, varies in severity from an electrophysiologic abnormality without overt clinical signs, to quadriplegia with respiratory failure. Sensory symptoms and signs are variable but tend to be mild. Usually the cranial nerves are spared and there are few or no dysautonomic manifestations. In general, this type of polyneuropathy appears after several days or more of bacterial sepsis or other overwhelming infection (now called *systemic inflammatory response syndrome [SIRS]*) and multiple organ failure, and is preceded in most instances by a confusional state or a depressed state of consciousness (“septic encephalopathy”).

The EMG and NCS findings of a primary axonal process with early denervation and a normal CSF distinguish

this entity from the typical demyelinating form of GBS. Autopsy material has usually disclosed little or no inflammatory changes in the peripheral nerves. Differentiating critical illness polyneuropathy from critical illness myopathy (see just below) and from the axonal form of GBS is difficult and depends on the context in which the illness occurs. All of these processes that occur in the intensive care unit, when extreme, can eliminate the motor nerve action potentials and when this configuration is found, the problem is most often attributed to the neuropathy, although this is not always correct. The toxic effects of drugs and antibiotics and nutritional deficiency must be considered in causation, but rarely can they be established. The many systemic mediators of sepsis are toxic to the peripheral nervous system; tumor necrosis factor has been proposed as one such endogenous toxin in causing neuropathy.

Critical illness polyneuropathy must also be distinguished from a poorly understood *acute quadriplegic myopathy* (critical illness myopathy) that also complicates critical illness (see Chap. 48). High doses of corticosteroids, particularly in combination with neuromuscular blocking agents, have been implicated. The acute myopathy, which affects both distal and proximal muscles, is sometimes heralded by an elevation in the serum creatine kinase (CK) concentration (at times up to several thousand units) and myopathic potentials in the EMG, and a unique degeneration of myofilaments in all the muscles is found. This illness is described in more detail in Chap. 48.

Acute Uremic Polyneuropathy

In addition to the well-known chronic sensory polyneuropathy associated with chronic renal failure that is discussed later in the chapter, there is a more rapid (“accelerated”) process that has not been widely appreciated as a cause of acute and subacute weakness. Most patients in our series were diabetics with stable end-stage renal failure who had been treated by peritoneal dialysis for their long-standing kidney disease (Ropper, 1993). In contrast to the better characterized and less severe chronic uremic neuropathy, generalized weakness and distal paresthesias progress over 1 or more weeks until a bedbound state is reached. The illness simulates subacute GBS. More aggressive dialysis or a change to hemodialysis has little immediate effect, although kidney transplantation is curative. Electrophysiologic studies show demyelinating features (slowing of conduction velocity), but usually not a conduction block. There is raised CSF protein concentration (not unexpectedly, for there is usually an element of diabetic neuropathy). A few reported cases have responded to plasma exchange or gamma globulin. As with the more common chronic uremic neuropathy, the cause of the acute form is unknown.

Acute Sensory Neuronopathy (Acute Sensory Ganglionopathy)

Attention was initially drawn to this entity by Serman and colleagues in a report of 3 adult patients with rapidly

evolving sensory ataxia, areflexia, numbness, and pain, beginning in the face and spreading to involve the entire body. In each instance, the symptoms began within 4 to 12 days following the institution of penicillin therapy for a febrile illness (antibiotics were subsequently shown not to be associated). Proprioception was profoundly reduced, but there was no weakness or muscle atrophy, despite generalized areflexia. The sensory deficit attained its maximum severity within a week, after which it stabilized and improved very little.

Electrophysiologic studies showed absent or slowed sensory conduction, but there were no abnormalities of motor nerve conduction or signs of denervation. In two patients, the CSF protein content was elevated to 126 and 175 mg/dL. Followup observations (for up to 5 years) disclosed no neoplastic or immunologic disorder, the usual identifiable causes of such a sensory neuropathy. Lacking pathologic material, it was assumed from the permanence of the condition that sensory neurons were destroyed (*sensory neuropathy*). A subsequent series of 42 patients reported by Windebank and colleagues emphasized an asymmetrical and brachial pattern of symptoms in some patients and initial involvement of the face in others. In contrast to Serman's cases, the CSF was usually normal and most patients had some improvement or a spontaneous resolution of symptoms. These authors viewed the process as a sensory neuropathy. In this and subsequent reports, as mentioned, antibiotics were not implicated.

This clinical pattern should be viewed as a syndrome rather than as a disease. There are two main presentations: with limb ataxia that does not have accompanying dysarthria or nystagmus, thus distinguishing it from a cerebellar disorder; and with generalized facial and truncal numbness that involves proximal and distal sensory areas and may include the top of the head, trunk, buttocks, scrotum, and oral mucosal membranes. The latter syndrome must be delineated from an evolving polyneuropathy, the early proximal symptoms being the most salient identifying feature for a ganglionopathy as mentioned in the introductory sections of this chapter. All the just described processes are accompanied by areflexia, but this may not be fully developed in the case of ganglionopathy for several days or longer.

Probably, most instances are immune and postinfectious in nature. The same pattern of sensory loss evolving in a subacute or chronic manner is well known to occur as a paraneoplastic illness, described further on in this chapter, or in association with the Sjögren syndrome, scleroderma, lupus erythematosus, paraproteinemia, HIV and human T-cell lymphotropic virus type I (HTLV-I) infection. Certain drugs and other agents, especially cisplatin and excessive intake of pyridoxine, are also causes of a sensory neuropathy. These are discussed again later, under "Drug-Induced Neuropathies and Neuronopathies." A rare form of GBS involves solely the large sensory fibers and produces ataxia, thereby simulating an acute sensory neuropathy. In GBS, however, there is usually some degree of proximal weakness and the sensory changes do not extend to the face and trunk.

Diphtheritic Polyneuropathy

The neurotoxic effects of *Corynebacterium diphtheriae* and the mode of action of the exotoxin elaborated by the bacillus are described in Chap. 43. Local action of the exotoxin may paralyze pharyngeal and laryngeal muscles (dysphagia, nasal voice) within 1 or 2 weeks after the onset of the infection and shortly thereafter may cause blurring of vision because of paralysis of accommodation, but these and other cranial nerve symptoms may be overlooked. At this stage, the cranial neuropathy must be distinguished from that of GBS, botulism, and most of all, from myasthenia gravis.

A polyneuropathy, appearing 5 to 8 weeks later, takes the form of an acute or subacute limb weakness with paresthesias and distal loss of vibratory and position sense. The weakness characteristically involves all extremities at the same time or may descend from arms to legs. The patient may be unable to stand or walk and occasionally the paralysis is so extensive as to impair respiration. The CSF protein is usually elevated (50 to 200 mg/dL). Deaths that occur after the pharyngeal infection has subsided are a result of cardiomyopathy or, less often, of severe polyneuropathy with respiratory paralysis. This type of polyneuropathy, now quite rare, should be suspected in the midst of an outbreak of diphtheritic infection, as occurred in Russia (Logina and Donaghy).

The important pathologic change is one of segmental demyelination without inflammatory reaction of spinal roots, sensory ganglia, and adjacent spinal nerves. Anterior horn cells, axons, peripheral nerves distally, and muscle fibers remain normal (Fisher and Adams).

Treatment Diphtheria antitoxin, given within 48 h of the onset of the infection, reduces the incidence and severity of neuropathic complications. Antitoxin is probably of little value once the polyneuropathy begins. Thereafter, treatment is purely symptomatic, along the lines indicated for GBS. The prognosis for full recovery is excellent once respiratory paralysis is circumvented.

Porphyric Polyneuropathy

A severe, rapidly advancing, more or less symmetrical and mainly motor polyneuropathy—often with abdominal pain, psychosis (delirium or confusion), and convulsions—may be a manifestation of *acute intermittent porphyria*. This type of porphyria is inherited as an autosomal dominant trait and is not associated with cutaneous sensitivity to sunlight. The metabolic defect is in the liver and is marked by increased production and urinary excretion of porphobilinogen and of the porphyrin precursor Δ -aminolevulinic acid. The peripheral and central nervous systems may also be affected in another hepatic type of porphyria (the variegate type). In the latter, the skin is markedly sensitive to light and trauma, and porphyrins are at all times found in the stools. Both of these *hepatic* forms of porphyria must be distinguished from the rarer *erythropoietic (congenital photosensitive)* porphyria, in which the nervous system is not affected.

The classic study of acute intermittent porphyria was made by Waldenstrom in 1957. The initial and often the most prominent symptom is moderate to severe colicky abdominal pain. It may be generalized or localized and is unattended by rigidity of the abdominal wall or tenderness. Constipation and intestinal distention (ileus) are frequent. Attacks last for days to weeks and repeated vomiting may lead to inanition. In latent forms, the patient may be asymptomatic or complain only of slight dyspepsia.

The disease can be identified after some time by its characteristic recurrent attacks, often precipitated by drugs such as sulfonamides, griseofulvin, estrogens, barbiturates, phenytoin, and the succinimide anticonvulsants. The possibility of sensitivity to these drugs must always be kept in mind when convulsions are being treated in the porphyric patient. The first attack rarely occurs before puberty, and the disease is most likely to threaten life during adolescence and early adulthood. In contrast, acute polyneuropathy that appears for the first time in mid- or late adult life is not likely to be porphyric.

The neurologic manifestations are usually those of an acute polyneuropathy involving the motor nerves more severely than the sensory ones; less often, both sensory and motor nerves are affected more or less equally and sometimes autonomic nerves as well. The symptoms may begin in the feet and legs and ascend, or they may begin in the hands and arms (sometimes asymmetrically) and spread in a few days to the trunk and legs. Often, the weakness predominates in the proximal muscles of the limbs and limb girdle muscles, in which case there is loss of knee jerks with preservation of reflexes at the ankles. Sensory loss, often extending to the trunk, is present in half the cases. Facial paralysis, dysphagia, and ocular palsies are features of only the most severe cases. The CSF protein content is normal or slightly elevated.

The course of the polyneuropathy is variable. In mild cases the symptoms regress in a few weeks. Severe cases may progress to a fatal respiratory or cardiac paralysis in a few days, or the symptoms may advance in a saltatory fashion over several weeks, resulting in a severe sensorimotor paralysis that improves only after many months.

A disturbance of cerebral function (confusion, delirium, visual field defects, and convulsions) is likely to precede the severe, but not always the mild, forms of polyneuropathy, or there may be none of these central features. Cerebral manifestations subside in a few days or weeks, although one of our patients was left with a lasting homonymous hemianopia. Tachycardia and hypertension are frequent in the acute phase of the disease and fever and leukocytosis may occur in severe cases. In general, the prognosis for recovery is excellent, although relapse of the porphyria may result in cumulative damage to the peripheral nervous system (see discussion further on under "Diagnosis of Recurrent or Relapsing Polyneuropathy").

In summary, the most characteristic features of porphyric neuropathy are the relapsing nature, acute onset, abdominal pain, psychotic symptoms, predominant motor neuropathy, often with an early bibrachial distribution of

weakness, truncal sensory loss, and tachycardia. Rarely, the neuropathy develops without other symptoms.

The pathologic findings in the peripheral nervous system vary according to the stage of the illness at which death occurs. In the first few days, the myelinated fibers may appear entirely normal, despite almost complete paralysis. If symptoms had been present for weeks, degeneration of both axons and myelin sheaths are found in most of the peripheral nerves. The relation between the abnormality of porphyrin biosynthesis in the liver and nervous dysfunction has never been explained satisfactorily.

The diagnosis is confirmed by the demonstration of large amounts of porphobilinogen and Δ -aminolevulinic acid in the urine. The urine turns dark when standing as a consequence of the formation of porphobilin, an oxidation product of porphobilinogen.

Treatment The use of intravenous glucose and intravenous hematin (4 mg/kg daily for 3 to 14 days) is recommended as the most effective therapy. Other aspects of treatment include respiratory support, use of beta-blocking agents (labetalol) if tachycardia and hypertension are severe, continued intravenous glucose to suppress the heme biosynthetic pathway, and pyridoxine (100 mg bid) on the supposition that vitamin B₆ depletion has occurred. Attempted *prevention* is of the utmost importance, since attacks can be precipitated by the aforementioned drugs as well as numerous others that are porphyrinogenic.

Acute Toxic Polyneuropathies

As indicated in Chap. 43, the peripheral nerves may be affected by a wide variety of toxins including metals, drugs, organophosphates, and industrial solvents. As a rule, the neuropathies induced by these agents fall into the subacute and chronic categories (to be discussed further on). However, certain drugs—notably triorthocresyl phosphate (TOCP) and other organophosphates (see Chap. 40), thallium and rarely, arsenic—produce a polyneuropathy that may be fatal in a matter of days. It should be stressed that organophosphate neuropathy can be identified in almost all instances by the severe anticholinergic effects that are apparent immediately after exposure. Severe and permanent motor paralysis is caused by TOCP; this ultimately proves to be a result of involvement of both upper and lower motor neurons.

Thallium salts, when taken in sufficient amount, produce a clinical picture resembling that of GBS or an acute sensory polyneuropathy. If the salts are taken orally, there is first abdominal pain, vomiting, and diarrhea, followed within a few days by pain and tingling in the toes and fingertips and then rapid weakening of muscles of the limbs, initially the distal ones. As the weakness progresses, the tendon reflexes diminish. Pain sensation is reduced more than tactile, vibratory, and position sense. Persistent acral pain with allodynia has been a major feature in 3 of the 5 patients we have examined; in 2 of our patients there was no weakness, only sensory loss and ataxia. All cranial nerves except the first and eighth may be affected; facial palsies, ophthalmoplegia, nystagmus, optic neuritis with visual impairment, and vocal

cord palsies are additional abnormalities but only in the most severely affected patients. The CSF protein rises to more than 100 mg. Death may occur in the first 10 days as a result of cardiac arrest. The early onset of painful paresthesias, sensory loss, and pain localized to joints, back, and chest, as well as *rapid loss of hair* (after a week or two), all serve to differentiate this neuropathy from GBS, porphyria, and other acute polyneuropathies. Relative preservation of reflexes is noteworthy and rapidly evolving complete alopecia is a striking feature. Patients with lesser degrees of intoxication may recover completely within weeks or months. Thallium salts act like potassium and a high intake of potassium chloride hastens the excretion of thallium. Chelating agents are of unproven value but are usually included in treatment.

Some cases of *arsenical* and possibly *mercurial* polyneuropathy may also develop acutely. More often these conditions evolve subacutely, for which reason they are discussed further on. As alluded to earlier and in Chap. 43, certain other toxic neuropathies, such as those related to organophosphate or diethylene chloride (Sterno) poisoning, may have an acute onset and progress over days.

In regard to this category of polyneuropathy, many instances are imputed to toxins by both patients and unskilled physicians with little substantiation. Before making such an attribution, it is useful to ask whether the clinical features are compatible with the known neurotoxicity of an environmental agent or drug; whether the severity of symptoms is consistent with degree of presumed exposure (real or imagined); whether the associated systemic signs of an intoxication are present; if other individuals similarly exposed are affected; and whether symptoms stabilize or improve once the patient is removed from the presumed source of exposure. Failure to satisfy these precepts generally signifies some other disorder.

Other Acute Polyneuropathies

On occasion, a vasculitic polyneuropathy as an isolated process or associated with lupus erythematosus, polyarteritis nodosa, and related disorders may develop as rapidly as GBS and careful clinical and electrophysiologic testing are needed to distinguish them. Three of our patients with polyarteritis and one with Churg-Strauss disease became completely paralyzed within a week and one died of intestinal perforation. However, most cases of neuropathy caused by vasculitis evolve more slowly, with the syndrome assuming an asymmetrical and multifocal distribution, for which reason it is described in the next section. There is no doubt that paraneoplastic neuropathies, discussed further in the subacute category, can evolve more rapidly than is typical for this process and thereby simulate GBS.

We have observed a few patients with alcoholism, occult carcinoma, Hodgkin disease, and renal transplantation develop an acute polyneuropathy, as rapid in its evolution as GBS, and acute episodes of this type have also been described in patients with Refsum disease.

Acute Autonomic Polyneuropathy (“Pure Pandysautonomia”)

Since the first description of such a case by Young and colleagues and Adams and associates, a number of others have been recorded and summarized by Low and colleagues. The condition, probably a type of postinfectious polyneuropathy in the category of GBS, is described in detail in Chap. 26. Some success has been achieved by treatment with IVIg. A subacute and more chronic form, also immune in nature, is described later under “Idiopathic Autonomic Neuropathy” and a paraneoplastic variety is known.

SYNDROME OF SUBACUTE SENSORIMOTOR PARALYSIS FROM PERIPHERAL NEUROPATHY

Placed in this category are neuropathies that evolve over several weeks to months and, after reaching their peak of severity, tend to persist for a variable period. Admittedly, the dividing line between such cases and those that evolve over somewhat shorter or longer periods is indistinct; there are many diseases of nerve that overlap both the acute and the early chronic categories. In contrast to the acute polyneuropathies, however, most that are subacute have prominent sensory features and are of axonal type. The main exception is a subacute inflammatory–demyelinative type, essentially a slow form of GBS, evolving over 4 to 8 weeks, as described by Hughes and coworkers. Similarly, some instances of diphtheritic neuropathy evolve subacutely. Despite these qualifications, in the end, a symmetrical polyneuropathy syndrome of *subacute type* most often proves to be caused by nutritional deficiency, (often complicated by alcoholism) by a remote effect of cancer (paraneoplastic, as described later), by poisoning with arsenic, lead, or by the toxic effects of any number of drugs used for therapeutic purposes (cisplatin, nitrofurantoin, isoniazid, etc.). Occasionally other drugs, metals, and industrial solvents are incriminated; these are discussed in Chap. 43.

Nutritional Deficiency Neuropathy

(See Chap. 41)

In the Western world, nutritional polyneuropathy is usually associated with chronic alcoholism. As indicated in earlier discussions, all data point to the identity or at least close relationship between alcoholic neuropathy and neuropathic beriberi. A nutritional factor is responsible for both, although in any given case it remains unclear whether the deficiency is one of thiamine, nicotinic acid, pyridoxine, pantothenic acid, folic acid, or a combination of these B vitamins. Our colleague M. Victor, who devoted considerable attention to this subject, was never persuaded of the existence of a form of polyneuropathy attributable solely to the toxic effect of alcohol, although claims of such an entity continue to be made and the perception persists among most physicians that alcohol is

directly damaging to nerves. Nutritional neuropathy and other neurologic complications of deficiency disorders (Strachan syndrome, pellagra, vitamin B₁₂ deficiency, and malabsorption syndromes) are described fully in Chap. 41. A predominantly sensory neuropathy with burning pain is typical of most forms of severe nutritional deprivation.

Paraneoplastic Polyneuropathy and Sensory Ganglionopathy (See Chap. 31)

Although capable of producing diverse clinical presentations, most often the remote effect of cancer takes the form of a predominantly distal, symmetrical sensory, or sensorimotor polyneuropathy. Weakness and atrophy, ataxia, and sensory loss of the limbs may advance over several weeks or months to the point where the patient is confined to a wheelchair or bed; usually the CSF protein concentration is mildly elevated. All these symptoms may occur months or even a year or longer before a malignant tumor is found, although usually the tumor is apparent and most often is a lung cancer.

In most series, a mixed sensorimotor polyneuropathy has been 4 to 5 times more frequent than a purely sensory one. However, the latter is a more specific syndrome identified with lung cancer (described originally by Denny-Brown); it is characterized by a loss of all modalities of sensation spreading from the distal to the proximal segments of the limbs and eventually to the trunk and face. There is loss of tendon reflexes, but motor power may be retained. It has also been appreciated that the sensory loss in the beginning may have a multifocal distribution. Another variety is characterized by initial sensory ataxia, similar to that discussed in the earlier section "Acute Sensory Neuronopathy (Sensory Ganglionopathy)." The illness reaches its peak in a few weeks or months and in a very few instances the development has been as rapid as that of GBS.

The pathologic changes are those of an inflammatory and destructive *sensory neuropathy and neuronopathy* (ganglionitis) and are sometimes part of a more widespread disorder of the nervous system related to the anti-Hu antibody (also termed *antinuclear neuronal antibody type 1 (ANNA-1)*; see Chap. 31). This polyneuropathy has proven to be most typical of small cell cancer of the lung. In a series of 71 patients with paraneoplastic sensory neuronopathy reported by Dalmau and colleagues, more than half were associated with symptomatic inflammatory lesions in the temporal lobes (limbic encephalitis), the brainstem, and, rarely, the anterior horn neurons of the spinal cord. Other distinctive paraneoplastic syndromes such as cerebellar degeneration and Lambert-Eaton myasthenic syndrome were combined with polyneuropathy in isolated cases and there were signs of dysautonomia in 28 percent. Our experience has been that most cases of the Lambert-Eaton syndrome have occurred in isolation, but there are many cases that exist in parallel with various neoplasms, including some of our patients with lymphomas of various types.

The CSF protein is mildly elevated but usually acellular. Sensory potentials are usually absent in all nerves after a few weeks, but may be spared early on. The localization

of anti-Hu antibody to the several affected regions of the nervous system and to the tumor itself has led to speculation that the lung tumors are typically small or inevident because the antibody suppresses tumor growth. Almost all cases of paraneoplastic sensory neuropathy and a proportion of the more nondescript sensory predominant or sensorimotor paraneoplastic polyneuropathies also demonstrate anti-Hu antibodies, making this testing useful in distinguishing paraneoplastic varieties of sensory neuropathy and neuronopathy from those caused by postinfectious or immune disorders such as Sjögren syndrome and HIV infection. The finding of high antibody titers should lead to chest imaging and, in appropriate cases, bronchoscopic or positron emission tomography (PET) examinations to detect an underlying cancer. A rare vasculitic mononeuropathy multiplex that occurs with cancer is discussed further on.

An unusual assortment of polyneuropathies has been associated with non-Hodgkin lymphomas of both T- and B-cell types and with several related conditions, such as Castleman disease (angiofollicular lymphoid hyperplasia), intravascular T-cell lymphoma (and the related lymphomatoid granulomatosis; see Chap. 31), hypersensitivity lymph node hyperplasia (angioimmunoblastic or immunoblastic lymphadenopathy), and Kimura disease (lymphoid hyperplasia with eosinophilia mainly involving skin). In most of these neuropathies, particularly the one associated with Castleman disease, there is a paraproteinemia, often polyclonal, thereby relating this group to the paraproteinemic neuropathies and to osteosclerotic myeloma, discussed later. In several of our patients, the neuropathic manifestations appeared simultaneously with lymph node enlargement in the groin, axilla, or thorax. Clinically, the illness may take the form of GBS, chronic demyelinating polyneuropathy, subacute motor polyneuropathy or anterior horn cell disease, lumbar and brachial plexopathy, or a polyradiculopathy—each occurring as a paralympomatous condition clearly separable from cases of meningeal and neural infiltration by tumor. Corticosteroids have been helpful in some of our patients with the lymphoid diseases; in others, the neuropathy resolves spontaneously or with radiation of the lymph nodes but otherwise progresses for months. Vallat and colleagues have summarized their experience with the more conventional types of neuropathy accompanying non-Hodgkin lymphoma. Intravascular lymphoma, a widespread neoplastic and vascular disease (described in Chap. 31), may infiltrate the peripheral nerves in a multiple mononeuropathy pattern.

The various forms of paraneoplastic polyneuropathy are manifest clinically in 2 to 5 percent of patients with malignant disease. The figures are higher if one includes the neuropathies accounted for by malnutrition and pressure palsies that occur in the later stages of cancer and those identified by EMG in asymptomatic patients (Henson and Urich). Carcinoma of the lung accounts for approximately 50 percent of the cases of paraneoplastic sensorimotor polyneuropathy and for 75 percent of those with pure sensory neuropathy (Croft and Wilkinson); nevertheless, these neuropathies may be associated with neoplasms of all types.

Although anti-Hu binds to the peripheral nerve, the immunopathology of the paraneoplastic polyneuropathies has not been completely defined. In the purely sensory type, there is not only a loss of nerve cells in the dorsal root ganglia but also an inflammatory reaction (Horwich et al)—much the same changes as occur with the sensory neuronopathy of Sjögren syndrome. In the mixed sensorimotor polyneuropathy, degeneration is greater in the distal than it is in the proximal segments of the peripheral nerves, but it extends into the roots in advanced cases. Dorsal root ganglion cells may be reduced in number in both types. If the histologic examination is performed early in the course of the neuropathy, sparse infiltrates of lymphocytes are observed distributed in foci around blood vessels. No tumor cells are seen in the nerves or spinal ganglia, unlike the rare instances of carcinomatous and lymphomatous mononeuropathy multiplex, in which tumor cells actually infiltrate nerves. Degeneration of the dorsal columns and chromatolysis of anterior horn cells are secondary to changes in the peripheral nerves and roots.

The prognosis of the paraneoplastic neuropathies is poor. Even though the polyneuropathy may stabilize or even remit to some extent on its own or with therapy, most patients succumb to the underlying tumor within a year.

Treatment If the tumor can be treated effectively, the neuropathy may improve, the exception being pure sensory neuronopathy, which rarely does so. Treatment with plasma exchange, gamma globulin, or immunosuppression has had only a minimal effect, but there are anecdotal reports of success with each of these treatments applied early in the course. In the report by Uchuya and colleagues, only 1 of 18 patients with a subacute sensory neuropathy improved and another became dependent for sustained improvement on immune globulin; most of the others stabilized or worsened and the authors concluded that treatment was of doubtful value. Corticosteroids have not been tested in a systematic way for paraneoplastic neuropathy and there is little clinical evidence to support their use.

Subacute Toxic Neuropathies

Arsenical Polyneuropathy

Of the neuropathies caused by metallic poisoning, that caused by arsenic is particularly well characterized. In cases of chronic poisoning, the neuropathic symptoms develop rather slowly, over a period of several weeks or months and have the same sensory and motor distribution as the nutritional polyneuropathies. Gastrointestinal symptoms, the result of ingestion of arsenic compounds, may precede the polyneuropathy, which is nearly always associated with anemia, jaundice, brownish cutaneous pigmentation, hyperkeratosis of palms and soles, and later with white transverse banding of the nails (Mees lines). The disease is accompanied by an excess of arsenic in the urine and hair. Pathologically, this form of arsenical neuropathy is categorized as of the dying-back (axonal degeneration) type.

In patients who survive the ingestion of a single massive dose of arsenic, a more rapidly evolving polyneuropathy may appear after a period of 8 to 21 days as discussed earlier. Diagnosis and treatment of arsenical

poisoning are discussed further in Chap. 43. Here it is emphasized that the ingestion of fish in many areas of the industrialized world gives high levels of blood and urine arsenic, but the metal is in the form of arsenobetaine, which has low toxicity and does not cause neuropathy.

Lead Neuropathy (Plumbism)

This is an uncommon disorder. In adults, it occurs following chronic exposure to lead paint or fumes (from smelting industries or burning batteries) or from ingestion of liquor distilled in lead pipes. Its most characteristic presentation is a motor mononeuropathy in the distribution of the radial nerves (wrist and finger drop). In a few personally observed patients this was the main abnormality, but there was also a sensory loss in the radial territory of the hand. Less commonly, there is foot-drop occurring alone or in combination with weakness of the proximal arm and shoulder girdle muscles. As pointed out in Chap. 43, lead neuropathy seldom occurs in children, in whom poisoning usually results in an encephalopathy. Although the neuropathy has been known since ancient times, details of the pathobiology are still obscure. Axonal degeneration with secondary myelin change and swelling and chromatolysis of anterior horn cells has been described. Lead accumulates in the nerve and may be toxic to Schwann cells or to endothelial capillary cells, causing edema.

The diagnosis is established by the history of lead exposure, the predominant and restricted motor involvement, associated medical findings (anemia, basophilic stippling of red blood cell precursors in the bone marrow, a “lead line” along the gingival margins, colicky abdominal pain, and constipation), and the urinary excretion of lead and coproporphyrins. Blood lead levels of more than 70 $\mu\text{g}/\text{dL}$ are always abnormal. In patients with lower levels, doubling of the 24-h urinary lead excretion following an infusion of the chelating agent CaNa₂ ethylenediaminetetraacetic acid (EDTA) indicates a significant degree of lead intoxication. Coproporphyrin in the urine is abnormal in any amount, but it may also be found in porphyria, alcoholism, iron deficiency, and other disorders as well as in lead intoxication.

Treatment consists of terminating the exposure to lead and eliminating lead from the bloodstream and the bones by chelation as discussed in Chap. 43. For this purpose, penicillamine, which is generally safe and can be administered orally, is preferable to dimercaprol (British anti-Lewisite [BAL]) or EDTA.

Other Metals and Industrial Agents

Chronic poisoning with *thallium* and sometimes with *lithium*, *gold*, *mercury*, and *platinum* (in the antineoplastic agents cisplatin and carboplatin as discussed further on) produces a sensorimotor polyneuropathy; these intoxications are discussed in Chap. 43 and the acute form was addressed earlier in the chapter. A predominantly motor neuropathy is induced by occupational exposure to metallic mercury and mercury vapor but any connection to the mercury content in dental amalgam has little credibility. Exposure to manganese, bismuth, antimony, zinc, and copper may give rise to systemic signs of poisoning; some of them affect the central nervous system (CNS)

but one cannot be certain that any of them specifically involves peripheral nerves. The devastating encephalopathy of organic mercury toxicity does not, to our knowledge, cause neuropathy.

As mentioned in Chap. 43, a predominantly motor polyneuropathy has been reported as a rare complication of gold therapy for rheumatoid arthritis. Most often the cumulative dose of gold had exceeded 1 g but in a few instances the neuropathy occurred with 0.5 g. Painful distal burning is the initial complaint with weakness and wasting following. The onset of weakness, although usually insidious, can be abrupt enough to simulate GBS. There have been trigeminal, facial, and oculomotor palsies. One of the unusual features, not shared with most other toxic neuropathies, is a marked rise in CSF protein concentration.

A distal, symmetrical sensorimotor (predominantly sensory) neuronopathy may follow exposure to certain hexacarbon industrial solvents. These include *n-hexane* (found in contact cements, thus affecting "glue sniffers" who inhale the vapors); *methyl n-butyl ketone* (used in the production of plastic-coated and color-printed fabrics); dimethylaminopropionitrile (DMAPN), used in the manufacture of polyurethane foam); the fumigant *methyl bromide*; and the gas sterilant *ethylene oxide*. Operating room nurses may be affected by the latter when the agent is absorbed through the skin, leaving a characteristic rash at exposed sites (usually the wrists, where a surgical gown ends). A mild peripheral neuropathy and CNS changes of memory loss and headaches have been reported from this agent by Brashear and colleagues. Nurses are also subject to a risk of *nitrous oxide* neurotoxicity and this usually takes the form of a myelopathy similar to that seen with cobalamin deficiency. Most cases are caused by repeated use of the gas to induce euphoria. As with vitamin B-12 deficiency, the syndrome may be mistaken for a neuropathy but nerve conduction studies fail to demonstrate one. The associated macrocytic anemia is reversed by the administration of B₁₂, but the neurologic illness may be less responsive as discussed in Chap. 41.

Triorthocresyl phosphate and *acrylamide* are potent peripheral nerve toxins. Both of these drugs cause a dying-back polyneuropathy with axonal degeneration and have been used experimentally to produce this effect. *Vacor*, a phenylnitrosourea rodenticide, taken as a suicidal agent, gives rise to a profound sensory and autonomic neuropathy with abdominal pain and hyperglycemia caused by acute pancreatitis.

Detailed accounts of the clinical and experimental neurotoxicology of these agents can be found in the monograph by Spencer and colleagues.

Drug-Induced Neuropathies and Neuronopathies

A large number of medications are potential sources of polyneuropathy of predominantly sensory type. Most are dose-dependent and are therefore more or less predictable after large cumulative doses of the drug have been given (e.g., in cancer chemotherapy) or after prolonged administration for other reasons. A more complete list than can be compiled here can be found in the review by England and Asbury.

Antineoplastic Drugs (See also Chap. 43.) Among chemotherapeutic agents in current use, particularly *cisplatin*, *carboplatin*, and *bortezomib*, are known to evoke a dose-dependent, predominantly sensory polyneuropathy, which begins several weeks after completion of therapy in at least half of the patients. Proprioception and vibratory sensation are most severely impaired. Some patients develop acrodynia and episodic color changes in the fingertips and toes suggesting that autonomic nerves are also involved; in severe cases there is sensory ataxia and pseudoathetosis. The severity of histopathologic changes in the peripheral nervous system corresponds to the concentration of platinum in these tissues, the highest being found in dorsal root ganglia. Secondary degeneration in the posterior columns is the basis for a Lhermitte symptom reported by some patients.

The taxanes *paclitaxel* and the more potent *docetaxel*, both cited as inhibitors of the depolymerization of neurotubules, are used mainly in the treatment of ovarian cancer. They produce a sensory polyneuropathy similar to that of cisplatin. The nerve lesion regresses slowly with a reduction in dosage. Pathologic studies have shown a neuronopathy and distal axonopathy affecting mainly large fibers.

For decades it has been known that peripheral neuropathy commonly complicates the use of *vincristine*, an antineoplastic agent most widely used in treatment of the lymphomas and leukemia. Paresthesias are the most common early symptom, and loss of ankle jerks is an early sign. Some degree of weakness usually precedes objective sensory loss; the extensor muscles of the fingers and wrists are affected; later the dorsiflexors of the toes and feet causing foot-drop or, more often in our experience, foot-drop may appear first. With the dose regimens currently used, the weakness is usually mild, but in the past, some patients became quadriparetic and bedbound. Adults are more severely affected than are children, as are persons with preexisting polyneuropathies. The neuropathy is strictly dose-related and reduction in dosage is followed by improvement of neuropathic symptoms although this may take several months. Many patients are then able to tolerate vincristine in low dosage, such as 1 mg every 2 weeks, for many months. Thalidomide produces a similar sensory neuropathy. It is finding use in the treatment of inflammatory conditions such as Behçet disease, graft versus host reactions, erythema nodosum, lepromatous eruptions, aphthous stomatitis in AIDS patients and highly vascular tumors certain tumors such as renal cell cancer.

Antimicrobial Drugs As mentioned in Chap. 43, *isoniazid* (INH)-induced polyneuropathy was a common occurrence in the early 1950s when this drug was first used for the treatment of tuberculosis. Symptoms of neuropathy appeared between 3 and 35 weeks after treatment was begun and affected approximately 10 percent of patients receiving therapeutic doses in the upper range (10 mg/kg daily). The initial symptoms are symmetrical numbness and tingling of the toes and feet spreading, if the drug is continued, to the knees and occasionally to the hands. Aching and burning pain in these parts then becomes prominent. In addition to sensory loss, examination usually

discloses a loss of tendon reflexes and weakness in the distal muscles of the legs. Severe degrees of weakness and loss of deep sensation are observed only rarely.

Isoniazid produces its effects on the peripheral nerves by interfering with pyridoxine metabolism, perhaps by inhibiting the phosphorylation of pyridoxine (the collective name for the B₆ group of vitamins) and decreasing the tissue levels of its active form, pyridoxal phosphate. The administration of 150 to 450 mg of pyridoxine daily in conjunction with the isoniazid completely prevents the neuropathy. The same mechanism is probably operative in the neuropathies that occasionally complicate the administration of the isoniazid-related substances such as *ethionamide*, used sometimes in the treatment of tuberculosis and the now little-used antihypertensive agent *hydralazine*. Paradoxically, the taking of *extremely high doses of pyridoxine* over a prolonged period may actually cause a disabling, predominantly sensory ganglionopathy (Schaumburg et al, 1983).

A relatively mild sensory neuropathy (acral paresthesia) associated with optic neuropathy occasionally complicates *chloramphenicol* therapy. The chronic administration of *metronidazole* may have the same effect (and can produce lesions in the deep cerebellum). The newer antimicrobial, *linezolid*, has been associated with a fairly severe sensory neuropathy in a few cases after prolonged use. A predominantly motor neuropathy has been reported with the chronic administration of *dapsone*, a sulfone used to treat leprosy and certain dermatologic conditions. *Stilbamidine*, used in the treatment of kala azar, may also induce a purely sensory neuropathy with a propensity to affect the trigeminal nerves.

The introduction, in 1952, of *nitrofurantoin* for the treatment of bladder infections was soon followed by reports of neurotoxicity attributable to the drug. The earliest symptoms are pain and tingling paresthesias of the toes and feet, followed shortly by similar sensations in the fingers. If the drug is not discontinued, the disorder progresses to a severe, symmetrical sensorimotor polyneuropathy. Patients with chronic renal failure are particularly prone to neurotoxicity from nitrofurantoin because of diminished drug excretion resulting in high tissue levels. To make matters more complex, the uremic state itself may be responsible for a polyneuropathy so that the distinction between uremic and nitrofurantoin neuropathy may be impossible. The neuropathologic studies of Lhermitte and colleagues disclosed an axonal degeneration in peripheral nerves and sensory roots.

Cardiac Drugs *Amiodarone*, a drug used for treating recalcitrant ventricular tachyarrhythmias, induces a motor-sensory neuropathy in about 5 percent of patients after several months of treatment. It may also cause a toxic myopathy. *Perhexiline maleate* for the treatment of angina pectoris may also cause a generalized, predominantly sensory polyneuropathy in a small proportion of patients. *Hydralazine* as a neurotoxic agent has already been mentioned. Affected persons show a striking neuronal lipodosis. Patients taking *niacin* to lower blood cholesterol levels may experience distal and truncal paresthesias, but an associated neuropathy has been identified.

Other Pharmaceutical Agents Causing Polyneuropathy

The development of a sensorimotor neuropathy similar to that produced by INH may be associated with the chronic use of disulfiram in the treatment of alcoholism. Its neurotoxic effects have been attributed to the action of *carbon disulfide*, which is produced during the metabolism of the drug, and is known to cause polyneuropathy and sometimes an optic neuropathy in workers in the viscose rayon industry. Pathologic data, although scant, tend to discredit this notion, insofar as disulfiram evokes a wallerian type of axonal degeneration, whereas carbon disulfide neuropathy is characterized by swollen (giant) axons that are filled with neurofilaments (Bouldin et al).

Some patients who have taken *phenytoin* for decades may lose ankle and patellar reflexes and acquire mild distal symmetrical impairment of sensation, slowed conduction velocity in the peripheral nerves of the legs and rarely, weakness of the distal musculature. The mechanism and frequency of this complication are not clear. The cholesterol-lowering *statin* drugs have been tentatively implicated in a painful, paresthetic distal axonal polyneuropathy with retained reflexes (Gaist et al). More often the problem with statins is one of a toxic myopathy. The frequency of polyneuropathy is low but, if no other explanation is identified, it may be advisable to discontinue the drug. *Colchicine* has long been known to cause a myopathy, but a few cases of predominantly axonal sensory neuropathy have also been reported (*neuromyopathy*).

Among various other agents that cause neuropathy are hydroxychloroquine and colchicine are known to cause a toxic neuropathy. The anesthetic agent *trichloroethylene*, as with the aforementioned stilbamidine, has a predilection for cranial nerves, particularly the fifth. The neurotoxicity is apparently caused by dichloroacetylene, formed as a product of trichloroethylene. The neuropathic potential of nitrous oxide has already been mentioned. Most of the group of TNF- α (TNF- α) inhibitors may cause a polyneuropathy, but this category of agents do not appear to have a direct toxic effect on nerves but instead alter immune function in some way that results in a process that simulates chronic inflammatory demyelinating polyneuropathy (see further on).

Residual effects of polyneuropathy were seen in patients with the toxic eosinophilia-myalgia syndrome; the problem was traced to the ingestion of *adulterated L-tryptophan*, which had been used in nonprescription drugs for insomnia. One patient under our care suffered permanent areflexic quadriplegia. There may be an eosinophilic infiltrate in nerves, but the neuropathy is probably the result of a direct toxic mechanism. A sensory neuropathy, resulting from excessive *pyridoxine* ingestion alluded to earlier, is still seen among individuals who take huge doses of vitamin supplements. *Amitriptyline* is capable of producing paresthesias, but the effect seems to be idiosyncratic and infrequent.

Diabetic Neuropathy

Diabetes mellitus is the most common cause of polyneuropathy in general clinical practice, for which reason it is accorded a separate section. We are referring mainly

to a generalized, predominantly sensory syndrome, but several focal or regional forms of peripheral nerve disease also result from diabetes and for convenience of exposition, are included here. In recent years, attention has also been directed to a possible association between a nondescript sensory polyneuropathy and impaired glucose tolerance, even without manifest diabetes, persistent hyperglycemia, or an elevation of hemoglobin A_{1c}. The survey by Sumner and colleagues makes a case for such an association, but we remain uncertain about the relationship between glucose intolerance alone and polyneuropathy. By statistically adjusting for relevant factors such as glycemic control and glycosylated hemoglobin, Tesfaye and colleagues have suggested that some cardiovascular risk factors subsumed under the term "metabolic syndrome" (triglyceride levels, body mass, hypertension) are themselves risk factors for diabetic polyneuropathy.

Approximately 15 percent of patients with diabetes have symptoms and signs of polyneuropathy, but nearly 50 percent of cross-sectional population samples have evidence of peripheral nerve damage as judged by nerve conduction abnormalities. The duration of diabetes is perhaps the most important factor. Fewer than 10 percent of patients have clinically evident polyneuropathy at the time of discovery of diabetes, but this figure rises to 50 percent after 25 years. The presence of diabetic retinopathy is associated with higher incidences of neuropathy. It is not surprising, therefore, that neuropathy is most common in diabetics older than 50 years; it is infrequent in those younger than age 30 years and is rare in childhood. Dyck and colleagues (1993) studied diabetics in Rochester, Minnesota, and found that 54 percent with type 1 (insulin-deficient) and 45 percent with type 2 (insulin-resistant) had polyneuropathy. The percentages were lower when patients were selected on the basis of clinical symptoms alone rather than on the presence of changes in nerve conduction; close to 15 percent at the time of diagnosis in both groups. In the syndromes described further on, both type 1 and type 2 diabetic patients are susceptible, the duration of diabetes being a major factor.

Several fairly distinct clinical syndromes of diabetic neuropathy have been delineated: (1) the most common as noted is a distal, symmetrical, primarily sensory polyneuropathy affecting feet and legs in a chronic, slowly progressive manner; the others are (2) acute ophthalmoplegia that affects the third, and less often the sixth, cranial nerve on one side; (3) acute mononeuropathy of limbs or trunk including a painful thoracolumbar radiculopathy; (4) an acute or subacute painful, asymmetrical, predominantly motor, multiple neuropathy affecting the upper lumbar roots and the proximal leg muscles ("diabetic amyotrophy"); (5) a more symmetrical, proximal motor weakness and wasting, usually without pain and with variable sensory loss, pursuing a subacute or chronic course; and (6) an autonomic neuropathy involving bowel, bladder, sweating and circulatory reflexes. These forms of neuropathy often coexist or overlap, particularly the autonomic and distal symmetrical types and the subacute proximal neuropathies.

Most of the syndromes listed here are likely to be a result of ischemia or infarction of nerves or nerve fascicles, because of a diabetic microvasculopathy. All but the first are special types of *mononeuropathy multiplex*. The polyneuropathy is associated with occlusion of small endoneurial blood vessels (vasonervorum) but possibly also incorporate a poorly understood metabolic abnormality; however, other theories of causation abound. In recent years, an inflammatory process has been postulated as yet another mechanism of peripheral nerve damage. These aspects are discussed further on.

Distal Sensory Diabetic Polyneuropathy

The *distal, symmetrical, primarily sensory form* of polyneuropathy is the most common type. It is usually a chronic process, sometimes unnoticed by the patient. The main complaints are persistent and often distressing numbness and tingling, usually confined to the feet and lower legs and worse at night. The ankle jerks are absent and, sometimes, the patellar reflexes as well. As a rule, sensory loss is confined to the distal parts of the lower extremities, but in severe cases the hands are involved and the sensory loss may even spread to the anterior trunk, simulating a sensory level of spinal cord disease (Said et al, 1983). Trophic changes in the form of deep ulcerations and neuropathic degeneration of the joints (Charcot joints) are encountered in the most severe and long-standing cases, presumably as a result of sensory analgesia, trophic changes, and repetitive injury. (Foot ulcerations are more common simply as a result of the microvascular disease of skin in diabetic patients.) Muscle weakness is usually mild, but in some patients a distal sensory neuropathy is combined with a proximal weakness and wasting of the types mentioned earlier. Treatment of the acral pain may be a major problem and is discussed further on.

In another group of patients with diabetic polyneuropathy the clinical picture may be dominated instead by loss of deep sensation, ataxia, and atony of the bladder, with only slight weakness of the limbs, in which case it resembles tabes dorsalis (hence the term *diabetic pseudotabes*). The similarity to tabes dorsalis is even closer if lancinating pains in the legs, unreactive pupils, abdominal pains, and neuropathic arthropathy are present.

Acute Diabetic Mononeuropathies

Among these, *diabetic ophthalmoplegia* is a common occurrence, usually in a patient with well-established diabetes. It commonly presents as isolated, painful third nerve palsy with sparing of pupillary function. In the first autopsied patient reported by Dreyfus and colleagues, there was an ischemic lesion in the center of the retroorbital portion of the third nerve. Subsequently, a similar case was described by Asbury and colleagues (1970). Slightly less often, the sixth nerve on one side is involved. The disorder was described earlier in Chap. 14.

Isolated involvement of practically all the major peripheral nerves has been described in diabetes, but the ones most frequently affected are the *femoral, sciatic, and peroneal nerves*, in that order. Rarely is a nerve in the upper extremity affected. As mentioned, the acute mononeuropathies, both cranial and peripheral, are

presumably a result of infarction of the nerve, but it is only in pathologic studies of the third nerve that this basis has been established. Recovery is the rule but may take many months.

Diabetic Multiple Mononeuropathies and Radiculoplexus Neuropathy (Diabetic Lumbar Plexopathy; Diabetic Amyotrophy; Garland Syndrome)

This category overlaps with the mononeuropathies. A syndrome of painful unilateral or asymmetrical multiple neuropathies tends to occur in older patients with relatively mild or even unrecognized diabetes. Multiple nerves are affected in a random distribution (mononeuropathy multiplex). The mononeuropathies often emerge during periods of transition in the diabetic illness, for example, after an episode of hyper- or hypoglycemia, when insulin treatment is initiated or adjusted, or when there has been rapid weight loss.

The most characteristic syndrome affects the lumbar roots. Pain, which can be severe, begins in the low back or hip and spreads to the thigh and knee on one side; the discomfort has a deep, aching character with superimposed lancinating jabs and there is a propensity for pain to be most severe at night. Weakness and later atrophy are evident in the pelvic girdle and thigh muscles, although the distal muscles of the leg may also be affected. The patellar reflex is lost on the affected side. Curiously, we have found the opposite patellar reflex to be absent in some patients without explanation. Deep and superficial sensation may be intact or mildly impaired, conforming to either a multiple nerve or multiple adjacent root distribution (i.e., L2 and L3, or L4 and L5). The pain lasts for several days and then gradually abates. Motor recovery is the rule although months and even years may elapse before it is complete. The same syndrome may recur after an interval of months or years in the opposite leg. The EMG shows denervation in the lumbar and sometimes adjacent myotomes.

This form of neuropathy has been referred to as *diabetic amyotrophy*, a term that draws attention to one facet of the syndrome. Garland's name (also Bruns's) has been attached to this diabetic lumbar radiculoplexopathy based on his thorough report (but he mistakenly attributed the condition to a spinal cord lesion). Clinical experience has shown that an identical painful lumbosacral neuropathy may develop in nondiabetics; possibly this form is also vasculopathic or vasculitic. While lumbar disc herniation, retroperitoneal hematoma compressing upper lumbar roots, carcinomatous meningeal seeding, and neoplastic and sarcoid infiltration of the proximal lumbar plexus enter into the differential diagnosis, the diabetic type is usually so distinctive as to permit recognition on clinical grounds alone. In one of the most informative reexaminations of this syndrome, Barohn and colleagues (1991) point out that there is considerable overlap between the chronic polyneuropathy of diabetes and this rapidly evolving regional disorder. They also point out a high incidence of involvement of the L5 root, but this is difficult to reconcile with the frequent finding of hip flexor and quadriceps weakness. As with the diabetic

mononeuropathies, the upper extremities are only rarely affected by this process.

Also observed in diabetic patients is a relatively painless syndrome of proximal symmetrical leg weakness, wasting, and reflex loss of more insidious onset and gradual evolution as discussed by Pascoe and colleagues. The iliopsoas, quadriceps, and hamstrings are involved in varying degrees. The muscles of the scapulae and upper limbs, usually the deltoid and triceps, are affected less frequently. Sensory changes, if present, are distal, symmetrical, and usually mild.

In an attempt to delineate these types of proximal diabetic neuropathies, it must be emphasized that they overlap and that distal parts of a limb may be involved to a mild degree and the evolution of symptoms varies. Whether the proximal and distal syndromes should be distinguished on pathologic or electrophysiologic grounds is not clear.

A syndrome of *thoracoabdominal radiculopathy* characterized by severe pain and dysesthesia is also well described. Almost always the diabetes has been of long standing (Kikta et al). The pain is distributed over one or several adjacent segments of the chest or abdomen; it may be unilateral, or less often bilateral, and, as with the lumbar radiculoplexopathy, sometimes follows a period of recent weight loss. Superficial sensory loss can be detected over the involved area in most patients. The pathology of this state is not known, but it is presumed to be an ischemic radiculopathy. The EMG changes consist of fibrillations of the paraspinal and abdominal muscles in one or more adjacent myotomes, corresponding to the painful area. With control of the diabetes, or perhaps spontaneously, recovery eventually occurs but it may be protracted. The differential diagnosis includes preeruptive herpes zoster, sarcoid infiltration of nerve roots, and thoracic disc rupture.

In all forms of diabetic polyneuropathy the CSF protein may be elevated from 50 to 150 mg/dL and sometimes higher. The protein concentration is usually normal in cases of diabetic mononeuropathy. Whether a slight elevation of CSF protein, discovered incidentally, can be attributed to diabetes in the absence of a polyneuropathy is uncertain.

Autonomic Diabetic Neuropathy

Symptoms of *autonomic involvement* include any combination of pupillary and lacrimal dysfunction, impairment of sweating and vascular reflexes, nocturnal diarrhea, atonicity of the gastrointestinal tract (gastroparesis) and bladder dilation, erectile dysfunction, and postural hypotension. The most striking examples in our experience include severe abdominal and limb pain in young type 1 diabetics, symptoms comparable to the crises of *tabes dorsalis* that required narcotics to control.

The basis of this type of autonomic involvement is not well understood. Duchen and associates, who studied the sympathetic ganglia in diabetic patients with autonomic symptoms, described vacuoles and granular deposits in sympathetic neurons and little if any neuronal degeneration; there was also a loss of myelinated nerve

fibers in the vagus and splanchnic nerves and the rami communicantes, as well as changes in neurons of the intermediolateral columns of the spinal cord.

Pathology and Pathophysiology of the Diabetic Neuropathies

In the typical symmetrical diabetic distal sensory polyneuropathy, loss of myelinated nerve fibers is the most prominent finding. In addition, segmental demyelination and remyelination of remaining axons are apparent in teased nerve fiber preparations. The latter findings are probably too severe and widespread to be simply a reflection of axonal degeneration. Occasionally, repeated demyelination and remyelination lead to onion-bulb formations of Schwann cells and fibroblasts, as it does in the relapsing inflammatory neuropathies. Unmyelinated fibers are also reduced in number in most specimens. Similar scattered lesions are found in the posterior roots and posterior columns of the spinal cord, and in the rami communicantes and sympathetic ganglia. Under the electron microscope, the basement membranes of intraneural capillaries are thickened and duplicated. There are changes in the microvasculature of the nerves as well, similar to what is seen in other organs and in the skin of diabetics.

As can be surmised from this discussion, uncertainties persist about the pathogenesis of the diabetic neuropathies. Both the cranial and peripheral mononeuropathies, as well as the painful, asymmetrical, predominantly proximal neuropathy of sudden onset, have been considered by most neuropathologists to be ischemic in origin, secondary to a vasculopathy of the vasa nervorum. Obliterative microvascular lesions were well illustrated by Raff and coworkers and corresponding multiple small infarcts were found in the nerve trunks in other studies. The observations of Dyck (1986b) and of Johnson and their associates also suggested that all forms of diabetic neuropathy had the same microvascular basis. The latter authors described multiple foci of fiber loss throughout the length of the peripheral nerves, beginning in the proximal segments and becoming more frequent and severe in the distal. This pattern of change differs from that observed in diffuse metabolic disease of Schwann cells and in the dying-back type of neuropathy. Fagerberg had earlier noted that the fascicular capillaries and epineural arterioles have thickened and hyalinized basement membranes, similar to the microvascular changes seen in the retina, kidney, and other organs. But occlusion of vessels and frank infarction of nerve has not been observed in most cases of polyneuropathy for which reason a vascular pathogenesis remains unsettled.

An alternative view has been offered, based largely on the work of Dyck and colleagues and of Said and coworkers (2003). They have found areas of perivascular inflammation and adjacent damage to nerve fascicles in the proximal radicular plexus syndrome. These findings, if valid, have implications for possible treatment with anti-inflammatory drugs.

Several biochemical findings implicated in diabetic polyneuropathy and their interpretations were reviewed

by Brown and Greene, who advanced the idea that persistent hyperglycemia inhibits sodium-dependent myo-inositol transport. Low levels of intraneural myo-inositol reduce phosphoinositide metabolism and sodium-potassium adenosine triphosphatase (ATPase) activity. Others have emphasized a deficiency of aldose reductase and an elevation of polyols (particularly sorbitol) as being causally important. The role of factors other than hyperglycemia that are subsumed under the "metabolic syndrome" mentioned earlier is also unclear. In reviewing these studies, one can only conclude that a convincing biochemical pathogenesis for neuropathy in diabetes has yet to be formulated.

Another group of novel findings holds that there is a reduction in trophic factors within diabetic nerves (nerve growth factor [NGF], vascular endothelial growth factor [VEGF], erythropoietin); partial reversal of the polyneuropathy has been obtained in animals by replacement of these factors through gene therapy. Trials addressing this mode of treatment are noted later.

Treatment The only preventive treatment for diabetic neuropathy is the maintenance of blood glucose concentration at close to normal range. The prevailing view, derived from long-term human studies, is that there is a relationship between peripheral nerve damage and inadequate regulation of the diabetes. This is supported by the findings of the National Diabetic Complications Trial, in which 715 patients with type 1 diabetes were followed for 6 to 10 years. There was a relation between strict glucose control by means of an intravenous insulin infusion system and a reduction or delay in the occurrence of painful neuropathic symptoms, retinopathy, and nephropathy. However, this came at the price of a threefold increase in hypoglycemic reactions (see also Samanta and Burden). Whether similar protective effects of glucose control apply to type 2 diabetes is not known, but for most patients rigid control is impractical. A number of small trials have been conducted with aldose reductase inhibitors based on theoretical considerations of the above-discussed metabolic changes. Some recent interest has also been directed at the therapeutic use of gangliosides, which are normal components of neuronal membranes and can be administered exogenously. These approaches have not entered routine practice.

Treatment using gene transfer had been pursued by our group. In experimental models of diabetic neuropathy, the intramuscular administration of VEGF has had a beneficial effect on several measures of nerve conduction and on the histologic changes of diabetic nerve damage in the treated limb (Ropper et al, 2009). Whether this was mediated by a trophic influence on nerves and Schwann cells, or is the result of angiogenesis, is not known. With similar intentions, two trials of NGF injections in almost 500 patients conducted by Apfel and colleagues gave equivocal results, the first being positive and the followup study not showing improvement. VEGF has resulted in improvement of sensory symptoms but not of nerve conduction or of the sensory examination in a trial we conducted.

The distressing paresthesias of the distal extremities can be managed with amitriptyline, other tricyclic antidepressants, or one of the newer generation of antidepressants, duloxetine, gabapentin, or pregabalin but the response is usually incomplete. Shooting, stabbing pain also responds to some degree to anticonvulsant drugs but only modest effects can be expected. Gabapentin may give reasonable results, perhaps in part because high doses are tolerated (Gorson et al, 1999). Topical creams with capsaicin, lidocaine or other substances, or compounds with several of these (including ketorolac, gabapentin, ketamine) have been found helpful by a few patients. Nerve blocks and epidural injections have been helpful in very few patients. In the proximal asymmetrical, truncal, or ophthalmoplegic neuropathies, the severe pain usually lasts for only a short period and requires the judicious use of analgesics, as outlined in Chap. 8. The *course* in patients with the distal, symmetrical sensory neuropathy is generally of slow progression, but in the other types improvement and eventual recovery may be expected over a period of months or years.

ASYMMETRICAL AND MULTIFOCAL POLYNEUROPATHIES (MONONEUROPATHY, OR MONONEURITIS MULTIPLEX) (Table 46-4)

In addition to diabetes, several systemic conditions are accompanied by acute or subacute involvement of *multiple individual nerves* serially or almost simultaneously. This configuration gives rise to the distinctive clinical picture of mononeuropathy multiplex. The most notable examples of this syndrome are associated with the vasculitides that produce nerve infarction, polyarteritis nodosa and other vasculitides and particularly a form of idiopathic vasculitis that is confined to the peripheral nervous

Table 46-4

CAUSES OF MONONEUROPATHY MULTIPLEX

Common

- Polyarteritis nodosa
- Microscopic polyangiitis
- Churg-Strauss disease
- Leprosy^a
- Wegener granulomatosis
- Diabetes
- Hereditary liability to preserve palsies
- Cryoglobulinemia
- Sarcoidosis
- Lyme disease
- HIV

Less Common

- Paraneoplastic
- Amyloidosis
- Systemic lupus
- Rheumatoid arthritis
- Leukemia-lymphoma infiltration
- Intravascular lymphoma
- Sjögren syndrome

^aLeprosy is the most common cause of this syndrome worldwide but infrequent in areas in which it is not endemic.

system, from which the associated term *mononeuritis multiplex* is derived. The distinctive features of the multiple mononeuropathy syndromes are the acute or subacute evolution of complete or almost complete sensorimotor paralysis in the distribution of single peripheral nerves. In addition to vasculitis or the nerves, sarcoidosis, forms of HIV-related neuropathy, Leprosy and Lyme disease may become manifest in this fashion, probably from infiltration or inflammation of nerves rather than infarction. The diabetic mononeuropathies were addressed in the preceding section.

Vasculitic Neuropathies

More than half of all cases of mononeuropathy multiplex can be traced to a *systemic vasculitis* involving the *vasa nervorum*. These are the main causes of mononeuritis multiplex. Included in this category are polyarteritis nodosa, the Churg-Strauss syndrome (allergic bronchial asthma and eosinophilia), rheumatoid arthritis, lupus erythematosus, scleroderma, cryoglobulinemia, Wegener granulomatosis, and the aforementioned idiopathic variety of vasculitis that is confined to the peripheral nerves and has no systemic manifestations. In Said's series of 425 cases of vasculitis (2005) affecting the peripheral nerves, 24 percent were associated with polyarteritis nodosa, 23 percent with rheumatoid arthritis, and about 32 percent with other connective tissue diseases; in 21 percent there were no signs of vasculitis beyond the peripheral nerves. Elevation of the sedimentation rate, C-reactive protein and other serologic abnormalities are typical features but not invariable of this group. The most recent addition to the diagnostic list has been a microscopic polyangiitis that is different from the vasculitis of medium-sized vessels that characterizes the remainder of the group. This subject has been reviewed by Collins, who summarizes guidelines for diagnosis.

Polyarteritis Nodosa

Almost 75 percent of cases of polyarteritis nodosa include involvement of the small nutrient arteries of peripheral nerves (these figures come from autopsy series), but a symptomatic form of neuropathy develops in about half this number. Nonetheless, involvement of the peripheral nerves may be the principal or first sign to the diagnosis, before the main components of the clinical picture—abdominal pain, hematuria, fever, eosinophilia, hypertension, vague limb pains, and asthma—had not fully declared themselves or had been misinterpreted.

Although characteristically a disease of multiple discrete mononeuropathies, the syndrome associated with polyarteritis nodosa may appear more or less generalized and symmetrical as a result of the accumulation of many small nerve infarctions; i.e., it can simulate a polyneuropathy. In these cases, careful clinical and electrophysiologic examinations disclose elements of mononeuritis that have been engrafted on an otherwise generalized process. For example, an asymmetrical foot- or wrist-drop or a disproportionate affection of one nerve in a limb, such as ulnar palsy with relative sparing of function of the adjacent median nerve, are clues to the multifocal nature of the process. More often it takes form throughout its course of random infarctions of two or more individual nerves.

The onset is usually abrupt with symptoms of pain or numbness at a focal site along a nerve or in the distal distribution of an affected nerve, followed in hours or days by motor or sensory loss in the distribution of that nerve and then by involvement in a saltatory fashion of other peripheral nerves. Both the spinal and cranial nerves may be affected but far less often than the nerves in the limbs. Virtually no two cases are identical.

The CSF is usually normal. Nerve biopsy, usually taken from the sural nerve, will in most cases show the necrotizing arteritis in medium-size vessels (fibrinoid necrosis of all 3 coats of the vessel walls), with infiltrating eosinophils and occlusion of vessels. Muscle biopsy may also show perivascular inflammation and necrosis, but the diagnostic yield is less than for biopsy of a nerve, particularly an affected one. On the basis of the smaller size of affected vessels and the presence of perinuclear antinuclear cytoplasmic autoantibodies (p-ANCA), Lhote and colleagues have differentiated a "microscopic" polyarteritis. Rapidly progressive glomerulonephritis and lung hemorrhage are the additional features of the latter disease, neuropathy occurring somewhat less frequently than in typical polyarteritis.

Treatment Based on the response to the systemic vasculitides with ANCA activity, mononeuritis multiplex caused by vasculitis has been treated with corticosteroids and either rituximab 375 mg/m² weekly for 4 weeks, or cyclophosphamide 1 g/m² intravenously once a month for several months, but other equivalent regimens have been suggested. For the corticosteroid regimen, we have used intravenous methylprednisolone, 1.5 mg/kg, for several days, followed by oral corticosteroid treatment. It appears from clinical experience that corticosteroids alone are often inadequate, but some clinicians have taken this approach initially. Azathioprine is a reasonable alternative if cyclophosphamide is not tolerated. Treatment must be continued for at least several months. In intractable cases and in those with systemic involvement, treatment with methotrexate may be indicated, or this may be used initially. Spontaneous remission and therapeutic arrest are known, but many cases have a fatal outcome from kidney and systemic complications. The infarctive nerve palsies and sensory loss of the mononeuropathies generally persist to a large degree even when the systemic disease is brought under control.

Churg-Strauss and Hypereosinophilic Syndrome

These closely related systemic illnesses involve multiple individual peripheral nerves, much as in polyarteritis. A characteristic feature is the excess of circulating and tissue eosinophils (more so than in polyarteritis) and a tendency of the vasculitis to involve the lungs and skin, in contrast to the renal and bowel infarctions of polyarteritis nodosa. There is considerable degree of pathologic and clinical overlap between both polyarteritis and Churg-Strauss necrotizing vasculitis with the more benign hypereosinophilic syndrome that is less aggressive and has a greater tendency for eosinophilic infiltration of other tissues. One medication (zafirlukast) that is used in Europe to treat asthma has precipitated several cases of Churg-Strauss disease. Rarely, the overall illness has apparently been

preceded by treatment with a macrolide antibiotic (e.g., azithromycin), estrogen, or carbamazepine, but these associations are uncertain and most cases are idiopathic.

In Churg-Strauss disease, rhinitis or asthma may be present for years and only later is there marked eosinophilia and organ infiltration, particularly an eosinophilic pneumonitis. The neuropathy that then develops in approximately three-quarters of patients is usually preceded by fever and weight loss and takes the form of an acute, painful mononeuritis multiplex. A granular cytoplasmic pattern of antineutrophil cytoplasmic autoantibodies (c-ANCA) of the same type that occurs in Wegener granulomatosis is found in more than half of cases. The histologic feature in nerve biopsies is similar to polyarteritis nodosa, but the eosinophilic infiltration tends to be more intense. We have seen other types of cutaneous diseases with vasculitic mononeuritis, the most impressive being a massive leukocytoclastic vasculitis of the skin (necrotic polymorphonuclear cells surrounding venules) resulting in large confluent hemorrhagic lesions.

The *idiopathic eosinophilic syndrome* comprises a heterogeneous group of disorders, the common features of which are a persistent and extreme degree of eosinophilia and eosinophilic infiltration of many organ systems. Neuropathy occurs in fewer than half of the cases, taking the form of a painful diffuse sensorimotor syndrome with axonal damage or of a mononeuritis multiplex (see Moore et al). The pathologic appearance is one of diffuse infiltration of the nerves by eosinophils rather than a vasculitis. The neuropathic effects are attributable to the infiltration itself or to a postulated tissue-damaging effect of the eosinophilic cell.

Treatment Both the Churg-Strauss and the idiopathic hypereosinophilic syndrome are treated initially with high doses of corticosteroids, with which the peripheral eosinophilia, as well as tissue damage, may abate in several weeks or months. Further immunosuppressive treatment in the forms of rituximab as discussed previously, azathioprine, methotrexate, or cyclophosphamide has been used in fulminant or refractory cases, which includes most of the ones that we have seen.

Wegener Granulomatosis

This disorder gives rise to asymmetrical multiple mononeuropathy indistinguishable from the other angiopathic neuropathies described earlier and, probably based on the same mechanism, mononeuropathies of the lower cranial nerves directly as they exit the skull and pass through the retropharyngeal tissues. The frequency of peripheral nerve involvement in Wegener disease is much lower than in the other of classic vasculitides and the affected vessels are of a smaller caliber than in polyarteritis nodosa. Nonetheless, DeGroot and colleagues emphasized in a prospective analysis of 128 patients with Wegener disease that 25 had evidence of mononeuritis multiplex, with the peroneal nerve most often involved, and an even greater number had distal polyneuropathy; however, the proportion of their cases in which neuropathy was the presenting or sole manifestation of disease was higher than in other series. The finding of circulating c-ANCA

is relatively specific for Wegener granulomatosis and for Churg-Strauss disease, as mentioned earlier (Specks et al), and helps to differentiate it from polyarteritis (which may be associated with p-ANCA) and from retropharyngeal carcinoma, chordoma, sarcoidosis, and herpes zoster. Wegener vasculitis as it affects the lower cranial nerves is discussed in Chap. 47.

Treatment is along the lines of corticosteroids and rituximab or cyclophosphamide as already discussed.

Essential Mixed Cryoglobulinemia

This process may be associated with a vasculitic mononeuritis multiplex as well as a more generalized polyneuropathy. In many cases, glomerulonephritis, arthralgia, and purpura are conjoined, reflecting the systemic nature of the vasculopathy, but the mononeuritis may occur in isolation. The evolution in the cases under our care has been slower than in the typical vasculitic neuropathies, sometimes taking weeks or months between attacks of mononeuropathy. The neurologic disorder may become quiescent for long periods, during which time considerable improvement may occur. There is no evident relationship between the mode of onset or severity of the neuropathy and the concentration of cryoprecipitable proteins in the serum. These proteins can be detected by cooling the serum and demonstrating a precipitation of IgG and IgM proteins that redissolve upon warming to 37°C (98.6°F). To demonstrate this phenomenon the blood sample must be carefully transported to the laboratory in a warm water bath. An association of cryoglobulinemia with hepatitis C is well known, but many patients have had polyneuropathy from cryoglobulins but without the infection.

Treatment Garcia-Bragado and colleagues suggested that the neuropathy can be stabilized by corticosteroids and cyclophosphamide, but rituximab has been increasingly employed rather than cyclophosphamide and plasma exchange; the comparison between approaches has not been systematically tested. If the underlying problem is hepatitis C infection, pegylated alpha-interferon and ribavirin are usually administered as antiviral agents, with rituximab if the neuropathy is severe. It is too early to judge if the new protease inhibitors for the treatment of hepatitis C will reduce the occurrence and degree of polyneuropathy. Other aspects of the condition are discussed further under "Polyneuropathy Associated with Paraproteinemia" and "Other Vasculitic Neuropathies."

Rheumatoid Arthritis

Some 1 to 5 percent of patients with rheumatoid arthritis have vasculitic involvement of one or more nerves at some time in the course of their disease, apart from more mundane pressure neuropathies as a result of thickened tendons and destructive joint changes. The arteritis is of small-vessel fibrinoid type and immune globulins are demonstrable in the walls of vessels. Most of the affected patients under our care have had severe rheumatic disease for many years and were strongly seropositive. In addition to the neuropathy, such patients often have rheumatoid nodules, skin vasculitis, weight loss, and fever. There are rarer forms of chronic progressive polyneuropathy

that complicate rheumatoid arthritis; they are described further on.

Systemic Lupus Erythematosus

Approximately 10 percent of patients with lupus exhibit symptoms and signs of peripheral nerve involvement, but only a negligible number occur before the established and more advanced stages of the disease (i.e., rarely has it been the initial presentation). In our several patients, the polyneuropathy has taken the form of a symmetrical, progressive sensorimotor paralysis, beginning in the feet and legs and extending to the arms, evolving over a period of several days or weeks, thereby simulating GBS. In a few, weakness and areflexia were more prominent than the sensory loss; the latter involved mainly vibratory and position senses. A more common syndrome in our experience has been a progressive or relapsing disease that cannot be distinguished clinically from chronic inflammatory demyelinating polyneuropathy (discussed further on). Multiple mononeuropathies have also been reported, as has involvement of the autonomic nervous system. An elevation of CSF protein that is found in some instances suggests nerve root involvement. Sural nerve biopsies may show vascular changes consisting of endothelial thickening and mononuclear inflammatory infiltrates in and around the small vessels for which reason the disease is included here with the other vasculitic neuropathies. Axonal degeneration is the most common change, but a chronic demyelinating pathology has also been described (Rechthand et al). Vascular injury from deposition of immune complexes is the proposed mechanism of nerve damage.

Isolated (Nonsystemic) Vasculitic Neuropathy

In contrast to the aforementioned disorders, which involve several tissues and organs in addition to the peripheral nerves, necrotizing vasculitis may be limited to the nerves. Cases of this type appear as often as all the other systemic vasculitic types together. This restricted form of mononeuritis multiplex usually presents as a subacute symmetrical or asymmetrical polyneuropathy with superimposed mononeuropathies or solely with multiple mononeuritis. Circulating antineutrophil cytoplasmic antibody (ANCA) is found in a few cases, but other tests for inflammatory and connective tissue diseases are negative. In the series reported by Collins and colleagues (2003), the sedimentation rate was mildly elevated, the mean being 38 mm/h, with only one-quarter having values greater than 50 mm/h. The main diagnostic difficulty in diagnosis arises when the EMG performed early in the course of illness shows conduction block that simulates a demyelinating polyneuropathy. Nerve biopsy should then settle the issue.

Treatment The neuropathy tends to be less aggressive (and nonlethal) than the systemic forms of vasculitic neuropathy and has usually responded to corticosteroids without treatment with cyclophosphamide (Dyck et al, 1987). However, in the aforementioned series reported by Collins, the use of cyclophosphamide for 6 months with corticosteroids resulted in a more rapid remission and fewer relapses. An expert group has provided guidelines for treatment specifically of this

condition that approximates this approach by adding an immunosuppressive agent to corticosteroids only if the disease behaves aggressively (Collins et al, 2010).

Other Vasculitic Neuropathies

In the past, administration of pooled serum for the treatment of various infections led to brachial plexus neuritis or to an immune mononeuropathy multiplex, presumably from deposition of antibody–antigen complexes in the walls of the vasa nervorum. A similar “serum sickness” reaction occurred after certain viral infections associated with arthritis, rash, and fever. The neuropathy that arises with hepatitis C infection may be of this type, perhaps mediated by the frequently associated cryoglobulinemia as mentioned earlier. Interferon, which has been effective in treating the hepatitis, may also ameliorate the neuropathy, but greater success has been achieved with cyclophosphamide. Pooled immunoglobulin for the treatment of diverse neuromuscular diseases such as Guillain-Barré syndrome and myasthenia gravis has not, to our knowledge, led to a serum-sickness neuropathy, but one of our patients with Churg-Strauss disease developed a fulminating vasculitic skin eruption while being treated with IVIg.

In 2 cases of severe systemic vasculitis related to administration of hydralazine, we observed no neuropathic features; whether this applies to other drug-induced vasculitides is not known. Minocycline is another drug that has been associated in rare instances with a vasculitis, including mononeuropathies. The increasing appearance of vasculitic neuropathy with *HIV infection*, including a type that is independent of CMV infection, has already been mentioned; such cases have tended to improve spontaneously or with corticosteroid therapy. In about half of these cases the CSF contains polymorphonuclear cells. From time to time a patient with a lymphoproliferative disorder such as Hodgkin disease will develop mononeuritis multiplex that is found by biopsy to be caused by vasculitis. (A chronic demyelinating, nonvasculitic polyneuropathy is more common with lymphomas of any type as discussed earlier.)

A rare *paraneoplastic variety of vasculitic neuropathy* has also been described. Oh reported 2 of his patients and reviewed 13 previous ones. The most common underlying cancer was of the small oat cell lung type. Anti-Hu antibodies that are typical of paraneoplastic neurologic diseases from this cancer are generally not detected (see Chap. 31). Other solid tumors (renal, gastric, gynecologic) have been associated with a similar neuropathy but only in a few instances. Almost all have had slightly elevated protein concentration in the CSF but few showed a pleocytosis. At autopsy, the vasculitis was limited to nerve and muscle.

The role of an obscure small-vessel vasculitis in otherwise idiopathic axonal polyneuropathies of elderly patients has been reported, but is, in our view, controversial. We have not found, as did Chia and colleagues, an unexpected vasculitis in the nerve biopsies of such patients. The vasoocclusive and infiltrative condition of intravascular lymphoma often includes a syndrome of multiple painless mononeuropathies as part of a larger multifocal illness of the central and peripheral nervous system.

Neuropathy of Critical Limb Ischemia

A few patients with severe atherosclerotic ischemic disease of the iliac or leg arteries will be found to have localized sensory changes or diminished reflexes. Usually, the other effects of ischemia—claudication and pain at rest, absence of distal pulses and trophic skin changes—are so prominent that the neurologic changes are minor by comparison. In experimental studies, combined occlusion of the aorta and multiple limb vessels are required to produce neural ischemia because of the profusely ramifying vasculature. In our experience of 12 patients with a critically ischemic leg, there was a neuropathy with a pronounced distal predominance; sensory loss in the feet was worse than the symptoms might suggest and there was mild weakness of the toes and depression or loss of the ankle reflex (Weinberg et al). Although paresthesias, numbness, and deep aching pain at rest were characteristic, the patients were more limited by symptoms of their vascular claudication than by the neuropathic ones. Restoration of circulation to the limb by surgical or other means resulted in some improvement of the regional neuropathy. Reviews of the literature on this subject can be found in the writings of Eames and Lange.

A poorly understood but presumably localized ischemic neuropathy occurs in the region of arteriovenous shunts that have been placed for the purpose of hemodialysis. Complaints of transient diffuse tingling of the hand are not uncommon soon after creation of the shunt but only a few patients develop persistent forearm weakness, numbness and burning in the fingers, reflecting variable degrees of ulnar, radial, and median nerve, and possibly also muscle, ischemia. The role of an underlying uremic polyneuropathy in facilitating this neuropathy has not been studied.

A progressive, symmetrical polyneuropathy as a result of systemic cholesterol embolism has been described by Bendixen and colleagues. An inflammatory and necrotizing arteritis surrounds embolic cholesterol material within small vessels and appears to account for the progression of symptoms. This neuropathic process is more often discovered at autopsy than it is in the clinic, being eclipsed during life by the cerebral manifestations of cholesterol embolism. The peripheral part of the illness simulates the polyneuropathy of a small-vessel polyarteritis.

Sarcoid Neuropathies

The generalized granulomatous disease of sarcoidosis infrequently produces subacute or chronic polyneuropathy, polyradiculopathy, or mononeuropathies. A painful, small-fiber sensory neuropathy has also been described by Hoitsma and colleagues. Any of the neuropathies may be associated with granulomatous lesions in muscles (polymyositis) or with signs of CNS involvement, most often of the stalk of the pituitary with diabetes insipidus or a myelopathy (see Chap. 44).

Involvement of a single nerve with sarcoid most often implicates the facial nerve (facial palsy), but sometimes multiple cranial nerves are affected in succession (see Chap. 47). Next in frequency is weakness and reflex and sensory loss, appearing sequentially

(polyradiculopathy), in the distribution of several spinal nerves or roots. The occurrence of large, irregular zones of sensory loss over the trunk is said to distinguish the neuropathy of sarcoidosis from other forms of mononeuropathy multiplex. This pattern particularly when accompanied by pain, resembles diabetic radiculopathy (see earlier in "Diabetic Multiple Mononeuropathies and Radiculoplexus Neuropathy").

Unlike the cases of sarcoid polyneuropathy we have reported (Zuniga et al), in the series of 11 patients with sarcoid neuropathy studied by Said and colleagues (2002), only 2 were known to have pulmonary granulomas before the onset of neuropathic symptoms; 6 had a focal or multifocal neuropathic syndrome (including 1 with a clinical and electrophysiologic pattern that simulated multifocal conduction block). The remainder had a nonspecific symmetric polyneuropathy, 1 of which had an acute onset. Facial diplegia was common, as is well known. The pathologic changes in nerve and muscle biopsy specimens consisted mainly of epineurial granulomas and endoneurial inflammatory infiltrates, but there were indications of necrotizing vasculitis in 7 cases. Among the cases we studied, 6 of 10 had a subacute or chronic sensorimotor polyneuropathy. It is notable that in only 2 of Said's patients were levels of angiotensin-converting enzyme elevated in the serum.

Lyme Neuropathies (See also Chap. 32)

The neuropathy that develops in 10 to 15 percent of patients with this disease takes several forms. Cranial nerve involvement is well known, uni- or bilateral facial palsy being by far the most frequent manifestation. Other cranial nerves may also be affected as may almost any of the spinal roots, mostly in the cervical or lumbar region. Even phrenic nerve palsy has been attributed to Lyme disease in a few cases. A concurrent mild or moderate aseptic meningoradiculitis (10 to 100 mononuclear cells/mm³) is characteristic (although this may also occur in HIV and CMV and other forms of neuritis). The CSF glucose is usually normal but has been slightly depressed in a few cases with multiple radiculopathies. Some of the CSF cells may have immature features suggesting a lymphomatous infiltration. (See further on and Chap. 32 for further details of the laboratory diagnosis.) There may be radicular pain not unlike that of cervical or lumbar disc or plexus disease.

The triad of cranial nerve palsies, radiculitis, and aseptic meningitis is most characteristic of Lyme disease during its disseminated phase, i.e., from 1 to 3 weeks after the tick bite or from the appearance of the typical rash. The disease tends to be seasonal in the period of maximal tick exposure. The special polyradiculitis form of Lyme is discussed further on.

Besides the just described cranial neuropathies, the following are the main neuropathic syndromes of Lyme disease: (1) multiple mononeuropathies (involvement of a single major nerve in the limbs, resulting in an isolated foot- or wrist-drop—a distinctly rare pattern); (2) lumbar or brachial plexopathy (the latter being well described but rare); (3) a predominantly sensory polyneuropathy in which paresthesias and loss of superficial sensation in the feet and legs are coupled with loss of ankle jerks;

(4) a generalized axonal polyneuropathy (Loggigian et al), mainly sensory and sometimes accompanied by a mild encephalopathy; and (5) acute GBS (we have encountered only 2 such cases in more than 400 patients with Guillain-Barré but the syndrome appears to be more common in Europe following *Borrelia* infection).

Electrophysiologic testing indicates that the various peripheral nerve syndromes frequently overlap. All of the preceding processes excepting the one that resembles GBS usually occur as subacute or late complications of Lyme disease, several months or, rarely, years after the initial infection (in untreated cases). These late neuropathic syndromes respond less favorably to treatment than do the acute ones, and have a less certain connection to the infection (see further on). As the disease is not fatal, there are few adequate pathologic studies of the peripheral nerves in Lyme disease. The infective agent has not been demonstrated in nerve tissue, but perivascular inflammation and vasculitic changes are found in small vessels within the nerves.

Lyme Polyradiculitis and Bannwarth Syndrome This is perhaps the best characterized, but not the most common, group of Lyme neuropathies. A painful lumbosacral polyradiculitis has long been known in Europe by the term *Bannwarth syndrome* (in France as *Garin-Bujadoux syndrome*). The pathogen in Europe is a *Borrelia* spirochete slightly different from the one that causes Lyme disease in North America. In Bannwarth syndrome there is an intense inflammatory reaction in the cauda equina, giving rise to sciatic and buttock pain and bladder dysfunction. Less frequently, a cervical polyradiculopathy occurs with shoulder and arm pain that cannot be distinguished on clinical grounds from brachial neuritis. Cases of Bannwarth syndrome from North American Lyme under our care have progressed subacutely over days or weeks and involved the L2-L3-L4 roots, first one leg, then the other, and, subsequently, the midcervical roots on one or both sides. Sparing of a proximal or distal part of a limb while the adjacent part is weakened gives rise to a striking syndrome. One or more thoracic radiculopathies may be added and cause local discomfort.

The nerve conduction tests show preservation of sensory potentials, which marks the process as radicular. Headache and a marked pleocytosis (over 100 mononuclear cells/mm³) in the spinal fluid may accompany the pain and usually precedes the radiculopathies by days. Polymerase chain reaction for the detection of the organism in the CSF gives variable results, especially after several days of neurologic illness. A value above unity of CSF to serum anti-Lyme antibodies is probably a dependable indicator of acute or subacute disease, but there have been few systematic studies of this measurement. Oligoclonal bands in the CSF are common as a reflection of these antibodies.

A similar syndrome of lumbar polyradiculitis may also be caused by the herpes and Epstein-Barr viruses or more often by an opportunistic CMV infection in a patient with AIDS.

Diagnosis This is both aided and at times confused by serologic testing (see Chap. 32). The enzyme-linked immunosorbent assay (ELISA) is not altogether satisfactory

because it frequently yields false-positive and, occasionally, false-negative results. Western blot testing of CSF is more specific. Information to the effect that the patient has lived in or visited an endemic area is useful, but far more compelling is evidence of a tick bite followed by the characteristic rash, or a well-defined history of nonneurologic manifestations of Lyme disease (cardiac, arthritic). Bilateral palsy in any of these clinical contexts also favors the diagnosis of Lyme.

Treatment Treatment of the Lyme neuropathic syndromes is with intravenous antibiotics, preferably ceftriaxone 2 g daily for 1 month. More prolonged or intravenous treatment has not been shown to be superior. Corticosteroids have an uncertain role in the painful radicular syndromes, but we have used them in low doses and they relieved pain. In most series, there is recovery or virtually complete resolution of radicular symptoms in approximately 90 percent of patients, although this may take months. Facial palsies also tend to improve, but with a lower rate of complete resolution. It has been stated that many of the peripheral and cranial neuropathies improve even without treatment, but this has not been studied systematically.

Sjögren Disease–Associated Neuropathies

This is a chronic, slowly progressive autoimmune disease characterized by lymphocytic infiltration of the exocrine glands, particularly the parotid and lacrimal glands, that results in keratoconjunctivitis sicca and xerostomia (dry eyes and mouth). These core features may be combined with arthritis or with a wide range of other abnormalities, notably lymphoma, vasculitis, IgM paraproteinemia, renal tubular defects (renal tubular acidosis), and, quite often, a predominantly sensory polyneuropathy (see review by Kaplan et al). In the series collected by Grant and colleagues, the neuropathy was the presenting problem in 87 percent of 54 patients with Sjögren disease. The sicca symptoms are often mild and reported only upon specific inquiry. A symmetrical sensory polyneuropathy or a sensory ganglionopathy are the most common patterns. Sensorimotor polyneuropathy, polyradiculoneuropathy, autonomic neuropathy, or mononeuropathy (most often of the trigeminal nerve, as described by Kaltrieder and Talal) are less common. We have observed yet another neuropathic syndrome taking the form of asymmetrical sensory loss, mostly of position sense and involving the upper limbs predominantly, in association with tonic pupils and trigeminal anesthesia that is probably a variant of the ganglionopathy.

The sensory polyneuropathies of the Sjögren syndrome are of particular interest to neurologists, as they will encounter most cases before other physicians (Griffen et al). More than 80 percent of affected patients are older women. The polyneuropathic syndrome often begins with paresthesias of the feet, usually mild in degree. The main clinical features are subacute and widespread sensory loss that may include the trunk and sometimes, profoundly diminished kinesthetic sense, giving rise to sensory ataxia of the limbs and of gait that reflect a ganglionitis. Loss of pain and temperature sensation is variable; tendon reflexes are abolished.

A nondescript large- or small-fiber distal sensory neuropathy is also known, for which reason testing for Sjögren-related serum antibodies is included in the general evaluation of polyneuropathies in older patients, and the heterogeneity of sensory neuropathy presentation has been emphasized by several authors. In time, some patients develop autonomic abnormalities such as bowel atony, urinary retention, loss of sweating, and pupillary changes. There is usually little or no pain, but there have been exceptions.

Diagnosis Sjögren disease–associated neuropathy or ganglionopathy should be suspected in an older woman with sensory neuropathy or neuronopathy, particularly if sicca symptoms are present. There may be telangiectasias over the bridge of the nose, on the lips, and fingers. The evaluation is aided by the Schirmer and Rose Bengal tests, which usually demonstrate a reduction of tearing. Even without this confirmatory test, we have found it advisable to perform a biopsy of the lip (at the epithelial–mucosal juncture) to detect inflammatory changes in the small salivary glands. This is a minor office procedure in most instances. The diagnosis of Sjögren syndrome from the biopsy requires at least 2 collections of 50 or more lymphocytes in a 4-mm² specimen. Some patients have serologic abnormalities such as antinuclear antibodies (anti-Ro, also termed SS-A, and anti-La, or SS-B) or monoclonal immunoglobulins, particularly of the IgM subclass. The frequency of specific Sjögren-specific antibodies varies between series; they may be useful as screening tests, but the lip biopsy appears to be more sensitive. In our series of 20 cases with minor salivary gland biopsies that demonstrated inflammatory changes diagnostic of the syndrome, only 6 had serologic evidence of the disease and 2 had positive serologic tests but a negative biopsy (Gorson and Ropper, 2003). The sedimentation rate in our patients was often slightly elevated; however, only 5 of our 20 had a value greater than 40 mm/min and many have had normal or only slightly elevated C-reactive protein levels. The main differential diagnostic entity, if the neuropathy appears subacutely, is a paraneoplastic sensory ganglionitis.

Mellgren and also Leger and their colleagues have stressed that a proportion of unexplained polyneuropathies in middle and late life are putatively caused by Sjögren syndrome. The latter authors found typical Sjögren abnormalities in the lip biopsies of 7 of 32 patients with chronic axonal polyneuropathy that could not otherwise be classified. Several other studies have corroborated this finding of inflammatory disruption of the minor salivary glands in obscure neuropathies, particularly in older women and in some men. The diagnosis in our clinics has not been nearly as frequent in this group. Nonetheless, a search for Sjögren disease may be revealing in otherwise obscure sensory neuropathies.

Nerve biopsies have variably revealed necrotizing vasculitis, inflammatory cell infiltrates, and focal nerve fiber destruction. Usually, the CSF protein is normal and there is no cellular reaction. The few times a dorsal root ganglion has been examined in autopsy material; there were infiltrates of mononuclear cells and lymphocytes and destruction of nerve cells.

Treatment Corticosteroids in doses of approximately 60 mg daily of prednisone, cyclophosphamide (100 mg per day), and rituximab (1,000 mg per day, 2 weeks apart) have been used when the neuropathy is severe and are indicated when there is vasculitis involving renal and pulmonary structures. We have initially administered prednisone 60 mg daily, sometimes in tandem with intermittent plasma exchange, but with little evidence of response, before adding a second immunosuppressive agent.

The review of the neurologic manifestations of Sjögren syndrome by Lafitte and by Berkowitz and colleagues are recommended.

Idiopathic Sensory Ganglionopathy (Chronic Ataxic Neuropathy)

In addition to the subacute pansenory syndrome described previously and paraneoplastic, postinfectious, and toxic processes, there is a yet another more chronic idiopathic syndrome characterized by severe global sensory loss and ataxia. We have encountered several such patients resembling the cases described by Dalakas. The numbness and sensory findings progressed over months and spread to proximal parts of the arms and legs and then to the trunk. The face and top of the scalp were finally involved. Despite ataxia and complete areflexia, muscular power remained normal and pain was not a problem. There are reports of fasciculations in a few patients, but not in the ones we have seen. Within a year, most of these patients became completely disabled from the ataxia, unable to walk or even feed themselves. Autonomic failure was another feature in a few and one of our patients became deaf. Extensive examinations for an occult cancer, paraproteinemia, Sjögren disease, Refsum disease, autoimmune diseases, and all potential causes of an ataxic neuropathy proved to be frustratingly negative. Of course, it is possible that some patients had an as yet undiscovered tumor. Yet other instances have had all the features of a truncal–limb sensory neuropathy, with little or no ataxia and only muted reflexes; these have had a more benign course but still no cause was found (Romero et al). Illa and colleagues (2001), in a review of 17 patients with idiopathic sensory ataxic neuropathy, found antibodies against the ganglioside GD₁ in only 1 case and concluded that the majority was not caused by an immunologic mechanism.

The motor nerve conduction studies have been normal or slightly impaired, while the sensory potentials were eventually lost (but they may at first be normal). A puzzling feature in 2 patients has been an unexpected preservation of many sensory nerve potentials even after a year of illness. In these cases, the process presumably lay in the dorsal roots rather than in the ganglia. In a few instances the MRI has shown a change in the posterior columns of the spinal cord, certainly as a secondary phenomenon from the root disease. The spinal fluid has generally contained a slightly elevated protein concentration with few or no cells, up to 18/mm³ in our cases.

Pathologic examination of the sensory ganglia in a few cases has disclosed an inflammatory process identical to that of Sjögren disease. Our attempts at treatment using plasma exchanges, IVIg, corticosteroids, and immunosuppressive agents have been mostly unsuccessful.

Also mentioned here is a subacute or chronic *idiopathic small-fiber ganglionopathy* that affects function primarily. These patients complain of pain and burning in proximal body parts, including the face, tongue, and scalp with reduced sensation of pinprick in affected areas. The reflexes may be preserved and vibration sensory perception may be preserved. Our experience with such patients and anecdotal responses to treatment was summarized by Gorson and colleagues (2008). Whether such aberrant proximal sensory complaints as “burning mouth syndrome” (see Chap. 10) are allied with this entity is not clear but they may occur together.

Idiopathic Autonomic Neuropathy

Under this term is collected a group of subacute and chronic dysautonomias that on extensive evaluation cannot be attributed to diabetes, amyloidosis, autoimmune disease, Fabry disease, HIV, toxin exposure, or another systemic disease. A few cases will be found to be due to one of several rare mutations in genes, of which four sites have been described so far (SPTLC1, HSN2, IKBKAP, NTRK1).

A number of such cases, almost half in the series of Suarez and colleagues (1994), have been acute in onset and conform most closely to the “pure pandysautonomia” condition described by Young and colleagues, discussed earlier as a variant of Guillain-Barré syndrome. The others follow a subacute or chronic course and about one-fourth of these have a serum antibody that is directed against the acetylcholine receptor of sensory ganglia (Klein et al). Orthostatic hypotension is the leading feature; in those with the previously mentioned antibody, pupillary changes and difficulty with accommodation, dry mouth and dry eyes, and gastrointestinal paresis were the most common findings according to Sandroni and colleagues. Perhaps a subgroup is in some way related to Sjögren syndrome as sicca symptoms are prominent, but these later features could just as well be a component of the autonomic failure. There is not enough information to determine if all these cases are accounted for by one process or to judge the effects of various immune treatments.

Migratory Sensory Neuritis (Wartenberg Syndrome)

The defining features of this unusual syndrome are searing and pulling sensations involving small cutaneous areas, that are evoked by extending or stretching the limb, as happens when reaching for an object, kneeling, or pointing with the foot. The pain is momentary but leaves in its wake a patch of circumscribed numbness. Cutaneous sensory nerves must be involved in some way and are irritated during such mechanical maneuvers. The areas involved are usually proximal to the most terminal sensory distribution of nerves encompassing, for example, a patch on the lateral side of the hand and the proximal fifth finger or a larger region over the patella (these were the sites affected in 3 of our patients). Recovery of the area of numbness takes several weeks, but it may persist if the symptoms are induced repeatedly. Except for these patches of cutaneous analgesia, the clinical examination is normal. Selected sensory nerves

may show abnormalities in conduction, but nerve conduction studies are for the most part normal. Matthews and Esiri have listed the many areas that may be affected in a single patient and have described an increase in the endoneurial connective tissue in a biopsied sural nerve. The syndrome may come in episodes over many years, without symptoms between attacks. A spurious diagnosis of multiple sclerosis is often made. The pathology is not certain, but some form of fibrosis or inflammation of cutaneous nerves has been suggested, perhaps similar to the condition of perineuritis described below.

Sensory Perineuritis

Under this title, Asbury and colleagues (1972) described a patchy, burning, painful, partially remitting distal cutaneous sensory neuropathy. The pathologic picture was one of inflammatory scarring restricted to the perineurium, with compression of the contained nerve fibers. As with the Wartenberg syndrome above, reflexes and motor function were unaffected. Digital nerves, as well as the medial and lateral branches of the superficial peroneal nerve, were the ones most often involved. Matthews and Squier have described a trigeminal and occipital distribution of painful sensory symptoms and 1 of the patients of Asbury and coworkers (1972) also had symptoms on the scalp. A Tinel sign is characteristically elicited by tapping the skin overlying the involved cutaneous nerves and is indicative of partial nerve damage and regeneration.

The differential diagnosis includes numerous other forms of painful sensory neuropathy, but the patchy and painful, and often burning, quality of symptoms distinguishes this process. The diagnosis can only be established with certainty by biopsy of a distal cutaneous branch of a sensory nerve. Perhaps some of the large group of patients with “burning” feet may have a small-fiber neuropathy that affects intradermal nerve fibers in a similar way (see further on).

Since the original report, the fibrosing perineurial pathologic changes that characterize perineuritis have been described in a number of polyneuropathies, mainly in diabetic patients but also in those with cryoglobulinemia, nutritional diseases, and malignancies (Sorenson et al). However, these patients displayed diverse clinical patterns of neuropathy, mainly mononeuritis multiplex and demyelinating neuropathy. Nonetheless, the pathologic feature of perineuritis may be less specific than initially thought but a perineuritis clinical syndrome is still a useful concept. A proportion of the idiopathic cases seem to respond to corticosteroids.

Celiac-Sprue Neuropathy

Among the multitude of odd neurologic manifestations attributed to this disease, the best known ones are cerebellar ataxia and myoclonus. In addition, Hadjivassiliou and colleagues have reported patients with a range of neuromuscular disorders in whom the neurologic symptoms antedated the diagnosis of the bowel disorder. A nondescript sensorimotor neuropathy was the most frequent, but one patient had mononeuropathy multiplex and Chin and colleagues have reported a multifocal neuropathy pattern. In a small prospective survey of treated celiac

disease, Luostarinen and colleagues found 23 percent with evidence of a polyneuropathy by nerve conduction testing, but the clinical findings were scant. Antigliadin antibodies (simple antibodies directed against gluten), as well as more specific anti-transglutaminase antibodies and histologic examination of a duodenal biopsy are confirmatory of the diagnosis. Luostarinen and colleagues suggested that a search be made for these antibodies in patients with polyneuropathies of obscure origin. It is not clear how many of their cases could be attributed to nutritional deficiency. We have not encountered a definite instance despite attempts to detect the special sprue antibodies in the evaluation of over 200 cases of otherwise obscure polyneuropathy.

Neuropathies Associated With AIDS (See also Chap. 33)

Patients infected with HIV are prone to several types of neuropathies, including a predominantly sensory type that may be painful, a lumbosacral polyradiculopathy, cranial (mainly facial nerve) and limb mononeuropathies, CIDP, GBS, and a vasculitic mononeuritis multiplex—none of which differs from the idiopathic or conventional varieties except that there is often a pleocytosis in the spinal fluid. Almost unique and common patterns in this group are the CMV cauda equina neuritis syndrome and an acute or subacute painful infiltrative lymphocytic neuropathy—the diffuse infiltrative lymphocytosis syndrome (DILS; Moulingier et al). Polyneuropathy may also be induced by antiviral agents that are used in the treatment of HIV infection, as discussed in Chap. 33.

SYNDROME OF POLYRADICULOPATHY (WITH AND WITHOUT MENINGEAL INFILTRATION)

These are among the most clinically complex diseases of the peripheral nerves. Involvement of multiple spinal nerve roots produces a distinctive or sometimes confusing constellation of findings, usually quite different from those of polyneuropathy and from multiple mononeuropathies. As described earlier, muscle weakness caused by polyradiculopathy is characteristically asymmetrical and variably distributed in proximal and distal parts of the limbs, reflecting a pattern of muscles that share common root innervations (e.g., the combination of weakness in hamstring and gastrocnemius, or of iliopsoas, quadriceps, and obturator). However, muscles with similar innervation are not necessarily affected to the same degree because of the disproportionate contribution of a given root to each muscle. Sensory loss tends also to be patchy and to involve both the proximal and distal aspects of a dermatome. Pain is common in a radicular pattern, but sometimes only in the distal distribution of the root or in the back. The sensory findings tend to be less prominent than the motor ones. In keeping with nerve root pattern, certain tendon reflexes may be spared; a normal ankle jerk combined with an absent knee jerk, or the opposite, are particularly suggestive of a polyradiculopathy (or a

lumbar plexopathy). Pain often takes the form of sharp jabs projected into the innervated zone of the involved root. As with mononeuritis multiplex, the cumulative effect of multiple root lesions can simulate a polyneuropathy in which case the tendency for polyradiculopathy to involve proximal muscles is the most helpful distinguishing feature.

A special pattern of polyradiculopathy occurs wherein all the sensory roots are involved, simulating *tabes dorsalis*. The clinical state is similar to that of a sensory ganglionopathy described earlier. Large- and small-fiber sensory loss is combined with ataxia while power is normal and there is no atrophy. A prominent feature is shooting and burning pain. We have occasionally found sensory loss over the anterior abdomen and thorax in these cases, a finding more typical of chronic dying-back axonal polyneuropathy.

Some of the diseases that affect nerve roots predominantly already have been discussed. They can be grouped into three broad categories: (1) diseases of the spinal column that compress adjacent roots; (2) infiltrative diseases of the meninges that secondarily involve the roots as they course through the subarachnoid space, mainly neoplastic of granulomatous infiltrations such as sarcoid; and (3) intrinsic neuropathies, inflammatory, infectious, or diabetic, that have a predilection for the radicular portion of the nerves. An elevated CSF protein and a pleocytosis usually accompany neoplastic or inflammatory meningeal diseases; the others show variable formulas in the spinal fluid.

Often what appears to be a polyneuropathy on clinical grounds will be found to have an electrophysiologic pattern of root disease at multiple spinal levels. McGonagle and colleagues estimated that polyradiculopathies accounted for 5 percent of all cases referred to their EMG laboratory and our experience approximates this. Consequently, careful EMG and nerve conduction testing is the most useful ancillary examination in cases of complex neuropathic syndromes because the pattern of muscle denervation can be ascertained with greater certainty than by clinical means and a common root pattern can then be logically derived. Of great confirmatory value is the preservation of sensory potentials in nerves that innervate regions of sensory loss and supply weak and denervated muscles. This proves that the lesion is located proximal to the dorsal root ganglion and spares the peripheral sensory axons. Loss of the F and H late responses is also typical of polyradiculopathies. The proximal location of the lesion can be further corroborated by early evidence of weakness and denervation in the paraspinal, gluteal, or rhomboid muscles, which are supplied by nerves that arise very proximally from the roots. In axonal cases of neuropathy, these proximal muscles are the last to be involved.

Among the acute and subacute meningeal radiculopathies, neoplastic infiltration (carcinomatous and lymphomatous) is the most common. Others are Lyme disease, sarcoidosis, herpes virus, arachnoiditis, AIDS-related cauda equina neuritis of CMV infection, or independently, EBV meningoradiculitis. In the past, meningeal syphilis of course was a common cause (*tabes dorsalis*).

Diseases of the spine, exemplified by lumbar and cervical spondylosis, commonly impinge on nerve roots,

as discussed in Chap. 11. Metastatic carcinoma of the vertebral bodies may compress one or several adjacent roots by encroaching on posterolateral recesses of the canal and proximal neural foramina. Among rare causes of polyradiculopathy is a chronic lumbosacral syndrome associated with dural eventrations surrounding nerve roots, which may complicate ankylosing spondylitis.

However, one is often confronted by a pattern of subacute or chronic polyradiculopathy and abnormal CSF formula for which extensive examination fails to identify any of the diseases enumerated above. This idiopathic form of polyradiculopathy comes to our attention several times yearly. Some will turn out to have a lymphomatous infiltration at autopsy for which reason we have on occasion asked a neurosurgeon to remove a midlumbar (L2 or L3) motor rootlet for examination. Also particularly difficult diagnostically is a polyradiculopathy that involves the motor roots exclusively or predominantly and is indistinguishable from motor neuron disease except for the absence of widespread denervation or of progressive upper motor neuron signs and differing from the immune motor neuropathies discussed further on by the absence of conduction block.

SYNDROME OF CHRONIC SENSORIMOTOR POLYNEUROPATHY

In these common syndromes, reduced sensation, weakness, muscular atrophy, and loss of tendon reflexes progress over a period of months or years. Within this large category, two groups are distinguished. In the first and *less chronic* of the two, the neuropathy appears over months or a year or two. Comprising this group are *acquired* processes such as certain metabolic and immune-mediated polyneuropathies. Paraneoplastic neuropathies may also fall into this category, although they are more often subacute in onset, being almost fully developed in a matter of weeks. Leprous neuritis is the one infectious member of this group and also the one exception to the rule that all chronic neuropathies are more or less symmetrical in pattern. The polyneuropathies that make up the second group are *far more chronic* than the first, evolving insidiously over many years or decades; these are mainly the *heredodegenerative* diseases of the peripheral nervous system caused by specific genetic mutations.

Acquired Forms of Chronic Polyneuropathy

Polyneuropathy Associated With Paraproteinemia

The occurrence of a chronic sensorimotor polyneuropathy in association with an abnormality of serum immunoglobulins is recognized with increasing frequency, but its boundaries are still not well established as will be apparent in the following discussion. The excess blood protein, called a *paraprotein* or "M-spike," is usually in the form of a monoclonal immunoglobulin. It may be an isolated abnormality or a by-product of a plasma cell malignancy, specifically multiple myeloma, plasmacytoma, or Waldenström macroglobulinemia. Several lines of evidence suggest that

a pathogenetically active antibody against components of myelin or axon is present in at least some of these cases. Special forms of neuropathy are also associated with amyloidosis. Both the acquired and genetic forms of amyloidosis are discussed further on.

Neuropathy With Monoclonal Gammopathy of Undetermined Significance (MGUS, Benign Monoclonal Gammopathy) The association of a nonneoplastic IgM monoclonal protein and a neuropathy was first described by Forssman and colleagues and was treated as coincidental until Kahn established a compelling statistical association between the two conditions. A more direct relationship was established by the finding of antiperipheral nerve antibodies in some patients who had such a protein in their blood. This category of polyneuropathy is associated with a monoclonal or sometimes polyclonal excess of immunoglobulin (IgG, IgM, or IgA, rarely others, mainly with a kappa light chain components; see Kyle and Dyck). These cases are far more common than those caused by a malignant plasma cell disorder. In our experience, monoclonal proteins underlie the largest group of otherwise unexplained neuropathies in adults.

The polyneuropathy associated with monoclonal gammopathy affects mainly, but not exclusively, males in the sixth and seventh decades of life. The onset is insidious over weeks and months or more, with numbness and paresthesias of the feet and then of the hands, followed by a relatively symmetrical weakness and slight wasting of these muscles. In some patients, sensory signs predominate. The tendon reflexes, eventually lost or diminished, may be preserved in the early phases of the illness. The course is usually slowly progressive, sometimes static after a year or so, and rarely remitting and relapsing. The CSF typically shows an elevation of the protein in the range of 50 to 100 mg/dL, and this is not due to passive diffusion of the excess paraprotein into the CSF.

The majority of cases of polyneuropathy with monoclonal gammopathy have a demyelinating or mixed axonal-demyelinating pattern on the EMG and nerve conduction study, but once the illness is well established, most will have predominantly axonal features. With few exceptions we have been unable to distinguish the axonal and demyelinating groups on clinical grounds or by their response to therapy (Gorson et al, 1997). Sural nerve biopsies show a loss of myelinated fibers of all sizes; unmyelinated fibers are mostly spared; hypertrophic changes, reflecting cycles of demyelination and remyelination with fibrosis are present in about half the cases according to Smith and colleagues. They found the monoclonal IgM antibody bound to surviving myelin sheaths and Latov and coworkers have shown that the serum IgM fraction often displays antimyelin activity.

Typically, the monoclonal protein in the blood is present in a concentration much less than 2 g/dL and there is no evidence of multiple myeloma or other malignant blood dyscrasia. It should be emphasized that routine serum protein electrophoresis (SPEP) fails to detect the majority of these paraproteins; immunoelectrophoresis (IEP) or the more sensitive immunofixation testing is required. The bone marrow aspirate shows a normal or only mildly increased proportion of

plasma cells, which are the source of the paraprotein and the plasma cells are not morphologically atypical as they are in myeloma. Insofar as myeloma becomes manifest in perhaps one-quarter of patients many years after the gammopathy has been recognized, the condition is termed *monoclonal gammopathy of undetermined significance* (MGUS), although the older term *benign monoclonal gammopathy* is less cumbersome.

The importance of excess immunoglobulin as a cause of neuropathy can be appreciated by noting that 6 percent of patients referred to the Mayo Clinic with chronic polyneuropathy of unknown cause and as many as 20 percent in our clinical material and in other series have proved to have a monoclonal paraproteinemia (of course, the majority of patients with a blood paraprotein do not develop neuropathy).

Despite the fact that IgG is the most frequent paraprotein in adults, a polyneuropathy is associated somewhat more often with the IgM class. Combining three large series of patients with neuropathy and monoclonal paraproteinemias (62 patients of Yeung et al, Gosselin et al, and our patients as reported by Simovic et al), 60 percent had IgM, 30 percent IgG, and 10 percent with IgA subclass paraproteins. An identical but infrequent condition exists in which only the light chain component of an immunoglobulin is overproduced by the plasma cells and is found exclusively in the urine (similar to the Bence Jones protein of multiple myeloma).

Four-fifths of patients have had a *kappa* light chain component, as mentioned previously, although *lambda* light chain has special significance as discussed further on in relation to plasmacytoma and the polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (POEMS) syndrome. In our experience and in that of others, patients with IgM paraprotein more often have severe sensory findings and a demyelinating type of nerve conduction abnormality when compared with the IgG group. However, with the exception of the special anti-MAG syndrome (see later), we have not found the extent of difference in clinical features and response to treatment between the immunoglobulin subclasses that has been reported by others (Simovic et al).

Although more than a dozen specific antibodies against myelin and other components of nerve have been identified among the paraproteins, the ones that give rise to the most distinctive clinical syndromes, present in 50 to 75 percent of patients with IgM-associated neuropathies, are those that react with a MAG, related glycolipids, or sulfatide components of myelin (the latter are referred to as sulfate-3-glucuronyl paragloboside [SGPG] and related sulfatides). Proprioceptive sensory loss with gait imbalance, tremor, and the Romberg sign are typical findings in the group with anti-MAG activity, while weakness and atrophy tend to appear later in the illness. Other IgM antineural antibodies have a more tentative connection to polyneuropathy. It is reasonable to assume that IgG monoclonal gammopathies are also capable of causing chronic neuropathies, but the evidence is less compelling and based mainly on the frequency of their presence in cases of otherwise unexplained polyneuropathy. Indeed, it has been suggested that in many reported instances the

association with neuropathy with IgG paraproteinemia is coincidental. The anti-MAG illnesses are relentlessly progressive at various rates in most patients at various rates but in about 15 percent of our patients with anti-MAG antibody the illness has been mild and static for years at a time, even without treatment.

Because of the risk of myeloma or Waldenström disease, bone marrow examination is generally performed some time in the course and particularly if the concentration of the paraprotein exceeds 3 g/dL or climbs progressively over years, or if other hematologic changes such as unexplained anemia or thrombocytopenia develop.

TREATMENT In most cases of uncomplicated monoclonal gammopathy with polyneuropathy that are associated with IgG or IgA paraproteins, particularly if not of long standing, plasma exchange may produce transient improvement for several weeks to months (Dyck et al, 1991). The treatment regimen generally is a total volume of approximately 200 to 250 mL/kg exchanged in each of 4 to 6 treatments over about 10 days and the removed plasma replaced with a mixture of albumin and saline.

In patients who have IgM serum activity against specific components of myelin (particularly anti-MAG), the results of treatment have been inconsistent and generally less favorable. Plasma exchange alone has effected transient improvement in half of cases but sustained improvement in only 10 to 20 percent of our patients. Series of plasma exchanges every 2 to 4 months has sometimes resulted in transient responses. According to some reports, the response to immunosuppression with intravenous cyclophosphamide or fludarabine, mycophenolate, or oral chlorambucil, when coupled with plasma exchanges, has been somewhat better, at times allowing a reduction in the frequency of exchanges but our experience has generally not affirmed this. Rituximab, which has the appeal of having a preferential effect on the B-cell lymphocyte population, after initial enthusiasm based on small series, has given conflicting and generally negative results in several trials but may be reasonable to try in intractable cases. A listing of the applicable trials that have been reported up to 2009 has been given by Brannigan.

Improvement with high-dose infused immune globulin (IVIg) has been transiently effective in half of our cases with typical paraproteinemia and in 20 percent of those with anti-MAG neuropathy but the illness nonetheless progresses in most patients. In almost all instances, immunosuppression and plasma exchanges or IVIg, if used, must be repeated indefinitely at intervals of 1 to several months as determined by the clinical course. An indwelling catheter is then usually required to allow repeated venous access. This group of neuropathies responds poorly or not at all to corticosteroids.

POEMS Syndrome, Osteosclerotic Myeloma, and Multiple Myeloma A neuropathy associated with *multiple myeloma* has already been mentioned; it complicates 13 to 14 percent of cases of multiple myeloma and has a disproportionately high association with the osteosclerotic form of the disease. An abnormal monoclonal globulin (mainly with the *kappa* light chain component in multiple myeloma but *lambda* in the osteosclerotic type)

is found in the serum of more than 80 percent of patients with myelomatous neuropathy.

In a special and small group of patients with osteosclerotic myeloma, there is a predominantly demyelinating sensorimotor polyneuropathy and systemic disease termed *POEMS* (i.e., polyneuropathy of moderate severity is associated with organomegaly, endocrinopathy, elevated *M* protein, and skin changes, mainly hypertrichosis and skin thickening). The same process has been referred to as the Crow-Fukase syndrome in Japan, where the disease is prevalent. In many cases there is lymphadenopathy attributable to the angiofollicular hyperplasia of Castleman disease. Another characteristic feature of the osteosclerotic-related polyneuropathy is a greatly elevated CSF protein.

The presence of the disease can be suspected from the presence of demyelinating features on the nerve conduction studies, an immunoglobulin spike in the blood, sometimes polyclonal or biclonal rather than monoclonal and, as mentioned, possessing a lambda light chain component. The diagnosis requires the demonstration of one or more osteosclerotic lesions by a radiographic survey of the long bones, pelvis, spine, and skull as well as a PET study, which usually shows the osteosclerotic lesions as highly active (a bone scan is insensitive) and a bone marrow examination, which shows a moderate increase in the number of well-differentiated plasma cells. In most of our patients there have been several discrete bone lesions concentrated in the ribs and spine; the skull and long bones may harbor such lesions as well, or there may be a single lesion, which is often situated in the spinal column. Biopsy of a bone lesion is justified. The organomegaly and skin changes are apparently the result of high levels of circulating VEGF that is produced by the tumor and is useful in confirming the diagnosis.

TREATMENT OF POEMS The neuropathy that complicates a solitary plasmacytoma may improve markedly following irradiation of the bone lesion. Multiple lesions, including those in the *POEMS* syndrome, when treated with chemotherapy (melphalan and prednisone) or focused radiation, may lead to some improvement or stabilization in the neuropathy. Treatment with plasma exchange has yielded uncertain but generally positive short-term results in our patients. Autologous stem cell transplantation or bevacizumab (a monoclonal antibody directed against VEGF) have been tried with mixed results (Kuwabara et al, 2008).

Waldenström Macroglobulinemia *Macroglobulinemia* was the term applied by Waldenström to a systemic condition occurring mainly in older persons and characterized by fatigue, weakness, and a bleeding diathesis. Immunoelectrophoretic examination of the blood disclosed a marked and mostly monoclonal increase in the IgM plasma fraction. About half of patients with Waldenström disease and polyneuropathy will have specific anti-MAG antibodies, similar to the approximately one-third of patients with nonmalignant IgM paraproteins. (An uncertain proportion of patients with a "benign" IgM paraprotein will, over the years, develop Waldenström disease.) A few patients with Waldenström hyperproteinemia have a hyperviscosity

state manifest by diffuse slowing of the retinal and cerebral circulations, giving rise to episodic confusion, coma, impairment of vision, and sometimes strokes (*Bing-Neel syndrome*). Most reports attribute this syndrome to infiltration of neural by malignant plasma cells rather than to hyperviscosity.

The polyneuropathy, when present, evolves over months or longer and may be asymmetrical, particularly at the onset, but becomes bilateral, mainly sensory, and distal. The pattern in our patients has been very slowly progressive, and initially limited to the feet and legs with sensory ataxia and loss of knee and ankle jerks. The CSF protein is usually elevated and the globulin fraction increased. In a case recorded by Rowland and colleagues, the polyneuropathy was purely motor and simulated motor neuron disease. Treatment is discussed further on.

Cryoglobulinemia As mentioned in the section on vasculitic neuropathies, *cryoglobulin*, a serum protein that precipitates on cooling, is usually of the IgG or IgM type and most often polyclonal. While cryoglobulinemia may occur without any apparent associated condition (essential cryoglobulinemia), it also accompanies a wide variety of disorders such as multiple myeloma, lymphoma, connective tissue disease, chronic infection, and particularly, hepatitis C. Peripheral neuropathy occurs in a small proportion both of the essential and symptomatic cases. Occasionally the neuropathy evolves over a period of a few days and remits rapidly. More often it takes the form of a distal symmetrical sensorimotor loss, which develops insidiously (76 percent of the cases in the series reported by Gemignani et al) in association with the Raynaud phenomenon and purpuric eruptions of the skin. Initially, the neuropathic symptoms may consist only of pain and paresthesias that may be precipitated by exposure to cold (as often, there is no cold sensitivity). Later, weakness and wasting develop, more in the legs than in the arms, and more or less in the same distribution as the vascular changes. In some cases there may be a mononeuropathy multiplex with severe denervation in the territory of the involved nerves (9 percent of the series reported by Gemignani et al; see also Garcia-Bragado et al). In a few cases, the two neuropathic syndromes have been combined. As remarked earlier, detection of cryoglobulin requires special handling of the blood sample. The specimen should be carried to the laboratory in a bath of warm water to prevent precipitation of the protein.

Any of the paraproteinemic states may be associated with an amyloid polyneuropathy, a subject accorded a separate section later in the chapter.

The pathology of the cryoglobulinemic and macroglobulinemic neuropathies has been incompletely studied and the mechanisms by which these disorders cause neuropathy are uncertain. One presumes that some component of the paraprotein acts as an antineural antibody or that deposition of the protein is in some way toxic to the nerves or to the endoneurial vessels. In our most thoroughly autopsied case, there was widespread distal axonal degeneration of nonspecific type without amyloid deposition or inflammatory cells; yet in other reported cases, amyloid has been found in the nerve and the neuropathy has been attributed directly to it. Immune

deposits of IgM had impregnated the inner layers of the perineurium in the case reported by Ongerboer de Visser and colleagues. Dalakas and Engel (1981b) have made similar observations. In yet other instances, the neuropathy of cryoglobulinemia is a result of the intravascular deposition of cryoglobulins, causing a more acute vasculitic mononeuropathy multiplex, as discussed earlier (Chad et al).

TREATMENT In the macroglobulinemic neuropathies, the use of prednisone, the alkylating agent chlorambucil, cyclophosphamide, and repeated plasma exchange has at times led to improvement both in the systemic and neuropathic symptoms, although recovery has been incomplete. The monoclonal antibody rituximab has been effective in small studies. The optimal treatment of cryoglobulinemic neuropathy has not been settled. We have used plasma exchange and added immunosuppression in the vasculitic variety of this disease.

Acquired Primary (Nonfamilial, AL) Amyloid Neuropathy

A hereditary type of amyloidosis (familial amyloidosis [FA]) is well known and is described further on. In addition, there are numerous sporadic instances of a peripheral neuropathy caused by amyloid deposition. As in the familial variety, the heart, kidneys, and gastrointestinal tract may be involved. This acquired type of amyloid disease has also been called *primary systemic amyloidosis* to distinguish it from the variety associated with chronic diseases. The term is misleading in that in most cases the amyloid is derived from a circulating paraprotein, but the proportion of "benign" and malignant plasma cell sources of the protein varies from one report to another. For example, in the large series collected by Kyle and Bayrd, only 26 percent of patients with primary amyloidosis had a malignant plasma cell dyscrasia. This agrees with our own experience, but other series have found rates of myeloma as high as 75 percent. In any case, 90 percent of primary amyloidosis is the result of a monoclonal protein in the blood (rarely polyclonal). Macrophage enzymes cleave the larger immunoglobulin molecules and the light chains aggregate to form amyloid deposits in tissue, or the plasma cells may produce light chains directly ("light chain disease"). Lambda light chain predominates in the idiopathic variety of amyloidosis and kappa light chain is more common in myeloma. In a few cases, the light chain is found only in the urine (as Bence Jones protein).

In primary amyloidosis there is no evidence of preceding or coexisting disease (except the association with paraproteinemia or multiple myeloma). *Secondary amyloidosis (AA)*, an infrequent occurrence nowadays, is the result of chronic infection or other chronic disease outside the nervous system and, as a rule, is not associated with neuropathy (e.g., it is not cited in the large recent series by Lachmann and colleagues [2007]). In contrast, *familial amyloidosis*, a third variety, is almost invariably associated with neuropathy but is associated with a paraprotein in only a small proportion of cases and the amount of immunoglobulin is small (see "Inherited [Familial Amyloidosis] Amyloid Neuropathies" later).

Primary amyloidosis is mainly a disease of older men, the median age at the time of diagnosis being 65 years. In our clinical material, the majority of the patients have had peripheral neuropathy, but this may reflect a referral bias as in other series, less than one-third were so affected (Kyle et al). The neuropathic symptoms and signs are similar to those of hereditary amyloid polyneuropathy discussed further on, but the progress of the disease is considerably more rapid.

The initial syndrome is primarily sensory—numbness, paresthesias, and very often, acral pain—signs that are mainly characteristic of involvement of small-diameter sensory fibers (loss of pain and thermal sensation). It is the painful aspect and the autonomic features discussed later that distinguish this disease from the other paraproteinemic neuropathies and indeed, from most other polyneuropathies. Weakness follows, initially limited to the feet but becoming more extensive as the disease progresses and eventually spreads to the hands and arms. Only later is there loss of mainly large fibers that mediate sensations of touch, pressure, and proprioception. Twenty-five percent of patients have carpal tunnel syndrome from infiltration of the flexor retinaculum. Exceptionally, patterns other than the painful and sensory predominant polyneuropathy have been associated with amyloidosis; preferential involvement of motor nerves, lumbar roots, plexopathy, and amyloidomas involving single nerves (sciatic, facial, trigeminal) have been reported. Unusual cases of mononeuritis multiplex are difficult to explain.

Autonomic involvement can be severe in amyloid neuropathy (familial or primary) and may become evident early in the course of the illness; several of our patients presented with disturbances of gastrointestinal motility such as episodic diarrhea and orthostatic dizziness or erectile dysfunction and bladder disturbances. The pupils may show a slow reaction to light, or there may be a reduction in sweating. An infiltrative *amyloid myopathy* also occurs as a rare complication of the disease; it presents as an enlargement and induration of many muscles, particularly those of the tongue (macroglossia), pharynx, and larynx.

Progression of the illness is relatively rapid, the mean survival being 12 to 24 months. An indolent neuropathy that evolves over years is unlikely to be a result of amyloidosis, although we have seen such a case. Death is a result of the renal, cardiac, or gastrointestinal effects of amyloid deposits, the manifestations of which are already evident in more than half of the patients who present with neuropathy. A nephrotic syndrome is also characteristic.

Analysis of the serum and urine, searching for an abnormal paraprotein, is the most useful screening test for amyloid neuropathy. Next in value is a microscopic examination of a biopsy of the abdominal fat pad, gingiva, or rectal mucosa for deposition of amyloid in tissue or blood vessels. Biopsy of the sural nerve or of the involved viscera has a high diagnostic yield; muscle tissue gives variable results. The liver biopsy is positive in virtually all cases of primary amyloid and the kidney shows amyloid infiltration

in 85 percent. In several of our patients with a clinical syndrome typical of amyloid neuropathy but in whom amyloid was absent in the sural nerve, the diagnosis was established only after sequential biopsy of numerous sites (fat pad, kidney, liver). If the sural nerve is severely depopulated of nerve fibers, the amount of congophilic staining and the characteristic amyloid birefringence may be meager and yield a spuriously negative result. It is also critical to ensure the accuracy of congophilic staining by comparison with positive and negative control tissue from the same laboratory. The CSF has a normal or mildly elevated protein concentration, but this does not distinguish the neuropathic process from many others.

Lachmann and colleagues (2002) emphasized that 10 percent of patients who appear by all the usual criteria to have primary amyloidosis will be found to have a genetic type. However, as mentioned, only a small proportion of the latter group has a monoclonal gammopathy and it tends to be of low concentration (it has been estimated to occur in one-quarter of familial cases but we have not encountered it). This difference and the rapid progression of the primary acquired form assist in distinguishing it from the genetic type that is discussed further on.

In addition to the more slowly evolving familial types, the differential diagnosis of acquired amyloid neuropathy includes the myelomatous varieties, toxic and nutritional small-fiber neuropathies, diabetic polyneuropathy, paraneoplastic polyneuropathy, Sjögren disease, and an idiopathic small-fiber sensory neuropathy, all of which cause pain and which we have encountered more frequently than amyloidosis.

TREATMENT OF AMYLOID NEUROPATHY The prognosis of primary amyloidosis and its associated neuropathy are dismal. Attempts at immunomodulation, immunosuppression (which may help the renal disease), or removal of amyloid by plasma exchange have been marginally effective. Another approach has been bone marrow suppression with high doses of melphalan followed by stem cell replacement (previously harvested from the patient). Several such patients have survived for years with marked improvement in the neuropathy. Recently, several small molecules designed to prevent the aggregation of amyloid fibrils have shown preliminary benefit as evidenced by biologic markers and in some clinical features. (In the familial type due to a transthyretin mutation discussed further on, liver transplantation has stabilized the process in the majority of patients, particularly those with the Val30Met mutation.)

Pain is a serious problem in the amyloid neuropathies that may be treated with transcutaneous fentanyl patches or with oral narcotic medications. Orthostatic hypotension responds to the use of leg stockings, midodrine, and mineralocorticoids, as well as sleeping with the bed elevated at the head so that the patient's entire body is angled down toward the feet.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

This form of polyneuropathy was separated from acute inflammatory polyradiculopathy, or GBS, by Austin in

1958 on the basis of a prolonged and relapsing course, enlargement of nerves, and responsiveness to corticosteroids. Excluding the duration of evolution, the acute and chronic forms are similar in many ways. Both are widespread polyradiculoneuropathies, usually with cytoalbuminologic dissociation of the CSF (raised protein concentration with few or no cells); both exhibit nerve conduction abnormalities characteristic of a demyelinating neuropathy (reduced conduction velocity and partial conduction block in motor nerves), and pathologically, both show similar multifocal perivenous inflammatory infiltrates. But there are also important differences, the most evident of which are the modes of evolution, responses to treatment, and prognosis. As a rule, chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) begins insidiously and evolves slowly, either in a steadily progressive or stepwise manner, attaining its maximum severity after several months. From the beginning it may be asymmetrical or involve the arms predominantly. However, in a small proportion of patients (16 percent in the series of McCombe et al [1987b] and a smaller proportion in our own series) the disease at first emerges from a mild or moderate case of GBS, in which case the illness becomes relapsing or simply worsens slowly and progressively.

An antecedent infection is usually not identified in patients with CIDP as it is in GBS. Furthermore, CIDP may be distinct immunologically from GBS, insofar as certain HLA antigens occur with greater frequency in patients with CIDP than they do in the normal population, whereas there are no clear HLA propensities in patients with GBS. Finally, in contrast to acute GBS, many cases of CIDP respond favorably to the administration of prednisone. An ambiguity is introduced here because, as mentioned in the section on GBS, Hughes (1992) has described a group of patients with polyneuritis in whom weakness progressed steadily for 4 to 12 weeks and who responded to corticosteroids (subacute GBS), in such cases, blurring the distinction between GBS and CIDP.

Chronic symmetric sensorimotor loss and areflexia coupled with nerve conduction findings of demyelination essentially defines the illness. Elevated spinal fluid protein concentration is so frequent that it might be added as a diagnostic criterion. The typical findings in nerve conduction studies are of multifocal conduction block as described in Chap. 45; prolonged distal latencies ("distal block"); nerve conduction slowing to less than 80 percent of normal values in several nerves; loss of late responses; and dispersion of the compound muscle action potentials—all reflecting demyelination in motor nerves. One or several of these changes have been present in 75 percent of our patients (Gorson et al, 1997). In the early stages of the disease, demyelinating features must be carefully sought by testing multiple nerves at several sites along their courses. After several months there is often some degree of axonal change (30 percent of our series), but the fundamental process continues to be one of multiple foci of demyelination. A fairly dependable finding is the absence of denervation changes early in the illness despite weakness and reduced amplitude of the motor action potential

(indicative of a demyelinating block to conduction at a proximal site).

Several large series of CIDP cases are available for review. Dyck and colleagues (1975) studied 53 patients in whom the neuropathy progressed for more than 6 months. The clinical course was monophasic and slowly progressive in about one-third, stepwise and progressive in another third, and relapsing in the remaining third. The periods of worsening or improvement were measured in weeks or months. Weakness of the limbs, particularly of the proximal leg muscles, or numbness, paresthesias, and dysesthesias of the hands and feet were the initial symptoms. In 45 of the 53 patients, the signs were those of a mixed sensorimotor polyneuropathy with weakness of the shoulder, upper arm, and thigh muscles in addition to motor and sensory loss in the distal parts of the limbs. In 5 patients the neuropathy was purely motor, and in 3, purely sensory. Cranial nerve abnormalities were distinctly unusual. Enlarged, firm nerves were found in 6 patients. Not emphasized in their series is the common occurrence of a cerebellar-like tremor in cases of long standing.

In the series reported by McCombe et al (1987b) comprising 92 patients, two major subgroups were recognized: *relapsing* (corresponding to the relapsing and stepwise progressive cases of Dyck et al [1975]) and *nonrelapsing* ones. In our own series of now over 100 patients, we have been impressed with several variant patterns of clinical presentation. In approximately 10 percent, numbness and weakness of the hands preceded involvement of the feet, which is unusual in other polyneuropathies, and a sensory ataxic form, a purely motor form, and mononeuropathies superimposed on a mild generalized polyneuropathy each accounted for approximately 5 percent.

As mentioned earlier, a small proportion of cases began as acute GBS but continue to progress or relapse in the following months (Gorson et al, 1997). Other comprehensive accounts of the disease have been given by Barohn, Cornblath, Dyck (1975), and Hughes and their associates. All of these studies have included cases with clinical progression for longer than 8 or 12 weeks; thus CIDP has come to be defined in part by a progressive polyneuropathy of this duration.

As might be imagined from the experience with GBS, there are variant syndromes that align with CIDP but have special clinical characteristics. The best characterized of these is *multifocal conduction block* (called multifocal acquired demyelinating sensory and motor neuropathy; *MADSAM*), but these are also described a polyradicular process that presents as an ataxic illness with large fiber attributable sensory loss and spared sensory nerve action potentials (see Sinnreich et al), and a slowly progressive distal neuropathy (*distal acquired demyelinating symmetrical neuropathy*; *DADS*). Regarding the last of these, there are distal sensory and sometimes motor, disturbances and greatly prolonged distal latencies in most patients, and two-thirds have an associated IgM monoclonal gammopathy with kappa light chain component; the illness responds poorly to treatment, aligning it clinically in some respects with

the anti-MAG neuropathies but in most clinical and electrophysiologic features appearing to be a variant of CIDP (see Katz et al).

The status of a predominantly *axonal* polyneuropathy that clinically simulates CIDP and responds to some extent to the same immunomodulating treatments has been described by Uncini and colleagues and by Gorson and Ropper. The present authors have the impression that it is an immune-mediated neuropathy comparable to CIDP but with preferential destruction of axons rather than of myelin. Its frequency as a cause of acquired polyneuropathy is unknown, but we see several new cases every year.

Also recognized is the frequency (up to 25 percent of the patients in some series, less often in our experience) with which there was a parallel systemic condition such as paraproteinemia, lymphoma, an undifferentiated reactive adenopathy or lupus, in association with an inflammatory demyelinating polyneuropathy (even aside from the rare DADS process mentioned above). These associations create problems in nosology that can be reconciled by labeling a given instance as, for example, "CIDP with paraproteinemia" or "CIDP with lupus," thus separating such cases from the idiopathic variety. These symptomatic inflammatory polyneuropathies respond to corticosteroids, albeit unpredictably, and to treatment of the underlying disease.

Laboratory Features The CSF protein is elevated in more than 80 percent of patients with CIDP, typically in the range of 75 to 250 mg/dL. In rare instances there is papilledema and a pseudotumor cerebri syndrome (see Chap. 30) in relation to extremely high levels of CSF protein (usually >1,000 mg/dL). Elevation of the CSF gamma globulin fraction and a mild lymphocytic pleocytosis are found in 10 percent of patients (often in those who are HIV-seropositive), a considerably higher percentage than in our series.

In sural nerve biopsy material, half are found to have interstitial and perivascular infiltrates of inflammatory cells, although one expects that most nerves would show these changes if a sufficient number could be sampled. Some specimens show only demyelination, or in cases of long standing, severe depletion of all nerve fibers. As in GBS, the demyelination appears to be affected by T cells and macrophages within the endoneurium and perineurium. The loss of myelinated fibers is variable and many of the remaining fibers are seen to be undergoing wallerian degeneration or show changes of segmental demyelination or demyelination-remyelination. Onion-bulb formations are conspicuous in recurrent and relapsing cases. The few adequate autopsy studies have shown only minimal or patchy inflammation and a considerable degree of axonal damage, probably reflecting the long duration of illness before examination. The presence of endoneurial and subperineurial edema has been emphasized by Prineas and McLeod.

Treatment Several trials have shown a short-term benefit from the intravenous infusion of high doses of gamma globulin (IVIg, total 2 g/kg in divided infusions over 2 to 5 days). More than half of our patients have

responded to this treatment, albeit for only several weeks or months, after which the infusions must be repeated to maintain clinical improvement. A desire to spare patients the side effects of indefinite prednisone administration (see later) makes this mode of therapy a reasonable alternative, in some cases for almost 10 years without ill effects. Patients who require treatment at such short intervals as to be impractical have benefited from the addition of small doses of prednisone or of an immunosuppressive drug as described below. The main drawbacks of IVIg are its expense and the several hours required for its infusion. Rare instances of nephrotic syndrome, aseptic meningitis, serum sickness, thrombotic venous, or arterial occlusion, including stroke and hypotension, have been reported, particularly if the infusion is too rapid.

Half of patients with CIDP also respond well to plasma exchanges. In a prospective double-blinded trial, Dyck and colleagues (1986a) found that plasma exchange administered twice weekly for 3 weeks had a beneficial effect on both neurologic disability and nerve conduction. The response to plasma exchange in our patients has been comparable to that obtained with IVIg and with steroids, but we have discerned that some patients respond to one type of treatment and not another. The effects of plasma exchanges in most patients subside in 10 to 21 days, or even less; in some, the response lasts longer as found by Dyck and colleagues (1986a) and in the series reported by Hahn and colleagues (1996a). For these reasons we prefer to try plasma exchange or immune globulin before committing a patient to long-term treatment with prednisone. The relative ease of administering IVIg favors its use first, followed by a series of plasma exchanges if there is no improvement. When there is a clear response, 3 or 4 brief series of plasma exchanges or repeated infusions of immune globulin may suffice to bring the patient to an improved level of function. These treatments can be supplemented by small doses of prednisone when frequent infusions or exchanges become impractical. It has been our experience that in about one-third of cases, IVIg and plasma exchange cease to have benefit after repeated use for 1 or more years.

Corticosteroids were formerly the mainstay of therapy, but many patients become dependent on the medication and correspondingly suffer side effects. Our approach has been to use corticosteroids as an adjunct to one of the previously mentioned treatments, but other centers use them first. The usual regimen begins with 60 to 80 mg of prednisone daily that is tapered over months to the lowest effective dose, typically 25 to 40 mg. Without substantiation by a controlled trial, we have found that corticosteroids can be withdrawn without relapse in some patients by slow tapering over many months or a year. Attempts to withdraw the steroids more quickly have led to further cycles of relapse.

A number of patients will have no response to corticosteroids within the first 1 or 2 months but will improve if treatment is continued. Barohn and colleagues (1989) have found that the earliest improvement occurs only after 2 months of treatment and is maximal at approximately 6 months. In addition to all the well-known side effects, the drug may produce tremor or exaggerate the

tremor caused by the neuropathy. Long remissions lasting several years have been reported with the use of pulses of orally administered high-dose or daily corticosteroids, for example, by Eftimov and colleagues, who used dexamethasone 40 mg per day for 4 days, repeated for 6 cycles, or daily prednisolone, 60 mg for 6 weeks. Should a sustained trial of prednisone therapy prove unsuccessful, a course of azathioprine (for at least 3 months), 3 mg/kg in a single daily dose, has been recommended (Dalakas and Engel, 1981a), but a controlled trial has failed to show benefit from this combination and we have had little success with it.

When the preceding measures prove unsatisfactory, cyclophosphamide, mycophenolate, rituximab, or another similar immunosuppressive medication can be added, but we have been unable to draw any firm conclusions as to the effectiveness of these combined regimens.

Some patients who have failed to benefit from the aforementioned treatments have seemingly improved in response to the administration of alpha-interferon; however, in larger trials, interferon allowed an increase in the interval between infusions of IVIg but was not an effective primary therapy. High-dose cyclophosphamide has proven helpful in several cases under our care, although it has often failed (see Brannagan et al and the review by Brannagan that lists the applicable clinical trials). The usual regimen is 50 mg/kg IV daily for 4 days followed by granulocyte-stimulating factor beginning on the tenth day until the absolute neutrophil count recovers. Individual reports of successful treatment by autologous stem cell transplantation after high-dose chemotherapy have appeared but 1 patient relapsed after 5 years (Vermuelen and van Oers). This may become an option in severe and treatment-resistant cases. We have no explanation for the remarkable improvement and continued good health of a few of our patients after a severe toxic bacterial infection (Ropper, 1996).

One of the most difficult problems in this field is the lack of useful clinical measurements to guide treatment with IVIg and plasma exchange and even the proper adjustment of the dose of corticosteroid. Often, one may be influenced by the patient's fear of losing any ground and even slight changes in sensory or motor symptoms.

It has been stated that patients with discrete relapses have a better prognosis than those with a progressive course. In McCombe's series (1987b), 73 percent were said to have eventually recovered, but the long-term outcome has generally been poor. In fewer than 10 percent of patients has the disease finally remitted; additionally, unexplained remission occurs occasionally. The 5-year followup of 38 patients by Kuwabara and colleagues gives a figure of 49 percent with full or partial remission, far higher than in our series.

Multifocal Motor Neuropathy and Multifocal Conduction Block

Several polyneuropathies that share many of the features of CIDP have been delineated on the basis of unique clinical, immune, or electrophysiologic attributes. These include particularly *multifocal motor neuropathy (MMN)* and

multifocal conduction block (also called *MADSAM* as mentioned earlier). The latter has as its main feature a block of mixed nerve conduction at focal sites in a limited number of nerves as described earlier. In multifocal motor neuropathy, only blocks in motor nerve conduction are evident.

The distinction between these two entities has been difficult. There are similarities in clinical features and response to treatment (see Delmont et al), but there is utility in separating them. Multifocal motor neuropathy, but not multifocal conduction block, is associated in half of cases with a particular IgM antibody, anti- G_{M1} , directed against a ganglioside component of peripheral myelin (Pestronk et al). For this reason, some view this illness as belonging to the class of paraproteinemic neuropathies (see earlier and Simmons et al) and it is certainly distinctive enough clinically to be categorized separately. Its importance as a clinical entity lies in the similarity of the clinical picture to a purely lower motor neuron type of amyotrophic lateral sclerosis (ALS) and, unlike ALS, its potential responsiveness to treatment. The pathophysiologic role of anti- G_{M1} antibodies is further displayed by a case of transplacental transmission of a motor neuropathy to a neonate (Attarian et al).

Multifocal motor neuropathy and motor conduction block predominate in men. They usually begin with an acute or subacute motor mononeuropathy, manifest, for example, as weakness of the wrist or foot-drop, and are often joined insidiously by another focal motor palsy. The process is painless, unlike vasculitic mononeuritis multiplex, involves the nerve incompletely, and, in its usual form, is unaccompanied by any sensory symptoms such as paresthesias or numbness. Despite the initially demyelinating character of the disorder, there is almost always atrophy of the weakened muscle within months and there may be a few fasciculations, thus simulating ALS. Nevertheless, the weakness tends to be disproportionate to atrophy. Usually, the tendon reflex is lost or muted in an affected region, but for unexplained reasons, some patients have one or more brisk reflexes. Our experience has been that this latter reflex change does not reach the point of appearing "pathologic" and that clonus and Babinski signs are categorically not part of the illness, as they are in ALS.

When there is an association of the motor features with sensory symptoms or sensory loss and there is slowing of sensory conduction in regions of motor conduction block (multifocal conduction block), the acronym MADSAM (multifocal acquired demyelinating sensory and motor neuropathy) has been used as noted earlier, but the disorder, while similar to multifocal conduction block, more resembles CIDP. This conforms to what has been called Lewis-Sumner syndrome based on the description by these authors and their colleagues of subacute, painless asymmetric, distal multiple mononeuropathies. The ulnar and median nerves were involved in their patients and there was motor conduction block and sensory slowing in affected nerves. Curiously, 2 of their 5 original patients had optic neuritis, a feature not reported subsequently. The disease is not directly connected to antibodies against G_{M1} , but a few patients with the sensorimotor disorder will display them.

Treatment For multifocal motor conduction block and motor neuropathy, with or without anti-GM1 antibodies, IVIg infusions have been effective, albeit temporarily, in more than half of patients. Some authoritative clinicians favor the early addition of rituximab in treatment-resistant cases or when the frequency of infusions is unsustainable and if that fails, cyclophosphamide. Other immune-modulating drugs have been tried in small series with various results. There is no response to corticosteroids. The MADSAM illness responds similarly to corticosteroids, IVIg, or plasma exchange, similar to the effects of these approaches in CIDP.

Uremic Polyneuropathy

Polyneuropathy is among the most common complications of chronic renal failure. Robson has estimated that neuropathy complicates end-stage renal failure in two-thirds of patients who are about to begin dialysis therapy. Bolton's figures are much the same; 70 percent of his patients being dialyzed regularly had polyneuropathy and in 30 percent of all his patients, it was moderate or severe in degree. As described originally by Asbury and associates (1963), the neuropathy takes the form of a painless, progressive, symmetrical sensorimotor paralysis of the legs and then of the arms. In some patients, the syndrome begins with burning dysesthesias of the feet or with sensations of creeping, crawling, and itching of the legs and thighs, which tend to be worse at night and are relieved by movement (comparable to "restless legs" syndrome described in Chap. 19). Renal failure that is accompanied by diabetes gives rise to a particularly severe form of polyneuropathy.

The combination of muscle weakness and atrophy, areflexia, sensory loss, and the graduated, distally predominant distribution of the neurologic deficit in the limbs leaves little doubt about the neuropathic nature of the disorder. Usually the neuropathy evolves slowly over many months. Infrequent instances of a more acute sensorimotor polyneuropathy that have been reported occur mainly in diabetic patients receiving peritoneal dialysis as discussed earlier (Ropper, 1993; Asbury et al, 1963). A rare uremic polymyositis with hypophosphatemia has also been described (Layzer). The neuropathy has been observed with all types of chronic kidney diseases. More important to the development of chronic neuropathy than the nature of the renal lesion are the duration and severity of the renal failure and symptomatic uremia.

With long-term hemodialysis, the neuropathic symptoms and signs stabilize but improve in relatively few patients. In fact, rapid hemodialysis may worsen the polyneuropathy (or perhaps its symptoms) temporarily. Peritoneal dialysis appears to be more successful than hemodialysis in improving the neuropathy, but this observation has not been firmly established. Complete recovery, occurring over a period of 6 to 12 months, usually follows successful renal transplantation for reasons given later.

The pathologic findings are those of a nonspecific and noninflammatory axonal degeneration. In rapidly progressive cases, there is a tendency for the large

fibers to be more affected; this is evident particularly on electrophysiologic testing that shows slowing of nerve conduction velocities, but there is no conduction block as occurs in other acquired demyelinating polyneuropathies. In all types of uremic polyneuropathies, pathologic changes are most intense in the distal segments of the nerves with the expected chromatolysis of their cell bodies.

The cause of uremic polyneuropathy is unknown. What has been called the "middle molecule" theory is plausible. The end stage of renal failure is associated with the accumulation of toxic substances in the range of 300 to 2,000 kDa molecular weight. Furthermore, the concentration of these substances, which include methyl guanidine and myoinositol, has been shown to correlate with the degree of neurotoxicity (Funck-Brentano et al). These toxins (and the clinical signs of neuropathy) are not greatly reduced by hemodialysis. In contrast, the transplanted kidney effectively eliminates substances of wide-ranging molecular weights, which would account for the almost invariable improvement of neuropathy after transplantation. As is the case with uremic encephalopathy, urea alone given to experimental animals and in controlled studies of humans, does not seem capable of inducing a metabolic neuropathy.

Alcoholic-Nutritional Polyneuropathy

As described at length in Chap. 41, in virtually all patients with alcoholic-nutritional polyneuropathy who for some reason remain untreated with vitamin and protein restoration, the weakness and atrophy of the legs, and to a lesser extent the arms, may reach an extreme degree. Thus this disease, although subacute in its evolution as described earlier in the chapter, becomes a frequent cause of chronic polyneuropathy. There are usually prominent sensory features and considerable acral pain and allodynia. Certain cases of diabetic neuropathy behave similarly.

Leprous Polyneuritis

This is the best example of an infectious neuritis, caused by the direct invasion of nerves by the acid-fast *Mycobacterium leprae*. The disease is still frequent in India and Central Africa and there are many lesser endemic foci, including parts of South America and Florida, Texas, and Louisiana, which border the Gulf of Mexico. Limited outbreaks have been reported during treatment for AIDS, with armadillos as the probable intermediate host.

The initial lesion in leprosy is an innocuous-appearing skin macule or papule, which is often hypopigmented and lacking in sensation; it is caused by the invasion of cutaneous nerves by *M. leprae*. In patients with a degree of immunologic resistance to infection, the disease progresses no further than this stage, which is spoken of as *indeterminate leprosy*, or it may evolve in several ways, depending mainly upon the resistance of the host. The bacilli may be locally invasive, producing a circumscribed epithelioid granuloma that involves cutaneous and subcutaneous nerves and results in a characteristic hypopigmented patch of superficial numbness

and sensory loss (*tuberculoid leprosy*). The underlying subcutaneous sensory nerves may be palpably enlarged. If a large nerve in the vicinity of the granuloma is invaded (the ulnar, median, peroneal, posterior auricular, and facial nerves are most frequently affected), a sensorimotor deficit in the distribution of that nerve is added to the patch of cutaneous anesthesia.

In contrast to the limited tuberculoid variety of leprosy, lack of resistance to the organism permits the proliferation and hematogenous spread of bacilli and the diffuse infiltration of skin, ciliary bodies, testes, lymph nodes, and nerves (*lepromatous leprosy*). Widespread invasion of the cutaneous nerves produces a symmetrical pattern of pain and temperature loss involving the pinnae of the ears (earlobes) and nose, as well as the dorsal surfaces of hands, elbows, forearms, and feet and anterolateral aspects of the legs—a distribution that is determined by the relative coolness of these parts of the skin. This *temperature-dependent pattern* is the most characteristic feature of the disease, as pointed out by our colleague T. Sabin. The sensory maps he has drawn (Fig. 46-4) are typical of established cases. The process evolves over years. Eventually, the anesthesia spreads to involve most of the cutaneous surface. Extensive sensory loss is followed by impaired motor function owing to invasion of muscular nerves where they lie closest to the skin (the ulnar nerve is the most vulnerable). There is loss of sweating in areas of sensory loss but otherwise the autonomic nervous system is unaffected. In distinction to other polyneuropathies, tendon reflexes are usually preserved in leprosy despite widespread sensory loss. Probably this is the result of sparing of most of the muscular and larger sensory nerves. Because of widespread anesthesia, injuries may pass unrecognized, with resultant infections, trophic changes, and loss of tissue. Variations in host immunity result in patterns of disease having both tuberculoid and lepromatous characteristics (dimorphous leprosy). Erythema nodosum occurs in a few cases. The diagnosis can be made from a skin scraping or biopsy, but multiple samples are often required.

The findings on nerve conduction studies are varied, but they usually include findings that are consistent with a generalized but heterogeneous sensorimotor polyneuropathy that includes features of demyelination such as slowed nerve conduction velocities, temporal dispersion and occasionally, conduction block.

Treatment All forms of leprosy require long-term treatment with sulfones (dapson being the most commonly used), rifampin, and clofazimine. The skin lesions of lepromatous leprosy are responsive to thalidomide, which itself may cause a sensory neuropathy (Barnhill and McDougall). Reactivation of disease, or a conversion from the tuberculoid to the lepromatous pattern, may occur during times of reduced immunity.

Polyneuropathy With Hypothyroidism

The status of this disorder is uncertain and the authors have not encountered a definite case. Although characteristic disturbances of skeletal muscle are known to complicate hypothyroidism, the demonstration of a definite

Figure 46-4. Patterns of sensory loss in leprosy. The localization of these areas to cooler portions of the body is unique to this disorder. There is almost universal analgesia but sparing of warmer regions such as the midline of the back, popliteal and antecubital spaces, lower abdomen and groin, and the head and neck. (From Sabin TD: Preservation of sensation in a cutaneous vascular malformation in lepromatous leprosy. *N Engl J Med* 282:1084, 1970, with permission.)

polyneuropathy has been infrequent. However, a number of elderly myxedematous patients complain of weakness and numbness of the feet, legs, and, to a lesser extent, hands, for which no other explanation can be found. Loss of reflexes, diminution in vibratory, joint-position, and touch-pressure sensations, and weakness in the distal parts of the limbs are the usual findings. The neuropathic

manifestations are seldom severe. Nerve conduction velocities are slowed and the protein content of the CSF is usually increased to more than 100 mg/dL. Possibly the latter finding is a reflection of the increased protein content of the serum in the hypothyroid state. The subjective improvement and complete or near-complete reversibility of neuropathic signs following treatment with thyroid hormones provides evidence of a hypothyroid etiology. In biopsies of nerve, an edematous protein infiltration of the endoneurium and perineurium, a kind of metachromatic mucoid material, has been seen. Dyck and Lambert (who should be credited for drawing attention to this neuropathy) noted segmental demyelination in teased fiber preparations. In electron-microscopic sections, a slight increase in glycogen, acid mucopolysaccharides, and aggregates of glycogen and cytoplasmic laminar bodies in Schwann cells have been observed by others.

Polyneuropathy of sensorimotor type has also been observed in association with a syndrome of chronic lymphocytic thyroiditis and alopecia (Hart et al).

Idiopathic Small-Fiber Sensory Polyneuropathy (Numb, Burning Feet Syndrome)

This, of course, does not have the status of a single entity, but all neurologists encounter numerous cases of a relatively nonprogressive idiopathic sensory polyneuropathy, mainly in older patients. Paresthesias of feet and lower legs, sensory loss, and absent ankle reflexes are the usual findings. The hands may be mildly affected, but leg weakness and imbalance are absent or minor. A painful variety is also known (see later).

The most common situation in our experience has been one that affects elderly women with slowly progressive (over years) *burning and numbness of the feet*, ascending to the ankles or midcalves. There are few findings on examination. Often, there is only mild loss of pinprick and thermal sensation; ankle reflexes may or may not be reduced. There is little progression over the years. Most of these cases are idiopathic, but there is a broad differential diagnosis, including the diseases mentioned earlier, as outlined by Mendell and Sahenk (Table 46-5 is adapted from their discussion).

Electrophysiologic tests are likewise normal or virtually so; a few show diminished sural nerve potentials and minor changes of motor amplitudes. When the causes listed in the table have been excluded, a substantial group of patients is left and are in need of symptomatic relief. Some have been helped by gabapentin or by antidepressants and analgesic cream applied nightly to the soles and toes. A few of the more severe cases have apparently responded to gamma globulin infusions, but these observations require corroboration (Gorson and Ropper, 1995). In a number of cases of burning feet, the intradermal sensory nerves in skin biopsy specimens are depleted, but the meaning of this finding is not certain (Periquet et al) and the clinical diagnosis of a small-fiber neuropathy in affected older patients can be inferred without this procedure.

Identifiable causes for painful sensory neuropathy in the elderly include mainly diabetes, alcoholic-nutritional

Table 46-5

CAUSES OF PAINFUL SENSORY NEUROPATHY

Common

- Nutritional
- Idiopathic in the elderly
- Diabetes
- Vasculitis
- Residue of Guillain-Barré syndrome
- Renal failure
- Connective tissue disease, especially Sjögren disease
- Human immune deficiency virus

Less common

- Amyloidosis, familial and primary
- Voltage gated sodium channel mutation
- Paraneoplastic
- Sarcoidosis
- Toxic neuropathy, esp. arsenic poisoning
- Fabry disease
- Perineuritis

Source: Adapted from Mendell and Sahenk.

deficiency states, connective tissue disease, amyloidosis, and vasculitis. Presumably, in the idiopathic cases, there is a similar small-fiber neuropathy, but the common clinical situation is that an etiology cannot be found. An alternative cause in these neuropathies that are characterized mainly by painful burning is that there is an abnormality of the sodium channel that renders the sensory neurons or fibers hyperexcitable. In the experience of the group from Maastricht, 8 of 28 patients in whom no etiologic diagnosis for small-fiber neuropathy could be found, there were mutations in the gene (*SCN9A*) encoding voltage-gated sodium channel $Na_v1.7$. The mutation caused a gain of function in this gene and allowed dorsal root ganglion neurons to become hyperexcitable (Faber et al). Yet another rare cause of this syndrome has been the finding of antibodies to peripherin, which is a dominantly inherited trait (Stogbauer et al).

GENETIC FORMS OF CHRONIC POLYNEUROPATHY

A polyneuropathy that advances slowly over 10 years or more is almost invariably genetic in origin. The neuropathic disease may be remarkably restricted, as in familial analgesia with foot ulcers, or extensive, as in familial peroneal muscular atrophy. The time of onset of these very chronic neuropathies is usually in early life but often cannot be dated with certainty by the patient or family. In infants, the condition may be mistaken for muscular dystrophy or infantile muscular atrophy until sensory testing becomes possible. In the developing child, whose musculature naturally increases in power and volume with age, it may be difficult to decide whether the disease is progressive but typically, there is trouble running or walking making it difficult to keep up with other children, repeated ankle injuries, toe catching, labeled as "clumsiness," or falls. Strongly indicative of one of these conditions at any age are pes cavus, hammertoes, and, in

extreme forms, talipes equinus. One of these deformities is commonly detected in most cases of inherited polyneuropathy. In later life, some of the inherited neuropathies are manifest as trophic changes of skin and bone in distal parts of the limbs indicate involvement of small (pain) fibers and the presence of deformed and degenerated joints (Charcot joint). The mutilating effects are the result of repeated injury to analgesic parts and to a lack of autonomic vascular reflexes. Atrophy of muscle and trophic changes in the skin are generally more marked than in the acquired forms of polyneuropathy.

The CSF protein content may be mildly or moderately elevated over a period of years. Charcot-Marie-Tooth (CMT) disease (type 1) shows slowed nerve conduction as a consequence of a disorder of myelin. A distinctive feature of hereditary neuropathy is the uniformity of the electrophysiologic changes, e.g., a similar degree of slowing of nerve conduction velocity in all the nerves, a feature that distinguishes this group from most acquired neuropathies. The distinction between the demyelinating and axonal types of inherited neuropathies is based on the motor nerve (typically ulnar or median nerve) conduction velocities in the arms, with slowing to velocities below 38 m/s defining the demyelinating category.

To the reader not immersed in neuromuscular diseases, the classification, nomenclature, and number of genes that give rise to this group of diseases is dizzying. One approaches the affected patient, however, in a more circumscribed way by noting that the dominantly inherited demyelinating types are designated CMT1 and the dominant axonal types, as CMT2. The group of myelinopathies with onset in infancy (also called Dejerine-Sottas disease or congenital hypomyelinating neuropathy), are subsumed under CMT3, whereas most recessively inherited neuropathies (both axonal and demyelinating) are termed CMT4. There are, in addition, forms with intermediate degrees of conduction slowing that are not easily classified. An older nomenclature uses the term hereditary motor-sensory neuropathies, or HMSNs, for the main CMT types. The hereditary sensory neuropathies (HSNs) and the hereditary sensory autonomic neuropathies (HSANs) are considered separate entities. This category includes a variety of metabolic neuropathies and types that do not fit into the CMT classification.

Recent genetic findings have in some ways simplified the matter of classification and have permitted the creation of a nosology that more or less parallels the clinical one. The systems in Tables 46-2 and 46-6 represent an attempt to conciliate the clinical and genetic data.

Of this large and varied group, only the sensorimotor Charcot-Marie-Tooth type is the one likely to be seen with any regularity by neurologists and general physicians. This group has become quite large as more individual mutations are discovered, but a small number accounts for the majority of cases. The commonly encountered varieties are indicated in italics in Table 46-6. The major forms of hereditary neuropathy are designated as subcategories of CMT disease, grouped by patterns of inheritance and described in more detail further on.

Inherited Polyneuropathies of Mixed Sensorimotor-Autonomic Types

Charcot-Marie-Tooth Disease Types 1 (Demyelinating) and 2 (Axonal) and Related Neuropathies (See Table 46-6)

Clinical Features These are the most common forms of inherited peripheral neuropathy and, indeed, among the most common of all inherited neurologic diseases. The early symptoms of childhood clumsiness and athletic imprecision are listed previously, to which are added foot deformities of high arches and hammer toes. There may have been ankle fractures, foot-drop, medical plantar foot calluses and a need for podiatric treatment at an early age, painless or foot ulcers. In adolescence, an "inverted champagne bottle" appearance of the forelegs may become apparent. The typical case of CMT has its onset during late childhood or adolescence, although neurologists are increasingly aware that some cases, particularly type 2, may not attract attention until middle life. CMT1 cases usually make their appearance during the first decade while the peak age of onset of CMT2 is in the second decade or even later. Both motor and sensory signs are said to be more severe in the first type (Harding and Thomas, 1980). Adult patients have difficulty dating the onset of symptoms, so much so that with milder forms, they may not even be aware of having a neuropathic illness. In some cases, the widespread nerve conduction changes only come to light when this test is performed for the diagnosis of an unrelated problem or when a parent becomes aware of their own neuropathy after their child proves to have the disease. Some types that present in adulthood may even have a subacute or seemingly acute presentation, particularly the myelin protein zero (MPZ) and the PMP22 deletion (hereditary liability to pressure palsies) types.

Because the clinical description was provided in 1886 almost simultaneously by Tooth in England and by Charcot and Marie in France, all of their names have been attached to it, even though similar cases had been recorded earlier by Eulenberg (1856), Friedreich (1873), Ormerod (1884), and Osler (1880). The two important advances in our understanding of this disease since the original descriptions have been the separation of the main subtypes on the basis of their electrophysiologic (EMG) features and the discovery of genetic mutations that cause most of these diseases.

The frequency of the disease cannot be stated with precision because of its clinical heterogeneity, but the usually quoted prevalence is 1 in 2,500 of the population, the most frequent subtype occurring in 1 in 4,000. This class of neuropathies is characterized clinically, as discussed previously, by the pattern of heredity, the speed of motor nerve conduction, and special clinical characteristics including the age of onset of symptoms such as difficulty walking and certain appended neuropathic syndromic findings such as hearing loss. From a genetic perspective, the classification is based on the gene that is affected and the nature of the mutation; deletions and duplications are the most common, but many single nucleotide polymorphisms have also been identified.

Table 46-6

CLASSIFICATION OF THE INHERITED PERIPHERAL NEUROPATHIES^a

	PATHOLOGY	ONSET	GENE	CLINICAL AND THERAPEUTIC FEATURES
I. Charcot-Marie-Tooth (CMT) and Related Disorders				
1. CMT1 (demyelinating, dominantly inherited)				
<i>CMT1A*</i>	demyelinating	c	PMP22 duplication	Early areflexia, distal weakness, sensory loss
<i>CMT1B*</i>	demyelinating	c, a	Myelin protein P0 (MPZ)	Early areflexia, distal weakness, sensory loss
CMT1C	demyelinating	a	Lipopolysaccharide-induced TNF- α (LITAF)	
CMT1D, CMT4E	demyelinating	c, a	Transcription factor EGR2	May be severe and congenital
CMT1F, CMT2E	demyelinating, axonal	c, a	Neurofilament light subunit (NEFL) or PMP22 point mutation	
Congenital hypomyelination	demyelinating	c	Rho guanine exchange factor	Mild or asymptomatic
2. CMT2 (axonal, dominantly inherited)				
<i>CMT2A*</i>	axonal	c, a	Kinesin KIF1B β motor protein	
CMT2A2 (alt)	axonal	c, a	Mitofusin (MFN2)	
CMT2B	axonal	a	GTP-binding protein RAB7	
CMT2C	axonal	c, a	TRPV4	Vocal cord, diaphragm paralysis
CMT2D	axonal	a	Glycyl t-RNA synthetase (GARS)	
CMT2F	axonal	c, a	Heat shock protein (BSPB1)	Slow, motor predominant
3. AR-CMT2—(recessively inherited axonopathy)				
AR-CMT2A	axonal		Nuclear membrane lamin (LMNA)	
4. CMT3 (Dejerine-Sottas disease)				
	demyelinating	inf	PMP22 most common; also P0, EGR2 (see above)	
5. CMT4 (recessively inherited myelin-axonopathy)				
CMT4A	demyelinating	c	Ganglioside-induced differentiation protein (GDAP1)	May be rapidly progressive
CMT4B	demyelinating	c	Myotubularin-related protein (MTMR2)	Focally folded myelin
CMT4B 2	demyelinating	c, a	SET-binding factor (MTMR13)	
CMT4C	demyelinating	c	SHT3TC2	Early scoliosis
CMT4D	demyelinating	c	Schwann cell protein Nm-ycDRG1 (NDRG1)	Neuropathy + hearing loss
CMT4F	demyelinating	c	Nuclear membrane protein (periaxin; PRX)	Early onset, severe
6. <i>CMT1 X (X-linked demyelinating)*</i>				
	demyelinating	c, a	GJB1	Similar to CMT1A
7. Recurrent brachial plexopathy (AD)				
	axonal	c, a	Unknown	Focal, painful brachial plexitis
8. <i>HNPP*</i>				
	axonal	c	<i>PMP22</i> gene deletion	Focal entrapments, chronic neuropathy
II. Hereditary Sensory and Autonomic Neuropathy (HSAN)				
1. HSAN1 (AD)				
	axonal	a	Serine palmitoyl transferase	Small-fiber sensory and distal motor deficits
2. HSAN2 (AR)				
	axonal	inf	Novel neuronal protein	
3. HSAN3 (Riley-Day, AR)				
	axonal	inf	Kinase-associated protein (IKBKAIP)	

(Continued)

Table 46-6

CLASSIFICATION OF THE INHERITED PERIPHERAL NEUROPATHIES* (CONTINUED)

	PATHOLOGY	ONSET	GENE	CLINICAL AND THERAPEUTIC FEATURES
4. HSAN4 (AR)	axonal	inf	TrkA/NGF receptor	Congenital SN with anhidrosis
5. HSAN5 (AR)	axonal	inf	Nerve growth factor-beta	Absent pain
III. Familial Amyloid Polyneuropathies (AD)				
1. Type 1—Portuguese	axonal	a	Transthyretin	Liver transplant may be beneficial
2. Type 2—Indiana/Swiss	axonal	a	Transthyretin	Liver transplant may be beneficial
3. Type 3—Van Allen	axonal	a	Apolipoprotein A1	
4. Type 4—Finnish	axonal	a	Gelsolin	Lax skin and “bloodhound” face; corticospinal, posterior column deficits
IV. Hereditary Disorders of Lipid Metabolism Causing Neuropathy (AR)				
1. Metachromatic leukodystrophy	demyelinating	inf-a	Arylsulfatase A and B	
2. Krabbe disease	demyelinating, axonal	inf-a	β -galactosidase	Early bone marrow transplant may be beneficial
3. Fabry disease	axonal	c	α -galactosidase	Heat-induced pain, macular rash
4. Adrenomyeloneuropathy (XR/XD)	demyelinating, axonal	inf-a	ABCD1 transporter	Early bone marrow transplant may be beneficial
5. Refsum disease	demyelinating	inf-a	Phytanoyl- α CoA-hydroxylase	Dietary restriction may ameliorate the disease
6. Tangier disease	axonal	a	ABCI	Small-fiber neuropathy, facial weakness, very low HDL
7. Bassen-Kornzweig	axonal	c	MTP	Acanthocytosis, cerebellar ataxia
V. Miscellaneous Inherited Neuropathies				
1. Giant axonal neuropathy (AR)	axonal	c	Gigaxonin	
2. Porphyria (AR)	axonal	c, a	Porphobilinogen deaminase	May respond to hematin, glucose
3. “Mitochondrial” neuropathies (NARP)	axonal			Retinitis pigmentosa
4. Severe PNS, CNS demyelination (AD)	demyelinating	inf, c	Myelin transcription factor SOX10	CNS, PNS hypomyelination

**Italicized* types with an asterisk are the most common in practice. CMT1A accounts for approximately 40 percent of cases with an identifiable mutation; CMT1B and HNPP approximately 6 percent each, and CMT1X approximately 6 percent of affected males. a, adult onset; c, childhood onset; inf, infantile onset.

As a guide to the frequency of various types, Saporta and colleagues in a study of over 1,000 patients from neuromuscular clinics found that two-thirds of patients had a mutation detected by conventional means. When combined with the mode of inheritance, the most common type was the typical demyelinating variety of Charcot-Marie-Tooth disease (CMT1A), and fewer than 10 percent each had X-linked CMT1X, hereditary liability to pressure palsies (HNPP), CMT1B, or the main axonal type, CMT2A; together, these implicated only 4 genes and all other forms, derived from about 30 other mutations, accounted for under 1 percent each. This is informative in guiding genetic testing in clinical circumstances.

Still, almost one-third of patients with a clear history of hereditary neuropathy had none of the currently detectable mutations.

The chronic degeneration of peripheral nerves and roots results in distal muscle atrophy beginning in the feet and legs and later involving the hands. The extensor hallucis and digitorum longus, the peronei, and the intrinsic muscles of the feet are affected early in life and this muscle imbalance produces the bony changes of pes cavus and *pied en griffe* (high arches and hammertoes). Later, all muscles of the legs and sometimes the lower third of the thigh become weak and atrophic. The thin legs have been likened to those of a stork or, if the lower

thigh muscles are affected, to an inverted champagne bottle. Eventually the nerves to the calf muscles degenerate and the ability to plantar flex the feet is lost. After a period of many years, atrophy of the hand and forearm muscles develops in some cases. The hands later become clawed. The wasting seldom extends above the elbows or above the middle third of the thighs. Paresthesias and cramps are present but only to a slight degree and there is always some impairment, usually also mild, of deep and superficial sensation in the feet and hands, shading off proximally. Rarely, the sensory loss is severe and perforating ulcers appear as they do in the pure sensory varieties of inherited neuropathy. The tendon reflexes are absent in the involved limbs. The illness progresses very slowly over decades, giving the impression of stabilization for long periods.

Walking difficulty, which is ultimately the main disability, is caused by a combination of sensory ataxia and weakness. Foot-drop and instability of the ankles are additional handicaps. The feet and legs may ache after use and cramps may be troublesome as mentioned, but otherwise pain is unusual; the feet may become cool, swollen, and blue, secondary to inactivity of the muscles of the feet and legs and their dependent position. There is usually no disturbance of autonomic function. Fixed pupils, optic atrophy, and nystagmus and endocrinopathies, epilepsy, and spina bifida, which have been reported occasionally in association with peroneal muscular atrophy, probably represent coincidental congenital disorders. The only distinguishing clinical feature between types 1 and 2, and this is present in only a minority of cases, is perhaps enlargement of the nerves in type 1, most easily appreciated by palpation of the greater auricular and peroneal nerves. The clinical heterogeneity of CMT disease has been alluded to in the previous discussion and is evident in the numerous mutations that give rise to similar chronic polyneuropathies. Restricted forms are known to affect only the peroneal and pectoral or scapular muscles (scapulo-peroneal form).

The *differential diagnosis* involves the distal muscular dystrophies, late forms of familial motor system disease, Friedreich ataxia, Roussy-Lévy syndrome (see later) and other familial polyneuropathies, and, in adult onset cases, CIDP and the paraproteinemic neuropathies, discussed earlier.

Electrophysiologic Features Dyck and Lambert (1975) and Harding and Thomas (1980) are credited with subdividing CMT into the two broad types based on the speed of motor nerve conduction in the ulnar or median nerves, as mentioned, slow (mean conduction velocity less than 38 m/s but often in the range of 20 m/s) in type 1, and normal or near-normal conduction in type 2. Electromyographers appropriately refer to these, respectively, as the demyelinating and axonal types. In both, the compound muscle action potentials and sensory potentials are greatly reduced in amplitude, but in type 2 there are findings of denervation in the EMG. In type 1 there is severe and widespread slowing of nerve conduction, but the electrical conduction block that characterizes acquired demyelinating neuropathies is not found and, in

distinction to almost most all acquired diseases of peripheral nerves, the electrophysiologic findings, particularly the pronounced slowing of conduction in CMT1, are uniform throughout the peripheral nervous system.

Genetic Features and Genetic Testing Aspects of the genetic causes of these diseases were addressed in the introductory comments and here it is emphasized that a few basic principles apply. First, only a small number of cases of Charcot-Marie-Tooth disease arise as de novo mutations (Hoogendijk et al). Second, different mutations in the same gene can give rise to more than one type of disease. Third, only four genes (*PMP22*, *MPZ*, *GJB1*, and *MFN2*) account for 92 percent of cases of CMT and this allows efficient testing in practice.

The most prevalent form of the disease is CMT1A, which displays an autosomal dominant pattern of inheritance with almost complete penetrance; it is due to duplication of *PMP 22* on chromosome 17 p11. Less often, CMT1 is autosomal recessive and even less frequently, X-linked dominant or X-linked recessive (see Table 46-6). Two common mutations in chromosomes 1 or 17 cannot be easily distinguished from one another on clinical grounds, but they have distinctive EMG features. The condition of *hereditary liability to pressure palsies* (HNPP) also displays an aberration on chromosome 17, but in the form of a deletion rather than a duplication of the gene for *PMP22*. This disease is discussed further on under "Brachial Plexus Neuropathies." The X-linked variant is the result of a mutation of the gene for connexin-32, another component of myelin. In a large proportion of CMT2 cases, the genetic basis cannot be established with current clinically available genetic testing. Undoubtedly, further studies of genes and gene products will continue to advance our understanding of the inherited neuropathies. For example, the study by Lupski and colleagues using whole genome sequencing has identified heretofore unknown compound heterozygous alleles that produce CMT phenotypes, most rare, but demonstrating that the frequency of unidentified mutations will be continuously be reduced.

Based on the finding that only a few mutations are implicated in the majority of cases of CMT, various algorithms have been designed, taking into account the degree of slowing of motor nerve conduction velocity and clinical features. For example, *PMP22* testing is a reasonable first step if the patient has the typical clinical appearance of CMT1A and motor nerve conduction is slower than 38 m/s. If this shows no mutation and there is male-to-male transmission, screening for CMT1X is performed, or if autosomal inheritance, for *MPZ* mutations (CMT1B). If these are unrevealing, a third step may be screening for point mutations in *PMP22*, *SIMPLE*, and *EGR2*. If the nerve conduction velocities are severely slowed, below 15 m/s, *PMP22* duplication or *MPZ* mutations are likely to be present. Those with intermediate conduction velocities, between 35 and 45 m/s are likely to have CMT1X or CMT1B and mutations in the corresponding genes. It is worth again noting that only a third of CMT2 cases will have mutations found by current methods. These prescriptions for testing will change as new sequencing methods are introduced

Pathologic Findings Degenerative changes in the nerves result in depletion of the population of large sensory and motor fibers, leaving only the condensed endoneurial connective tissue. As far as one can tell, axons and myelin sheaths are both affected, the distal parts of the nerve more than the proximal ones. In type I, the nerves may be enlarged, with “onion-bulb” formations of Schwann cells and fibroblasts, as in Dejerine-Sottas disease (CMT3; type III HMSN in the Dyck classification). This change can often be seen in sural nerve biopsies. Anterior horn cells are slightly diminished in number and some are chromatolyzed as a secondary change. Dorsal root ganglion cells suffer a similar fate. The disease involves sensory posterior root fibers with degeneration of the posterior columns of Goll more than of Burdach. The autonomic nervous system remains relatively intact. The muscles contain large fields of atrophic fibers (group atrophy). Some of the larger fibers have a target appearance and may show degenerative changes. All these muscle changes are typical of neurogenic denervation. Former claims of a coincidental myelopathy and degeneration of spinocerebellar and corticospinal tracts probably indicate that the associated disease was really Friedreich ataxia or some other combination of chronic myelopathy and neuropathy.

Treatment No specific treatment is known. Stabilizing the ankles by arthrodeses is indicated if foot-drop is severe and the disease has reached the point where it is not progressing. Pediatric orthopedic specialists have experience with several techniques to stabilize the joints of weakened limbs. Regular exercise, but avoiding excessive weight training, is usually prescribed. In mild and early cases, fitting the legs with light braces and the shoes with springs to overcome foot-drop can be helpful.

Hereditary Neuropathy With Pressure Palsies

This unusual but distinctive process of multiple recurrent local neuropathies, first reported by Earl and colleagues, is caused by a deletion of the *PMP22* gene, the one that is duplicated in the previously described CMT1A. In both CMT1A and hereditary neuropathy with pressure palsies (HNPP), the *PMP22* gene is functionally normal and these disorders arise because the total amount of the protein is abnormal. In CMT1A the gene is duplicated on one chromosome, thereby increasing the total *PMP22* protein; by contrast, in HNPP, the gene is deleted so that the *PMP22* protein is at approximately half-normal levels. HNPP is transmitted as a dominant trait. In these individuals, the focal neuropathies and plexopathies are generally not painful (in contrast with related conditions of hereditary neuralgic amyotrophy discussed further on). Focal nerve lesions are often provoked by slight or even brief compression. In addition to recurrent focal nerve palsies, most individuals with HNPP have an underlying chronic but slowly progressive demyelinating sensorimotor neuropathy that is mild on clinical examination (e.g., not all cases show areflexia). Electrophysiologic studies are abnormal, but may be only subtly so, with some slowing of conduction and distal motor and sensory nerve abnormalities, particularly across sites of compression.

Nerve biopsies from these patients are most remarkable for the presence of localized nerve sheath thickening with duplication of the myelin lamellae (so-called tomaculae, meaning sausage shaped).

Hypertrophic Neuropathy of Infancy (Dejerine-Sottas Disease, Congenital Hypomyelination, CMT3)

This relatively rare but striking neuropathy is inherited as an autosomal recessive trait. It begins in childhood or infancy, earlier than the typical form of peroneal muscular atrophy. Walking is delayed in onset and then progressively impaired. Pain and paresthesias in the feet are early symptoms, followed by the development of symmetrical weakness and wasting of the distal portions of the limbs. Talipes equinovarus postures with clawfeet and later clawhands are common. All modalities of sensation are impaired in a distal distribution, and the tendon reflexes are absent. Miotic, unreactive pupils, nystagmus, and kyphoscoliosis have been observed in some cases. The trunk and other cranial nerves are spared. The ulnar, median, radial, posterior tibial and peroneal nerves stand out like tendons and are easily followed with the gently roving finger. The enlarged nerves are not tender. Unlike other forms of hereditary neuropathy, the CSF protein is persistently elevated in Dejerine-Sottas disease, in all likelihood because the spinal roots are enlarged. Nerve conduction velocities are markedly reduced, even when there is little or no functional impairment. Patients are usually more disabled than those with peroneal muscular atrophy and are confined to wheelchairs at an early age. Treatment is purely symptomatic.

It is important to emphasize that the occurrence of hypertrophic neuropathy is not confined to this particular inherited disease. If one groups all patients in whom the nerves are diffusely enlarged (incorrectly called “hypertrophic” as it is mainly a nonspecific reaction of the epineurial and perineurial connective tissue that contributes to the bulk of the nerves), several diseases, both genetic and acquired, are included. The identifying histologic lesion in these cases is the “onion bulb,” which consists of a whorl of overlapping, intertwined, attenuated Schwann cell processes that encircle naked or finely myelinated axons and of endoneurial fibrofilaments. Enlarged nerves have been described in cases of recurrent demyelinating polyneuritis (CIDP), familial amyloidosis, Refsum disease, CMT type I, and other diseases. As was first pointed out by Thomas, any pathologic process that causes recurrent segmental demyelination and subsequent repair and remyelination may have this effect. In some patients with a history of early childhood hereditary polyneuropathy, the nerves are not yet palpably enlarged, but the characteristic Schwann cell abnormalities are revealed in biopsy material from a cutaneous nerve.

Phenotype-Genotype Correlations in the Inherited Sensorimotor Polyneuropathies

As the molecular basis of the inherited polyneuropathies has been elucidated, it has become clear that diverse mutations and molecular defects can give rise to the same

clinical phenotype. From a neurobiologic perspective, it is intriguing that both Dejerine-Sottas and Roussy-Lévy syndromes are linked to a recessively inherited loss of the myelin protein P0, and that the salient clinical features of this disorder are manifestations of defective nerve myelination. However, it has also become apparent that nearly identical clinical syndromes are associated with mutations in the genes for PMP22 and for the Schwann cell DNA-binding protein EGR2. Moreover, while some mutations in the P0 gene cause infantile-onset neuropathies with the Dejerine-Sottas and Roussy-Lévy phenotypes, other mutations in the same gene cause adult onset neuropathies. Although the early-onset cases show marked slowing of nerve conduction, the adult ones have conduction velocities that are typically above 35 m/s. The infancy-onset cases reveal major disruptions of folding of compact myelin, whereas in the adult-onset cases subtle alterations in the myelin protein P0 lead to a slow, predominantly axonal degeneration in adult life. Many other insights into the genetic and structural alterations of this vast category of disease have been revealed and can be appreciated from reading subspecialty texts on the subject, including the chapters by Amato and Russell and the monograph by Klein, Xuan and Shy, and the study by Saporta and coworkers, which are recommended.

Inherited Polyneuropathies of Predominantly Sensory Type

Common to the diseases comprising this group are insensitivity to pain, lancinating pains, and ulcers of the feet and hands, leading to osteomyelitis, osteolysis, stress fractures, and recurrent episodes of cellulitis. Because similar symptoms and signs occur in syringomyelia, leprosy, and tabes dorsalis, there is considerable uncertainty in older writings on this subject as to whether the reported cases were examples of one of these diseases or of hereditary neuropathy. According to Dyck and Lambert (1975), it was Leplat in 1846, who first described plantar ulcers (*mal perforant du pied*).

Mutilating Hereditary (Dominant) Sensory Polyneuropathy in Adults (Hereditary Sensory and Autonomic Neuropathy Type 1)

The characteristic features of this group of polyneuropathies are an autosomal dominant mode of inheritance and onset of symptoms in the second decade or later. Characteristically this begins with subtle loss of sensation for painful stimuli in the feet (e.g., inability to feel the hot sand or hot water in a tub). As the disease evolves, there is involvement of the feet with calluses of the soles and, later, episodes of blistering, ulceration, and lymphangitis followed by osteomyelitis and osteolysis, shooting pains, distal sensory loss with greater affection of pain and thermal sensation than of touch and pressure, loss of sweating, diminution or absence of tendon reflexes, and only slight loss of muscle power. Over time, loss of pain sensation in the fingers leads to fingertip ulcerations, osteomyelitis, and amputations.

The plantar ulcer overlying the head of a metatarsal bone is the most dreaded complication, because it often leads to osteomyelitis. Infection of the pulp of the fingers

and paronychias are uncommon. Some patients have a mild pes cavus and weakness of the peroneal and pretibial muscles, with foot-drop and steppage gait. Lancinating pains may occur in the legs, thighs, and shoulders, and, exceptionally, the pain may last for days or longer and be as disabling as that of tabes dorsalis; however, in the majority of patients there is no pain whatsoever. Neural deafness was present in one of Denny-Brown's patients. In that case, which was studied postmortem, there was a loss of small nerve cells in the lumbosacral dorsal root ganglia; the dorsal roots were thin, and the fibers in the posterior columns of the spinal cord and those in the peripheral nerves were diminished in number. Myelinated and unmyelinated fibers were both affected. Both axonal degeneration and segmental demyelination have been demonstrated in teased nerve preparations. Sensory nerve conduction may be absent or is uniformly slowed in every nerve tested.

It must be emphasized that despite its categorization as a "sensory and autonomic neuropathy," the most common, dominantly inherited form, termed *HSAN1*, also entails progressive, disabling, distal motor weakness, a consequence of ongoing axonopathy and denervation. *HSAN1* is a consequence of a loss of function of the enzyme serine palmitoyltransferase, which is the rate-limiting step in the biosynthesis of sphingolipids.

Recessive Mutilating Sensory Polyneuropathy of Childhood

Here the pattern of inheritance is autosomal recessive. Onset is in infancy and early childhood and walking is delayed; there is pes cavus deformity and the first movements are ataxic. Ulcerations of the tips of toes and fingers and repeated infections of these parts result in the formation of paronychias and whitlows. The tendon reflexes are absent, but power is well preserved. All sensory modalities are impaired (touch-pressure somewhat more than pain-temperature), mainly in the distal parts of the limbs but also over the trunk. In addition, there are reports of several sibships in which multiple members had a sensory neuropathy manifest by a generalized insensitivity to pain of the type described later. The lesions and electrophysiologic findings are similar to those in the dominantly inherited sensory neuropathy described previously.

In all types of hereditary sensory neuropathies, measures must be taken to prevent stress fractures, acral mutilation, and infection. This is more difficult in the small child who does not understand the problem.

It is also now evident that some of the infantile hereditary sensory neuropathies are a result of a disruption of molecular signaling pathways for neurotropic substances, such as nerve growth factor, that are critical to neural development.

Congenital Insensitivity to Pain

In *congenital insensitivity or indifference to pain*, a syndrome in which the patient throughout life is unreactive to the pain of injury, there is no loss of the ability to distinguish pinprick and other noxious stimuli from nonnoxious ones. Furthermore, the nervous system of such individuals seems to be normal. There is another variety characterized by universal analgesia (Swanson et al). This latter type is

inherited as an autosomal recessive trait and at least one form involves the gene for a nerve growth factor receptor located on chromosome 1q immediately adjacent to the site of the mutation for Charcot-Marie-Tooth disease type 1B (see Table 46-6). During childhood, one of the patients of Swanson and colleagues had high fever when the environmental temperature was raised and the other had orthostatic hypotension. One of the patients died in his twelfth year and was found to have an absence of small neurons in the dorsal root ganglia, an absence of Lissauer tracts, and a decrease in size of the descending spinal tracts of the trigeminal nerves. Sweat glands were present in the skin but were not innervated.

Multiple Symmetrical Lipomas With Sensorimotor Polyneuropathy

Whereas the usual cutaneous lipomas have no neurologic accompaniments, this clinical curiosity, known as Launois-Bensaude disease, consists of symmetrical lipomas of the neck and shoulders that are associated with polyneuropathy and sometimes, deafness. A mitochondrial disorder of similar genetic origin as the MERRF syndrome (see Chap. 37) has been identified (see Neumann's review for clinical details).

Polyglucosan Disease

This interesting process was mentioned in Chap. 39 in relation to dementia in which it is pointed out that there is a multisystem neurologic disease characterized by the widespread deposition in nervous tissue of corpora amyloacea, in this disease termed *polyglucosan bodies*. The main presentation of this disorder is of slowly progressive motor and pronounced sensory loss in the legs due to an axonal polyneuropathy, neurogenic bladder, and a degree of upper motor neuron signs that may also be evident. It is the early appearance of the urinary difficulties or the upper motor neuron features that mark the illness as unusual in relation to other polyneuropathies. Biopsy of the sural nerve demonstrates profuse deposition of the polyglucosan bodies in the endoneurium. When dementia occurs, either with the neuropathy or in isolation, the corpora amyloacea are found throughout the cerebrum. The process is detailed by Robitaille and colleagues and an upper motor neuron presentation that simulates amyotrophic lateral sclerosis, by McDonald and coworkers.

The bodies are made up largely of glucose polymers that are well known to occur in the aging brain and, when present in small numbers, have been assigned an innocuous meaning. In the usual type of polyglucosan disease, which is found in individuals of Ashkenazic Jewish origin, there is a deficiency in glycogen branching enzyme (GBE) that is shared with glycogenosis type IV, and infantile recessive process, Anderson disease. As such, it could be considered with the other neuropathies that have an identifiable metabolic cause, discussed as a group further on. However, a proportion of cases do not have the inherited GBE enzyme abnormality.

Riley-Day Familial Dysautonomia

(See also Chap. 26)

This disorder, inherited as an autosomal recessive trait, affects predominantly children of Ashkenazic

Jewish heritage. Familial dysautonomia is usually manifested soon after birth (poor sucking, failure to thrive, unexplained fever, episodes of pneumonia). Hyporeflexia and impairment or loss of pain and temperature sensation, with relative preservation of pressure and tactile sense, are the main manifestations. Motor fibers are probably involved as well, but only to a slight degree; this is shown more effectively by reduced motor conduction velocity in peripheral nerves than it is by weakness. At a later age, the neuropathy becomes overshadowed by other manifestations of the disease, notably repeated infections and abnormalities of the autonomic nervous system—lack of tears, corneal ulceration, fixed pupils, blotchiness of the skin, defective temperature control, cold hands and feet, excessive sweating, lability of blood pressure, postural hypotension, difficulty in swallowing, esophageal and intestinal dilation, emotional instability, recurrent vomiting, and stunted growth. The tongue lacks fungiform papillae.

Nerve biopsy reveals a diminution of small myelinated and unmyelinated fibers, which explains the impairment of pain and temperature sensation. In autopsy material, sympathetic and parasympathetic ganglion cells and, to a lesser extent, nerve cells in the sensory ganglia are diminished in number. Patients excrete increased amounts of homovanillic acid and decreased amounts of vanillylmandelic acid and methoxyhydroxyphenylglycol. Weinshilboum and Axelrod demonstrated a decrease in serum dopamine β -hydroxylase, the enzyme that converts dopamine to norepinephrine. The disease is caused by a mutation in a gene that expresses a kinase-associated protein (see HSAN3 in Table 46-6). There is no treatment for the disease except to provide symptomatic relief of gastrointestinal symptoms and orthostatic fainting.

Other examples of congenital polyneuropathy with absence of autonomic function, probably differing from the Riley-Day dysautonomia, have been reported. Some of these develop transient episodes of reflex sympathetic dystrophy. A congenital failure of development of neural elements derived from the neural crest has been postulated.

Ataxia-telangiectasia and Chédiak-Higashi disease are other genetic diseases with a recognized metabolic abnormality that may cause a polyneuropathy. They are described in Chap. 37, with the hereditary metabolic disorders.

Other Forms of Inherited Sensory Neuroopathy

Included here are numerous disorders similar to the ones described in the preceding pages but caused by different mutations; neuropathy with cerebellar degeneration; and the neuropathies in which there are recognized metabolic abnormalities, including familial amyloidosis. Some years ago a young man and woman with universal anesthesia affecting head, neck, trunk, and limbs came to attention (Adams et al); all forms of sensation were absent. The patients were areflexic but retained nearly full motor power; their movements were ataxic. Autonomic functions were impaired but not abolished. In a sural nerve biopsy, nearly all fibers—large and small, myelinated and unmyelinated—had disappeared. Surprisingly, there were

no trophic changes of any kind. Donaghy and coworkers and others have described a variant of the recessively inherited form of sensory neuropathy in which there was an associated neurotrophic keratitis and a selective loss of small myelinated fibers in sural nerve biopsies. We continue to observe variant and unclassifiable cases of purely motor, sensory, or mixed types in which genetic testing does not reveal a mutation such as these every year.

Hereditary Areflexic Dystasia (Roussy-Lévy Syndrome)

In 1926, Roussy and Lévy reported 7 cases of a dominantly inherited ataxic and neuropathic malady that had not previously been described. Its close relation to Friedreich ataxia and the amyotrophy of Charcot-Marie-Tooth disease was recognized. On the basis of molecular genetic testing, these relationships been clarified. Most classifications group it with CMT1 on the basis of the causative mutations and nerve conduction studies.

The condition is a sensory ataxia with pes cavus and areflexia, affecting mainly the lower legs and progressing later to involve the hands. Some degree of sensory loss, mainly of vibratory and position sense, is described in all cases. Atrophy of the muscles of the legs and postural tremor eventually become prominent, but the patients do not have signs of cerebellar disease (dysarthria, tremor, nystagmus). Kyphoscoliosis, a feature typical of Friedreich disease, has been described in several cases. Although the feet may be cold or slightly discolored, no autonomic defects are documented and the nerves are not palpably enlarged. Electrocardiographic abnormalities similar to those of Friedreich ataxia have been noted in one family but are not usual. The onset in many patients is during infancy, possibly dating from birth, and the course is relatively benign; all descendants of the original Roussy-Lévy family were still able to walk during their seventh decade of life.

On clinical and pathologic grounds, Dyck and Lambert (1975) placed the Roussy-Lévy kinships within the category of the demyelinating type of Charcot-Marie-Tooth disease (CMT1). The mode of inheritance of the two syndromes, their benign course, pattern of neurologic signs, slow nerve conduction, and biopsy features (demyelination of nerve fibers with onion-bulb formation) are much the same. This view has been reinforced by the genetic findings reported by Planté-Bordeneuve and colleagues. In affected members of the original Roussy-Lévy family, these investigators identified a point mutation in the domain of the myelin protein gene PO, the same gene that is implicated in Dejerine-Sottas disease. Most currently studied cases (there are few) have point mutations in PMP22 or MPZ. Based on limited pathologic study, there is no cerebellar degeneration; nevertheless, the shared clinical features with Friedreich ataxia are unmistakable and create diagnostic confusion before genetic testing.

Polyneuropathy With Cerebellar Degeneration (See "Predominantly Cerebellar Forms of Hereditary and Sporadic Ataxia" in Chap. 39)

Several such cases of adult onset have come to our attention over the years. Unlike Friedreich disease, the ataxia is mild and there is no kyphoscoliosis, but pes cavus or hammer-toe deformities are found, attesting to the early

onset of the neuropathy. The lower legs become atrophic and findings characteristic of CMT such as absent ankle reflexes and mild to moderate loss of distal deep sensibility are present. There is no Romberg sign and no Babinski signs. The outstanding feature is a profound atrophy of the cerebellar hemispheres, and to some extent of the vermis, on MRI. Although the illness is slowly progressive, our patients, like those with Roussy-Lévy disease, have remained highly functional into late age, having difficulty mostly with maintaining balance when dancing or wearing high-heeled shoes. The EMG is consistent with CMT2. The electrocardiogram has been normal. Several, but not all, such patients have had a family history of a similar process, but the available genetic testing has failed to reveal the site of a mutation. As mentioned, the process can simulate Friedreich ataxia in some respects. The genetic basis is uncertain and various genotypes have been reported in single families.

Polyneuropathy With Spastic Paraplegia

From time to time we have observed children and young adults with unmistakable progressive spastic paraplegia superimposed on a sensorimotor polyneuropathy of extremely chronic evolution. Sural nerve biopsy in 2 of our cases disclosed a typical "hypertrophic" polyneuropathy. In another case, only loss of nerve fibers was found. Cavanaugh and colleagues and Harding and Thomas (1984) reported similar patients. Our patients were severely disabled, being barely able to stand on their atrophic legs. An even more ambiguous form of disease was described by Vucic and colleagues in which there is typical CMT but with brisk reflexes. There were Babinski signs in half the patients and spastic dysphonia in a few others. The mutation is not known.

Although few in number, some cases of chronic polyneuropathy are combined with optic atrophy, with or without deafness or retinitis pigmentosa, and Dyck and Lambert (1975) classed these in a separate group. Jaradeh and Dyck have also described a hereditary motor-sensory polyneuropathy with the later development of a parkinsonian or a choreic-dystonic syndrome that responded to L-dopa. Most cases of this type have had an autosomal recessive inheritance.

Hereditary Recurrent Brachial Plexopathy (Hereditary Neuralgic Amyotrophy)

This entity, mentioned earlier in relation to hereditary neuropathy with pressure palsies because of the implication of a similar genetic locus, is discussed in the later section under "Brachial Neuritis, Brachial Plexitis (Neuralgic Amyotrophy, Parsonage-Turner Syndrome)."

Inherited Polyneuropathies with a Recognized Metabolic Disorder

Refsum Disease (HMSN IV)

This rare disorder, named after Refsum who made the first clinical observations, is inherited as an autosomal recessive trait and has its onset in late childhood, adolescence, or early adult life. It is slowly progressive but may be punctuated by acute or subacute worsening.

Diagnosis is based on a combination of clinical manifestations—retinitis pigmentosa, ataxia, and chronic polyneuropathy—coupled with the metabolic marker of the disease, an increase in blood phytanic acid. Phytanic acid accumulates because of a deficiency of the peroxisomal enzyme, phytanoyl-coenzyme A (CoA) hydroxylase. The deficiency is caused by mutations in one of two disparate genes. Cardiomyopathy and neurogenic deafness are present in most patients, and pupillary abnormalities, cataracts, and ichthyotic skin changes (particularly on the shins) are added features in some. Anosmia and night-blindness (nyctalopia) with constriction of the visual fields may precede the neuropathy by many years. The polyneuropathy is sensorimotor, distal, and symmetrical in distribution, affecting the legs more than the arms. All forms of sensation are reduced, often deep sensation more so than pain and thermal sense, and tendon reflexes are lost. The CSF protein is increased, sometimes markedly. Usually, the polyneuropathy develops gradually, although in some patients it has a subacute onset or, after being established for some time, a tendency to worsen fairly abruptly.

Although the nerves may not be palpably enlarged, “hypertrophic” changes with onion-bulb formation are invariable pathologic features. The metabolic defect has been discovered to be in the utilization of dietary phytol; a failure of oxidation of phytanic acid—a branched-chain tetramethylated 16-carbon fatty acid—that accumulates in the absence of activity of the enzyme phytanoyl-CoA-hydroxylase. The relation between the increased phytanic acid and the polyneuropathy is uncertain.

Clinical diagnosis is confirmed by the finding of increased phytanic acid in the blood of a patient with a chronic, mainly sensory neuropathy; the normal level is less than 0.3 mg/dL but in patients with this disease, it constitutes 5 to 30 percent of the total fatty acids of the serum lipids. Urinary phytanic acid concentration is also raised. Genetic testing reveals the mutation.

Treatment Diets low in phytol may be beneficial but this is difficult to judge, because after an acute attack there is sometimes a natural remission. The claimed effects of plasma exchange have also been difficult to interpret. In some patients there is a very slow progression of the disease, and in others, a more rapid progression with death from cardiac complications.

Mitochondrial Neuropathy

Like the cases of mitochondrial disease with neuropathy reported by Tuck and McLeod, we have observed several in which the clinical picture was almost identical to that of Refsum disease, but elevations in phytanic acid were not present. Mild ichthyosis, sensorineural deafness, ataxia of mixed tabetic-cerebellar type, areflexia, and retinitis pigmentosa were the main findings, conforming to the NARP syndrome described in Chap. 37. None of our cases had a family history of a similar disorder. Sural nerve biopsy showed loss of large fibers. There was an identifiable mitochondrial disorder in most of the recently studied cases, as described in Chap. 37. It should be remarked that most mutations of mitochondrial DNA cause a myopathy with multisystem disease, but not a neuropathy. The onset of the disease is in childhood or adolescence with slow progression.

Abetalipoproteinemia (Bassen-Kornzweig Syndrome) (See also Chap. 37)

This rare autosomal recessive childhood disorder was described in Chap. 37 with the inherited metabolic disorders of the nervous system and commented upon with neuroacanthocytosis in Chap. 39, although there is no relationship between the two processes. It is mentioned here because the brunt of the neurologic disorder falls upon the peripheral nerves. *Acanthocytosis* of red blood cells is its identifying feature. The earliest neurologic finding is usually diminution or absence of tendon reflexes, detected as early as the second year of life. Later, when the child is first able to cooperate in sensory testing, a loss of vibratory and position sense is found in the legs. Cerebellar signs (ataxia of gait, trunk, and extremities; titubation of the head; and dysarthria), muscle weakness, ophthalmoparesis, Babinski signs, and loss of pain and temperature sense are the other characteristic neurologic abnormalities, in more or less this order of frequency. Developmental delay, usually mild, occurs in some patients. Irregular progression occurs over a few years, and many patients are unable to stand and walk by the time they reach adolescence.

Skeletal abnormalities include pes cavus and kyphoscoliosis, which are secondary to the early onset neuropathy. Constriction of the visual fields and ring scotomata are manifestations of the macular degeneration and retinitis pigmentosa in some cases. Cardiac enlargement and congestive failure are serious late complications.

Neuropathologic findings consist of demyelination of peripheral nerves and degeneration of nerve cells in the spinal gray matter and cerebellar cortex. Diagnosis is confirmed by the finding of red blood cell acanthocytes, low serum cholesterol, and β (low-density)-lipoproteins. The disease is caused by defects in a triglyceride transfer protein, as discussed in Chap. 37. A deficiency of vitamin E, as a result of malabsorption, may be a factor, and large doses of the vitamin should be tried as therapy.

A closely related disease, also with familial hypobetalipoproteinemia, was described by van Buchem and coworkers. It, too, is associated with malabsorption syndrome, ill-defined weakness, ataxia, dysesthesia of the legs, and Babinski signs. There is no sensory loss.

Tangier Disease

This is a rare, familial, small-fiber neuropathy of which we have seen a few cases, inherited as an autosomal recessive trait. It is named for the island off the Virginia coast where the first-described patients resided. The mutation eliminates the function of the adenosine triphosphate (ATP)-cassette transporter protein. It results in a deficiency of high-density lipoprotein, extremely low serum cholesterol, and high triglyceride concentrations in the serum. Perhaps on the basis of these abnormalities, the patients are disposed to early and severe atherosclerosis. The presence of enlarged, yellow-orange (cholesterol-laden) tonsils is said to be a frequent manifestation (of course, previous tonsillectomies obviate this sign). About half of the reported cases have had neuropathic symptoms, taking the form of an asymmetrical sensorimotor neuropathy that fluctuates in severity.

The sensory loss is predominantly for pain and temperature and extends over the entire body; at times it is limited to the face and upper extremities, simulating syringomyelia (“pseudosyringomyelia”). Tactile and proprioceptive sensory modalities tend to be preserved. The polyneuropathy may come in attacks—that is to say, it simulates a recurrent process. Muscular weakness, if present, affects either the lower or upper extremities or both, particularly the hand muscles, which may undergo atrophy and show denervation by EMG. In a small number of patients there has been facial diplegia out of proportion to weakness elsewhere. In one of our patients, the pain and temperature loss was restricted to the head, neck, and arms. Tendon reflexes are often lost or diminished. Transient ptosis and diplopia have been reported. Nerve conduction is slowed.

Fat-laden macrophages are present in the bone marrow and elsewhere. No complete pathologic studies are available. There is no known treatment but dietary measures to reduce triglycerides may help, particularly in preventing atherosclerosis but the influence on the neuropathy is uncertain.

Fabry Disease (Anderson-Fabry Disease) (See also Chap. 37)

The genetic and metabolic aspects of this sex-linked disorder caused by deficiency of alpha-galactosidase A were considered with the inherited metabolic diseases. Here we offer some additional remarks about the painful neuropathic component. It bears commenting that 10 percent of heterozygous women display neuropathic symptoms, but usually of later onset and lesser degree than in males.

The pain, which is usually the initial symptom in childhood and adolescence, often has a burning quality or occurs in brief lancinating jabs, mostly in the fingers and toes, and may be accompanied by paresthesias of the palms and soles. Changes in environmental temperature and exercise may induce pain in “crises,” an identifying feature. These abnormalities are a result of the accumulation of glycolipid (ceramide trihexoside) in peripheral nerves, both perineurally and intraneurally, as well as in cells of the spinal ganglia and the anterior and intermediolateral horns of the spinal cord. Ohnishi and Dyck demonstrated a preferential loss of small myelinated and unmyelinated fibers and small neurons of dorsal root ganglia, and Cable and colleagues reported autonomic changes in other cases. Involvement of the sensory ganglia and the associated degenerative changes in the afferent fibers are thought to be the likely cause of the thermally induced painful sensory phenomena (Kahn).

Later in the illness there is progressive impairment of renal function and cerebral and myocardial infarction. The characteristic dermal feature is the presence of numerous dark red macules and papules (angiokeratomas), up to 2 mm in diameter, over the trunk and limbs, most closely clustered over the thighs and lower trunk and around the umbilicus (*angiokeratoma corporis diffusum*). The comprehensive review by Brady and Schiffman is recommended.

Treatment Phenytoin, carbamazepine, gabapentin, or amitriptyline may be helpful in alleviating the pain

and dysesthesias. As discussed in Chap. 37, enzyme replacement therapy has become available and seems to lead to partial remission of many of the features including the neuropathic ones.

Polyneuropathy of Acromegaly and Gigantism

Nerve entrapment, particularly of the median nerve, is a well-known feature of acromegaly. Pickett and colleagues identified carpal tunnel syndrome in 56 percent of acromegalics. Also recognized as a complication of acromegaly, but not because of multiple nerve entrapments, is *polyneuropathy* characterized by paresthesia, loss of tendon reflexes in the legs, and atrophy of slight degree in the distal leg muscles. Sometimes there are enlarged nerves. In the case reported by Stewart, the enlargement was the result of hypertrophic changes in the endoneurial and perineurial tissues, similar to those that occur in other so-called hypertrophic neuropathies of inflammatory or hereditary origin. In cases of extreme gigantism, a more severe polyneuropathy has sometimes been reported, to the point of causing Charcot joints (Daughaday).

Mentioned here is a case we have observed in which a severe and slowly progressive relatively symmetric motor neuropathy occurred in a patient with Pyle disease, a metaphyseal dysplasia that resembles acromegaly.

Metachromatic Leukodystrophy (See also Chap. 37)

In this metabolic disease, the congenital absence of the degradative enzyme sulfatase leads to massive accumulation of sulfatide throughout the central and peripheral nervous systems and to a lesser extent in other organs. The abnormality is transmitted as an autosomal recessive trait. Progressive cerebral deterioration is the most obvious clinical feature, but hyporeflexia, muscular atrophy, and diminished nerve conduction velocity reflect the presence of a neuropathy. Early in the course of the illness, the weakness, hypotonia, and areflexia may suggest Werdnig-Hoffmann disease; in older children there may be a complaint of paresthesias and demonstrable sensory loss. Bifacial weakness has been reported but must be rare. Sensory and motor conduction velocities are greatly slowed similarly in all nerves. Metachromatically staining granules accumulate in the cytoplasm of Schwann cells in nerves as well as in the cerebral white matter. There is loss of peripheral myelinated fibers. The measurement of arylsulfatase A activity in peripheral leukocytes or urine and biopsies of sural nerves are used to establish the diagnosis, even early in the course of the illness.

Inherited (Familial Amyloidosis, TTR Amyloidosis) Amyloid Neuropathies (See Table 46-6)

As noted earlier in the discussion of acquired (primary) amyloidosis, *amyloid* is a descriptive term for any of the proteins that are deposited in filamentous beta-pleated sheets; it can be derived from a number of precursor protein sources. Peripheral neuropathy is a common and often the most prominent manifestation of amyloidosis. The polyneuropathies are of two main types—those associated with familial amyloidosis (referred to as FA) and the other

associated with primary (nonfamilial) systemic deposition of amyloid (termed AL), which is derived from a circulating monoclonal protein. The acquired type has been discussed earlier. The most notable difference between these two types is the absence of a significant amount of paraprotein in the inherited forms (see further on). The amyloidosis that is secondary to chronic infectious or inflammatory disease, referred to as AA, is an increasingly rare condition and, in any case, does not affect the nerves.

In the following described most common familial amyloidoses, the amyloid is derived from an inherited abnormality of serum protein transthyretin (TTR, formerly called "prealbumin"). Several different amino acid substitutions have been identified in each type of amyloidosis. In the originally described Andrade type, methionine replaces valine at amino acid 30; therefore this has been referred to as *transthyretin amyloidosis* and as the *TTR met 30 type*. However, there are over 100 variants in the transthyretin gene that can give rise to amyloidosis.

The *familial amyloid polyneuropathies* comprise several distinct groups, as enumerated in Table 46-6. The pattern of inheritance in all types is autosomal dominant; males and females are affected with equal frequency. Although a descriptive classification based on the ethnic or geographic origin of affected families is still in use and is retained in the narrative categorization below, it is now possible to categorize the diseases according to their genetic causes and the corresponding chemical structure of the amyloid protein that is deposited in tissue. The recent cloning of many of the amyloid protein genes has made possible not only the detection of the common transthyretin mutation but also DNA tests for some of the other types of familial amyloidoses. Lachmann and colleagues emphasize the high frequency of genetic defects in amyloid precursor proteins and the finding in one-quarter of cases of a low-level monoclonal gammopathy. Characteristic of all the amyloid polyneuropathies is the preferential involvement of small-diameter sensory and autonomic nerves and deposition of amyloid in various organs. Sensory loss, therefore, dominates the picture and pain and autonomic changes are prominent in most varieties of the disease.

The following are the main recognized types of *familial amyloid neuropathies*.

1. **The Portuguese (Andrade) type.** Andrade, in 1939, recognized that a chronic familial illness known as "foot disease" among the inhabitants of Oporto, Portugal, was a special type of amyloid polyneuropathy. He was not the first to have seen amyloid in degenerating nerve but deserves credit for identifying the disease as one of the hereditary familial polyneuropathies. By 1969 he had studied 148 sibships, comprising 623 individuals, among whom there were 249 with polyneuropathy. Descendants of this family have been traced to Africa, France, and Brazil. Other foci of the disease have been reported in Japan (Araki et al; Ikeda et al), the United States (Kantarjian and DeJong), Germany (Delank et al), Poland, Greece, Sweden, and northwest Ireland (Staunton et al). As far as one can tell, these are separate, unrelated probands in different ethnic groups.

The age of onset of this form of familial amyloid polyneuropathy is between 25 and 35 years. The disease progresses slowly and terminates fatally in 10 to 15 or more years. The initial symptoms are usually numbness, paresthesias, and sometimes pain in the feet and lower legs. Weakness is minimal, and the tendon reflexes, although diminished, may be retained early in the course of the illness. Pain and thermal sense are reduced more than tactile, vibratory, and position sense (a "pseudosyringomyelic") pattern. Autonomic involvement is another important characteristic—loss of pupillary light reflexes and miosis, anhidrosis, vasomotor paralysis with orthostatic hypotension, alternating diarrhea and constipation, and erectile dysfunction. These autonomic changes tend to be more extensive than the sensory ones. Difficulty in walking also develops and has its basis in a combination of faulty position sense and mild muscle weakness. Later, tendon reflexes are abolished and the legs become thin. The nerves are not enlarged. Cranial nerve involvement (facial weakness and numbness, loss of taste) is a late manifestation and occurs in only a few cases.

The clinical details vary somewhat from case to case, even within a family. Cardiac enlargement and irregularities in cardiac rhythm as a result of bundle-branch or atrioventricular (AV) block occur early in some and late in others. A few patients have had severe amyloid cardiomyopathy from the onset (Ikeda et al). Weight loss may be pronounced owing to anorexia and disordered bowel function and the later development of a malabsorption syndrome. The liver may become enlarged (as it may in the acquired form). Vitreous opacities (veils, specks, and strands) may progress to blindness but this has been rare; in a few, there has been an impairment of hearing. Involvement of the CNS—manifest as behavioral abnormalities, cerebellar ataxia, and bilateral corticospinal signs—has also been reported in a few cases but their nature and pathologic basis is controversial (Ikeda et al). A nephrotic syndrome and uremia terminate life in some patients. The CSF may be normal or the protein content may be increased (50 to 200 mg/dL); the blood is normal except for anemia caused by amyloidosis of the bone marrow. This is probably the most common transthyretin mutation-derived amyloidosis.

2. **Familial amyloidosis with carpal tunnel syndrome (Swiss type).** Falls and coworkers, in 1955, and later Rukavina and associates described a large group of patients of Swiss stock living in Indiana who developed, in their fourth and fifth decades, a syndrome of acroparesthesias in the hands as a result of deposition of amyloid in the connective tissues and beneath the carpal ligaments. Similar kindreds of German descent were recognized in Maryland. There were sensory loss and atrophic muscle weakness in the distribution of the median nerves, which were compressed. Section of the carpal ligaments relieved the symptoms. In some of the patients, other nerves of the arms were said to have become involved later.

Vitreous deposits have been observed frequently in this form of the disease. As with the Portuguese type, an abnormal transthyretin is the basis of the deposition of amyloid.

3. **Iowa type.** In 1969, van Allen described an Iowa kindred with onset, in their thirties, of a fairly severe sensorimotor neuropathy, involving the legs and then the arms. There was amyloid deposition in the testes, adrenal glands, and kidneys (the usual cause of death), as well as a high incidence of peptic ulcer disease. The amyloid in this disease is derived from a mutated apolipoprotein A1, in which there is an amino acid substitution.
4. **Cranial neuropathy with corneal lattice dystrophy and facial palsies.** This unusual form of amyloid neuropathy was first described in three Finnish families by Meretoja, hence the label "Finnish type." Subsequently, it was reported from several different parts of the world in families of non-Finnish heritage. The disease usually begins in the third decade with lattice corneal dystrophy. Vitreous opacities are not observed, and visual acuity is little affected. Peripheral neuropathy may not be evident until the fifth decade, at which time the facial nerves, particularly their upper branches, become affected. The nerves of the limbs are involved even later and to a much lesser extent than in other amyloid neuropathies. In advanced cases there is a distinctive appearance of excessive skin folds about the face, facial diparesis, dysarthria, spasticity, and dense loss of posterior column function. At postmortem examination, deposits of amyloid are found in virtually every organ, mainly in the kidneys and blood vessels and in the perineurium of affected nerves.

The amyloid fibrils are derived from the protein gelsolin. The latter is normally an actin-binding protein, but it is also an important constituent of basement membranes, which may explain the deposition of amyloid in the cornea and skin.

Diagnosis of Familial Amyloid Neuropathy When the characteristic painful small-fiber type of sensory disturbance and autonomic changes are coupled with a family history of the same constellation, the diagnosis is not difficult. As noted in the earlier section on the acquired paraproteinemic neuropathy, the presence of a monoclonal (rarely polyclonal) immunoglobulin in the blood is found in only a limited number of patients with familial amyloid cases and it is usually just above the upper limit of normal for the immunoglobulin subclass. Otherwise the two types of amyloid diseases, FA and AL, are quite similar and, indeed, approximately 10 percent of cases considered by history and examination to be acquired will be found to have the genetic disorder (Lachmann et al). The situation has been clarified by the availability of commercial gene sequencing to detect mutations in transthyretin that are related to amyloidosis.

Pathologic Findings Amyloid deposits are demonstrable in the walls of blood vessels, the interstitial (endoneurial) tissues of the peripheral somatic and autonomic

nerves, and in the spinal and autonomic ganglia and roots. There is a loss of nerve fibers, the unmyelinated and small myelinated fibers being more depleted than the large myelinated ones. The anterior horn and sympathetic ganglion cells are swollen and chromatolyzed because of involvement of their axons, and the posterior columns of the spinal cord degenerate, also on a secondary basis.

The pathogenesis of the fiber loss in familial amyloidosis, as in the acquired type, is not fully understood. On the basis of their findings in a sporadic case of amyloid polyneuropathy with diabetes mellitus, Kernohan and Woltman suggested that amyloid deposits in the walls of the small arteries and arterioles interfered with the blood supply in the nerves and that amyloid neuropathy is essentially an ischemic process. In other cases, however, the vascular changes are relatively slight and the degeneration of the nerve fibers appears to be related to their compression and distortion by the endoneurial deposits of amyloid or, alternatively, there may be a direct toxic effect of the embedded amyloid. Amyloid also deposits in the tongue, gums, heart, gastrointestinal tract, kidneys, and many other organs, where it may act as a tissue toxin or has a mechanically disrupting effect on cells.

Treatment In recent years, liver transplantation has proved curative of some of the familial amyloid polyneuropathies, but obviously it has no role in the acquired forms. According to Herlenius and colleagues, more than 500 patients at the time of their writing had received liver transplants with a 77 percent rate of survival, equivalent to liver transplantation for other diseases. Two novel approaches, a small molecule, tafamidis, that prevents the aggregation of amyloid fibrils by stabilizing it in a tetrameric form (Coelho et al, 2012) and interfering RNA therapy (RNAi) that are delivered in lipid nanoparticles that reduces the production of mutant amyloid (Coelho et al, 2013) are both promising.

Problems in Diagnosis of the Chronic Polyneuropathies

This is the group of peripheral nerve diseases that has given the present authors the most difficulty. The cause of acute and many of the subacute and relapsing forms of nerve disease usually can be established by widely available clinical and laboratory methods. It is the early and late chronic polyneuropathies that continue to baffle the neurologist and general physician, despite the respectable advances that have been made in the field of genetic testing.

Diagnosis of Early Chronic Polyneuropathy

A *sensorimotor paralysis*, which evolves over several weeks (subacutely) or more slowly, over many months or a year or two, and involves legs more than arms and distal parts more than proximal should lead to a search for diabetes, occult neoplasia (carcinoma, lymphoma, multiple myeloma, or plasmacytoma), HIV infection, paraproteinemia (including amyloid neuropathy), systemic autoimmune disease, and CIDP. In our experience, the *subacute and chronically evolving demyelinating neuropathies* (over months) that have slowed motor conduction velocities,

conduction block, and relatively normal needle EMG studies generally turn out to be variants of CIDP, some with a paraproteinemia. Marked weakness and reduced muscle action potential amplitudes in the face of minimal denervation, even if present in only a few nerves, also indicate the presence of focal demyelination. Most of the mixed axonal-demyelinating cases in which one eventually arrives at a diagnosis will also be related to an immune (paraproteinemic) or inflammatory (CIDP) process. In exceptional cases, a neoplastic process may remain hidden for as long as 2 or 3 years after the onset of neuropathy. An environmental toxin, endocrine disorder (except for diabetes), or nutritional cause is seldom identified, despite the frequent attribution of obscure polyneuropathies to such causes. Nonetheless, history of exposure to industrial or hobbyist toxins, sociopathy or psychopathy that would lead to toxin ingestion, or foreign travel should be sought and the evaluation should include testing for heavy metals in obscure cases. Unusual causes of nutritional deficiency such as celiac sprue and other malabsorption syndromes (Whipple disease, Crohn disease, chronic hepatic disease, and particularly intestinal bypass surgery) have usually been obvious enough when present, so that the experienced clinician rarely overlooks them. Perhaps sprue is able to cause a neuropathy with minimal gastrointestinal symptoms. Vitamin B₁₂ deficiency should be sought in cases of large-fiber neuropathy. A difficult problem is that of an older person with a mild, nonprogressive sensorimotor polyneuropathy in whom there is evidence of mild hypothyroidism, marginally low vitamin B₁₂ and folic acid levels in the blood, a somewhat unbalanced diet, perhaps an excessive alcohol intake, and an abnormal glucose tolerance response. It is easy to propose but hard to prove that any of these factors is relevant. Vitamin replacement should be undertaken nonetheless if no other cause is found.

In the *purely or predominantly sensory polyneuropathies not caused by diabetes*—some painful, some not, and some with marked ataxia—an association with occult carcinoma, an IgM or other paraproteinemia, primary and familial amyloidosis, or Sjögren syndrome are the primary considerations. The problem of a mild sensory neuropathy in an elderly patient with or without burning feet was discussed earlier. When the symptoms are confined to the feet and legs, hereditary sensory neuropathy must always be considered if the condition is long standing. Intoxications with pyridoxine or metals account for a few chronic sensory neuropathies. Despite all these considerations, we still regularly encounter patients in whom the cause is not disclosed by any of the available tests. We have watched helplessly as some of these patients were reduced to a bed and wheelchair existence and others suffered from pain until they became dependent on opiates.

Table 46-7 lists the laboratory tests that are useful in the investigation of this group of neuropathies, with electrophysiology being most valuable.

Diagnosis of Late Chronic Polyneuropathy

The majority of these (evolving over years) prove to be hereditary or one of the infrequent sporadic mutations

Table 46-7

LABORATORY TESTS FOR THE INVESTIGATION OF SUBACUTE AND CHRONIC POLYNEUROPATHIES

Distal Symmetric Polyneuropathies^a

- Serum glucose, glucose tolerance test, hemoglobin A_{1c}
- Anti-Hu antibody
- Immunoelectrophoresis of serum and urine
- Antimyelin-associated glycoprotein (MAG) and SGPG
- Anti-G_{M1} antibody (if evidence of multifocal motor conduction block)
- Vitamin B₁₂ and methylmalonic acid levels
- Human immune deficiency virus antibody
- Lyme antibody Western blot
- Heavy metal concentrations in blood and tissue
- Blood urea nitrogen
- Anti-gliadin and anti-transglutaminase antibodies
- Vitamin E levels
- Genetic testing for Charcot-Marie-Tooth disease and related hereditary neuropathies as indicated in text

Mononeuropathy Multiplex

- Sedimentation rate, C-reactive protein
- p-ANCA, c-ANCA
- Cryoglobulins
- Hepatitis serologies
- HIV
- Angiotensin converting enzyme (ACE) and chest imaging for sarcoid
- CMV
- PMP22 deletion in appropriate circumstances
- Consider nerve biopsy

Sensory Ganglionopathy

- Sedimentation rate, C-reactive protein
- Anti-SSA/SSB
- Anti-Hu and related paraneoplastic antibodies
- Pyridoxine level if appropriate
- Consider biopsy of minor salivary gland of lip

Small-Fiber Painful Neuropathy

- Serum glucose, glucose tolerance test, hemoglobin A_{1c}
- HIV
- Transthyretin (TTR) mutation
- Above listed testing pertaining to rheumatologic diseases
- Heavy metal concentrations
- Vitamin B levels and carotene
- Alpha-galactosidase A concentration (Fabry disease)
- Voltage-gated sodium channel sequencing (1.7)
- Consider autonomic testing and skin biopsy for nerve fiber quantification
- Consider abdominal fat pad biopsy for amyloidosis
- Consider nerve biopsy for microscopic vasculitis

^aTesting for each category of neuropathy is determined for Sjögren disease by clinical circumstances and results of electrophysiologic studies. See England et al, 2009.

of the genes that are responsible for the inherited types. The observations of Dyck and coworkers (1981), referred to in the introduction to this chapter, are of interest in this respect. In a series of 205 patients who were referred to the Mayo Clinic with neuropathies of unknown cause, 86 were found to have an inherited form of disease. With appropriate genealogic data, the diagnoses of the peroneal muscular atrophy of Charcot-Marie-Tooth disease can usually be made on clinical grounds alone (high arches, distal foreleg atrophy, chronicity, etc.). Sporadic cases are more difficult. Some of the patients who have consulted us in adulthood for an obscure polyneuropathy report having had operations on their feet and toes for these reasons, but the connection to a genetic neuropathy had

not been previously made. Additional hints are frequent sprained ankles and the need to tape the ankles during adolescence in order to run or participate in sports. Dyck and associates found that direct examinations of the patients' siblings, children, parents, and other close relatives were often successful in revealing a hereditary basis for the neuropathy. Sometimes, the absence of ankle reflexes or foot deformities in their relatives discloses the diagnosis.

DNA testing for the main forms of Charcot-Marie-Tooth disease is available from commercial laboratories and has increased the diagnostic certainty. A comment has already been made regarding the utility of such testing and the small number of mutations that give rise to over one-third of cases of inherited sensorimotor neuropathy. As already alluded to, individuals with a chronic demyelinating neuropathy, pes cavus or hammer toes, and a likely autosomal dominant pattern of inheritance probably have CMT1A and sequencing for PMP22 duplication may be undertaken. If there is male-to-male transmission, CMT1X is likely and the *GJB1* gene may be investigated. If both genes lack causative mutations in a demyelinating case, CMT1B is possible, especially if motor nerve conduction velocities are very slow (below 15 m/s), and the *MPZ* gene is suspect. Whether testing beyond this, which would include the *SIMPLE*, *PMP22*, and *EGR2* genes that occur in low frequency with CMT1A, is worthwhile depends on the clinical circumstances. Some cases of axonal, CMT2, will have one of several very low-frequency mutations that have been delineated. Numerous easily accessible algorithms for genetic testing have been published, similar to the guidance in the article by Saporta and colleagues, that are based on inheritance, nerve conduction velocity, and clinical features and we have not reproduced them here.

Slowly progressive polyneuropathy with features of central nervous system degeneration, particularly cerebellar ataxia, most often has a genetic basis, but a small number are found to be the result of a genetic metabolic disorder such as a leukodystrophy.

In contrast, a few young patients have come to our attention in whom a gradually progressive polyneuropathy that evolved over almost a decade turned out to be an acquired chronic inflammatory demyelinating condition rather than the expected genetic type. The absence of a family history of neuropathy and of high arches and heterogeneous slowing of both nerve conduction velocities and reductions in motor amplitudes on the nerve conduction studies provided hints to the acquired nature of the condition.

Finally, it should be conceded again that even after the most assiduous clinical and laboratory investigation, a substantial proportion of chronic neuropathies remain unexplained.

Diagnosis of Recurrent or Relapsing Polyneuropathy

Several types of neuropathies are particularly prone to recurrence: CIDP, Refsum disease, Tangier disease, and porphyria, the last of which may display attacks that

recur spontaneously or are precipitated by the administration of various drugs. Repeated exposure to environmental toxins can do the same. Approximately 2 percent of patients with GBS have one or more relapses, in which the clinical and pathologic changes differ little between episodes. Some instances of mononeuritis multiplex, especially when associated with cryoglobulinemia, are also characterized by remissions and relapses over many years, although the remissions are incomplete. A common cause of relapse is the withdrawal of corticosteroids in CIDP patients who are dependent on these drugs; similarly, lapses in the treatment of paraproteinemic neuropathies cause similar fluctuations in symptoms. Enlargement of nerves may occur with repeated attacks from any of these diseases. It is self-evident that patients who have recovered from an episode of alcoholic-nutritional or toxic polyneuropathy will develop a recurrence if they again subject themselves to intoxication or nutritional deficiency.

Neuropathic symptoms that fluctuate in relation to environmental factors such as cold (cryoglobulinemia), heat (Fabry and Tangier diseases), or intermittent exposure to heavy metal or other type of poisoning may simulate an inherently relapsing polyneuropathy.

MONONEUROPATHY, MONONEUROPATHY MULTIPLEX, AND PLEXOPATHY

The diagnosis of this group of neuropathies rests on the finding of motor, reflex, and sensory changes confined to the territory of a single nerve; of several individual nerves affected in a random manner (*mononeuritis* or *mononeuropathy multiplex*); or of a plexus of nerves or part of a plexus (*plexopathy*). Certain neuropathies of this type—traceable mainly to polyarteritis nodosa or other vasculitides, leprosy, sarcoid, or diabetes—have already been discussed and are the main causes of the multiple mononeuropathy pattern. In addition to the signs of mononeuropathy multiplex, pain overlying the site of nerve infarction or distally is characteristic. The CSF protein is usually normal or slightly elevated, and in certain of these diseases there is a CSF pleocytosis (e.g., HIV, Lyme disease). Inflammatory neuropathy and the multifocal motor neuropathy caused by antibodies to G_{M1} also may be considered, because of their clinical similarity, in this group.

In identifying a process as caused by single or multiple mononeuropathies, the reader can refer to Table 46-1, which lists the roots, nerves, and muscles that are involved in particular movements, and to Table 46-4, which gives the main etiologies of mononeuropathy multiplex.

Brachial Plexus Neuropathies

Brachial plexus neuropathies, or brachial plexopathies, comprise an interesting group of neurologic disorders. Most develop without apparent cause and manifest

themselves by sensorimotor derangements ascribable to one or more of the cords of the plexus. Some are a result of infiltration by tumor, compression, obscure infections (possibly viral), and the delayed effects of radiotherapy. Of obvious cause are those that result from trauma, in which the arm is hyperabducted or the shoulder violently separated from the neck. Difficult births are an important source of such traction injuries to the plexus, but their nature is also evident. Rarely, the brachial plexus or other peripheral nerves may be damaged at the time of an electrical injury, either from lightning or from a household or industrial source (see "Electrical Injuries" in Chap. 44). Direct compression of parts of the plexus by adjacent skeletal anomalies (cervical rib, fascial bands, narrowed thoracic outlet) represents another, still somewhat controversial, category of brachial plexus injury. A subcutaneous or intramuscular injection of vaccine or foreign serum was in the past sometimes followed by a brachial plexopathy, usually partial. There are also plexus lesions of presumed toxic nature, such as those following heroin injection. Granulomatous diseases such as sarcoid and secondary inflammatory processes related to lymphoma may implicate a plexus and an ischemic condition resulting from thrombosis of the subclavian artery or vein (Paget-Schrötter syndrome) is known.

More common, however, is an idiopathic *brachial plexus neuritis* of obscure origin, also called *Parsonage-Turner syndrome*, discussed further on. It stands apart as a special clinical entity, often difficult to distinguish from other types of brachial and axillary pain. Some of these cases, surprisingly, are familial; others occur in small outbreaks, but most are sporadic.

In assessing the type and degree of plexus injury, electrophysiologic testing is of particular importance. Early after a traumatic injury or other acute disease of the plexus, the only electrophysiologic abnormality may be an absence of late responses (F wave). After 7 to 10 days or more, as the process of wallerian degeneration proceeds, sensory potentials are progressively lost and the amplitudes of compound muscle action potentials are variably reduced. Fibrillation potentials, indicative of denervation, then begin to appear in the corresponding muscles. Even later, usually after several weeks, signs of reinnervation can be detected. In more chronic cases, all of these features are evident when the patient is first studied. The pattern of denervated muscles allows a distinction to be made between a plexopathy, radiculopathy, and mononeuritis multiplex based on the known patterns of muscle innervation (see Table 46-1). If denervation changes are found in the paraspinal muscles, the source of weakness and pain is in the intraspinal roots, proximal to the plexus. In this case, the sensory potentials are retained. MRI may expose metastatic deposits of the plexus, but small nodular lesions may escape detection and one then defers to the clinical data if the circumstances suggest an infiltrative or compressive lesion.

The anatomic plan of the brachial (and lumbosacral) plexus and their relations to blood vessels and bony structures (Fig. 46-5) and one of the detailed monographs on the peripheral nerves should be consulted.

We often resort to the illustrations of individual nerves and plexuses that are well demonstrated in the monograph published by the Guarantors of Brain.

For orientation, it is enough to remember that the brachial plexus is formed from the anterior and posterior divisions of cervical roots 5, 6, 7, and 8 and thoracic nerve root 1. The fifth and sixth cervical roots merge into the upper trunk, the seventh root forms the middle trunk, and the eighth cervical and first thoracic roots form the lower trunk. Each trunk divides into an anterior and posterior division. The posterior divisions of each trunk unite to form the posterior cord of the plexus. The anterior divisions of the upper and middle trunks unite to form the lateral cord. The anterior division of the lower trunk forms the medial cord. Two important nerves emerge from the upper trunk (dorsal scapular nerve to the rhomboid and levator scapulae muscles, and long thoracic nerve to the anterior serratus). The posterior cord gives rise mainly to the radial nerve. The medial cord gives rise to the ulnar nerve, medial cutaneous nerve to the forearm, and medial cutaneous nerve to the upper arm. This cord lies in close relation to the subclavian artery and apex of the lung and is the part of the plexus most susceptible to traction injuries and to compression by tumors that invade the costoclavicular space. The median nerve is formed by the union of parts of the medial and lateral cords.

Lesions of the Entire Brachial Plexus

In this case, the entire arm is paralyzed and hangs uselessly at the side; the sensory loss is complete below a line extending from the shoulder diagonally downward and medially to the middle third of the upper arm. Biceps, triceps, radial, and finger reflexes are abolished. The usual cause is vehicular trauma, especially motorcycle injury.

Upper Brachial Plexus Paralysis

This is a result of injury to the distal fifth and sixth cervical roots, the most common causes of which are forceful separation of the head and shoulder during difficult delivery, pressure on the supraclavicular region during anesthesia, immune reactions to injections of foreign serum or vaccines, and idiopathic brachial plexitis (see later). The muscles affected are the biceps, deltoid, supinator longus, supraspinatus and infraspinatus, and, if the lesion is very proximal, the rhomboids. The arm hangs at the side, internally rotated and extended at the elbow. Movements of the hand and forearm are unaffected. The prognosis for spontaneous recovery is generally good, although this may be incomplete. Injuries of the upper brachial plexus and spinal roots incurred at birth (termed in older literature as Erb-Duchenne palsy) usually persist throughout life.

Lower Brachial Plexus Paralysis

This is commonly the result of traction on the abducted arm in a fall or during an operation on the axilla, infiltration or compression by tumors extending from the apex of the lung (superior sulcus or Pancoast syndrome), or compression by cervical ribs or bands. Injury may occur during birth, particularly with breech deliveries

Figure 46-5. Diagram of the brachial plexus: the components of the plexus have been separated and drawn out of scale. Note that peripheral nerves arise from various components of the plexus: roots (indicated by cervical roots 5, 6, 7, 8, and thoracic root 1); trunks (upper, middle, lower); divisions (anterior and posterior); and cords (lateral, posterior, and medial). The median nerve arises from the heads of the lateral and medial cords. (From Haymaker and Woodhall, *Peripheral Nerve Injuries*, 2nd ed. Philadelphia, Saunders, 1953, by permission.)

(termed Dejerine-Klumpke paralysis). There is weakness and wasting of the small muscles of the hand and a characteristic clawhand deformity. Sensory loss is limited to the ulnar border of the hand and the inner forearm; if the first thoracic motor root is involved, there may be an associated paralysis of the cervical sympathetic nerves with a Horner syndrome. Invasion of the lower plexus by tumors is usually painful; postradiation lesions are more likely to cause paresthesias without pain (Lederman and Wilbourn, 1984).

Infraclavicular Lesions Involving Cords of the Brachial Plexus (See Fig. 46-5)

A lesion of the *lateral cord* causes weakness of the muscles supplied by the musculocutaneous nerve and the lateral root of the median nerve; it manifests mainly as a weakness of flexion and pronation of the forearm. The intrinsic muscles of the hand innervated by the medial root

of the median nerve are spared. A lesion of the *medial cord* of the plexus causes weakness of muscles supplied by the medial root of the median nerve and the ulnar nerve. The effect is that of a combined median and ulnar nerve palsy. A lesion of the *posterior cord* results in weakness of the deltoid muscle, extensors of the elbow, wrist, and fingers, and sensory loss on the outer surface of the upper arm.

One group of infraclavicular injuries, often iatrogenic, results from damage to the subclavian or axillary vessels and the formation of pseudoaneurysms or hematomas. Small puncture wounds—as might occur with catheterization of the subclavian vein, anesthetic block of the brachial plexus, or transaxillary arteriography—are likely to produce this type of injury. As mentioned earlier, thrombosis of the vessels of the neurovascular subclavian bundle are a rare cause. Other frequent causes of injury to the cords are dislocation of the head of the humerus, direct axillary trauma (stab wounds), and supraclavicular

compression during awkward positioning of the arm in an operation. Any cords of the plexus may be injured or they may be affected in various combinations.

Thoracic Outlet Syndrome

This subject is discussed extensively in Chap. 11.

Brachial Neuritis, Brachial Plexitis (Neuralgic Amyotrophy, Parsonage-Turner Syndrome)

This illness develops abruptly in an otherwise healthy individual; it may also complicate an infection, an injection of vaccine or antibiotic, childbirth, surgical procedures of any type, or the use of heroin. Magee and DeJong, in 1960, and Tsairis and coworkers, in 1972, reported large series of cases and amplified a well-known clinical picture. The term *neuralgic amyotrophy* was applied to this symptom complex by Parsonage and Turner, who wrote extensively on the subject. Their term for the condition is appropriate, as the clinical and EMG findings suggest a lesion of the peripheral nerves of the shoulder girdle and upper arm rather than in the cords of the plexus. Actually, the site of the pathologic changes has not been established. Our patients have nearly all been adults, ranging from 20 to 65 years of age. Males may be slightly more susceptible.

Beginning as an ache or deep burning in and around the shoulder that is centered over the deltoid, at the root of the neck or in the axilla, and suspected at first of being only a muscle strain, the pain rapidly becomes very intense and may include a component of burning. The onset can be remarkably abrupt and occasionally awakens the patient from sleep. It is made worse by movements that involve the muscles in the region and the patient searches for a comfortable position. Narcotics are usually required to suppress the pain. After a period of several days there is a rapid development of muscular weakness and thereafter, sensory and reflex impairment. With the development of weakness, the pain begins to subside. In a few cases, the neurologic disorder occurs with little or no antecedent pain. Possibly in some there is pain that is not followed by demonstrable weakness. A small proportion of cases are bilateral at the outset, or the opposite side is affected weeks later but most cases remain one-sided.

Unlike restricted radicular lesions, which almost never cause complete paralysis of a muscle, certain muscles involved in brachial neuritis, such as the serratus anterior, deltoid, biceps, or triceps, may be totally or almost paralyzed, sometimes in isolation (see later). Rarely are all the muscles of the arm involved (4 of 99 cases of Tsairis et al). Most of the neurologic deficits in our patients have been localized around the shoulder and upper arm. Either the biceps or triceps reflex may be abolished. In a few cases there has been an additional median, radial, anterior, or posterior interosseous nerve palsy that can be detected and isolated by EMG to a site distal to the plexus (see later). Affected patients usually have no fever, leukocytosis, or increased sedimentation rate. Occasionally there is a mild pleocytosis (10 to 50 white blood cells/mm³) and slightly increased protein in the CSF, but most cases have a normal formula and sampling of CSF is not necessary for diagnosis.

Recovery of paralysis and restoration of sensation are usually complete in 6 to 12 weeks, but sometimes not for a year or longer. In approximately 10 percent of cases

there is residual weakness and wasting of the affected muscles and a similar number have had a recurrence some time later on the same or the opposite side. A number of our elderly patients with this condition have had little recovery of motor function over 5 years. In a series of 246 cases described by van Alfen and colleagues that may be consulted for descriptions of the many clinical variations of this illness, they found that a considerable proportion had chronic pain and residual weakness. (Their series included idiopathic and hereditary brachial plexopathy, of the type addressed in the next section.

Motor nerve conduction becomes impaired in 7 to 10 days, as described earlier. The lesions are presumably of axonal type, and electrophysiologic features of denervation follow. There are *highly restricted forms* that affect only one or two nerves of the brachial plexus, as mentioned earlier. The most common of these is probably an isolated palsy of the serratus anterior (long thoracic nerve). The suprascapular, axillary, posterior interosseus, and phrenic nerves are other occasional sites of solitary neuritis. In the case of a unilateral phrenic nerve paralysis, there is mild dyspnea on exertion and one hemidiaphragm is found to be elevated on the chest radiographs. When the process is not progressive and no mediastinal lesion can be detected with extensive imaging, a phrenic palsy can be assumed to fall into this idiopathic category. We have twice seen a Horner syndrome in association with brachial neuritis but the former finding is always of greater concern as a sign an infiltrating neoplasm or granulomatous process.

We have had experience with patients who had this syndrome following parvovirus B19 infection, as has been cited in the literature. Most cases had been preceded within days by an erythematous rash spreading from the limbs to the trunk and face, somewhat similar to the eruption of fifth disease caused by this virus in children. One of our patients had no premonitory features, but her child had just recovered from an illness that was called fifth disease by the pediatrician. Some reported patients have had preceding influenza-like symptoms and adenopathy as well. A summary of cases that have appeared in the literature can be found in the paper by Maas and coworkers. Duchowny and colleagues described a patient in whom a typical brachial neuritis occurred as part of a febrile illness that proved to be caused by a CMV infection and the same has been observed (albeit rarely) in patients with AIDS. A few outbreaks of brachial neuritis have been recorded and prompted the suggestion that the Coxsackievirus was the cause. Whether Lyme infection can cause brachial neuritis is unsettled, but we have seen at least one instance that was more of a cervical radiculopathy—there was a pleocytosis in the CSF. The therapeutic use of interleukin-2 and interferon has apparently precipitated a few cases. In the past, when animal antisera were in common use, this entity was frequent; in the modern era it has been seen rarely after injection of tetanus toxoid, typhoid-paratyphoid vaccine, and triple vaccine (pertussis, diphtheria, and tetanus).

Plexitis also occurs as an uncommon idiopathic complication of the *postpartum state* (Lederman and Wilbourn, 1996). Some of these are repetitive or bilateral and some are familial, but otherwise the plexopathy has no distinguishing features from the idiopathic type. The hereditary variety is described later.

One must differentiate idiopathic brachial plexitis from the following conditions: (1) spondylosis or ruptured disc with root compression, particularly the C5 and C6 roots, in which paralysis is rarely as severe as it is in plexitis; (2) brachialgia from bursitis, labral tear, or rotator cuff syndrome; (3) polymyalgia rheumatica; (4) entrapment neuropathies, particularly of the subscapular or dorsal scapular nerve; (5) carcinomatous plexopathy; (6) radiation plexopathy; and (7) sarcoid and other granulomatous infiltrations. Dissection of the vertebral artery may rarely simulate the pain and weakness of brachial neuritis (Berrion et al).

Pathologic data are sparse, but Suarez and coworkers (1996) have reported collections of intense mononuclear inflammation in fascicles of the plexus obtained by biopsy. Perivascular lymphocytes were found in the endoneurial space and, less so, in the epineurium.

Therapy is purely symptomatic, but we have usually embarked on a course of steroids and, in a few cases, other immunosuppressants, when the illness continued to advance over many weeks. Corticosteroids sometimes have a beneficial effect on pain and have also been successful in some cases of lumbosacral plexitis. Uncontrolled observations by van Eijk and coworkers on the use of prednisolone in 50 patients has suggested that pain relief and motor outcome were better than in untreated patients.

Hereditary Brachial Plexopathy (Hereditary Neuralgic Amyotrophy)

Rarely, an acute and painful *recurrent brachial neuropathy* occurs in a familial pattern. The inheritance is autosomal dominant and the attacks, which are painless, occur most commonly in the second and third decades of life. The authors have observed this syndrome in 3 generations of a family, some members having had 5 attacks at ages ranging from 3 to 45 years. We have had experience with the contemporaneous onset of brachial plexitis in an adult brother and sister who shared the same household but had no family history of a similar problem. A shared exposure to viral or environmental agents was suspected. Lower cranial nerve involvement and mononeuropathies in other limbs are conjoined in some instances (see Taylor). Attacks may be spontaneous or precipitated by compression, slight stretching, or minor trauma to the region of the plexus. In one family, attacks have been triggered by events that activate the immune system (fevers, infections, surgical procedures). In several such families, there are subtle characteristic facial features including narrowed and horizontally positioned eyes and a long nasal bridge (Modigliani face). Cleft palate and unusual skin folds and creases have been observed in other kindreds (Jeannot et al).

The clinical course is usually benign with good recovery of each episode, but residual deficits may accumulate after recurrent attacks. In Dutch families affected by the disease, Alfen and colleagues have pointed out that some patients experience a more chronic and undulating course rather than discrete attacks.

Madrid and Bradley examined the sural nerves from two patients with familial recurrent brachial neuropathy. In teased single nerve fibers they found sausage-like segments of thickened myelin and redundant loops of myelin with secondary constriction of the axon. In addition, nerve

fibers showed a considerable degree of segmental demyelination and remyelination. They called this aberration of myelin formation "tomaculous" neuropathy (from *tomaculum*, "sausage"), changes that are now appreciated as valid but relatively nonspecific.

The genetic basis for this is a mutation of SEP11. Another cause of recurrent brachial palsy, or of derivative syndromes involving nerves in the arms, is HNPP, discussed in the earlier section on inherited neuropathies and due to a deletion in the *PMP22* gene ("Hereditary Neuropathy With Pressure Palsies"). As commented there, the gene defect is also on chromosome 17, but it is not the one associated with familial brachial neuritis (see Chance et al). Some confusion has arisen because CMT1A, HNPP, and the familial brachial palsy disease all have chromosome 17 defects. Pressure palsies in HNPP are painless and there is usually an underlying and slowly advancing polyneuropathy. In some families, such as the one reported by Thomas and Ormerod, the distinction between hereditary neuralgic amyotrophy (HNA) and HNPP was unclear as the recurrent brachial plexopathies were painful (consistent with the former), but there was also a painless multifocal sensory neuropathy (consistent with the latter).

Brachial Neuropathy following Radiation Therapy

This is usually a complication of irradiation of the axilla for carcinoma of the breast. Stoll and Andrews studied a group of 117 such patients who were treated with high-voltage, small-field therapy and had received either 6,300 or 5,775 cGy in divided doses. Of those receiving the larger dose, 73 percent developed weakness and sensory loss in the hand and fingers between 4 and 30 months after treatment, most of them after 12 months. In 1 autopsied case, the brachial plexus was ensheathed in dense fibrous tissue; distal to this zone, both myelin and axons had disappeared (wallerian degeneration), presumably as a result of entrapment of nerves in fibrous tissue; possibly a vascular factor was also operative.

Kori and coworkers, who analyzed the brachial plexus lesions in 100 patients with cancer, also found that doses exceeding 6,000 cGy were associated with radiation damage. Usually the upper plexus was involved and was sometimes associated with a painless lymphedema. Myokymic discharges and fasciculations are particularly suggestive of radiation damage. In patients who received lower doses, the development of brachial plexopathy usually indicated tumor infiltration; these lesions affected the lower plexus more than the upper; they were often painful and accompanied by Horner syndrome (see Lederman and Wilbourn, 1984). Rarely, radiation may give rise many years later to a malignant tumor of nerve or the surrounding connective tissue, a sarcoma in 2 cases familiar to us.

Herpes Zoster Plexitis, Neuritis, and Ganglionitis (See Chap. 33)

This organism is perhaps the best defined infectious cause of the above listed syndromes, but its identification is usually obvious on the basis of the skin eruption of shingles. Cases are known in which radicular pain precedes

the eruption by many days or in which shingles do not appear, thereby simulating a herniated disc (zoster sine herpette). These conditions are discussed with the other viral infections of the nervous system in Chap. 33.

Brachial Mononeuropathies (See Table 46-1)

Long Thoracic Nerve (of Bell)

This nerve is derived from the fifth, sixth, and seventh cervical nerves and supplies the serratus anterior muscle, which fixates the lateral scapula to the chest wall. Paralysis of this muscle results in an inability to raise the arm over the head and winging of the medial border of the scapula when the outstretched arm is pushed forward against resistance. The nerve is injured most commonly by carrying heavy weights on the shoulder or by strapping the shoulder to the operating table. As stated earlier, the neuropathy may be the only affected nerve in a brachial plexus neuropathy of either the inherited or idiopathic variety (Phillips).

Suprascapular Nerve

This nerve is derived from the fifth (mainly) and sixth cervical nerves and supplies the supraspinatus and infraspinatus muscles. Lesions may be recognized by the presence of atrophy of these muscles and weakness of the first 15 degrees of abduction (supraspinatus) and of external rotation of the arm at the shoulder joint (infraspinatus). The latter muscle is tested by having the patient flex the forearm and then, pinning the elbow to the side, asking him to swing the forearm backward against resistance. This nerve is often involved as a result of a herniated C5-C6 disc (see Chap. 11), or as part of a brachial plexus neuropathy of either the sporadic or inherited type. It may be affected during infectious illnesses and may be injured in gymnasts, or as a result of local pressure from carrying heavy objects on the shoulder (“meatpacker’s neuropathy”). An entrapment syndrome has also been reported; it is characterized by pain and weakness on external rotation of the shoulder joint with atrophy of the infraspinatus muscle (Table 46-8). Decompression of the nerve where it enters the spinoglenoid notch relieves the condition.

Axillary Nerve

This nerve arises from the posterior cord of the brachial plexus (mainly from the C5 root, with a smaller contribution from C6) and supplies the teres minor and deltoid muscles. It may be involved in dislocations of the shoulder joint, fractures of the neck of the humerus, disc protrusion, and brachial neuritis; in other instances, no cause may be apparent. The anatomic diagnosis depends on recognition of paralysis of abduction of the arm (in testing this function, the angle between the side of the chest and the arm must be greater than 15 degrees and less than 90 degrees), wasting of the deltoid muscle, and slight impairment of sensation over the outer aspect of the shoulder.

Musculocutaneous Nerve

The origin of this nerve is from the fifth and sixth cervical roots. It is a branch of the lateral cord of the brachial plexus and innervates the biceps brachii, brachialis, and

Table 46-8

ENTRAPMENT NEUROPATHIES

NERVE	SITE OF ENTRAPMENT
Suprascapular	Spinoglenoid notch
Lower trunk or medial cord of brachial plexus	Cervical rib or band at thoracic outlet
Median	
Wrist	Carpal tunnel
Elbow	Between heads of pronator teres (pronator syndrome) ^a
Ulnar	
Wrist	Guyon’s canal (ulnar tunnel)
Elbow	Bicipital groove, cubital tunnel
Posterior interosseous nerve	Radial tunnel—at point of entrance into supinator muscle (arcade of Frohse) ^a
Lateral femoral cutaneous (meralgia paresthetica)	Inguinal ligament
Obturator	Obturator canal ^a
Posterior tibial	Tarsal tunnel; medial malleolus-flexor retinaculum ^a
Interdigital plantar (Morton metatarsalgia)	Plantar fascia: heads of third and fourth metatarsals

^aThese are not well-defined syndromes and may be subject to overdiagnosis. Alternative diagnoses should be considered. For example, multifocal motor neuropathy and brachial neuritis account for cases that may be incorrectly attributed to radial tunnel syndrome and cases of distal sensory neuropathy may be attributed to tarsal tunnel syndrome.

coracobrachialis muscles. Lesions of the nerve result in wasting of these muscles and weakness of flexion of the supinated forearm. Sensation may be impaired along the radial and volar aspects of the forearm (lateral cutaneous nerve). Isolated lesions of this nerve are usually the result of fracture of the humerus.

Radial Nerve

This nerve is derived from the sixth to eighth (mainly the seventh) cervical roots and is the distal extension of the posterior cord of the brachial plexus. It innervates the triceps, brachioradialis, and supinator muscles, and continues below the elbow as the posterior interosseous nerve, which innervates the extensor muscles of the wrist and fingers, the main abductor of the thumb (the abductor pollicis longus, which is easier to isolate than the median nerve innervated abductor pollicis brevis), and the extensors of the fingers at both joints. A complete proximal radial nerve lesion results in paralysis of extension of the elbow, flexion of the elbow with the forearm midway between pronation and supination (a result of paralysis of the brachioradialis muscle), supination of the forearm, extension of the wrist and fingers, and extension and abduction of the thumb in the plane of the palm. If the lesion is confined to the posterior interosseous nerve, only the extensors of the wrist and fingers are affected. Sensation is impaired over the posterior aspects of the forearm and over a small area on the radial aspect of the dorsum of the hand.

The radial nerve may be compressed in the axilla ("crutch" palsy), but more frequently at a lower point, where the nerve winds around the humerus (see Table 46-8); pressure palsies incurred during an alcoholic stupor and fractures of the humerus commonly injure the nerve at the site of injury. It is susceptible to lead intoxication and is frequently involved as part of brachial neuritis and mononeuritis multiplex.

Median Nerve

This nerve originates from the fifth cervical to the first thoracic roots but mainly from the sixth cervical root and is formed by the union of the medial and lateral cords of the brachial plexus. It innervates the pronators of the forearm, long finger flexors, and abductor and opposens muscles of the thumb and is a sensory nerve to the palmar aspect of the hand. Complete interruption of the median nerve results in inability to pronate the forearm or flex the hand in a radial direction, paralysis of flexion of the index finger and terminal phalanx of the thumb, weakness of flexion of the remaining fingers, weakness of opposition and abduction of the thumb in the plane at a right angle to the palm (abductor and flexor pollicis brevis), and sensory impairment over the radial two-thirds of the palm and dorsum of the distal phalanges of the index and third fingers. The nerve may be injured in the axilla by dislocation of the shoulder and in any part of its course by stab, gunshot, or other types of wounds, and like the radial nerve, is often a component of the mononeuritis multiplex syndrome. Incomplete lesions of the median nerve between the axilla and wrist may result in causalgia (see further on).

Carpal Tunnel Syndrome (See also Chap. 11.) Compression of the median nerve at the wrist (*carpal tunnel syndrome*) is the most common disorder affecting the median nerve and the most frequent nerve entrapment syndrome. The problem arises usually as a result of excessive use of the hands and occupational microtrauma. Infiltration of the transverse carpal ligament with amyloid (as occurs in multiple myeloma and amyloidosis) or thickening of connective tissue in rheumatoid arthritis, acromegaly, mucopolysaccharidosis, and hypothyroidism are less commonly identified causes. It is also common for the condition to make its appearance during pregnancy. In elderly individuals, the cause of the carpal tunnel syndrome is often not apparent. According to Kremer and colleagues, it was McArdle, in 1949, who first suggested that the cause of this syndrome was compression of the median nerve at the wrist and that the symptoms would be relieved by division of the flexor retinaculum forming the ventral wall of the carpal tunnel. Dysesthesias and pain in the fingers, referred to for many years as "acroparesthesia" came to be recognized as a syndrome of median nerve compression only in the early 1950s.

The syndrome is essentially a sensory one; the loss or impairment of superficial sensation affects the palmar aspect of the thumb and the index and middle fingers (especially the index finger) and may or may not split the ring finger (splitting does not occur with a plexus or root lesion). The paresthesias are characteristically worse during the night. As pointed out in Chap. 11, the pain in

carpal tunnel syndrome may radiate into the forearm and even into the region of the biceps and rarely, to the shoulder. Weakness and atrophy of the abductor pollicis brevis and other median-innervated muscles occur in only advanced cases of compression. Electrophysiologic testing confirms the diagnosis by demonstrating prolonged sensory conduction across the wrist and explains cases in which operation has failed (see the review by Stevens).

Several provocative tests are useful. The Phalen maneuver consists of hyperflexion of the wrist for 30 to 60 s—usually performed by opposing the outer surfaces of the hands with the wrists flexed. The Tinel sign is elicited by lightly tapping the volar aspect of the wrist at the transverse carpal ligament (distal to the first wrist crease). Both of these tests are meant to elicit pain or paresthesias over the digits innervated by the median nerve. The sensitivity of these tests is close to 50 percent, but their specificity is considerably higher. Other tests involving prolonged pressure over the median nerve have been devised, but they are of uncertain value, e.g., Durken's test of the Phalen maneuver combined with digital compression of the nerve.

TREATMENT Surgical division of the carpal ligament with decompression of the nerve is curative but is required only in severe and protracted cases. Splinting of the wrist to limit flexion almost always relieves the discomfort but denies the patient the full use of the hand for some time. It is a useful temporizing measure for a few weeks, as is the injection of hydrocortisone into the carpal tunnel. Studies of oral corticosteroids give conflicting results. Treatment of an underlying condition such as arthritis, hypothyroidism and possibly diabetes, is often helpful. Some patients have benefited, paradoxically, from the stopping of corticosteroids or estrogen. Also, some practitioners favor the use of nonsteroid antiinflammatory medication, but we have been generally unimpressed with the results. Most often, splinting and local steroid injections are very satisfactory in the short-term, especially if the symptoms are of recent onset.

Another less common site of compression of the median nerve is at the elbow, where the nerve passes between the two heads of the pronator teres, or just above that point behind the bicipital aponeurosis. It gives rise to the "pronator syndrome," in which forceful pronation of the forearm produces an aching pain (see Table 46-8). There is weakness of the abductor pollicis brevis and opponens muscles and numbness of the first three digits and palm.

Ulnar Nerve

This nerve is derived from the eighth cervical and first thoracic roots. It innervates the ulnar flexor of the wrist, the ulnar half of the deep finger flexors, the adductors and abductors of the fingers, the adductor of the thumb, the third and fourth lumbricals, and muscles of the hypothenar eminence. Complete ulnar paralysis is manifest by a characteristic clawhand deformity; wasting of the small hand muscles results in hyperextension of the fingers at the metacarpophalangeal joints and flexion at the interphalangeal joints. The flexion deformity is most pronounced in the fourth and fifth fingers, as the lumbrical muscles of the second and third fingers, supplied by the median nerve, counteract the deformity. Sensory loss

occurs over the fifth finger, the ulnar aspect of the fourth finger, and the ulnar border of the palm.

The ulnar nerve is vulnerable to pressure in the axilla from the use of crutches, but it is most commonly injured at the elbow by fracture or dislocation involving the joint. *Delayed ("tardive") ulnar palsy* may occur many months or years after an injury to the elbow that had resulted in a cubitus valgus deformity of the joint. Because of the deformity, the nerve is stretched in its groove over the ulnar condyle and its superficial location renders it vulnerable to compression. A shallow ulnar groove, quite apart from abnormalities of the elbow joint, may expose the nerve to compressive injury from more innocuous situations such as prolonged resting of the arm on the side of a chair or even excessive flexion of the elbow. Anterior transposition of the ulnar nerve is a simple and effective form of treatment for these types of ulnar palsies. Compression of the nerve may occur just distal to the medial epicondyle, where it runs beneath the aponeurosis of the flexor carpi ulnaris (*cubital tunnel*). Flexion at the elbow causes a narrowing of the tunnel and constriction of the nerve. This type of ulnar palsy is treated by incising the aponeurotic arch between the olecranon and medial epicondyle. Yet another site of ulnar nerve compression is in the ulnar tunnel at the wrist. Prolonged pressure on the ulnar part of the palm may result in damage to the deep palmar branch of the ulnar nerve, causing weakness of small hand muscles but no sensory loss. This site is most often implicated in patients who hold tools or implements tightly in the hand for long periods (we have seen it in

machinists and professional cake decorators). The lesion is localizable by nerve conduction studies.

A syndrome of burning pain (causalgia) and associated symptoms (causalgia) may follow incomplete lesions of the ulnar nerve (or other major nerves of the limbs) and is described further on.

Lumbosacral Plexus and Crural Neuropathies

The twelfth thoracic, first to fifth lumbar, and first, second, and third sacral spinal nerve roots compose the lumbosacral plexuses and innervate the muscles of the lower extremities (Fig. 46-6 and Table 46-1). The following are the common plexus and crural nerve palsies.

Lumbosacral Plexus Lesions

Extending as it does from the upper lumbar area to the lower sacrum and passing near several lower abdominal and pelvic organs, this plexus is subject to a number of special injuries and diseases. The cause may be difficult to ascertain because the primary disease is often not within reach of the palpating fingers, either from the abdominal side or through the anus and vagina; even refined radiologic techniques may not reveal it. Diagnosis involves exclusion of spinal root (cauda equina) lesions by EMG, examination of CSF if root disease is likely, and MRI of the plexus. The clinical findings help to focus studies on the appropriate part of the lumbosacral plexus.

The main effects of upper lumbar plexus lesions are weakness of flexion and adduction of the thigh and

Figure 46-6. Diagram of the lumbar plexus (left) and the sacral plexus (right). The lumbosacral trunk is the liaison between the lumbar and the sacral plexuses. (From Haymaker and Woodhall, *Peripheral Nerve Injuries*, 2nd ed. Philadelphia, Saunders, 1953, by permission.)

extension of the leg, with sensory loss over the anterior thigh and leg; these effects must be distinguished from the symptoms and signs of femoral neuropathy (see later). Lower plexus lesions weaken the posterior thigh, leg, and foot muscles and abolish sensation over the first and second sacral segments (sometimes the lower sacral segments also). Lesions of the entire plexus, which occur infrequently, cause weakness or paralysis of all leg muscles with atrophy, areflexia, and anesthesia from the toes to the perianal region and autonomic loss with warm, dry skin.

The types of lesions that involve the lumbosacral plexus are rather different from those affecting the brachial plexus. Cancer, diabetes, and an idiopathic variety (Dyck et al) have dominated our material. Trauma is a rarity except with massive pelvic, spinal, and abdominal injuries because the plexus is so well protected. Occasionally, a pelvic fracture will damage the sciatic nerve as it issues from the plexus. In contrast, some part of the plexus may be damaged during surgical procedures on abdominal and pelvic organs, often for reasons that may not be entirely clear. For example, hysterectomy has on a number of occasions led to neurologic consultation in our hospitals because of numbness and weakness of the anterior thigh. Either the cords of the upper part of the plexus or the femoral nerve were compressed by retraction against the psoas muscle, or in vaginal hysterectomy (when thighs are flexed, abducted, and externally rotated) the femoral nerve was compressed against the inguinal ligament. A similar injury may be associated with vaginal delivery (see further on). Lumbar sympathectomy has also been associated with upper plexus lesions, of which the most disabling sequelae are burning pain and hypersensitivity of the anterior thigh. Appendectomy, pelvic explorations, and hernial repair may injure branches of the upper plexus (ilioinguinal, iliohypogastric, and genitofemoral nerves), with severe pain and slight sensory loss in the distribution of one of these nerves. The pain may last for months or a year or more.

The lumbar plexus may be compressed by an aortic atherosclerotic aneurysm. Usually there is pain that radiates to the hip, the anterior thigh, and occasionally the flank. Slight weakness in hip flexion and altered sensation over the anterior thigh are found on examination. Plexus involvement with tumors is commonplace and presents special difficulties in diagnosis. Carcinoma of either the cervix or prostate may seed along the perineural lymphatics and cause pain in the groin, thigh, knee, or back without much in the way of sensory, motor, or reflex loss. The pain is more often unilateral than bilateral. The CSF and spinal canal (by MRI) are normal. Testicular, uterine, ovarian, and colonic tumors or retroperitoneal lymphomas, by extending along the paravertebral gutter, implicate various parts of the lumbosacral plexus. Instances of endometriosis that involve the plexus have also been reported, in which case pain fluctuates in parallel with the menstrual cycle (a similar condition exists that implicates only the sciatic nerve. The neurologic symptoms are projected at a distance in the leg and may or may not be confined to the territory of any one nerve. Pelvic and

rectal examinations may be negative, and CT scanning and MRI may be necessary to show such lesions. If all these examinations are negative, exploratory laparotomy may have to be undertaken.

In cancer patients, it is sometimes difficult to distinguish the effects of radiation on the lumbosacral plexus from those of metastatic tumor, as is the case in relation to the brachial plexus. Again, the earliest symptom in metastatic lumbosacral plexopathy is usually pain, whereas in radiation plexopathy it is weakness (Thomas et al). Plexopathy from metastatic tumor is usually unilateral and detectable by CT scanning; radiation plexopathy is as often bilateral and changes are not evident in CT or MRI scans. Fasciculations and myokymia are more likely to be seen in patients with radiation plexopathy, which seemingly occurs more frequently in patients with diabetic neuropathy.

Sarcoidosis is another cause and may be responsive to corticosteroids.

Reference has already been made to femoral nerve injury during parturition, but other *puerperal complications* are also observed. Back pain in the latter part of pregnancy is, of course, common, but there are instances in which the patient complains of severe pain in the back of one or both thighs during labor and after delivery has numbness and weakness of the leg muscles with diminished ankle jerks. *Parturitional lumbosacral plexus injuries* occur with a frequency of 1 per 2,000 deliveries. This injury is usually unilateral and is manifest by pain in the thigh and leg and symptoms and signs of involvement of the superior gluteal and sciatic nerves (Feasby et al). The attribution of these symptoms to pressure of the fetal head on the sacral plexus(es) is conjectural. A limited plexopathy, occurring after difficult vaginal delivery, mainly impairs sensation in the perineum and sphincteric function (Ismael et al). The perineal muscles may show signs of denervation. Protrusion of an intervertebral disc may also occur during delivery and simulate plexus injury.

Idiopathic Lumbosacral Plexitis In addition to the diabetic type detailed earlier in the chapter, an idiopathic *neuralgic amyotrophy* or *lumbosacral plexitis*, analogous to the brachial variety, has been observed. Bradley and coworkers have recorded such cases and their paper can be referred to for the clinical details. After causing widespread unilateral or bilateral sensory, motor, and reflex changes in a leg, lumbosacral plexitis may leave the patient with dysesthesias as troublesome as those that follow herpes zoster (which also may occur at this level). Loss of sweating and warmth of the feet indicate interruption of autonomic fibers by lesions in peripheral nerves rather than in roots. The sedimentation rate may be elevated. Dyck and colleagues inferred an autoimmune basis from biopsy material and immunosuppressant drugs were possibly beneficial in 4 of 6 cases reported by Bradley and coworkers. The outcome is variable with complete recovery being uncommon.

Diabetic amyotrophy caused by involvement of the lumbar plexus and roots was discussed in an earlier section ("Diabetic Multiple Mononeuropathies and Radiculoplexus Neuropathy").

Lateral Cutaneous Nerve of the Thigh (Meralgia Paresthetica)

This sensory nerve originates from the second and third lumbar roots and supplies the anterolateral aspect of the thigh from the level of the inguinal ligament almost to the knee. The nerve penetrates the psoas muscle, crosses the iliacus, and passes into the thigh by coursing between the attachments of the lateral part of the inguinal ligament to just anterior to the anterior superior iliac spine. Compression (entrapment) may occur at the point where it passes between the two prongs of attachment of the inguinal ligament.

Compression of the nerve results in uncomfortable paresthesias and sensory impairment in its cutaneous distribution, a common condition known as *meralgia paresthetica* (*meros*, "thigh"). Usually numbness and mild sensitivity of the skin are the only symptoms, but occasionally there is a persistent distressing burning pain. Perception of touch and pinprick are reduced in the territory of the nerve; there is no weakness of the quadriceps or diminution of the knee jerk. The symptoms are characteristically worsened in certain positions and after prolonged standing or walking. Occasionally, for an obese person, sitting is the most uncomfortable position. Obesity, pregnancy, and diabetes mellitus may be contributory factors. Most often the neuropathy is unilateral, but Ecker and Woltman found 20 percent of their patients to have bilateral symptoms.

Most of our patients with meralgia paresthetica request no treatment once they learn of its benign character. Weight loss and adjustment of restrictive clothing or correction of habitual postures that might compress the nerve are sometimes helpful. A few with the most painful symptoms have demanded a neurectomy or section of the nerve, but it is always wise to perform a lidocaine block first, so that the patient can decide whether the persistent numbness is preferable. In one specimen of nerve obtained at operation, we found a discrete traumatic neuroma. Corticosteroid injections at the point of entrapment may have helped in a few cases, but this has not been studied in a systematic way.

Obturator Nerve

This nerve arises from the third and fourth and to a lesser extent the second lumbar roots. It supplies the adductors of the thigh and contributes to the innervation of the internal and external rotators. The adductors have the added function of contributing to flexing the hip. The nerve may be injured by the fetal head or forceps during the course of a difficult labor or compressed by an obturator hernia. Rarely, it is affected with diabetes, polyarteritis nodosa, and osteitis pubis and by retroperitoneal spread of carcinoma of the cervix, uterus, and other tumors (Rogers et al).

Femoral Nerve

This nerve is formed from the second, third, and fourth lumbar roots. Within the pelvis it passes along the lateral border of the psoas muscle and enters the thigh beneath the Poupart ligament, lateral to the femoral artery.

Branches arising within the pelvis supply the iliacus and psoas muscles. Just below the Poupart ligament the nerve splits into anterior and posterior divisions. The former supplies the pectineus and sartorius muscles and carries sensation from the anteromedial surface of the thigh; the posterior division provides the motor innervation to the quadriceps and the cutaneous innervation to the medial side of the leg from the knee to the internal malleolus. The distinction between femoral neuropathy and a third lumbar root lesion is made by detecting weakness of the hip adductor (innervated by the obturator nerve) in the case of the root lesion.

Following injury to the femoral nerve, there is weakness of extension at the knee, wasting of the quadriceps muscle, and failure of fixation of the knee. The knee jerk is abolished. If the nerve is injured proximal to the origin of the branches to the iliacus and psoas muscles, there is additionally weakness of hip flexion.

The most common cause of femoral neuropathy is diabetes. The nerve may also be involved by pelvic tumors. Not uncommon is injury to the nerve during pelvic operations. Usually this is the result of improper placement of retractors, which may compress the nerve directly or indirectly by undue pressure on the psoas muscle. Bleeding into the iliacus muscle or the retroperitoneum, observed in patients receiving anticoagulants and in hemophilia patients, is a relatively common cause of isolated femoral neuropathy (Goodfellow et al). The presenting symptom of iliacus hematoma is pain in the groin spreading to the lumbar region or thigh, in response to which the patient assumes a characteristic posture of flexion and lateral rotation of the hip. A palpable mass in the iliac fossa and the signs of femoral nerve compression (quadriceps weakness and loss of knee jerk) follow in a day or two. Infarction of the nerve may occur in the course of diabetes mellitus and polyarteritis nodosa. Not infrequently acute femoral neuropathy is of indeterminate cause.

Sciatic Nerve (See also Chap. 11)

This nerve is derived from the fourth and fifth lumbar and first and second sacral roots, for which reason a ruptured disc at any of these levels may simulate sciatic neuropathy (sciatica). The sciatic nerve supplies motor innervation to the hamstring muscles and all the muscles below the knee through its two divisions, the tibial and peroneal nerves (see later); the sciatic nerve conveys sensory impulses from the posterior aspect of the thigh, the posterior and lateral aspects of the leg, and the entire sole. In complete sciatic paralysis, the knee cannot be flexed and all muscles below the knee are paralyzed. Weakness of gluteal muscles and pain in the buttock and posterior thigh point to nerve involvement in the pelvis. Lesions beyond the sciatic notch spare the gluteal muscles but not the hamstrings. Partial compressive lesions are more common and tend to involve peroneal-innervated muscles more than tibial ones, giving the impression of a peroneal palsy.

Rupture of one of the lower lumbar intervertebral discs is the most common cause of sciatica, although it does, of course, not directly involve the sciatic nerve. The associated motor and sensory findings allow localization

of the root compression (L4-L5 disc compressing L5 root: pain in posterolateral thigh and leg with numbness over the inner foot and weakness of dorsiflexion of the foot and toes; L5-S1 disc compressing S1 root: pain in posterior thigh and leg, numbness of lateral foot, weakness of foot plantar flexion and loss of ankle jerk), as discussed in Chap. 11.

The sciatic nerve is commonly injured by fractures of the pelvis or femur, fracture/dislocation of the hip, gunshot wounds of the buttock and thigh, and the injection of toxic substances into the lower gluteal region. Total hip arthroplasty is another cause. Tumors of the pelvis (sarcomas, lipomas) or gluteal region may compress the nerve. Sitting for a long period with legs flexed and abducted (lotus position) under the influence of narcotics or barbiturates or lying flat on a hard surface in a sustained stupor may severely injure one or both sciatic nerves or branches thereof. The nerve may be involved by neurofibromas and infections and by ischemic necrosis in diabetes mellitus and polyarteritis nodosa. Cryptogenic forms of sciatica occur and in a referral practice are more frequent than those of identifiable cause. Partial lesions of the sciatic nerve occasionally result in causalgia (see further on).

The common Morton neuroma, typically between the third and fourth metatarsals, causes interdigital or intermetatarsal pain and can be detected by MRI. It is subject to surgical section. Also mentioned here is a distressingly painful compression of the plantar branches of the sciatic nerve.

Common Peroneal (Fibular) Nerve

Just above the popliteal fossa the sciatic nerve divides into the tibial nerve (*medial, or internal, popliteal nerve*) and the common peroneal nerve (*lateral, or external, popliteal nerve*). The latter swings around the head of the fibula to the anterior aspect of the leg, giving off the *superficial peroneal nerve* that provides musculocutaneous branches (to the peroneal muscles) and to the *deep peroneal nerve* (formerly called *anterior tibial nerve*). Branches of the latter supply the dorsiflexors of the foot and toes (anterior tibialis, extensor digitorum longus and brevis, and extensor hallucis longus muscles) and carry sensory fibers from the dorsum of the foot and lateral aspect of the lower half of the leg. There was weakness of dorsiflexion of the foot (foot-drop) in all of the 116 cases of common peroneal neuropathy reported by Katirji and Wilbourn, and numbness of the dorsum of the foot was present in most cases. Weakness of eversion of the foot is usually demonstrable; because inversion is a function of the L5 root and the tibial nerve, it is spared in peroneal palsy, thereby allowing a distinction between foot-drop at the two sites. (Foot eversion should be tested with the ankle passively dorsiflexed.) Pain is variable.

Pressure during an operation or sleep or from tight plaster casts, obstetric stirrups, habitual and prolonged crossing of the legs while seated, and tight knee boots are the most frequent causes of injury to the common peroneal nerve. The point of compression of the nerve is where it passes over the head of the fibula. Emaciation in patients with cancer or AIDS increases the incidence of

these types of compressive injuries. The nerve may also be affected in diabetic neuropathy and injured by fractures of the upper end of the fibula. A Baker cyst, which consists of inflamed synovium extending into the retro-popliteal space, may compress the nerve, and it may be damaged by muscle swelling or small hematomas behind the knee in asthenic athletes. The prognosis is generally good in cases of partial paralysis.

Tibial Nerve

This, the other of the two divisions of the sciatic nerve (it divides in the popliteal fossa), supplies all of the calf muscles—i.e., the plantar flexors and invertors of the foot and toes—after which it continues as the posterior tibial nerve. This nerve passes through the tarsal tunnel, an osseofibrous channel that runs along the medial aspect of the calcaneus and is roofed by the flexor retinaculum. The tunnel also contains the tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles and the vessels to the foot. The posterior tibial nerve terminates under the flexor retinaculum and divides into medial and lateral plantar nerves (supplying the small muscles of the foot).

Complete interruption of the tibial nerve results in a calcaneovalgus deformity of the foot, which can no longer be plantar-flexed and inverted. There is loss of sensation over the plantar aspect of the foot.

The posterior tibial nerve may be compressed in the *tarsal tunnel* (an entrapment syndrome as discussed below) by thickening of the tendon sheaths or the adjacent connective tissues or by osteoarthritic changes. Neuromuscular experts have expressed concern that this is one of the over diagnosed entrapment syndromes. Tingling pain and burning over the sole of the foot develop after standing or walking for a long time. Pain in the ankle or foot is added in some cases and the pain may be referred proximally along the sciatic nerve. Pressure over the nerve in the inferior malleolar region produces pain, which radiates to the terminal distributions of the nerve. Usually there is no motor deficit. Relief is obtained by severing the flexor retinaculum.

Entrapment Neuropathies

Reference has been made in several places in the preceding pages to the most frequently encountered entrapment neuropathies. A nerve passing through a tight canal is trapped and subjected to constant movement or pressure, forces not applicable to nerves elsewhere. The epineurium and perineurium become greatly thickened, strangling the nerve, with the additional possibility of demyelination. Function is gradually impaired, sensory more than motor, and the symptoms fluctuate with activity and rest. The most frequently compressed nerves are the median, ulnar, peroneal, tibial, and plantar in approximately that order. It is well to keep in mind the systemic processes that enhance pressure palsies by infiltration of the nerve or surrounding tissues. The main ones are hypothyroidism, amyloid, pregnancy, and hereditary liability to pressure palsies.

Table 46-8 lists the common entrapment neuropathies and the locations of compression. Detailed accounts

of these disorders are contained in the monographs of Dawson and colleagues and of Asbury and Gilliat.

Complex Regional Pain Syndrome; Causalgia, Reflex Sympathetic Dystrophy

(See Chaps. 8 and 11)

One unfortunate result of partial injury to a peripheral nerve is the delayed appearance of severe pain roughly in the distribution of the affected nerve. This complex problem, which consists of burning pain termed *causalgia* and associated local trophic and autonomic changes that are subsumed under the term *reflex sympathetic dystrophy*, is discussed further in Chap. 8 in the context of other pain syndromes and in Chap. 11.

Traumatic Interruption of Nerves

Although the management of such lesions is best delegated to specialized neurosurgeons, several aspects

involve the neurologist. Surgical advances have allowed the successful apposition of severed nerve ends. The current recommendation is that end-to-end suturing of the stumps within 72 h should be undertaken to repair a sharp and clean division. In cases where the nerve is found on exploration to be bluntly severed with ragged ends, most surgeons recommend tacking the free ends to adjacent connective tissue planes and attempting the repair in 2 to 4 weeks. Most injuries, however, are blunt and retain some continuity of the nerve. If such continuity across the traumatized region can be demonstrated by electrophysiologic examination, operation is unnecessary. In the absence of improvement in the clinical and electrophysiologic features after several months (up to 6 months for plexus lesions), surgical repair may facilitate limited healing. Pain that appears months or years after injury suggests the development of a neuroma at the site of nerve section; a Tinel sign at that site aids in identifying this problem.

Diseases of the Cranial Nerves

The cranial nerves are susceptible to a number of special diseases, some of which do not affect the spinal peripheral nerves. For this reason alone they are considered separately. Certain of the cranial nerves and their disorders have already been discussed: namely, disorders of olfaction in Chap. 12; of vision and extraocular muscles in Chaps. 13 and 14; of cochlear and vestibular function in Chap. 15; and craniofacial pain in Chap. 10. There remain to be described the disorders of the facial (VII) nerve and of the lower cranial nerves (IX to XII), as well as certain diseases that affect the trigeminal (V) nerve. These are considered here.

The Fifth, or Trigeminal, Nerve

Anatomic Considerations

The fifth nerve (Fig. 47-1) is a mixed sensory and motor nerve. It conducts sensory impulses from the greater part of the face and head; from the mucous membranes of the nose, mouth, and paranasal sinuses; and from the cornea and conjunctiva. It also provides the sensory innervation of the dura in the anterior and middle cranial fossae. The cell bodies of the sensory part of the nerve lie in the *gasserian*, or semilunar, *ganglion*. This, the largest sensory ganglion in humans, lies in the inferomedial part of the middle cranial fossa in a recess called Meckel's cave. The central axons of the ganglion cells form the sensory root of the nerve. These fibers, on entering the lateral mid pons, divide into short ascending and long descending branches. The former are concerned mainly with tactile and light pressure sensation and synapse with second-order neurons in the principal sensory nucleus. Proprioceptive afferents from facial muscles and the masseter also ascend to terminate in the mesencephalic nucleus. The fibers that mediate pain and temperature sensation do not end in these nuclei but form long descending branches of the spinal trigeminal tract. This pathway, which contains both facilitatory and inhibitory fibers, together with its adjacent nucleus, extends from the junction of the pons and medulla to the uppermost segments (C2 or C3) of the spinal cord (as evidenced by the relief of facial pain after medullary trigeminal tractotomy).

The spinal trigeminal nucleus in the upper cervical cord is a continuation of the spinal tract of Lissauer and *substantia gelatinosa*; the main trigeminal sensory

nucleus in the pons and medulla is a continuation of the nucleus of the medial lemniscus. From all parts of the principal sensory and spinal trigeminal nuclei, second-order fibers cross to the opposite side and ascend to the thalamus. They come to lie in the most medial part of the spinothalamic tract and lateral part of the medial lemniscus. These systems of fibers are called the *trigeminothalamic tract*. In addition, the secondary trigeminal neurons project to the facial and hypoglossal nuclei bilaterally, the salivatory nuclei, the cuneate nuclei of the upper cervical segments, and other cranial nerve nuclei. The principal sensory and spinal trigeminal nuclei receive fibers from the reticular formation, the thalamus, the nucleus tractus solitarius, and the somatosensory cortex.

The peripheral branches of the gasserian ganglion form the three sensory divisions of the nerve. The first (ophthalmic) division passes through the cavernous sinus and superior orbital fissure; the second (maxillary) division also passes through the cavernous sinus and leaves the middle fossa through the foramen rotundum; and the third (mandibular), does not traverse the cavernous sinus and instead exits Meckel's cave inferiorly through the foramen ovale.

The motor portion of the fifth nerve, which supplies the masseter and pterygoid muscles, has its origin in the trigeminal motor nucleus in the mid pons; the exiting fibers pass underneath (but not through) the gasserian ganglion and become incorporated into the mandibular nerve. The masseter and pterygoid muscles are used in chewing and are implicated in a number of brainstem reflexes, the best known of which is the jaw jerk. Tapping the chin with the jaw muscles relaxed stimulates proprioceptive afferents that terminate in the mesencephalic nucleus of the midbrain, which sends collaterals to the motor nucleus of the fifth nerve and causes the masseters to contract. This reflex is enhanced in spastic bulbar (pseudobulbar) palsy. Another pontine reflex that uses afferent trigeminal sensory nerves is the blink reflex. Tapping of the brow or bridge of the nose evokes bilateral blink through activation of the orbicularis oculi muscles (facial nerve efferents). Touching the eyelids and cornea (corneal reflex) does the same.

Because of their wide anatomic distribution, complete interruption of both the motor and sensory fibers of the trigeminal nerve is rarely observed. In contrast,

Figure 47-1. Scheme of the trigeminal nuclei and some of the trigeminal reflex arcs. I, ophthalmic division; II, maxillary division; III, mandibular division. (Originally from Ramon y Cajal S: *La Textura del Sistema Nervista del Hombre y los Vertebrados*, Madrid, Moya, as adapted from Carpenter MB, Sutin J: *Human Neuroanatomy*, 8th ed. Baltimore, Williams & Wilkins, 1982, by permission.)

partial dysfunction of the trigeminal nerve, particularly of the sensory part, is common, the main symptoms being facial numbness and pain. The various cranial nerve and brainstem syndromes in which the fifth nerve is involved are listed in Tables 47-1, 31-5, and 34-3, the last in relation to stroke syndromes of the brainstem that affect the nerve in its fascicular course or in its nucleus.

Diseases Affecting the Fifth Nerve

A variety of diseases may affect the peripheral branches of the trigeminal nerves, the gasserian ganglion, and the roots (sensory and motor). Hughes has summarized them and the main ones are described below. The role of the nerve in migraine is discussed in Chap. 10.

Trigeminal Neuralgia (See also "Trigeminal Neuralgia" in Chap. 10) The most frequent and at the same time the most elusive disease of the fifth nerve from the standpoint of its pathologic basis is *trigeminal neuralgia* (*tic douloureux*). This condition has been known since ancient times, having been described by Arateus in the first century A.D., by John Locke in 1677, by Nicolaus Andre in 1756, and by John Fothergill in 1776 (according to Katusic et al).

The overall incidence rate for both sexes combined is 4.3 per 100,000 persons per year, but it is higher for women than for men (in a ratio of 3:2) and is much higher in the elderly. The mean age of onset is 52 to 58 years for the idiopathic form and 30 to 35 years for the symptomatic forms, the latter being caused by trauma or vascular, neoplastic, and demyelinating diseases. In the last decade it has become apparent, mainly from the work of Jannetta, that a proportion of cases is a result of compression and secondary demyelination of trigeminal nerve rootlets by small branches of the basilar artery (see Love and Coakham).

The paroxysmal nature of the facial pain, its unilaterality, the tendency to involve the second and third divisions of the trigeminal nerve, an intensity that makes the patient grimace or wince (tic), the presence of a trigger point on the face, the lack of demonstrable sensory or motor deficit, and its response in more than half of the cases to antiepileptic drugs are characteristic. The diagnosis of "idiopathic" trigeminal neuralgia and its differentiation from other forms of intermittent facial pain described below—as well as from cluster headache, dental neuralgia, temporomandibular joint pain, and

Table 47-1

EXTRAMEDULLARY CRANIAL NERVE SYNDROMES

SITE	CRANIAL NERVES INVOLVED	EPONYMIC SYNDROME	USUAL CAUSE
Sphenoidal fissure	III, IV, ophthalmic, V, VI	Foix	Invasive tumors of sphenoid bone, aneurysms
Lateral wall of cavernous sinus	III, IV, ophthalmic (occasionally maxillary), V, VI	Tolosa-Hunt	Aneurysms or thrombosis of cavernous sinus; invasive tumors from sinuses and sella turcica; sometimes recurrent, benign granulomatous reactions, responsive to steroids
Retrosphenoidal space fossa	II, III, IV, V, VI	Jaccoud	Large tumors of middle cranial
Apex of petrous bone	V, VI	Gradenigo	Petrositis, tumors of petrous bone
Internal auditory meatus	VII, VIII		Tumors of petrous bone (dermoids, etc.), vestibular schwannoma
Pontocerebellar angle	V, VII, VIII, and sometimes IX		Vestibular schwannomas, meningiomas
Jugular foramen	IX, X, XI	Vernet	Tumors (glomus jugulare), venous sinus thrombosis, and aneurysms
Posterior laterocondylar space	IX, X, XI, XII	Collet-Sicard	Tumors of parotid gland, carotid body; secondary and lymph node tumors, tuberculous adenitis, carotid artery dissection
Posterior retroparotid space	IX, X, XI, XII, and Homer syndrome	Villaret	Same as above, and granulomatous lesions (sarcoid, fungi)
Posterior retroparotid space	X and XII, with or without XI	Tapia	Parotid and other tumors of, or injuries to, the high neck

(See also Tables 31-5 and 34-3.)

atypical facial pain—is usually not difficult, especially if there is a trigger point and no demonstrable evidence of sensory or motor impairment. Furthermore, the vascular compressive form is difficult to diagnose without high-resolution neuroimaging or exposure at operation and most such cases are therefore characterized as idiopathic until revealed as vascular in causation.

In rare instances, trigeminal neuralgia is preceded or accompanied by hemifacial spasm, a combination that Cushing called *tic convulsif*. This may be indicative of a tumor (cholesteatoma), an aneurysmal dilatation of the basilar artery or one of its branches, or an arteriovenous malformation that compresses both the trigeminal and facial nerves. Trigeminal neuralgia and glossopharyngeal neuralgia (pain in the tonsillar region) may also be combined in these conditions.

Trigeminal Neuropathies and Neuritis Of the conditions that damage the branches of the trigeminal nerve, facial and cranial injuries, and fractures are probably the most common, but they do not usually come to the attention of neurologists. The most superficial branches of the nerve—the supratrochlear, supraorbital, and infraorbital—are the ones usually involved by trauma. The sensory loss is present from the time of the injury, and partial regeneration may be attended by constant pain.

Of the various inflammatory and infectious diseases that affect the trigeminal nerves or ganglia, *herpes zoster* ranks first. Persistent pain after herpetic infection of the fifth nerve is a serious problem, not responding well to any type of treatment. This subject is discussed in Chap. 10 with other forms of facial pain. Middle ear infections and osteomyelitis of the apex of the petrous bone may spread to the ganglion and root, also implicating the sixth cranial nerve (*Gradenigo syndrome*). HIV infection has not been

clearly implicated in infection of the fifth nerve (as it has in the seventh nerve), but reactivation of latent herpes zoster is seen with AIDS.

The trigeminal root may be compressed or invaded by intracranial meningiomas, vestibular schwannomas, trigeminal schwannomas, cholesteatomas, and chordomas and by tortuous branches of the basilar artery. Sinus tumors and metastatic disease may also infiltrate the nerve, causing pain and a gradually progressive sensory loss. Demyelination at the trigeminal root entry point into the pons is another well-characterized cause in cases of multiple sclerosis (Fig. 47-2).

The ophthalmic division of the fifth nerve may be involved in the wall of the cavernous sinus in combination with the third, fourth, and sixth nerves by a variety of processes, including thrombosis of the cavernous sinus. Tumors of the sphenoid bone (myeloma, metastatic carcinoma, squamous cell carcinoma, and lymphoepithelioma of the nasopharynx) may involve branches of the trigeminal nerve at their foramina of entry or exit. An unusual perineural infiltration of superficial branches of the nerve by squamous cell skin cancers of the face is discussed further on under “Multiple Cranial-Nerve Palsies.” The mandibular division of the nerve may be compressed by the roots of an impacted third molar (wisdom) tooth. Well known to clinicians is a sign of numbness of the chin and lower lip from infiltration of the mental nerve as the first indication of metastatic carcinoma of the breast, prostate, or multiple myeloma. Massey and colleagues have described the details of 19 such cases of the “numb-chin” sign.

Neurologists also encounter instances of slowly evolving unilateral or bilateral trigeminal neuropathy in which sensory impairment is confined to the territory

Figure 47-2. Left-sided facial sensory loss due to demyelination of the trigeminal root entry zone in a patient with multiple sclerosis. Abnormal enhancement of the nerve root is seen on T1 postgadolinium MRI.

of the trigeminal nerve, sometimes associated with pain, paresthesias, or disturbances of taste. This type of loss of facial sensation can also occur as part of a widespread sensory neuropathy or ganglionopathy that occurs as a paraneoplastic effect of cancer (see Chap. 31) or with Sjögren disease.

As common is an association between *isolated trigeminal neuropathy* and immune-mediated connective tissue diseases. Of 22 such cases described by Lecky and colleagues, 9 had either scleroderma or mixed connective tissue disease, and a similar number had either organ- or nonorgan-specific serum autoantibodies. Several specific antibody tests are used to establish the diagnosis of scleroderma. The symptoms may involve the other side of the face years later. Hughes has also described cases of trigeminal neuropathy with scleroderma, lupus erythematosus, and Sjögren disease. We have seen several patients with Sjögren disease in whom the trigeminal neuropathy and the associated antibodies or inflammation of the minor salivary glands were evident well before the characteristic sicca syndrome or other systemic manifestations of the disease. The condition may remain troublesome for years. Pathologic data are limited but point to an inflammatory lesion of the trigeminal ganglion or sensory root. Stilbamidine and trichloroethylene are known to cause sensory loss, tingling, burning, and itching exclusively in the trigeminal sensory territory.

Spillane and Wells, many decades ago, discussed an isolated trigeminal neuropathy (it had been called *Spillane's trigeminal neuritis*). Four of their 16 patients had an associated paranasal sinusitis, but subsequent reports have failed to substantiate a causal relationship between

sinusitis and cranial neuritis. One wonders how many of these individuals had connective tissue disease. A less common form of idiopathic trigeminal sensory neuropathy with which we have limited experience has an acute onset and a tendency to resolve completely or partially, in much the same manner as Bell's palsy, with which it is sometimes associated (Blau et al). A recurrent variety of acute trigeminal symptoms of uncertain origin has been reported in the dental literature. We have had experience with two patients whose facial numbness was a component of an upper cervical disc syndrome that included numbness on the same side of the body; presumably the cervical spinal trigeminal nucleus or tract was compressed. Facial numbness, of course, also occurs with diverse conditions such as syringomyelia that affect the spinal nucleus of the trigeminal nerve but there are additional signs of brainstem or upper cervical cord disease.

An idiopathic pure unilateral *trigeminal motor neuropathy* is known but is a clinical rarity. Chia described five patients in whom an aching pain in the cheek and unilateral weakness of mastication were the main features. Electromyography (EMG) showed denervation changes in the ipsilateral masseter and temporalis muscles. The outcome was favorable.

In most cases of trigeminal neuropathy, except those caused by tumor, herpes zoster, and demyelination, the results of gadolinium-enhanced MRI are normal, as is the cerebrospinal fluid (CSF). The function of the nerve may be studied by the recording of blink reflexes. A few laboratories have developed an evoked potential test specifically of the trigeminal nerve.

The Seventh, or Facial, Nerve

Anatomic Considerations

The seventh nerve is mainly a motor nerve, supplying all the muscles concerned with facial expression on one side.

The sensory component is small (the nervus intermedius of Wrisberg); it conveys taste sensation from the anterior two-thirds of the tongue and, variably, cutaneous sensation from the anterior wall of the external auditory canal. The taste fibers at first traverse the lingual nerve (a branch of the trigeminal mandibular) and then join the chorda tympani, which conveys taste sensation via the facial nerve to the nucleus of the tractus solitarius. Secretomotor fibers originate in the superior salivatory nucleus and innervate the lacrimal gland through the greater superficial petrosal nerve and the sublingual and submaxillary glands through the chorda tympani (Fig. 47-3).

Several other anatomic facts are worth noting. The motor nucleus of the seventh nerve lies ventral and lateral to the abducens nucleus, and the intrapontine fibers of the facial nerve partly encircle and pass dorsolaterally to the abducens nucleus before emerging from the lower pons, just lateral to the corticospinal tract. The impression made by these looping fibers of the seventh nerve is visible in the floor of the upper fourth ventricle as a protuberance, the *facial colliculus*. In this region of the pons, infiltrative lesions affect the sixth and seventh nerves simultaneously.

Figure 47-3. Scheme of the seventh cranial (facial) nerve. The motor fibers are represented by the *heavy blue line*. Parasympathetic fibers are represented by *regular dashes*; special visceral afferent (taste) fibers are represented by *long dashes and dots*. A, B, and C denote lesions of the facial nerve at the stylomastoid foramen, distal to the geniculate ganglion, and proximal to the geniculate ganglion. Disturbances resulting from lesions at each of these sites are described in the text. (From Carpenter MB, Sutin J: *Human Neuroanatomy*, 8th ed. Baltimore, Williams & Wilkins, 1982, by permission.)

The facial nerve enters the internal auditory meatus with the vestibulocochlear nerve bundle and then bends sharply forward and downward around the anterior boundary of the vestibule of the inner ear. At this angle (*genu*) lies the sensory ganglion (named *geniculate* because of its proximity to the genu). The nerve continues in its own bony channel, the facial canal, within which, just distal to the geniculate ganglion, it provides a branch to the pterygopalatine ganglion, i.e., the greater superficial petrosal nerve, which exits the skull through the vidian canal and innervates the lacrimal, nasal, and palatine glands. Somewhat more distally, it gives off a small motor branch to the stapedius muscle and is then joined by the chorda tympani, which projects to the submandibular ganglion and in turn, the submandibular and sublingual glands. The motor root of the facial nerve exits the skull at the stylomastoid foramen and then passes through the parotid gland and subdivides into five branches that supply the facial muscles, the stylomastoid muscle, the platysma, and the posterior belly of the digastric muscle.

A complete interruption of the facial nerve at the stylomastoid foramen paralyzes all muscles of facial expression on the same side. The corner of the mouth droops, the creases and skin folds are effaced, the forehead is unfurrowed, the palpebral fissure is widened and the eyelids will not close completely. Upon attempted closure

of the lids, both eyes roll upward (Bell phenomenon), but the one on the paralyzed side remains visible because of lack of eyelid closure. The lower lid sags also, and the punctum falls away from the conjunctiva, permitting tears to spill over the cheek. (In contrast, the paralyzed frontalis muscle in patients of Asian origin sometimes lowers the eyelid and makes the palpebral fissure appear narrowed.) Food and secretions collect between the teeth and cheek, and saliva may dribble from the corner of the mouth. The patient complains of heaviness or numbness and sometimes an aching pain in the face, but sensory loss can usually not be demonstrated. Taste, however, is intact because the chorda tympani has separated from the main trunk of the facial nerve proximal to the stylomastoid foramen.

If the lesion is in the facial canal above the junction with the chorda tympani but below the geniculate ganglion, all the preceding symptoms are present but in addition, taste is lost over the anterior two-thirds of the tongue on the same side. The nerve to the stapedius muscle is also usually involved with a lesion at this site and there is *hyperacusis* (sensitivity to sudden loud sounds). If the geniculate ganglion or the motor root proximal to it is damaged, lacrimation and salivation may be reduced. Lesions at this point may also affect the adjacent eighth nerve, causing deafness, tinnitus, or dizziness.

Bell's Palsy

The most common disease of the facial nerve is Bell's palsy (incidence rate of 23 per 100,000 people annually according to Hauser et al). The disorder affects men and women more or less equally and occurs at all ages and all times of the year. There is controversy regarding an increased incidence in women during the third trimester of pregnancy, particularly in the 2 weeks preceding delivery and in the first 2 weeks postpartum; up to a threefold increase has been cited by some authors, but others have failed to find this disproportion. Bell's palsy is probably more common in diabetic patients and possibly in those with hypertension than in the healthy population.

Regarding the causation of Bell's palsy, a viral agent has long been suspected, as was discussed by Baringer, any such a mechanism has been established with a reasonable certainty for the majority of cases. Burgess and colleagues identified the DNA of herpes simplex virus (HSV) in the geniculate ganglion of an elderly man who died 6 weeks after the onset of Bell's palsy. Murakami and coworkers (1996), using the polymerase chain reaction, found HSV type I in the endoneurial fluid surrounding the seventh nerve in 11 of 14 cases of Bell's palsy; the fluid was obtained during surgical decompression of the nerve in severe cases. The same investigators produced facial paralysis by inoculating HSV into the ears and tongues of mice; virus antigens were then found in the facial nerve and geniculate ganglion. Varicella zoster virus (VZV) was not found in any of their patients but was isolated from patients with the Ramsay Hunt syndrome, which overtly follows shingles (see further on). Patients with fracture or other infections of the temporal bone yielded neither HSV nor VZV gene sequences. In the light of these findings, the term *idiopathic facial paralysis*, until now the accepted synonym for Bell's palsy, is not entirely appropriate. As one might expect, the opportunity to examine the facial nerve in the course of Bell's palsy occurs very rarely. Only a handful of such cases are on record, all showing varying degrees of degeneration of nerve fibers. One case was said to show inflammatory changes, but these may have been misinterpreted (see Karnes).

The onset of Bell's palsy is acute; about one-half of cases attain maximum paralysis in 48 h and practically all within 3 or 4 days. Pain behind the ear may precede the paralysis by a day or two and in a few patients is intense and persistent. Although a report by the patient of fullness or numbness in the face is common, in a small number there is hypesthesia in one or more branches of the trigeminal nerve. The explanation of this finding is not clear. Impairment of taste is present in most patients but it rarely persists beyond the second week of paralysis. This indicates that the lesion has extended proximal to the point at which the chorda tympani joins the facial nerve. Hyperacusis or distortion of sound is then experienced in the ipsilateral ear and, as mentioned, indicates paralysis of the stapedius muscle.

The facial nerve in Bell's palsy often displays abnormal signal on gadolinium-enhanced MRI although this may be difficult to appreciate in axial sections if the change is in the vertical part of the facial canal. There is a mild increase

of lymphocytes and mononuclear cells in the CSF in a few instances. Cases with more pronounced contrast enhancement of the facial nerve apparently have a worse prognosis (Kress). The enhancement presumably reflects inflammation and swelling along the course of the facial nerve.

Fully 70 percent of patients recover completely within a month or two and 85 percent achieve near-normal facial function, as reviewed by Gilden. Recovery of taste precedes recovery of motor function; if taste returns in the first week, it is a good prognostic sign. But early recovery of some motor function in the first 5 to 7 days is the most favorable sign. EMG may be of value in distinguishing temporary conduction defects from a pathologic interruption of nerve fibers; if there is evidence of denervation after 10 days, one may expect a long delay in the onset of recovery, measured in terms of months. Recovery then proceeds by axonal regeneration, a process that may take 2 years or longer and is often incomplete.

Bell's palsy recurs in approximately 8 percent of cases in several series (van Amstel and Devriese; Pitts et al), presumably as a result of reactivation of the latent herpes virus. The palsy reemerges during an infection or pregnancy, or for no apparent reason. The interval between episodes is unpredictable but has been 10 years, on average. Recurrent forms of facial paralysis also occur with Lyme disease and sarcoidosis, and in a familial variety as mentioned below.

Treatment Protection of the eye during sleep is generally employed in the management of Bells' palsy. There is no evidence that surgical decompression of the facial nerve is effective, and it may be harmful. The administration of prednisone (40 to 60 mg/d, or an equivalent corticosteroid) during the first week to 10 days after onset has been beneficial in several trials. These medications are thought to decrease the possibility of permanent paralysis from swelling of the nerve in the tight facial canal.

The finding of viral genome surrounding the seventh nerve suggested that antiviral agents might be useful in the management of Bell's palsy but most evidence from large randomized trials, particularly the one conducted by Sullivan and colleagues, fails to support the use of these drugs alone or in combination with steroids. The numerous earlier studies suggesting benefit from the combined antiviral and steroid treatments must be viewed in the context of these larger prospective trials. In appropriate circumstances, testing should be undertaken for infectious causes that would require alternative therapy (e.g., Lyme, HIV, and perhaps mycoplasma) but this is not routinely required. The treatment of facial palsy caused by VZV (Ramsay Hunt syndrome) with antiviral drugs is discussed later.

Other Causes of Facial Palsy

Lyme disease commonly involves the facial nerve, as indicated in Chap. 32. The mechanism is uncertain but there is, so far, no evidence of direct spirochetal infection of the nerve. The diagnosis is likely when there has been a tick bite with well-documented erythema migrans or arthritis. Several of our Lyme-infected patients have had almost simultaneous facial palsy and mild distal sensory polyneuropathy. HIV infection is another well-known infectious cause of facial palsy. The facial palsy of both

Lyme and HIV infections is associated with a pleocytosis in the spinal fluid, for which reason serologic and CSF examination may be useful if there is suspicion of either process. Rarely, chicken pox in children may be followed in 1 to 2 weeks by facial paralysis. Tuberculous infection of the mastoid and middle ear or of the petrous bone is a cause of facial paralysis in parts of the world where this infection is particularly common. Facial palsy may occur during or soon after infectious mononucleosis and was observed occasionally in poliomyelitis. The facial nerve is also frequently involved in leprosy. Bilateral involvement of the facial nerve is commented on below. The nerve is often involved in sarcoidosis, where the lesion is probably in the meninges as discussed in the following section.

The *Ramsay Hunt syndrome*, caused by herpes zoster of the geniculate ganglion, consists of a facial palsy associated with a vesicular eruption in the external auditory canal, other parts of the cranial integument, and mucous membrane of the oropharynx. This infection may be initially indistinguishable from Bell's palsy as the vesicles may not become apparent for days, or they never appear. Often the eighth cranial nerve is affected as well, causing nausea, vertigo, and deafness. Murakami and colleagues (1998) showed that the virus can be detected even before the emergence of typical vesicles by collecting exudate from the skin of the pinna on a Schirmer strip (otherwise used to quantitate tearing) and applying polymerase chain reaction (PCR) techniques. In this way, in a matter of a few hours, they documented VZV infection in 71 percent of patients with Ramsay Hunt syndrome without vesicles. Currently, treatment with acyclovir, valacyclovir, or famciclovir is recommended, and there is no clear role for corticosteroids. The randomized trial by Whitley et al and review by Sweeney and Gilden are recommended to the interested reader.

Tumors of the parotid gland or ones that invade the temporal bone (carotid body, cholesteatoma, and dermoid) or granulomatosis including the earlier mentioned sarcoidosis, or pachymeningitis at the base of the brain may produce a facial palsy; the onset is insidious and the course progressive. Fracture of the temporal bone (usually with damage to the middle or internal ear), otitis media, and middle ear surgery are uncommon causes. The orientation of the petrous fracture determines the prognosis (see discussion in Chap. 35). Acoustic neuromas, neurofibromas, glomus jugulare tumors, and aneurysmal dilatations of the vertebral or basilar artery may involve the facial nerve. Pontine lesions, most often vascular or neoplastic, cause facial palsy, usually in conjunction with other neurologic signs. Weakness of only a portion of the facial musculature, associated with numbness in the same region, may be the result of perineural tumor invasion by squamous cell or other skin cancers (see further on under "Multiple Cranial-Nerve Palsies"). An autosomal dominant syndrome of facial palsy, multiple truncal café-au-lait spots and mild developmental delay was described by Johnson and colleagues.

Bilateral Facial Palsy

Bell's palsy may be bilateral, but only rarely is the involvement on the two sides simultaneous. The truly

contemporaneous appearance of *bilateral facial paralysis* (facial diplegia) is most often a manifestation of the Guillain-Barré syndrome (GBS) and may also occur in Lyme disease and rarely, with HIV infection. There are numerous other causes of bilateral facial palsy, all of them infrequent. Keane (1994) listed the idiopathic (now presumably mainly viral) variety, GBS, and meningeal infiltration by tumor as the most common causes, but also found two cases of syphilis among 43 patients. The bilateral syndrome has been reported in approximately 7 of every 1,000 patients with sarcoidosis, although our impression is that it is more frequent. When acute in onset and associated with parotid gland swelling from sarcoidosis, it has been referred to as *uveoparotid fever*, or *Heerfordt syndrome*. In typical cases of sarcoidosis, the paralysis on each side tends to be temporally separated by weeks or more. Mononucleosis may affect both sides of the face almost simultaneously; this is probably a form of GBS. Bilateral palsy is also a feature of the developmental disorder, Möbius syndrome (see Chap. 38).

Less common is the *Melkersson-Rosenthal syndrome*, consisting of the triad of *recurrent facial paralysis*, facial (particularly labial) edema, and less constantly, plication of the tongue. The syndrome begins in childhood or adolescence and may be familial. Biopsy of the lip or skin may reveal a granulomatous inflammation. The cause is not known and, despite the cardinal feature of angioneurotic edema, complement levels are normal. A series of biopsied cases has been reported by Elias and colleagues.

Kennedy syndrome, causes bifacial weakness in addition to bulbar palsy as the disease progresses; preceding facial fasciculations are characteristic. Facioscapulohumeral muscular dystrophy, as the name implies, incorporates facial weakness but would not be mistaken for Bell's palsy (see Chap. 48). The same is true for the rare form of amyloidosis associated with crystal lattice deposits in the cornea that typically involves both facial nerves.

Causes of *recurrent Bell's palsy* have been listed earlier and are summarized by Pitts and colleagues.

Facial Hemiatrophy (Parry-Romberg Syndrome)

This obscure disorder occurs mainly in females and is characterized by a disappearance of fat in the dermal and subcutaneous tissues on one or both sides of the face, giving the appearance of facial paresis. It usually begins in adolescence or early adulthood and is slowly progressive. In its advanced form, the affected side of the face is gaunt and the skin thin, wrinkled, and rather dark; the hair may turn white and fall out, and the sebaceous glands become atrophic; the muscles and bones are not involved as a rule. The condition is a form of *lipodystrophy*, but the localization within a myotome suggests the operation of some neural factor (possibly a growth factor) of unknown nature. A variegated coloration of the iris and a congenital oculosympathetic paralysis are found in some cases. Rarely, certain central nervous system abnormalities referable to the ipsilateral hemisphere (mainly focal seizures, migraine, trigeminal neuralgia, and ventricular dilatation), are conjoined (Hosten). The significance of

these associations is unclear. Wilson and Hoxie have pointed out the frequent coexistence of facial asymmetry in adults with congenital or early onset superior oblique palsy and compensatory head tilt or torticollis.

Aberrant Effects of Recovery from Facial Nerve Palsy

If a peripheral facial paralysis has existed for some time and return of motor function has begun but is incomplete, a contracture with diffuse myokymic activity may appear. The palpebral fissure becomes narrowed, and the nasolabial fold deepens. Spasms of facial muscles may develop and persist indefinitely, being initiated by any facial movement. With the passage of time, the corner of the mouth and even the tip of the nose may become pulled to the affected side. This is a special acquired form of hemifacial spasm, the more common variety of which is described below.

Anomalous or aberrant regeneration of the seventh nerve fibers, following Bell's palsy or other injury, may result in other curious disorders that represent limited types of synkineses. The most common is the "jaw-winking" phenomenon (also called *Wartenberg* or *inverse Marcus-Gunn sign*), in which jaw movements, especially lateral movements (engaging the pterygoid muscle), cause an involuntary closure of the eyelid ipsilateral to the movement. If regenerating fibers originally connected with the orbicularis oculi become connected with the orbicularis oris, closure of the lids may cause a retraction of the corner of the mouth; or if visceromotor fibers originally innervating the salivary glands later come to innervate the lacrimal gland, anomalous tearing (crocodile tears) occurs whenever the patient salivates. A similar mechanism explains gustatory sweating of the cheek and upper lip.

Hemifacial Spasm

The facial muscles on one side may be involved in painless irregular clonic contractions of varying degree (*hemifacial spasm*). This condition usually develops in the fifth and sixth decades, affects women more than men, and often proves to be caused by a compressive lesion of the facial nerve, usually by a tortuous branch of the basilar artery that lies on the ventral surface of the pons and forms a loop under the proximal seventh nerve. Less often the cause of compression is a fusiform basilar artery aneurysm or a vestibular schwannoma or meningioma. Multiple sclerosis is another rare cause.

The spasm usually begins in the orbicularis oculi muscle and gradually spreads to other muscles on that side of the face, including the platysma. Paroxysms may be induced or aggravated by voluntary and reflexive movements of the face.

The pathophysiology of the spasm is believed to be focal demyelination at the site of nerve root compression by the vessel. The demyelinated axon is presumed to activate adjacent nerve fibers by ephaptic transmission ("artificial" synapse of Granit et al). Another possible source of the spasm is spontaneous ectopic excitation arising in injured fibers. Nielsen and Jannetta have shown that ephaptic transmission disappears after the nerve is decompressed.

Treatment Jannetta has attributed virtually all cases to a compression of the root of the facial nerve by an aberrant looped blood vessel. Microsurgical decompression of the root with the interposition of a pledget between the vessel and the facial nerve relieved the facial spasm in most of his operative patients. These results were corroborated by Barker and associates in a series of 705 patients followed postoperatively for an average period of 8 years; 84 percent achieved an excellent result. An even higher rate of benefit was obtained in a prospective series by Illingworth and colleagues (cure of 81 of 83 patients).

Surgical decompression of the aforementioned vascular loop, which involves exploration of the posterior fossa, however, carries some risk. The facial muscles may be weakened, sometimes permanently. Another complication has been deafness as a result of injury of the adjacent eighth nerve. Also, there is a risk of recurrence of the spasms, usually within 2 years of the operation (Piatt and Wilkins). Tight dural closure is required to prevent CSF leakage from the posterior fossa.

We suggest that patients with idiopathic hemifacial spasm should first be treated medically. Alexander and Moses noted that carbamazepine in doses of 600 to 1,200 mg/d controls the spasm in two-thirds of the patients. Baclofen or gabapentin can be tried if carbamazepine fails. Some patients cannot tolerate these drugs, have only brief remissions, or fail to respond; they may be treated with botulinum toxin injected into the orbicularis oculi and other facial muscles. The hemifacial spasms are relieved in this way for 4 to 5 months and injections can be repeated without danger. Some patients have been injected repeatedly for more than 5 years without apparent adverse effects. Failing these conservative measures, surgery may be appropriate.

Other Disorders of the Facial Nerve

Facial myokymia is a fine rippling activity of all the muscles of one side of the face mentioned earlier and in Chap. 48. It develops most often in the course of multiple sclerosis or a brainstem glioma, and can be seen in some disorders of the neuromuscular junction (e.g., neuromyotonia). It has also occurred after other diseases of the facial nerve, e.g., in GBS, in which case it is usually bilateral. We have seen it more often in the recovery stage than in the early phase of GBS. The fibrillary nature of the involuntary movements and their arrhythmicity tend to distinguish them from the coarser intermittent facial spasms and contracture, tics, tardive dyskinesia, and clonus. The EMG pattern is one of spontaneous asynchronous discharge of adjacent motor units, appearing singly or in doublets or triplets at a rate varying from 30 to 70 cycles per second. Demyelination of the intrapontine part of the facial nerve and possibly supranuclear disinhibition of the facial nucleus, have been the postulated mechanisms. But the observation of facial myokymia in GBS informs us that the abnormal movement may have its origin in a lesion at any point along the nerve.

A clonic or tonic contraction of one side of the face may be the sole manifestation of a cerebral cortical seizure. Involuntary recurrent spasm of both eyelids (*blepharospasm*, as discussed in Chaps. 6 and 14) may occur with almost

any form of dystonia, but is most frequent in elderly persons as an isolated phenomenon, and there may be varying degrees of spasm of the other facial muscles (see Chap. 6). Although relaxant and tranquilizing drugs are of little help in this disorder, injections of botulinum toxin into the orbicularis oculi muscles give temporary or lasting relief. A few of our patients have been helped (paradoxically) by L-dopa; baclofen, clonazepam, and tetrabenazine in increasing doses may be helpful as well. In the past, failing these measures, the periorbital muscles were destroyed by injections of doxorubicin or surgical myectomy. With the advent of botulinum treatment, there is no longer a need to resort to these extreme and irreversible measures. In some cases, blepharospasm subsides spontaneously. Rhythmic unilateral myoclonus, akin to palatal myoclonus (actually a tremor as noted in Chap. 6), may be restricted to facial, lingual, or laryngeal muscles.

Hypersensitivity of the facial nerve occurs in hypocalcemic tetany; spasm of the facial muscles is elicited by tapping in front of the ear (Chvostek sign) but this phenomenon is seen in many normal individuals.

The Ninth, or Glossopharyngeal, Nerve

Anatomic Considerations

This nerve arises from the lateral surface of the medulla by a series of small roots that lie just rostral to those of the vagus nerve. The glossopharyngeal, vagus, and spinal accessory nerves leave the skull together through the jugular foramen and are then distributed peripherally. The *ninth nerve* is mainly sensory, with cell bodies in the inferior, or petrosal, ganglion (the central processes of which end in the nucleus solitarius) and the small superior ganglion (the central fibers of which enter the spinal trigeminal tract and nucleus). Within the nerve are afferent fibers from baroreceptors in the wall of the carotid sinus and from chemoreceptors in the carotid body. The baroreceptors are involved in the regulation of blood pressure, and chemoreceptors are responsible for the ventilatory responses to hypoxia. The somatic efferent fibers of the ninth nerve are derived from the nucleus ambiguus, and the visceral efferent (secretory) fibers, from the inferior salivatory nucleus. These fibers contribute in a limited way to the motor innervation of the striated musculature of the pharynx (mainly of the stylopharyngeus, which elevates the pharynx), the parotid gland, and the glands in the pharyngeal mucosa. A discussion of its role in swallowing is found in Chap. 26.

It is commonly stated that this nerve mediates sensory impulses from the faucial tonsils, posterior wall of the pharynx, and part of the soft palate as well as taste sensation from the posterior third of the tongue. However, an isolated lesion of the ninth cranial nerve is a rarity and therefore the effects are not fully known. In one personally observed case of bilateral surgical interruption of the ninth nerves, verified at autopsy, there had been no demonstrable loss of taste or other sensory or motor impairment. This suggests that the tenth nerve may be responsible for these functions, at least in some individuals. The role of the ninth nerve in the reflex control of blood pressure and ventilation has been alluded to

earlier but referable clinical manifestations from damage of this cranial nerve are infrequent except perhaps for syncope as noted below.

One may occasionally observe glossopharyngeal palsy in conjunction with vagus and accessory nerve involvement because of a tumor in the posterior fossa or an aneurysm or intracranial dissection of the vertebral artery, or thrombosis of the sigmoid sinus or internal jugular vein. The nerves may be compressed as they pass through the jugular foramen. Hoarseness as a result of vocal cord paralysis, some difficulty in swallowing, deviation of the soft palate to the sound side, anesthesia of the posterior wall of the pharynx, and weakness of the upper trapezius and sternomastoid muscles make up the clinical picture (see Table 47-1, jugular foramen syndrome). On leaving the skull, the ninth, tenth, and eleventh nerves lie adjacent to the cervical internal carotid artery, where they can be damaged (presumably made ischemic) by a dissection of that vessel.

Glossopharyngeal Neuralgia (See additional discussion of this subject in Chap. 10)

This disorder, first described by Weisenburg in 1910, resembles trigeminal neuralgia in many respects except that the unilateral stabbing pain is localized to one side of the root of the tongue and throat. It is far less common than trigeminal neuralgia. Sometimes the pain overlaps the vagal territory beneath the angle of the jaw and external auditory meatus. It may be triggered by coughing, sneezing, swallowing, and pressure on the tragus of the ear. Temporary blocking of the pain by anesthetizing the tonsillar fauces and posterior pharynx with 10 percent lidocaine spray is diagnostic. Rarely, herpes zoster may involve the glossopharyngeal nerve. Fainting as a manifestation of vagoglossopharyngeal neuralgia is described in Chap. 10.

The same antiepileptic and other drugs that are helpful in the treatment of tic douloureux may be used to treat glossopharyngeal neuralgia, but their efficacy is difficult to judge. Regarding vascular compression of the nerve as a cause of glossopharyngeal neuralgia, Resnick and colleagues have reported the results of microvascular decompression of the ninth nerve in 40 patients; in 32 of these, relief of symptoms was complete and was sustained during an average followup of 4 years; 3 patients remained with permanent weakness of structures ostensibly innervated by the ninth nerve. A similar high rate of success has been achieved by others. If syncope is associated with the pain, it can be expected to cease with abolition of the attacks of pain. Syncope can also occur when the ninth nerve is involved by tumors of the parapharyngeal space; most of these are squamous cell carcinomas and both the ninth and tenth nerves are implicated. Section of rootlets of the ninth nerve has reportedly reduced or abolished the episodes of fainting in these cases.

The Tenth, or Vagus, Nerve

Anatomic Considerations

This nerve has an extensive sensory and motor distribution and important autonomic functions. It has two ganglia: the *jugular*, which contains the cell bodies of the somatic sensory nerves (innervating the skin in the concha

of the ear), and the *nodose*, which contains the cell bodies of the afferent fibers from the pharynx, larynx, trachea, esophagus, and thoracic and abdominal viscera. The central processes of these two ganglia terminate in relation to the nucleus of the spinal trigeminal tract and the tractus solitarius, respectively. The motor fibers of the vagus are derived from two nuclei in the medulla—the nucleus ambiguus and the dorsal motor nucleus. The former supplies somatic motor fibers to the striated muscles of the larynx, pharynx, and palate; the latter supplies visceral motor fibers to the heart and other thoracic and abdominal organs. The distribution of vagal fibers is illustrated in Fig. 47-4, and their participation in swallowing is described in Chap. 26, which the reader is encouraged to consult.

Complete interruption of the intracranial portion of one vagus nerve results in a characteristic pattern of paralysis. The soft palate droops on the ipsilateral side

and does not rise in phonation. The uvula deviates to the normal side on phonation, but this is an inconstant sign in disease. There is loss of the gag reflex on the affected side and of the *curtain movement* of the lateral wall of the pharynx, whereby the faucial pillars move medially as the palate rises in saying “ah.” The voice is hoarse, often nasal, and the vocal cord on the affected side lies immobile in a “cadaveric” position, i.e., midway between abduction and adduction. With partial lesions, movements of abduction are affected more than those of adduction (Semon’s law). There may be a loss of sensation at the external auditory meatus and back of the pinna. Usually no change in visceral function can be demonstrated with a unilateral lesion except by special autonomic testing. If the pharyngeal branches of both vagi are affected, as in diphtheria, the voice has a nasal quality, and regurgitation of liquids through the nose occurs during the act of swallowing.

Figure 47-4. Anatomic features of the vagus nerve. Note the relationship to the spinal-accessory and glossopharyngeal nerves at the jugular foramen and the long course of the left recurrent laryngeal nerve, which is longer than the right and hooks around the aortic arch (not shown).

Diseases Affecting the Vagus

Complete bilateral paralysis is said to be incompatible with life, and this is probably true if the nuclei are entirely destroyed in the medulla by poliomyelitis or some other disease. However, in the cervical region, both vagi were blocked with procaine in the treatment of intractable asthma in past days without mishap. Of interest in this regard, Johnson and Stern reported a case of bilateral vocal cord paralysis in association with familial hypertrophic polyneuropathy, and Plott relates three brothers with congenital laryngeal abductor paralysis caused by bilateral dysgenesis of the nucleus ambiguus. Bannister and Oppenheimer have called attention to defects of phonation and laryngeal stridor as early features of autonomic failure in multiple system atrophy (see Chap. 39). We have seen several such patients in whom stridor was a prominent feature of the illness, in one patient for almost a year before other features of the degenerative disease became evident.

The vagus nerve may be implicated at the meningeal level by tumors neoplastic meningitis, and infectious processes and within the medulla by vascular lesions (e.g., the lateral medullary syndrome of Wallenberg, as described in Chap. 34), by motor neuron disease, and occasionally by sarcoid. Herpes zoster may attack this nerve, either alone or together with the ninth nerve as part of a jugular foramen syndrome. The vagus is often affected along with the glossopharyngeal nerve in spontaneous dissection of the carotid artery at the base of the skull. The nerves may be damaged in the course of thyroid surgery and may be involved in cases of advanced alcoholic or diabetic neuropathy. A fact of some importance is that the left recurrent laryngeal nerve, because of its long course under the aortic arch, is damaged as a result of thoracic disease. There is no dysphagia with lesions at this point in the nerve because the branches to the pharynx (but not to the larynx) have already been given off. For this reason, an aneurysm of the aortic arch, an enlarged left atrium, mediastinal lymph nodes from bronchial carcinoma, and a mediastinal or superior sulcus lung tumor are more frequent causes of an isolated (left) vocal cord palsy than are intracranial diseases. Finally, the vagus is compressed by lesions of the jugular foramen as part of a multiple cranial nerve syndrome as summarized in Table 47-1; metastatic tumors such as from the prostate or breast and jugular vein thrombosis are typical causes.

It is estimated that in one-quarter to one-third of all cases of paralysis of the recurrent laryngeal nerve no cause can be established, i.e., they are idiopathic. The highest incidence is in the third decade, and males are more susceptible than females. Of the 21 cases reported by Blau and Kapadia, 5 recovered completely and 5 partially within a few months; no other disease appeared in the 8-year period that followed. Berry and Blair described palsies of the superior and recurrent laryngeal nerves, occurring as part of isolated vagal neuropathies. A few were bilateral and, again, the majority of the cases were idiopathic and had much the same prognosis as isolated palsies of the recurrent laryngeal nerve.

Laryngeal neuralgia is a rare entity in which paroxysms of pain are localized over the upper portion of the thyroid cartilage or hyoid bone on one or both sides. The pain may be evoked by coughing, yawning, talking, or sneezing. In the case reported by Brownstone and coworkers, the symptoms were relieved by carbamazepine.

Neurologic Diagnosis of Vocal Cord Paralysis

When confronted with a case of vocal cord palsy, the physician is advised to determine the site of the lesion. If intramedullary, there are usually ipsilateral cerebellar signs, loss of pain and temperature sensation over the ipsilateral face and contralateral arm and leg, and an ipsilateral Bernard-Horner syndrome (see Table 34-3). If the lesion is extramedullary but intracranial, the glossopharyngeal and spinal accessory nerves are frequently involved as well (jugular foramen syndrome; see Table 47-1). If extracranial in the posterior lateral condylar or retroparotid space, there may be a combination of ninth, tenth, eleventh, and twelfth cranial-nerve palsies and a Horner syndrome. Combinations of these lower cranial-nerve palsies, which have a variety of eponymic designations (see Table 47-1) are caused by various tumors, both primary and metastatic, or by chronic inflammations or granulomas involving lymph nodes at the base of the skull. If there is no palatal weakness and no pharyngeal or palatal sensory loss, the lesion is below the origin of the pharyngeal branches, which leaves the vagus nerve high in the cervical region. The usual site of disease is then the mediastinum.

The Eleventh, or Spinal Accessory, Nerve

Anatomic Considerations

This is a purely motor nerve, of spinal rather than cranial origin. Its fibers arise from the anterior horn cells of the upper four or five cervical segments and enter the skull through the foramen magnum. Intracranially, the accessory nerve travels for a short distance with the part of the tenth nerve that is derived from the caudalmost cells of the nucleus ambiguus; together, the two roots are referred to as the *vagal-accessory nerve* or the *cranial root of the accessory nerve*. The two roots together leave the skull through the jugular foramen. The vagus fibers then rejoin the main trunk of the vagus. The motor fibers derived from the upper cervical segments of the spinal cord form an "external ramus" and innervate the ipsilateral sternocleidomastoid and trapezius muscles. Only the somatic motor fibers constitute the accessory nerve in the strict sense. In patients with torticollis, however, division of the upper cervical motor roots or the spinal accessory nerve has often failed to ablate completely the contraction of the sternocleidomastoid muscle. This suggests a wider innervation of the muscle, perhaps by fibers of apparent vagal origin that join the accessory nerve for passage through the jugular foramen.

A complete lesion of the accessory nerve results in weakness of the sternocleidomastoid muscle and upper part of the trapezius (the lower part of the trapezius is innervated by the third and fourth cervical roots through the cervical plexus). Weakness can be demonstrated by asking the patient to shrug his shoulders; the affected side

will be found to be weaker, and there will often be evident atrophy of the upper part of the trapezius. With the arms at the sides, the shoulder on the affected side droops and the scapula is slightly winged; the latter defect is accentuated with lateral movement of the arm (with serratus anterior weakness, winging of the scapula is more prominent and occurs on forward elevation of the arm). When the patient turns his head forcibly against the examiner's hand, preferably starting with the head deviated to the opposite side, the sternocleidomastoid of the opposite side does not contract firmly beneath the fingers. This muscle can be further tested by having the patient press his head forward against resistance or lift his head from the pillow.

Motor neuron disease, poliomyelitis, syringomyelia, and spinal cord tumors may involve the cells of origin of the spinal accessory nerve. In its intracranial portion, the nerve is usually affected along with the ninth and tenth cranial nerves by herpes zoster or by lesions of the jugular foramen (glomus tumors, neurofibromas, metastatic carcinoma, internal jugular vein thrombosis). Tumors at the foramen magnum may also damage the nerve. In the posterior triangle of the neck, the eleventh nerve can be damaged during surgical operations and by external compression or injury. Compressive-invasive lesions of this nerve may be visualized by CT or MRI of the posterior cervical space.

A benign disorder of the eleventh nerve, akin to Bell's palsy, has been described by Spillane and by Eisen and Bertrand. It begins with pain in the low lateral neck that subsides in a few days and is followed by weakness and atrophy in the distribution of the nerve. Also, a recurrent form of spontaneous accessory neuropathy has been described (Chalk and Isaacs). About one-quarter to one-third of eleventh nerve lesions are estimated to be of this idiopathic type; most, but not all, of the patients recover.

Bilateral sternocleidomastoid and trapezius palsy, which occurs with primary disease of muscles—e.g., polymyositis and muscular dystrophy—may be difficult to distinguish from a bilateral damage to the accessory nerves or the motor nuclei (progressive bulbar palsy). The supranuclear innervation of the spinal accessory nuclei is apparently mainly ipsilateral as evidenced by contraversive turning of the head during a seizure, the result of contraction of the ipsilateral sternocleidomastoid muscle. Whether this is attributable to a direct ipsilateral tract, or to double crossing of the supranuclear tracts, is not known.

The Twelfth, or Hypoglossal, Nerve

Anatomic Considerations

This is also a pure motor nerve, which supplies the somatic musculature of the tongue. It arises as a series of rootlets that issue from the ventral medulla between the pyramid and inferior olivary complex. The nerve leaves the skull through the hypoglossal foramen and innervates the genioglossus muscle, which acts to protrude the tongue; the styloglossus, which retracts and elevates its root; and the hypoglossus, which causes the upper surface to become convex. Complete interruption of the nerve results in paralysis of one side of the tongue. The tongue curves slightly to the healthy side as it lies in the mouth,

but on protrusion it deviates to the affected side, owing to the unopposed contraction of the healthy genioglossus muscle. By pushing against the tongue in the cheek, one can judge the degree of weakness. The tongue also cannot be moved with natural facility, causing difficulty with handling food in the mouth as well as mild but characteristic *lingual dysarthria*. The denervated side becomes wrinkled and atrophied, and fasciculations can be seen.

Isolated lesions of the hypoglossal nerve roots are rare. Occasionally an intramedullary lesion, usually a stroke, damages the emerging fibers of the hypoglossal nerve, corticospinal tract, and medial lemniscus (see Table 34-3). The result is paralysis and atrophy of one side of the tongue, together with spastic paralysis and loss of vibration and position sense in the opposite arm and leg. Poliomyelitis and motor neuron disease may destroy the hypoglossal nuclei. The latter is the most common cause of a bilaterally atrophic and fasciculating tongue. Lesions of the basal meninges and of the occipital bones (tumor invasion, platybasia, invagination of the occipital condyles, Paget disease) may involve the nerve in its extramedullary course, and it is sometimes damaged in operations on the neck including carotid endarterectomy. Goodman and coworkers showed a dissecting aneurysm of the carotid artery to have compressed the hypoglossal nerve, with resultant weakness and atrophy of the tongue. Rare instances of temporal arteritis and Takayasu arteritis affecting the carotid artery and adjacent twelfth nerve have been described. Lance and Anthony have described the simultaneous occurrence of nuchal-occipital pain and ipsilateral numbness of the tongue, provoked by the sudden, sharp turning of the head and termed it the *neck-tongue syndrome*. The phenomenon has been attributed to compression in the atlantoaxial space of the second cervical root, which carries some of the sensory fibers from the tongue, via the hypoglossal nerve, to the C2 segment of the spinal cord.

It is worth mentioning here that the tongue is often red and smooth in vitamin-deficiency states. *Glossodynia* (burning mouth syndrome discussed in Chap. 10), a condition most frequently seen in the elderly and in young women, may or may not be accompanied by redness and dryness, but not by lingual weakness. A habit of tongue-thrusting and teeth-clenching is often associated. The ascription of these motor abnormalities to a psychogenic mechanism does not agree with the authors' experience (see Quinn).

SYNDROME OF BULBAR PALSY

This syndrome is the result of weakness or paralysis of muscles that are supplied by the motor nuclei of the lower brainstem, i.e., the motor nuclei of the fifth, seventh, and ninth to twelfth cranial nerves. (Strictly speaking, the motor nuclei of the fifth and seventh nerves lie outside the "bulb," which is the old name for the medulla oblongata.) Involved are the muscles of the jaw and face; the sternocleidomastoids and upper parts of the trapezii; and the muscles of the tongue, pharynx, and larynx. If weakness develops rapidly, as may happen in GBS, diphtheria, or poliomyelitis, there is no time for muscle atrophy.

Myasthenia gravis, inclusion body myopathy, and polymyositis on rare occasions may produce such a picture, but motor neuron disease is the most common cause. When the latter disease is isolated to the bulbar muscles, it has been called *progressive bulbar palsy*. The more chronic diseases—e.g., progressive bulbar palsy and Kennedy bulbospinal atrophy (forms of motor neuron disease) and the childhood form of Fazio-Londe disease—result in marked wasting and fasciculation of the facial, tongue, sternocleidomastoid, and trapezius muscles. All of these disorders must be differentiated from pseudobulbar palsy that is discussed in Chaps. 23 and 25.

MULTIPLE CRANIAL-NERVE PALSIES

As one can readily understand, several cranial nerves may be affected by a single disease process. The first clinical problem that arises is whether the lesion lies within or outside the brainstem. Lesions lying on the surface of the brainstem, infiltrating the meninges, or situated at the base of the skull are characterized by involvement of adjacent cranial nerves (often occurring in succession and sometimes painful) and by late and only slight, if any, involvement of the long sensory and motor pathways. These are discussed later and listed in Table 47-1 by their eponymic designations. The opposite is true of intramedullary, intrapontine, and intramesencephalic lesions; lesions within the brainstem that involve cranial nerves often produce a crossed-sensory or motor paralysis (cranial nerve signs on one side of the body and tract signs on the opposite side). In this way, a number of distinctive brainstem syndromes, to which eponyms have been attached, are produced. These are listed in Table 34-3 because they are most often the result of brainstem stroke. An extramedullary lesion is more likely to cause bone erosion seen radiographically. The special problems of multiple cranial-nerve palsies of the ocular motor nerves are addressed in Chap. 14.

Involvement of multiple cranial nerves outside the brainstem may be the result of trauma; localized infections such as herpes zoster (subacute onset); Lyme disease as reported by Schmutzhard and colleagues; cytomegalovirus (CMV) infection in an HIV patient; Wegener granulomatosis, sarcoidosis, or other types of granulomatous diseases or compression by tumors and saccular aneurysms (more chronic development with pain). *The sequential painless affection of contiguous or noncontiguous nerves over several days or weeks is particularly characteristic of meningeal carcinomatosis or lymphomatosis.* In the series of 79 cases accumulated by Keane (2005), tumor was by far the most common underlying cause of multiple cranial-nerve palsies particularly schwannomas, metastases, and meningiomas; trauma, infection, and vascular disease followed in frequency after neoplasm. The eighth nerve is commonly incorporated in these neoplastic meningeal infiltrations. Among the solid tumors that cause local compression of nerves, neurofibromas, schwannomas, meningiomas, cholesteatomas, carcinomas, chordomas, and chondromas have all been observed. Nasopharyngeal carcinoma

Figure 47-5. Nasopharyngeal carcinoma invading the anterior right side of the base of the skull and causing third and fifth nerve palsies. Axial CT windowed for bones.

(Schmincke tumor or lymphoepithelioma) may implicate several cranial nerves in succession by invading the base of the skull (mainly the fifth and sixth but also higher nerves; Fig. 47-5), as do basilar invagination and Chiari malformation. Several lower cranial nerves may be involved on one side by a carotid artery dissection. In France, a successive involvement of all cranial nerves on one side has been called the *Garcin syndrome*, or hemibasal syndrome. It has been reported in chondromas and chondrosarcomas of the clivus, but may occur with nasopharyngeal carcinomas. Table 47-2 lists the main causes of multiple cranial-nerve palsies of extramedullary origin in our experience.

Table 47-2

CAUSES OF EXTRAMEDULLARY MULTIPLE CRANIAL NERVE PALSIES

Meningeal processes

- Carcinomatous and lymphomatous meningitis
- Sarcoidosis and Wegener granulomatosis
- Infectious radiculitis (tuberculous, fungal, syphilitic, Lyme)
- Idiopathic pachymeningitis

Lesions affecting nerves at the skull base

- Metastasis of solid tumor or lymphomatous infiltration
- Local spread from nasopharyngeal tumor, chordoma, sarcoma
- Trauma
- Vascular occlusion or dissection (carotid artery dissection, jugular vein thrombosis)
- Paget disease, basilar invagination, Arnold-Chiari, and other bony disorders

Processes within nerves

- Perineural invasion of spindle cell, basal cell, parotid, and squamous cell cancer
- Granulomas and infectious diseases (Listeria, sarcoid, Wegener granulomatosis, diphtheria, HIV, Lyme disease, CMV infection in AIDS, Sjögren syndrome, idiopathic)
- Herpes zoster and other viral and postinfectious inflammatory lesions (GBS)
- Mixed connective tissue disease

Idiopathic

- Tolosa-Hunt–like syndrome affecting nonorbital nerves
- Post- and parainfectious

Multiple or single cranial-nerve palsies of abrupt onset may precede or accompany infectious mononucleosis and sometimes other viral or mycoplasmal diseases. DeSimone and Snyder assembled a series of 20 such cases associated with mononucleosis; bilateral facial paralysis was the most common presentation, bilateral optic neuritis the next most common, and in 3 cases, three or four cranial nerves were involved. The prognosis is excellent. The question of *viral infections of cranial nerves* is always raised by acute neuropathies of the facial, trigeminal, and vestibulocochlear nerves, especially when the condition is bilateral, involves several nerves in combination, or is associated with a pleocytosis in the spinal fluid. Actually, the only proved viral etiologies in this group of cases are herpes simplex, herpes zoster, and cytomegalovirus infections. Because neural deafness, vertigo, and other cranial-nerve palsies have been observed in conjunction with the postinfectious encephalomyelitides of *Mycoplasma*, varicella, measles, rubella, mumps, and scarlet fever, they probably share an immune-mediated mechanism. Some cases formerly thought to be postinfectious in nature may be true infections of the nerve. The same may be said of the single and multiple cranial-nerve palsies that are sometimes associated with HIV and CMV infections. Treatment of the parainfectious cases is symptomatic; the prognosis for recovery is good in many cases. The main causes of bilateral facial palsy were discussed earlier in the chapter. A purely motor disorder of the facial and oropharyngeal muscles without atrophy always raises the question of myasthenia gravis or a muscular dystrophy.

Quite often one observes an acute or subacute form of *multiple cranial neuropathy of undetermined cause*. Juncos and Beal reported on 14 cases of this type, incorporating 6 well-documented cases of the Tolosa-Hunt orbitocavernous sinus syndrome with oculomotor palsies. In the group that was not attributable to Tolosa-Hunt, the onset was with facial pain and headache (temporo-frontal), followed within days by abducens palsy (12 of 14), oculomotor palsy (6 of 14), trigeminal palsy (5 of 14), and facial weakness (4 of 14), and less often by involvement of the eighth, ninth, and tenth cranial nerves (unilaterally in most instances). Increased CSF protein and pleocytosis occurred in several. The prompt relief of pain upon administration of steroids was similar to that obtained in the Tolosa-Hunt syndrome. The mode of recovery, which usually occurred within a few months, was also much the same in the two groups of patients. Juncos and Beal concluded that the clinical features of the two groups overlapped and that their separation into two syndromes was arbitrary. We have seen a relapsing form of this illness in young adults, responsive on each occasion to steroids and stabilizing after several years. Numerous tests of the CSF by polymerase chain reaction revealed no viruses. Conceivably, some of these cases represent variant forms of GBS, inasmuch as they may be preceded by a nonspecific infection and may at times be accompanied by areflexia or evanescent paresthesias and elevated CSF protein without pleocytosis. Others probably are examples of the entity described by Juncos

and Beal, possibly reflecting a granulomatous process in the pachymeninges.

As a more chronic affliction, we have observed numerous cases in which cranial nerves were affected sequentially over a period of many years (*polyneuritis cranialis multiplex*). Two were later found to have tuberculosis of cervical lymph nodes (presumably tuberculous scrofula), and three had sarcoidosis. No cause was determined in the rest. Symonds had similar experience. It is usually worth obtaining a biopsy of an enlarged cervical lymph node in these circumstances.

Chapter 14 discusses the special case of painful multiple oculomotor palsies. The main causes are GBS, botulism, myasthenia gravis, thyroid ophthalmopathy, and diphtheria. In cases of chronic evolution, oculopharyngeal dystrophy and mitochondrial myopathy (progressive external ophthalmoplegia) must also be considered.

In cases of *Tolosa-Hunt* syndrome in which the orbital or cavernous sinus has been biopsied, a nonspecific granuloma has been found as discussed in Chap. 14. *Sarcoid* and *tuberculosis* have been the causes of a few cases, as noted earlier. In *Wegener granulomatosis*, multiple cranial-nerve palsies, usually lower ones, are reported. The administration of cyclophosphamide has led to remission.

The *cavernous sinus syndrome*, discussed in Chaps. 32, and 34 and elsewhere in the book, consists of various combinations of oculomotor palsies and upper trigeminal sensory loss, usually accompanied by signs of increased pressure or inflammation of the venous sinus. The third, fourth, fifth, and sixth cranial nerves are affected first on one side only, but any of the processes that infiltrate or obstruct the sinus may spread to the other side. The main causes are septic or aseptic thrombosis of the venous sinus due to trauma, hypercoagulable states, or adjacent infections in adjacent structures, carotid artery aneurysm, carotid-cavernous fistulae, and neoplastic infiltration. Keane (1996) summarized his experience with an astonishing 151 instances of cavernous sinus syndrome and found trauma and surgical procedures to be the most common causes, followed by neoplasms (specifically those originating in the nasopharynx), pituitary tumors, metastases, and lymphomas; our experience has tended more toward local infectious causes in diabetic patients and hypercoagulable states.

A special cause of multiple cranial-nerve palsies that has been brought to our attention is an infiltration along the distal nerves in the skin and subcutaneous tissues by squamous cell carcinomas of the face, especially by spindle cell and other atypical varieties of tumor. A variant of malignant melanoma, "lentigo maligna" may do the same but has more of a tendency to infiltrate along larger nerves to the base of the skull and cause larger areas of loss of facial sensation and pain, vertigo, and deafness. This type of perineural spread first causes very restricted unilateral palsies and sensory loss related to the superficial branches of the fifth and seventh cranial nerves in one region of the face and then extends to the base of the skull and to the ventral brainstem. According to Clouston and colleagues, who have presented five cases in detail, the initial symptoms are usually pain

and numbness in the area underlying the skin lesion and facial weakness confined to the same regions of the face; this pattern is a result of the proximity of fifth and seventh nerve branches in the skin and subcutaneous tissues. Various combinations of oculomotor palsies may follow

as a result of tumor entry into the orbit via the infraorbital branch of the maxillary nerve. Occasionally there is no pain. We have also observed a similar regional pattern of extracranial involvement of trigeminal and facial nerves with an infiltrative mixed-cell tumor of the parotid gland.

Diseases of Muscle

Skeletal, or voluntary, muscle constitutes the principal organ of locomotion, as well as a vast metabolic reservoir. Disposed in more than 600 separate muscles, this tissue makes up as much as 40 percent of the weight of adult human beings. An intricacy of structure and function undoubtedly accounts for its diverse susceptibility to disease, for which reason the main anatomic and clinical facts are provided as an introduction to the muscle diseases.

A single muscle is composed of thousands of muscle fibers that extend for variable distances along its longitudinal axis. Each fiber is a relatively large and complex multinucleated cell varying in length from a few millimeters to several centimeters (34 cm in the human sartorius muscle) and in diameter from 10 to 100 μm . Some fibers span the entire length of the muscle; others are joined end to end by connective tissue. Each muscle fiber is enveloped by an inner plasma membrane (the sarcolemma) and an outer basement membrane. The multiple nuclei of each fiber, which are oriented parallel to its longitudinal axis and may number in the thousands, lie beneath the plasma membrane (sarcolemma); hence they are termed *subsarcolemmal*, or *sarcolemmal nuclei*.

The cytoplasm (sarcoplasm) of the cell is abundant, and it contains myofibrils and various organelles such as mitochondria and ribosomes. Each myofibril is enveloped in a membranous net, the sarcoplasmic reticulum (SR; see Fig. 45-2). Extensions of the plasma membrane into the fiber form the transverse tubular system (T tubules), which are extracellular channels of communication with the intracellular sarcoplasmic reticulum. The SR and T tubules are anatomically independent but functionally related membrane systems. The junctional gap between the T tubules and SR is occupied by protein formations that are attached to the SR and are referred to as *junctional feet*; the latter have been identified as ryanodine receptors and are responsible for the release of calcium from the SR, which is a critical step in exciting the muscle (see Franzini-Armstrong).

The myofibrils themselves are composed of longitudinally oriented interdigitating filaments (myofilaments) of contractile proteins (actin and myosin), additional

structural proteins (titin and nebulin), and regulatory proteins (tropomyosin and troponin). The series of biochemical events by which these proteins, under the influence of calcium ions, accomplish the contraction and relaxation of muscle is described in Chap. 45. Droplets of stored fat, glycogen, various proteins, many enzymes, and myoglobin, the latter imparting the red color to muscle, are contained within the sarcoplasm or its organelles.

The individual muscle fibers are surrounded by delicate strands of connective tissue (endomysium), which provide their support and permit unity of action. Capillaries, of which there may be several for each fiber, and nerve fibers lie within the endomysium. Muscle fibers are bound into groups or *fascicles* by sheets of collagen (perimysium), which also bind together groups of fascicles and surround the entire muscle (epimysium). The latter connective tissue tunics are richly vascularized, different types of muscle having different arrangements of arteries and veins. The muscle fibers are attached at their ends to tendon fibers, which, in turn, connect with the skeleton. By this means, muscle contraction maintains posture and imparts movement.

Other notable characteristics of muscle are its natural mode of contraction, that is, through neural innervation—and the necessity of intact innervation for the maintenance of its normal tone and trophic state. Each muscle fiber receives a nerve twig from a motor nerve cell in the anterior horn of the spinal cord or nucleus of a cranial nerve; the nerve twig joins the muscle fiber at the *neuromuscular junction* or *motor endplate*. As was pointed out in Chaps. 3 and 45, groups of muscle fibers with a common innervation from one anterior horn cell constitute the *motor unit*, which is the basic physiologic unit in all reflex, postural, and voluntary activity.

Embedded in the surface membrane are several types of ion channels that are responsible for maintaining the electrical potential and propagating depolarizing currents across the muscle membrane. Diseases of these channels are discussed in Chap. 50. Also constituting a large part of the membrane is a series of anchoring structural proteins, the nature of which have been thoroughly elucidated in the past few decades. These are described in detail in relation to the muscular dystrophies.

In addition to motor nerve endings, muscle contains several types of sensory endings, all of them mechanoreceptors: Free nerve endings subserve the sensation of deep pressure-pain; Ruffini and pacinian corpuscles are pressure sensors; and the Golgi tendon organs and muscle spindles are tension receptors and participate in the maintenance of muscle tone and reflex activity. The Golgi receptors are located mainly at the myotendon junctions; pacinian corpuscles are localized in the tendon but are also found sparsely in muscle itself. Muscle spindles are specialized groups of small muscle fibers that regulate muscle contraction and relaxation, as described in Chap. 45. All of these receptors are present in highest density in muscles that are involved in fine movements.

Muscles are not equally susceptible to disease, despite the apparent similarity of their structure. In fact, practically no disease affects all muscles in the body and each pathologic entity has a characteristic topography within the musculature. The topographic differences between diseases provide incontrovertible evidence of structural or physiologic differences between muscles that are not presently disclosed by the light or electron microscope, that is, the factors responsible for the selective vulnerability of certain muscles are not known but several hypothetical explanations come to mind. One may relate simply to fiber size; consider, for example, the large diameter and length of the fibers of the glutei and paravertebral muscles in comparison with the smallness of the ocular muscle fibers. The number of fibers composing a motor unit may also be of significance; in the ocular muscles, a motor unit contains only 6 to 10 muscle fibers (some even fewer), but a motor unit of the gastrocnemius contains as many as 1,800 fibers. Also, the eye muscles have a much higher metabolic rate and a richer content of mitochondria than the large trunk muscles. Differences in patterns of vascular supply may permit some muscles to withstand the effects of vascular occlusion better than others. Histochemical studies of skeletal muscles have disclosed that within any 1 muscle, there are subtle metabolic differences between fibers, certain ones (type 1 fibers) being richer in oxidative and poorer in glycolytic enzymes and others (type 2 fibers) having the opposite distribution. The distribution of certain structural proteins may alter the topography of disease expression; for example, the eye muscles do not contain dystrophin, a submembrane protein that is deficient in Duchenne muscular dystrophy, which explains the muscles' lack of involvement in this disease. The endomysial fibroblasts of eye muscles contain an abundance of glycosaminoglycans, which renders them susceptible to thyroid diseases. Diseases of the neuromuscular junction show a distribution of weakness in relation to the density of these junctions in different muscles. Doubtless other differences will be discovered.

Normal muscle is endowed with a population of embryonic muscle precursor cells, known as satellite cells, and, as a result, it possesses a remarkable capacity to regenerate, a point often forgotten. It has been estimated that enough new muscle can be generated from a piece of normal muscle the size of a pencil eraser to

provide normal musculature for a 70-kg adult. However, with complete destruction of the muscle fiber, this regenerative capacity is greatly impaired. Inflammatory and metabolic destructive processes are usually followed by fairly complete restoration of the muscle cells, provided that some part of each fiber has survived and the endomysial sheaths of connective tissue have not been severely disrupted. Unfortunately, many pathologic processes of muscle are chronic and unrelenting. Under such conditions, any regenerative activity fails to keep pace with the disease and the loss of muscle fibers becomes permanent. The bulk of the muscle is then replaced by fat and collagenous connective tissue, typical, for example, of the muscular dystrophies.

The Development and Aging of Muscle (See also Chap. 29)

The accepted view of the embryogenesis of muscle is that muscle fibers form by fusion of myoblasts soon after the latter differentiate from somatic mesodermal cells. Muscle connective tissue derives from the somatopleural mesoderm. After fusion of the myoblasts, a series of cellular events including the sequential activation of myogenic transcription factors leads to myofibril formation. The newly formed fibers are thin, centrally nucleated tubes (appropriately called *myotubes*) in which myofilaments begin to be produced from polyribosomes. As myofilaments become organized into myofibrils, the nuclei of the muscle fiber are displaced peripherally to a subsarcolemmal position. Once the nuclei assume a peripheral position, the myofiber is fully formed. The detailed mechanisms whereby myoblasts seek one another, the manner in which each of a series of fused nuclei contributes to the myotube, the formation of actin and myosin fibrils, Z-discs, and the differentiation of a small residue of satellite cells on the surface of the fibers are reviewed by Rubenstein and Kelly.

The mechanisms that determine the number and arrangement of fibers in each muscle are not as well understood. Presumably the myoblasts themselves possess the genetic information that controls the program of development, but within any given species there are wide individual variations that account for obvious differences in the size of muscles and their power of contraction.

The number of fibers assigned to each muscle is probably attained by birth, and growth of muscle thereafter depends mainly on the enlargement of fibers. Although the nervous system and musculature develop independently, muscle fibers continue to grow after birth only when they are active and under the influence of nerve. Measurements of muscle fiber diameters from birth to old age show the growth curve ascending rapidly in the early postnatal years and less rapidly in adolescence, reaching a peak during the third decade. After puberty, growth of muscle is less in females than in males, and such differences are greater in the arm, shoulder, and pelvic muscles than in the leg; growth in ocular muscles is about equal in the 2 sexes. At all ages, disuse of muscle decreases fiber size by as much as 30 percent, and overuse increases

the size by about the same amount (work hypertrophy). Normally, type 1 (oxidative enzyme-rich) fibers are slightly smaller than type 2 (phosphorylative enzyme-rich) fibers; the numerical proportions of the 2 fiber types vary in different muscles in accordance with the natural functions of that muscle. The exercising of young animal muscle causes a hypertrophy of high-oxidative type 1 fibers and an increase in the proportion of low-oxidative type 2 fibers; aging muscle lacks this capacity; exercise produces only an increase in the proportion of type 2 fibers (Silbermann et al). No such data are available in humans, but clinical observation suggests that with aging, the capacity of muscle to respond to intense, sustained exercise is diminished.

During late adult life, the number of muscle fibers diminishes and variation in fiber size increases as mentioned in Chap. 29 on aging. The variations are of 2 types: *group atrophy*, in which clusters of 20 to 30 fibers are all reduced in diameter to about the same extent, and *random single-fiber atrophy*. Also, muscle cells, like other cells of postmitotic type, are subject to aging changes (lipofuscin accumulation, autophagic vacuolization, enzyme loss) and to death. Group atrophy, present to a slight degree in the gastrocnemii of almost all individuals older than 60 years, represents denervation effect from an aging-related loss of lumbar motor neurons and peripheral nerve fibers. Further comments regarding muscle and aging can be found in the work of Tomlinson and colleagues and in Chap. 29.

Denervation from spinal motor neuron or nerve disease at every age has roughly the same effect; namely, atrophy of muscle fibers (first in random distribution, then in groups) and later, degeneration. Muscle necrosis at all ages excites a regenerative response from sarcolemmal and satellite cells in any intact parts of the fibers. If this occurs repeatedly, the regenerative potential wanes, with ultimate death of the fiber leading to permanent depopulation of fibers with the expected muscle weakness.

APPROACH TO THE PATIENT WITH MUSCLE DISEASE

The number and diversity of diseases of striated muscle greatly exceed the number of symptoms and signs by which they express themselves clinically; thus, different diseases share certain common symptoms and syndromes. To avoid excessive repetition in the description of individual diseases, we discuss here, in one place, the broad clinical manifestations of muscle disease.

The physician is initially put on the track of a myopathic disease by eliciting complaints of muscle weakness or fatigue, pain, limpness or stiffness, spasm, cramp, twitching, or a muscle mass or change in muscle volume. Of these, the symptom of weakness is by far the most frequent and at the same time the most elusive. As remarked in Chap. 24, when speaking of weakness, the patient often means excessive fatigability and poor endurance. Although fatigability in the strict sense of gradually reduced power with ongoing use of a muscle

may be a feature of muscle diseases, particularly those affecting the neuromuscular junction such as myasthenia gravis, it is far more frequently a complaint of patients with chronic systemic disease or with anxiety or depression. As stated in Chap. 24, fatigue is an abstruse symptom, always requiring analysis and interpretation. When not attended by manifest reduction in muscle power, it is usually nonmuscular in origin. It may, on medical investigation, prove to be a systemic manifestation of infection, metabolic or endocrine disorder, severe anemia, reduced cardiopulmonary function, or neoplasia. More often, when expressed as a feeling of poor endurance, weariness, and disinclination to undertake or sustain mental and physical activity, it is indicative of neurasthenia, a psychiatric manifestation common to states of chronic anxiety and depression. An elusive syndrome of life-long exercise intolerance, often accompanied by muscle cramps during exercise, has been traced in a limited number of cases to mutations in the cytochrome *b* gene of the mitochondrial DNA (Andreu et al), but these are rare. The subject of fatigue as a physiologic phenomenon and as a clinical feature of many psychiatric and medical diseases, including those that are predominantly myopathic, is considered fully in Chap. 24.

Evaluation of Muscle Weakness and Paralysis

Rather than relying on the patient's report to distinguish between fatigability and weakness, it is more informative to observe the patient during the performance of certain common activities such as walking, climbing stairs, and arising from a sitting, kneeling, squatting, or reclining position or using the arms over the head. Difficulty in performing these tasks signifies weakness rather than fatigue. Sometimes the weakness of a group of muscles becomes manifest only after a period of activity; for example, the feet and legs may "drag" only after the patient has walked a long distance. The physician, upon being told this by the patient, should attempt to conduct the examination under circumstances that duplicate the complaints. Of course, these impairments of muscle function may be caused by a neuropathic or central nervous system (CNS) disturbance rather than of a myopathic one, but usually these conditions can be separated by the basic methods indicated further on in this chapter and in Chaps. 3 and 24.

Reduced strength of muscle contraction—manifest by diminished power of single contractions against resistance (peak power) and during the sustained performance of prolonged or repetitive movements (i.e., endurance)—are the indubitable signs of muscle or neuromuscular disease. In such testing, the physician may encounter difficulty in enlisting the patient's cooperation. The tentative, hesitant performance of the asthenic or suggestible individual, or the hysteric or malingerer, poses difficulties that can be surmounted by experience and by the techniques described in Chap. 3. In infants and small children, who cannot follow commands, one assesses muscle power by the resistance to passive manipulation or by observing performance while the child is engaged in natural activities. The patient may be reluctant to fully

contract the muscles in a painful limb; indeed, pain itself causes a reflex diminution in the power of contraction (*algic paresis*). Estimating the strength of isometric contractions that do not require the painful part to be moved is a way around this difficulty.

Ascertaining the extent and severity of muscle weakness requires a systematic examination of the main groups of muscles. The patient is asked to contract each group with as much force as possible, while the examiner opposes the movement and offers a graded resistance in accordance with the degree of residual power (isokinetic contraction). Alternatively, the patient is asked to produce a maximal contraction and the examiner estimates power by the force needed to overcome or "break" it (isometric contraction or maximum voluntary isometric contraction). If the weakness is unilateral, one has the advantage of being able to compare it with the strength on the normal side. If it is bilateral, the physician must refer to his concept of what constitutes normalcy based on experience in muscle testing. With practice, one can distinguish true weakness from unwillingness to cooperate, feigned or neurasthenic weakness, and inhibition of movement by pain.

To quantitate the degree of weakness, a rating scale may be required. Widely used is the one proposed by the Medical Research Council (MRC) of Great Britain, which recognizes 6 grades of muscle strength as follows:

- 0—Complete paralysis
- 1—Minimal contraction
- 2—Active movement only with gravity eliminated
- 3—Full movement against gravity but cannot offer resistance to manual muscle opposition
- 4—Active movement against gravity and resistance but can be overcome by manual muscle opposition
- 5—Normal strength

Further gradations may be added, specified as 4+ for barely detectable weakness and 4 for easily detected weakness, 3+ and 3, and so on, allowing for 10 grades of power.

The ocular, facial, lingual, pharyngeal, laryngeal, cervical, shoulder, upper arm, lower arm and hand, truncal, pelvic, thigh, and lower leg and foot muscles are examined sequentially. In the case of muscle disease, it is most convenient to test the same muscle from each side. To fully and properly use tools such as the MRC scale and to detect mild weakness, muscles such as the neck flexors and extensors must be tested with the patient in the prone and supine positions. The anatomic significance of each of the actions tested, that is, what roots, nerves, and muscles are involved, can be determined by referring to Table 46-1. A practiced examiner can survey the strength of these muscle groups in 2 to 3 min.

A word of caution is in order. In manually resisting the patient's attempts to contract the large and powerful trunk and girdle muscles, the examiner may fail to detect slight degrees of weakness, particularly in well-muscled individuals. These muscle groups are best examined by having the patient use the muscle groups for their intended purposes: squat and kneel and then assume the

erect posture, arise from and, walk on toes and heels, and lift a heavy object (e.g., *Harrison's Principles of Internal Medicine*) over his head. The strength of muscles of the hand can be quantified with a dynamometer; for research purposes, similar but more sophisticated devices exist for other muscle groups (see Fenichel et al). Nonetheless, the examiner should not dismiss the patient's complaint of weakness simply if it cannot be substantiated by the examination.

Changes in the Contractile Process and Definition of Terms

In the *myasthenic states* there is a rapid failure of contraction in the affected muscles during sustained or repetitive activity. For instance, after the patient looks upward at the ceiling for a few minutes, the eyelids progressively droop; closing the eyes and resting the levator palpebrae muscles causes the ptosis to lessen or disappear. Similarly, holding the eyes in a far lateral position will induce diplopia and strabismus. These effects, in combination with restoration of power by the administration of neostigmine or edrophonium, are the most valuable clinical criteria for the diagnosis of myasthenia gravis, as described in Chap. 49.

The opposite of the myasthenic phenomenon, an increment in power with a series of several voluntary contractions is a feature of the *Lambert-Eaton myasthenic syndrome*, which is associated in approximately 50 percent of cases with small cell carcinoma of the lung. The same increment occurs in botulism. In both instances there is an increase in the amplitude of compound muscle action potentials on the nerve conduction studies obtained following brief exercise (10 to 15 sec), or at high rates of repetitive nerve stimulation (20 to 50 Hz), as described in Chap. 45.

Other abnormalities may be discovered by observing the speed and efficiency of contraction and relaxation during one or a series of maximal actions of a group of muscles. In myxedema, for example, stiffness and slowness of contraction in a muscle such as the quadriceps may be seen on change in posture (*contraction myoedema*) and by direct percussion of a muscle, and there is an associated prolonged duration of the tendon reflexes. Slowness in relaxation of muscles is another feature of hypothyroidism, accounting for the complaint of uncomfortable tightness of proximal limb muscles. A curious *rippling phenomenon* in muscles may be the result of several processes and occurs as an inherited autosomal dominant trait. After a period of relaxation, stiffening and rippling occurs in the contracting or stretched muscles.

A prolonged failure of relaxation following contraction of a muscle is characteristic of *myotonia*, which typifies certain diseases: myotonia congenita, myotonic dystrophy, and paramyotonia congenita. True myotonia, with its prolonged discharge of membrane action potentials, requires strong contraction to elicit, is more evident after a period of relaxation, and tends to disappear with repeated contractions as discussed further in relation to the ion channel disorders in Chap. 50. This persistence

of contraction is demonstrable also by tapping a muscle (*percussion myotonia*), a phenomenon easily distinguished from the electrically silent local bulge (*myoedema*) induced by tapping the muscle of a myxedematous or cachectic patient and from the brief fascicular contraction that is induced by tapping a normal or partially denervated muscle; the latter is referred to as *idiomuscular contraction*. In paramyotonia congenita one observes *paradoxical myotonia*, which refers to an increase in the degree of myotonia during a series of contractions (the reverse of what happens in the usual type of myotonia).

The effect of cold on muscle contraction may also prove informative; either paresis or myotonia, lasting for a few minutes, may be evoked or enhanced by cold. This is most prominent in the paramyotonia of Eulenburg, but it may occur to some degree in all the other myotonic disorders. Also, a cold pack applied to a ptotic eyelid of myasthenia will often reduce the weakness.

Myotonia and myoedema must also be distinguished from the recruitment and spread of involuntary spasm induced by strong and repeated contractions of limb muscles in patients with mild or localized tetanus, with the "stiff man" syndrome and with dystonias of various types. These are not primary muscle phenomena but are neural in origin, a result of an abolition of inhibitory mechanisms and also taken up in Chap. 50.

In practice, the term *contracture* is applied (somewhat indiscriminately as discussed previously) to all states of fixed muscle shortening. Several distinct types can be recognized. In *true physiologic contracture* a group of muscles, after a series of strong contractions, remain shortened for many minutes because of failure of the metabolic mechanism necessary for relaxation. In this shortened state, the electromyogram (EMG) remains relatively silent, in contrast to the high-voltage, rapid discharges observed with cramp, tetanus, and tetany. True physiologic contracture occurs in McArdle disease (phosphorylase deficiency), phosphofructokinase deficiency, and possibly in another condition, as yet undefined, where phosphorylase seems to be present. Yet another type of exercise-induced contracture, described originally by Brody, has been attributed by Karpati and coworkers to an autosomal recessive deficiency of calcium adenosine triphosphatase in the sarcoplasmic reticulum in type 2 muscle fibers. True contracture needs to be distinguished from paradoxical myotonia (see earlier) and from cramp, which in certain conditions (dehydration, tetany, pathologic cramp syndrome, amyotrophic lateral sclerosis [ALS]) can also be initiated by one or a series of strong voluntary muscle contractions.

It is appropriate here to comment on *pseudocontracture* (*myostatic or fibrous contracture*), for which the term *contracture* is used in general medicine. This is the common form of muscle and tendon shortening that follows prolonged fixation and inactivity of the normally innervated muscle (as occurs in a broken limb immobilized by a cast or flaccid weakness of a limb that is allowed to remain immobile). Here the shortened state of the muscle and tendons has no clearly established anatomic, physiologic, or chemical basis. Fibrosis of muscle, a state

following chronic fiber loss and immobility of muscle, is another cause of muscle shortening. Depending on the predominant position, certain muscles are both weakened and shortened. Flexor fibrous contracture of the arms is a prominent feature of the Emery-Dreifuss form of muscular dystrophy. It also accounts for the rigidity and kyphoscoliosis of the spine, which are so frequently a part of myopathic diseases. The latter state is distinguished from *ankylosis* by the springy nature of the resistance, coincident with increased tautness of muscle and tendon during passive motion, and from *Volkman contracture*, in which there is fibrosis of muscle and surrounding tissues as a result of ischemic injury, usually after a fracture of the elbow.

Arthrogryposis is another form of fibrous contracture that is found in newborns, involving multiple muscle groups; it occurs in association with several diseases that have two features in common: an onset during intrauterine life and an alteration of the neural or muscular apparatus that results in muscular weakness. In other words, contractures and fixity of the limbs in arthrogryposis are the result of reduced mobility of the developing joints, consequent upon muscle weakness during fetal development. Most often the cause is a loss or failure of development of anterior horn cells, as in Werdnig-Hoffman disease, but the abnormality may be in the nerve roots, peripheral nerves, or motor endplates, or in the muscle itself. The *rigid spine syndrome* (RSS) in children is yet another form of fibrous contracture, presumably the result of an unusual axial muscular dystrophy.

Notably, few of the primary muscle diseases are painful. When pain is prominent and continuous during rest and activity, there will usually be evidence of disease of the peripheral nerves, as in alcoholic-nutritional neuropathy, or of adjacent joints and ligaments (rheumatoid arthritis, polymyalgia rheumatica). Pain localized to a group of muscles is more a feature of torticollis and dystonias. Pain tends not to be prominent in polymyositis and dermatomyositis, but there are exceptions, as commented below. Pain tends to be more definite in polyneuritis, poliomyelitis, and polyarteritis nodosa than it is in polymyositis, various forms of dystrophy, and other myopathies. If pain is present in polymyositis, it usually indicates coincident involvement of connective tissues and joint structures. Hypothyroidism, hypophosphatemia, and hyperparathyroidism are other sources of a myalgic myopathy. Certain drugs produce muscle aches in susceptible individuals. They include the "statin" lipid-lowering drugs, clofibrate, captopril, lithium, colchicine, beta-adrenergic blocking drugs, penicillamine, cimetidine, suxamethonium, and numerous others (see the table contained in the review by Mastaglia and Laing).

There are probably a limited number of mechanisms of muscle pain. Prolonged and sustained contraction gives rise to a deep aching sensation. Contraction under ischemic conditions—as when the circulation is occluded by a tourniquet or from atherosclerotic vascular disease—induces pain; the pain of intermittent claudication is presumably of this type and is not accompanied by cramp. It was postulated that lactic acid or some other metabolite

accumulates in muscles and activates pain receptors, but there is also evidence to the contrary. The delayed pain, swelling, and tenderness that occur after sustained exercise of unconditioned muscles are evidently a result of fiber necrosis (Armstrong).

Muscle biopsy infrequently reveals the cause of these painful syndromes, but it may be undertaken in cases of suspected metabolic or dystrophic muscle disease. In their retrospective series, Filosto and colleagues determined that the biopsy was most likely to be helpful if there was exercise-induced muscle pain and the creatine kinase (CK) concentration was greatly elevated; even then two-thirds of the entire group had either normal or nonspecific findings on the biopsy.

Having listed all these causes of proximal pains, all physicians are aware that arthritic and mundane musculoskeletal complaints are more common causes of discomfort.

Benign fasciculations, a common finding in otherwise normal individuals, can be identified by the lack of muscular weakness and atrophy and by the small-size muscle fascicles involved and repetitive appearance in only or regions. The recurrent twitches of the eyelid or muscles of the thumb experienced by most normal persons are often referred to inaccurately as “live flesh” or myokymia but are benign fasciculations of this type. Individuals with truly benign fasciculations have normal EMGs (i.e., they have no fibrillations) as demonstrated in a large series of such patients studied and followed for many years by Blexrud and colleagues. *Myokymia* is a less common condition, in which there are repeated twitchings and rippling of a muscle at rest.

Muscle cramps, despite their common occurrence, are a poorly understood phenomenon. They occur at rest or with movement (action cramps), and they are frequently reported in motor system disease, tetany, dehydration after excessive sweating and salt loss, metabolic disorders (uremia and hemodialysis, hypocalcemia, hypothyroidism, and hypomagnesemia), and certain muscle diseases (e.g., rare cases of Becker muscular dystrophy and congenital myopathies). Gospe and colleagues reported a familial (X-linked recessive) type of myalgia and cramps associated with a deletion of the first third of the dystrophin gene, which is the one implicated in Duchenne dystrophy; strangely, there was no weakness or evidence of dystrophy. Lifelong, severe cramping of undetermined type has also been seen in a few families. The dramatic Satoyoshi syndrome is characterized by continuous, painful leg cramps, alopecia universalis, and diarrhea.

Far more frequent than all these types of cramping, and experienced at one time or another by most normal persons, is the benign form (*idiopathic cramp syndrome*) in which no other neuromuscular disturbance can be found. Most often benign cramps occur at night and affect the muscles of the calf and foot, but they may occur at any time and involve any muscle group. Some patients state that cramps are more frequent when the legs are cold and daytime activity has been excessive. In others, the cramps are provoked by the abrupt stretching of muscles, are very painful, and tend to wax and wane before they disappear. The EMG counterpart is a high-frequency

discharge. Although of no pathologic significance, the cramps in extreme cases are so persistent and readily provoked by innocuous movements as to be disabling. Cramps of all types need to be distinguished from *sensations of cramp* without muscle spasm. The latter is a dysesthetic phenomenon in certain polyneuropathies. The disorders that simulate cramps, such as stiff-man syndrome and other forms of continuous muscle fiber activity that have various bases, is discussed in Chap. 50.

Contrasted to cramp is the already described physiologic contracture, observed in McArdle disease and related metabolic myopathies, in which increasing muscle shortening and pain gradually develop during muscular activity. Unlike cramping, it does not occur at rest, the pain is less intense, and the EMG of the contracted muscle at the time is relatively silent. Continuous spasm intensified by the action of muscles and with no demonstrable disorder at a neuromuscular level is a common manifestation of localized tetanus and also follows the bite of the black widow spider. There may also be difficulty distinguishing cramps and spasms from the early stages of a dystonic illness.

Altered structure and function of muscle are not accurately revealed by palpation. Of course, the difference between the firm, hypertrophied muscle of a well-conditioned athlete and the slack muscle of a sedentary person is as apparent to the palpating fingers as to the eye, as is also the persistent contraction in tetanus, cramp, contracture, fibrosis, and extrapyramidal rigidity. The muscles in dystrophy are said to have a “doughy” or “elastic” feel, but we find this difficult to judge. In the Pompe type of glycogen storage disease, attention may be attracted to the musculature by an unnatural firmness and increase in bulk. The swollen, edematous, weak muscles in acute rhabdomyolysis with myoglobinuria or severe polymyositis may feel taut and firm but are usually not tender. Areas of tenderness in muscles that otherwise function normally, a state called *myogelosis*, have been attributed to fibrositis or fibromyositis, but their nature has not been divulged by biopsy.

Topography and Patterns of Myopathic Weakness

In almost all the diseases under consideration, some muscles are affected and others spared, each disease displaying its own pattern. Restated, the topography or distribution of weakness tends to be alike in all patients with the same disease. The pattern of weakness is as important a diagnostic attribute of muscular disease as for the various diseases of the peripheral nervous system discussed in Chap. 46, but the configurations differ in important ways. *As a general rule, muscle diseases are identified by a predominantly proximal weakness that is symmetric.*

The following patterns of muscle involvement constitute a core of essential clinical knowledge in this field. Subacute and chronic evolution of weakness is distinguished in each category from more acute causes.

Ocular Palsies Presenting as Ptosis, Diplopia, and Strabismus Primary diseases of muscle do not involve the pupil, and in most instances their effects are bilateral.

In lesions of the third, fourth, or sixth cranial nerves, a neural origin is disclosed by the pattern of ocular muscle palsies, abnormalities of the pupil, or both. When weakness of the orbicularis oculi (muscles of eye closure) is added to weakness of eye opening (levator palpebrae; ptosis), it nearly always signifies myasthenia gravis and occasionally, a rare primary disease of muscle (progressive external ophthalmoplegia [PEO]). Other causes of *subacute and chronic* development of *relatively pure* weakness of the muscles of eye movement are oculopharyngeal dystrophy, and exophthalmic (hyperthyroid) ophthalmopathy. In PEO, the muscles, including the levators of the eyelids, become paralyzed almost symmetrically over a period of years. In most cases, this disorder is a form of mitochondrial myopathy. Oculopharyngeal dystrophy involves primarily the levators of the eyelids and, to a lesser extent, other eye muscles and pharyngeal-upper esophageal striated muscles. It begins in middle or late adult life and later, and—like PEO—tends only decades later to involve girdle and proximal limb muscles.

There are several other less common chronic myopathies in which external ophthalmoplegia is associated with involvement of other muscles or organs, namely, the congenital ophthalmoplegia of the Goldenhar-Gorlin syndrome (see Aleksic et al); the Kearns-Sayre syndrome (retinitis pigmentosa, heart block, short stature, generalized weakness, and ovarian hypoplasia); other congenital myotubular and mitochondrial myopathies; and nuclear ophthalmoplegia with bifacial weakness (Möbius syndrome). Rarely, eye muscle weakness may occur at a late stage in a few other dystrophies and ptosis has a wider diagnostic range that includes myotonic dystrophy. Although not a regular feature of the disease, ophthalmoparesis can occur in the Lambert-Eaton myasthenic syndrome.

Ptosis is variable in all of these conditions. When present in infantile myopathic disease, it is frequently a marker of the congenital myasthenic syndromes. Trichinosis is a rare cause, associated also with periorbital edema.

Bifacial Palsy Presenting as an Inability to Smile, to Expose the Teeth, and to Close the Eyes Varying degrees of bifacial weakness are observed in myasthenia gravis, usually conjoined with ptosis and ocular palsies. On occasion, weakness of facial muscles may be combined with myasthenic weakness of the masseters and other bulbar muscles without involvement of ocular muscles. Facial weakness and ptosis are features of myotonic dystrophy. More severe or complete facial palsy occurs in facioscapulohumeral dystrophy, sometimes presenting several years before weakness of the shoulder girdle muscles. Bifacial weakness is also a feature of certain congenital myopathies (centronuclear, nemaline), Kennedy type of degenerative bulbospinal motor neuron disease, and the Möbius syndrome of the absence of the facial nuclei (in combination with abducens palsies).

Advanced scleroderma, Parkinson disease, or a pseudobulbar state can immobilize the face to the point of simulating myopathic or neuropathic paralysis, but always in a context that makes the cause obvious.

Bulbar (Oropharyngeal) Palsy Presenting as Dysphonia, Dysarthria, and Dysphagia With or Without Weakness of Jaw or Facial Muscles Myasthenia gravis is the most frequent cause of this syndrome and must also be considered whenever a patient presents with the solitary finding of a hanging jaw or fatigue of the jaw while eating or talking; usually, however, ptosis and ocular palsies are conjoined. Dysphagia and dysphonia may be early and prominent signs of polymyositis, as well as inclusion body myositis (IBM), and may appear in patients with myotonic dystrophy, because of upper esophageal atonia.

Combinations of these palsies are not typically of muscular or neuromuscular origin but instead are observed as an *acute syndrome* in botulism, in brainstem stroke, and at the outset of Guillain-Barré syndrome. Diphtheria and bulbar poliomyelitis are now rare diseases that may present in this way. Progressive bulbar palsy (motor neuron disease) may be the basis of this syndrome (see Chap. 39); the last of these diagnoses is most obvious when the tongue is withered and twitching. Syringobulbia, basilar invagination of the skull, and certain types of Chiari malformation may reproduce some of the findings of bulbar palsy by involving the lower cranial nerves. Rare cases of progressive aphonia include the X-linked Kennedy syndrome of bulbospinal atrophy.

Cervical Palsy Presenting With Inability to Hold the Head Erect or to Lift the Head From the Pillow ("Hanging, or Dropped, Head" Syndrome, "Camptocormia") This is caused by weakness of the posterior neck muscles and of the sternocleidomastoids and other anterior neck muscles. In advanced forms of this syndrome, the head may hang with chin on chest unless the patient holds it up with the hands. There may be difficulty differentiating the condition from a dystonic anterocollis; in the latter there is palpable tonic spasm of the sternomastoid and posterior neck muscles. A pattern of neck and spine extensor weakness also occurs in advanced Parkinson disease. A common error in all these cases is to attribute the problem to structural disease of the cervical spine.

This topographic pattern occurs most often in idiopathic polymyositis and IBM, in which cases it is often combined with mild dysphagia, dysphonia, and weakness of girdle muscles. The same symptom may be a feature of motor neuron disease and is infrequently the presenting feature of that process. Myasthenic patients commonly complain of an inability to hold up their heads late in the day; both flexors and extensors of the neck are found to be weak. Occasionally, this pattern of weakness is observed in patients with nemaline rod myopathy. Cases of hanging head have appeared many years after local radiation of the neck and thorax for Hodgkin disease as described by Rowin and colleagues and with syringomyelia (Nalini and Ravishankar).

There is, in addition, a poorly characterized local myopathic process isolated to the cervical paraspinal muscles, which has no distinguishing histopathologic or histochemical features but has accounted for many of the cases of neck extensor weakness that we have encountered. The condition is observed in elderly persons, in some series mainly men, but our experience has included

as many women. There is severe but relatively nonprogressive weakness of the neck extensors and only mild weakness of shoulder girdle and proximal arm muscles. Katz and colleagues have suggested the designation “isolated neck extensor myopathy” in preference to dropped head syndrome. What has been referred to as a *bent spine syndrome* (for which the term *camptocormia* is also used) is probably the same entity and may follow after years of the condition affecting the neck, or it may surface independently. These conditions of cervical weakness are reviewed by Umapathi and colleagues and by Azher and Jankovic. Several recent series have suggested that mutations in RYR1 that encodes for ryanodine receptor may be a common cause of late onset axial myopathy and neck extensor weakness-bent spine syndrome (Løseth et al). Mutations in RYR1 are more commonly associated with the central core congenital myopathy or malignant hyperthermia as noted in a later section.

The major types of progressive muscular dystrophies, when advanced, usually affect the anterior neck muscles severely. Syringomyelia, spinal accessory neuropathy, some form of meningoradiculitis, and loss of anterior horn cells in conjunction with systemic lymphoma or carcinoma may differentially paralyze the various neck muscles.

Weakness of Respiratory and Trunk Muscles Usually the diaphragm, chest, and trunk muscles are affected in association with shoulder and proximal limb muscles, but occasionally, isolated weakness of the respiratory muscles is the initial or the dominant manifestation of a muscle disease. Dyspnea and diminished vital capacity first bring the patient to the pulmonary clinic. The main causes are motor neuron disease, myasthenia gravis and less often because of their rarity, glycogen storage disease (acid maltase deficiency—Pompe disease), mitochondrial myopathies, and nemaline myopathy. Polymyositis may cause respiratory weakness, but pulmonary difficulty is more often the result of interstitial lung disease. Unilateral paralysis of the diaphragm may result from compression of the phrenic nerve in the thorax by tumor or aortic aneurysm; an idiopathic or postinfectious variety may be related to brachial plexitis (see Chap. 46). The diaphragm and accessory muscles may be severely affected in some types of muscular dystrophies, but usually in association with pelvocrural and shoulder muscle weakness. Nocturnal dyspnea, sleep apnea, and respiratory arrest may occur, particularly in myasthenics and in patients with glycogen storage myopathies, and respiratory failure may threaten life in severe myasthenia gravis, Guillain-Barré syndrome, and poliomyelitis.

As a general observation, in the acute neuromuscular paralyses, the cervical and shoulder muscles and the diaphragm, all of which share a common innervation, show a similar degree of weakness. Asking the patient to count aloud on 1 maximal breath can help detect diaphragmatic weakness (counting to 20 equates with a vital capacity of approximately 2 L). Paradoxical inward movement of the abdomen with inspiration is another sign of diaphragm weakness. Disorders of breathing and ventilation are discussed in Chaps. 26 and 46 in relation to its most dramatic presentation in the Guillain-Barré syndrome.

Bibrachial Palsy and the Dangling-Arm (Flail-Arm) Syndrome Weakness, atrophy, and fasciculations of the hands, arms, and shoulders characterize the common form of motor neuron disease, ALS. Primary diseases of muscle hardly ever weaken these parts disproportionately. A diffuse weakness of both arms and the shoulder muscles may occur in the early stages of Guillain-Barré syndrome, paraneoplastic neuropathy, and amyloid polyneuropathy, in special forms of immunoglobulin (Ig) M-related paraproteinemic, or in inflammatory polyneuropathy (e.g., brachial neuritis) and porphyric polyneuropathy. A lesion affecting the central portion of the spinal cord in the cervical region produces this same pattern, but in that case there is an associated loss of pain and thermal sensation in the upper limbs and shoulders, signs that exclude disease of muscle.

Proximal Limb-Girdle Palsies Presenting as Inability to Raise the Arms or to Arise From a Squatting, Kneeling, or Sitting Position This is the common pattern of a number of myopathies. Polymyositis, IBM, dermatomyositis, and the muscular dystrophies most often manifest themselves in this fashion. The endocrine and the acquired metabolic myopathies (e.g., Cushing disease, hyperthyroidism, and steroid or statin administration) are other typical causes. Proximal limb weakness is a feature of myasthenia but almost always after the development of ocular or pharyngeal involvement. The childhood Duchenne, Becker, and limb-girdle types of dystrophies tend first to affect the muscles of the pelvic girdle, gluteal region, and thighs, resulting in a lumbar lordosis and protuberant abdomen, a waddling gait, and difficulty in arising from the floor and climbing stairs without the assistance of the arms. Climbing up by placing the hands on the thighs (Gower sign) is particularly characteristic of the dystrophies. Facioscapulohumeral dystrophy affects the muscles of the face and shoulder girdles foremost, and it is manifest by incomplete eye closure, inability to whistle and to raise the arms above the head, winging of the scapulae, and thinness of the upper arms with preserved forearm bulk (“Popeye” effect). Certain early or mild forms of dystrophy may selectively involve only the peroneal and scapular muscles. In milder forms of polymyositis, weakness may be limited to the neck muscles or to the shoulder or pelvic girdles.

A number of other diseases of muscle may express themselves by a disproportionate weakness of girdle and proximal limb musculature. An intrinsic metabolic myopathy, such as the adult form of acid maltase deficiency and the familial types of periodic paralysis, may affect only this region. The congenital myopathies (central core, nemaline, myotubular) cause a relatively nonprogressive weakness of girdle muscles more than distal ones. Proximal muscles are occasionally implicated in spinal muscular atrophy or late onset type and in Kennedy bulbospinal atrophy.

Bicrucial Palsy Presenting as Lower Leg Weakness With Inability to Walk on the Heels and Toes, or as Paralysis of All Leg Muscles With the exception of certain distinctive distal types of muscular dystrophies, this pattern, usually due to weakness of peroneal, anterior tibial, and thigh muscles, is usually not a result of myopathy.

Symmetrical weakness of the lower legs is more often caused by polyneuropathy. In cases of total leg and thigh weakness, one first considers a spinal cord disease. Motor neuron disease may begin in the legs, asymmetrically and distally as a rule, and affect them disproportionately to other parts of the body. Thus the differential diagnosis of distal or generalized leg weakness involves more diseases than are involved in the restricted paralyses of other parts of the body.

Isolated Quadriceps Femoris Weakness *Isolated quadriceps femoris weakness* may be the expression of several diseases. In adults, the most common cause is IBM (where it may be unilateral or asymmetrical) or, a restricted form of Becker muscular dystrophy. In thyrotoxic and steroid myopathies, the major effects are on the quadriceps muscles. If unilateral or bilateral with loss of patellar reflex and sensation over the inner leg, this condition is most often the result of a femoral neuropathy, as occurs from diabetes, or of an upper lumbosacral plexus lesion. Injuries to the hip and knee cause rapid disuse atrophy of the quadriceps muscles. A painful condition of infarction of the muscle on 1 side is seen in diabetic patients.

Distal Bilateral Limb Palsies Presenting as Foot-Drop with Steppage Gait (With or Without Pes Cavus), Weakness of All Lower Leg Muscles, and Later Wrist-Drop and Weakness of Hands The principal cause of this syndrome is a familial polyneuropathy, mainly of the Charcot-Marie-Tooth type (see Chap. 46); the course is over decades. Chronic nonfamilial polyneuropathies, particularly paraproteinemic and inflammatory ones with motor conduction block and exceptionally, some forms of familial progressive muscular atrophy and distal types of progressive muscular dystrophy, and sarcoid myopathy may also present in this way. In myotonic dystrophy, there may be weakness of the leg muscles as well as the forearms, sternocleidomastoids, face, and eyes. With these exceptions, the generalization that *girdle weakness without sensory changes is indicative of myopathy and that distal weakness is indicative of neuropathy is clinically useful.*

Generalized or Universal Paralysis: Limb (but Usually Not Cranial) Muscles, Involved Either in Attacks or as a Chronic Persistent, Progressive Deterioration When acute in onset and *episodic*, this syndrome is usually a manifestation of familial or acquired hypokalemic or hyperkalemic periodic paralysis. One variety of the hypokalemic type is associated with hyperthyroidism, another with hyperaldosteronism. Attacks of porphyric neuropathy and of Refsum disease with generalized weakness have an episodic nature. Widespread paresis (rather than paralysis) that has an acute onset and lasts many weeks is at times a feature of a severe form of idiopathic or parasitic (trichinosis) polymyositis and, rarely, of the toxic effects of certain pharmaceutical agents, particularly those used to treat hypercholesterolemia. Idiopathic polymyositis and, rarely, IBM may involve all limb and trunk muscles, but usually spare the facial and ocular muscles, whereas the weakness in trichinosis is mainly in the ocular and lingual muscles. In infants and young children, a chronic and persistent generalized weakness of all muscles, except those of the eyes, always raises the question of Werdnig-

Hoffman spinal muscular atrophy or, if milder in degree and relatively nonprogressive, of one of the congenital myopathies or polyneuropathies. In these diseases of infancy, paucity of movement, hypotonia, and retardation of motor development may be more obvious than weakness, and there is arthrogryposis at birth.

Paralysis of Single Muscles or a Group of Muscles

This is usually neuropathic, less often spinal or myopathic. Muscle disease does not need to be considered except in certain instances of pressure-ischemic necrosis of muscle as a result of local pressure or infarction, as in monoplegic alcoholic myopathy or in diabetic muscle infarction. The weakness of IBM has a preference for certain sites, specifically parts of the quadriceps, or of the forearm muscles, particularly the long finger flexors (flexor digitorum profundus), and also therefore enters into consideration.

From this exposition of the topographic aspects of weakness, one can appreciate that each neuromuscular disease exhibits a predilection for particular groups of muscles. Apart from these patterns that suggest certain possibilities of disease and exclude others, diagnosis depends on the age of the patient at the time of onset and tempo of progression, the coexistence of medical disorders, certain laboratory findings (serum concentrations of muscle enzymes, EMG, and biopsy findings), and genetic determinants.

The symptoms and signs of muscle disease are considered in this chapter mainly in connection with the age of the patient at the time of onset, their mode of evolution, and the presence or absence of familial occurrence. Because many muscle diseases are hereditary, a careful family history is important. The pattern of inheritance has diagnostic significance and, if genetic counseling or prenatal diagnosis is a consideration, a detailed genealogical tree becomes essential. When historical data are insufficient, it is often necessary to examine siblings and parents of the proband. The molecular genetics and other genetic aspects of the heritable muscle diseases, subjects of intense interest in recent years, are discussed at appropriate points in the chapter.

In summary, the clinical recognition of myopathic diseases is facilitated by a prior knowledge of a few topographic syndromes, the age of the patient at the onset of the illness, a familial occurrence of the same or similar illnesses, and of the medical setting in which weakness evolves. Diagnostic accuracy is aided by the intelligent use of the laboratory examinations discussed in Chap. 45, particularly the muscle enzymes, EMG, and muscle biopsy.

THE INFECTIOUS MYOPATHIES

The discovery that striated skeletal muscle and that cardiac muscle could be the sole targets of a number of infectious agents came about during the era of the development of microbiology and occupied the attention of many prominent clinicians, including Osler. As these diseases were being characterized, however, a number of other inflammatory states affecting muscle were found

for which there was no infectious cause. Later, an autoimmune mechanism was postulated, but even today this is not securely established. This group of idiopathic inflammatory myopathies figures so prominently in clinical myology that we devote a separate section to the subject. First, the infections of muscle are described.

Parasitic Myositis

Included here are trichinosis, toxoplasmosis, parasitic and fungal infections, and a number of viral infections. The related but unclassifiable entity of sarcoid myopathy is addressed in a later section of this chapter.

Trichinosis

This parasitic disease is caused by the nematode *Trichinella spiralis*. Its general features are discussed in Chap. 32. Regarding the myopathic aspect of the illness, the authors have been most impressed with the ocular muscle weakness, which results in strabismus and diplopia; with weakness of the tongue, resulting in dysarthria; and with weakness of the masseter and pharyngeal muscles, which interferes with chewing and swallowing. Any weakness of limb muscles is usually mild and more severe proximally than distally. However, the diaphragm may be involved, as well as the myocardium. The affected muscles are slightly swollen and tender in the acute stage of the disease. Often, there is conjunctival, orbital, and facial edema, sometimes accompanied by subconjunctival and subungual splinter hemorrhages. As the trichinae become encysted over a period of a few weeks, the symptoms subside and recovery is complete. Many, perhaps the majority, of infected patients are asymptomatic throughout the invasive period, and as much as 1 to 3 percent of the population in certain regions of the country will be found at autopsy to have calcified trichinella cysts in their muscles with no history of parasitic illness. Heavy infestations have been known to end fatally, usually from cardiac and diaphragmatic involvement. In these more massive infections, the brain also may be involved, probably by emboli that arise in the heart from an associated myocarditis.

Diagnosis Clinically, one should suspect the disease in a patient who presents with a puffy face and tender muscles. Eosinophilia is practically always present in the peripheral blood (>700 cells/mm³), although the sedimentation rate is often normal. The CK level is moderately elevated. A skin test using *Trichinella* antigen is available, but it is unreliable. The enzyme-linked immunosorbent assay (ELISA) blood test is more accurate, but it becomes positive only after 1 or 2 weeks of illness. Biopsy of almost any muscle (usually the deltoid or gastrocnemius), regardless of whether it is painful or tender, is probably the most reliable confirmatory test. More than 500 mg of muscle may be required to demonstrate larvae, but smaller specimens will almost invariably show an inflammatory myopathy. Muscle fibers undergo segmental necrosis, and the interstitial inflammatory infiltrates

contain a predominance of eosinophils. This accounts for the edema, pain, and tenderness of heavily infested muscles. The capsules of the larvae gradually thicken in the first month of the infection and then calcify. The EMG may exhibit profuse fibrillation potentials, a phenomenon attributed on theoretical grounds to the disconnection of segments of muscle fibers from their motor endplates (Gross and Ochoa).

Treatment No treatment is required in most cases. In patients with severe weakness and pain, a combination of thiabendazole, 25 to 50 mg/kg daily in divided doses for 5 to 10 days, and prednisone, 40 to 60 mg/d, is recommended. Albendazole, in a single oral dose of 400 mg daily, is equally effective but is not available in the United States except by special request (from Smith Kline Beecham). Recovery, as mentioned, is complete as a rule, except in rare patients with cerebral infarcts. Other aspects of this parasitic infestation are discussed in Chap. 32.

Toxoplasmosis

This is an acute or subacute systemic infection caused by the encephalitozoon *Toxoplasma gondii*. Most *Toxoplasma* infections in immunocompetent patients, which occur in up to 10 to 30 percent of the population, are asymptomatic, but there may be fever and varying degrees of involvement of the skin, lymph nodes, retina, myocardium, liver, brain, and muscle. In one such case studied by our colleagues, *Toxoplasma* organisms and pseudocysts were detected in skeletal muscle (Kass et al); wherever a parasitic pseudocyst had ruptured, there was focal inflammation. Some muscle fibers had undergone segmental necrosis, but this was not prominent (one contained the organism), accounting for the relative paucity of muscle symptoms. With the emergence of AIDS, many more toxoplasmic infections of the brain, but also including those of skeletal muscle, were seen (Gherardi et al). However, physicians who see many cases of AIDS have indicated to us that a primary AIDS myopathy and treatment-related muscle diseases are more common (see later). Again, in this population, brain infestation with *Toxoplasma* is many times more common than is myositis. The subject of AIDS and toxoplasmic infection is discussed in greater detail in Chap. 32.

The myopathy, which occurs with variable fever, lymphopenia, and failure of other organs, consists of weakness, wasting, myalgia, and elevated CK levels. Presumably, the immunocompromised patient is unable to respond to protozoan infections, allowing latent infections to be reactivated. Sulfadiazine in combination with pyrimethamine or trisulfapyrimidine, which act synergistically against the toxoplasmic trophozoites, improves the muscle symptoms and reduces serum CK. Folic acid is given in addition.

Other Parasitic and Fungal Infections of Muscle

Echinococcosis, cysticercosis, trypanosomiasis (Chagas disease), sparganosis, toxocariasis, and actinomycosis have all been known to affect skeletal muscle on occasion, but the major symptoms relate more to involvement

of other organs. Only cysticercosis may first claim the attention of the clinical myologist because of a dramatic pseudohypertrophy of thigh and calf muscles. Hydatids infest the paravertebral and lumbar girdle muscles in 5 percent of cases and may lead to their enlargement. Coenurosis and sparganosis are causes of movable lumps in the rectus abdominis, thigh, calf, and pectoralis muscles. Protozoan infections of muscle—microsporidiosis, African and American trypanosomiasis—which occurred only rarely until a decade ago, are now being observed in immunodeficient (HIV-infected) individuals in endemic areas. The reader who seeks more details may refer to the chapter on parasitic myositis by Banker (2004).

Viral Infections of Muscle

HIV and Human T-Lymphotropic Virus Type I Myositis

HIV and human T-lymphotropic (or leukemia) virus type I (HTLV-I) are increasingly common causes of viral myositis (Engel and Emslie-Smith). Moreover, as discussed further on, zidovudine (ZVD), a drug included in many regimens to treat HIV infections, may itself induce a myopathy with myalgia and weakness that is, at times, indistinguishable from HIV myopathy (Dalakas et al).

An inflammatory, and presumed infectious, myopathy may develop early in the course of HIV infection but is rarely the initial manifestation. The pattern is like that of idiopathic polymyositis with painless weakness of the girdle and proximal limb muscles. Reflexes are diminished in most cases, but this is difficult to interpret in view of the high incidence of concomitant polyneuropathy. Serum CK is elevated, and the EMG shows an active myopathy with fibrillations, brief polyphasic motor units, and complex repetitive discharges.

The myopathologic changes in AIDS are also like those of idiopathic polymyositis described further on. Additionally, in some cases electron microscopy discloses the presence of nemaline (rod) bodies within type 1 fibers, similar to those observed in the congenital form of nemaline myopathy discussed further on. As implied earlier, the pathogenesis of the AIDS myopathy has not been firmly established as there is scant evidence of a direct viral infection of the muscle fibers. An immune basis has been suggested in view of a response to corticosteroids, plasma exchange, and gamma globulin, comparable to the beneficial effects in the idiopathic variety of polymyositis. Corticosteroids in doses similar to those used in the treatment of idiopathic polymyositis are effective in ameliorating the weakness, but they entail special risks in immunocompromised patients.

The clinical features of putative ZVD-induced myopathy are much the same as those of HIV myopathy except that moderate pain is said to be characteristic of the drug-induced variety. The myopathy has been attributed to the mitochondrial toxicity of the drug, which may account for the presence of “ragged red” fibers in biopsy specimens. The onset of symptoms appears to be related to the sustained administration of high doses of the drug (1,200 mg daily for a year or longer). Cessation or reduction in

dosage of the drug diminishes the muscular discomfort within weeks, but strength recovers more slowly.

A myopathy caused by HTLV-I infection also simulates polymyositis in its clinical and histologic features. The illness occurs most often in endemic areas but is less common than the myelopathy that is associated with the virus.

Distinguished from the HIV- and ZVD-related inflammatory myopathies is the severe generalized muscle wasting that characterizes advanced, cachectic AIDS. Muscle enzymes are normal and strength is affected little, especially considering the loss of muscle bulk. Histologically, there is atrophy of type 2 fibers. The pathogenesis of this cachectic syndrome is uncertain; it has been attributed to a multiplicity of systemic factors, including circulating catabolic cytokines, just as in other wasting syndromes such as cancer.

Other Viral Myopathies

In most patients with pleurodynia (epidemic myalgia, Bornholm disease), muscle biopsies disclose no abnormalities and there is no clear explanation of the pain. However, group B Coxsackie virus has been isolated from striated muscle of a few patients with this disorder. A necrotizing myositis has been suspected in a number of patients with influenza; under the electron microscope, some muscle fibers contain structures with the features of influenza virions. Malaise, myalgia, and slight weakness and stiffness were the clinical manifestations. Because of the myalgia, it is difficult to know how much of the weakness is only apparent. Recovery has been complete within a few weeks. In 1 patient with generalized myalgia and myoglobinuria, the influenza virus was isolated from muscle (Gamboa et al). These observations suggest that the intense muscle pain in certain viral illnesses might be the result of a direct viral infection of muscle. However, there are many cases of influenzal myalgia, mainly of the calves and thighs, such as those reported by Lundberg and by Antony and coworkers, in which it was not possible to establish that there was a muscular disorder at all. In the condition described as *epidemic neuromyasthenia* (benign myalgic encephalomyelitis, Icelandic disease), in which influenza-like symptoms were combined with severe pain and weakness of muscles, a viral cause was postulated, but an organism was never isolated. The illness has been absorbed into the large and indistinct category of chronic fatigue syndrome (discussed in Chap. 24).

Despite these ambiguities, viral myositis is an established entity in myopathology. Echo 9, adenovirus 21, herpes simplex, Epstein-Barr virus, coxsackievirus, and *Mycoplasma pneumoniae* have all been cited by Mastaglia and Ojeda and by others as causes of sporadic myositis with rhabdomyolysis. In these infections the nonmyopathic aspects of the disease usually predominate; in some of them, the evidence of invasion of muscle has not been fully substantiated, as in many instances a nonspecific (Zenker-type) degeneration could have explained the muscle findings. The existence of a postinfectious type of polymyositis is also unsettled.

IMMUNE-INFLAMMATORY MYOPATHIES (POLYMYOSITIS, DERMATOMYOSITIS, INCLUSION BODY MYOSITIS, NECROTIZING MYOPATHY)

These are common diseases that affect primarily the striated muscle and skin and sometimes connective tissues. The term used to describe the disease reflects the tissues involved. If the inflammatory changes are restricted clinically to the striated muscles, the disease is called *polymyositis* (PM); if, in addition, the skin is involved, it is called *dermatomyositis* (DM), although the two diseases are now understood to be immunopathologically distinct. Either may be associated with a connective tissue disorder, in which case the designation is PM or DM with rheumatoid arthritis, rheumatic fever, lupus erythematosus, scleroderma, Sjögren syndrome, or mixed connective tissue disease, as the case may be. There is also an important but inconsistent relationship of these myositides and systemic carcinoma, as discussed further on.

Both diseases have been known since the nineteenth century. Polymyositis was first described by Wagner in 1863 and 1887, and DM was established as an entity by Unverricht in a series of articles written from 1887 to 1891. A modern classification introduced in the monograph of Walton and Adams included categories associated with neoplasia and with connective tissue diseases. References to the original articles and a survey of the literature since that time can be found in the monograph of Kakulas and Adams and in the chapters on the PM and DM syndromes by Engel and colleagues.

It is emphasized further on that there is disagreement regarding the frequency of PM as an independent entity. Amato and Griggs have expressed the opinion that many cases so classified are a result of DM, an immune necrotizing myopathy commented on below, or IBM, or are related to an underlying connective tissue disease. Even other cases are examples of muscular dystrophy with secondary inflammatory changes. The main point of controversy has been the proposal they favor, that isolated PM is rare and overdiagnosed (see van der Muelen et al).

Inflammatory myopathy coexists with numerous systemic diseases as discussed, and some authors consider it to be a syndrome rather than a disease. The current authors continue to see a few well-studied and convincingly documented cases of "classic" PM that are unassociated with other disease.

Recently added to the traditional group of inflammatory myopathies is an increasingly recognized *immune-mediated necrotizing myopathy* (IMNM); instances of myopathy that were previously classified as either dermatomyositis or polymyositis are now recognized as being the result of antibodies to anti-signal recognition particle (SRP), and some cases of necrotizing myopathy that are due to statins are similarly caused by antibodies directed at HMGCoA reductase, and not a direct toxic effect of the medication. This process emphasizes that clinicians should conduct a careful evaluation before concluding that a patient has idiopathic polymyositis.

Polymyositis

This is an idiopathic *subacute or chronic and symmetrical weakness of proximal limb and trunk muscles without dermatitis*. The onset is usually insidious and the course progressive over a period of several weeks or months. It may develop at almost any age and in either sex; however, the majority of patients are 30 to 60 years of age, and a smaller group shows a peak incidence at 15 years of age; women predominate in all age groups. A febrile illness or benign infection may precede the weakness, but in most patients the first symptoms develop in the absence of these or other apparent initiating events.

The usual mode of onset is with mainly painless weakness of the proximal limb muscles, especially of the hips and thighs and to a lesser extent the shoulder girdle and neck muscles. Often, the patient cannot easily determine the time of onset of weakness. Certain actions—such as arising from a deep or low chair or from a squatting or kneeling position, climbing or descending stairs, walking, putting an object on a high shelf, or combing the hair—become increasingly difficult. Pain of an aching variety in the buttocks, calves, or shoulders is experienced by approximately 15 percent of patients, and it may indicate a combination of PM and rheumatoid arthritis, tendonitis, or other connective tissue disorder.

When the patient is first seen, many of the muscles of the trunk, shoulders, hips, upper arms, and thighs are usually involved. The posterior and anterior neck muscles (the head may loll) and the pharyngeal, striated esophageal, and laryngeal muscles (dysphagia and dysphonia) may be involved as well. In restricted forms of the disease, only the neck or paraspinal muscles (camptocormia) may be implicated. Ocular muscles are not affected in PM, but there are rare instances of combined PM and myasthenia gravis. The facial, tongue, and jaw muscles are only occasionally affected, and the distal muscles, namely the forearm, hand, leg, and foot are spared in 75 percent of cases. The respiratory muscles are weakened to a minor degree and in only an exceptional case is there dyspnea, the cause of which is revealed only by an intercostal muscle biopsy (Thomas and Lancaster). Occasionally, the early symptoms predominate in one proximal limb before becoming generalized. As emphasized further on, onset after age 50 years, normal CK, or aberrant patterns of weakness, such as early wrist or finger flexor, quadriceps, or ankle dorsiflexor involvement, are indicative of IBM.

The muscles are usually not tender, and atrophy and reduction in tendon reflexes, although sometimes present, are far less pronounced than they are in patients with chronic denervation atrophy, IBM, or Lambert-Eaton myasthenic syndrome (the last of these is discussed in Chap. 49). As the weeks and months pass, the weakness and muscle atrophy progress unless treatment is initiated. Without physical therapy, fibrous contracture of muscles eventually develops. Some elderly individuals with a particularly chronic form of the disease may present with severe atrophy and fibrosis of muscles; the response to treatment in such cases is poor.

In both PM and DM, there may be involvement of organs other than muscle. In a surprising number of our

cases of PM (and DM), cardiac abnormalities have been observed and in a small proportion of these, sudden death has occurred. The cardiac manifestations have taken the form of relatively minor electrocardiographic (ECG) changes, but several patients have had arrhythmias with clinical consequences. Among the fatal cases, about half have shown necrosis of myocardial fibers at autopsy, usually with only modest inflammatory changes. Interstitial lung disease is another known association in a few cases; its frequency ranges from 5 to 47 percent in different series (see further on under "Laboratory Diagnosis of PM and DM"), but the lower figure is probably correct. Exceptionally, there is a low-grade fever, especially if joint pain coexists.

Dermatomyositis

The presentation of muscle weakness is similar to that of polymyositis, but the denominative feature is a rash. Most often, the skin changes precede the muscle syndrome and take the form of a localized or diffuse erythema, maculopapular eruption, scaling eczematoid dermatitis, or exfoliative dermatitis. Sometimes, skin and muscle changes evolve together over a period of 3 weeks or less. A characteristic form of the skin lesions are patches of a scaly roughness over the extensor surfaces of joints (elbows, knuckles, and knees) with varying degrees of pink-purple coloration. Red, raised papules may be present over exposed surfaces such as the elbows, knuckles, and distal and proximal interphalangeal joints (Gottron papules); these are particularly prominent in DM of childhood. Also typical is a lilac-colored (heliotrope) change in the skin over the eyelids, on the bridge of the nose, on the cheeks, and over the forehead; it may have a scaly component. Itching may be a troublesome symptom in regions of the other skin eruptions. A predominance of rash over the neck and upper shoulders has been termed the *V sign*, while rash over the shoulders and upper arms, the *shawl sign*. This distribution suggests that the skin changes reflect heightened photosensitivity (a feature shared with pellagra). Periorbital and perioral edema are additional findings but mainly in fulminant cases. Skin changes may be transient and in some instances are restricted to 1 or more patches of dermatitis; they are difficult to appreciate in dark-skinned individuals. Evanescent and restricted skin manifestations are emphasized because they are frequently overlooked and provide clues to diagnosis. In the healing stage, the skin lesions leave whitened atrophic scars with a flat, scaly base.

In contrast to PM, DM affects children and adults about equally. Among adults, DM is more frequent in females whereas in childhood, males and females are affected equally.

Other physical signs include periarticular and subcutaneous calcifications that are common in the childhood form. Signs of associated connective tissue disease are more frequent than in pure PM (see further on). The Raynaud phenomenon has been reported in nearly one-third of the patients and a similar number have dilated or thrombosed nail fold capillaries. Whether this signifies the presence of a systemic autoimmune tissue disease has

not been clarified. Others subsequently develop a mild form of scleroderma, and an associated esophageal weakness is demonstrated by fluoroscopy in up to 30 percent of all patients. The superior constrictors of the pharynx may be involved, but cinefluoroscopy may be necessary to demonstrate the abnormality.

Carcinoma With Adult Polymyositis or Dermatomyositis At one time this was a controversial subject and in some respects it remains so because of widely varying incidences of concurrence between systemic malignancy with PM and DM (see Engel et al and Buchbinder and Hill). In the large series reported by Sigurgeirsson and colleagues, 9 percent of 396 patients with PM were found to have carcinoma, either at the time of diagnosis of the muscle disease or within 5 years. DeVere and Bradley reported that 29 percent of their overall group of DM patients had an associated carcinoma; this figure rose to 40 percent if the patient was older than 40 years, and to 66 percent if the patient was both male and older than 40 years. This, however, is higher than reported in most other series. The relationship between myositis and malignancy is not understood; nonetheless, the connection appears valid, even if of uncertain frequency.

The neoplastic processes linked most often with myositis are lung and colon cancer in men and breast and ovarian cancer in women; however, tumors have been reported in nearly every organ of the body. In about half the cases, myositis antedates the clinical manifestations of the malignancy, sometimes by 1 to 2 years, a duration that then brings the association into question. The morbidity and mortality of patients with this combination is usually determined by the nature of the underlying tumor and its response to therapy. Occasionally, excision of the tumor is attended by remission of the myositis, but information on this point comes mostly from sporadic reports.

Dermatomyositis of Childhood

Idiopathic myositis occurs in children, but less frequently than in adults. Some cases tend to be relatively benign but otherwise do not differ from the syndrome in adults. More frequently, there is a distinctive illness, described by Banker and Victor, which differs in some respects from the usual adult form of the disease. In these children and adolescents, there is greater involvement of blood vessels in the connective tissue of multiple organs, as well as in skin and muscle. This childhood form of DM begins, as a rule, with typical skin changes accompanied by anorexia and fatigue. Erythematous discoloration of the upper eyelids (the previously noted heliotrope rash), frequently with facial edema, is another characteristic early sign. The erythema spreads to involve the periorbital regions, nose, malar areas, and upper lip as well as the skin over the knuckles, elbows, and knees. Cuticular overgrowth, subungual telangiectasia, and ulceration of the fingertips may be found. Capillary prominence in the nail beds and avascular regions in the cuticle are said to be characteristic but need to be sought with a magnifying lens or ophthalmoscope (these signs are also seen in the "CREST" [calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, telangiectasia] form of scleroderma).

Symptoms of weakness, stiffness, and pain in the muscles usually follow but may precede the skin manifestations. The weakness is generalized but always more severe in the muscles of the shoulders and hips and proximal portions of the limbs. A tiptoe gait, the result of fibrous contractures of flexors of the ankles, is a common late abnormality. Tendon reflexes are depressed or abolished, but only commensurate with the degree of muscle weakness. Intermittent low-grade fever, substernal and abdominal pain (like that of peptic ulcer), melena, and hematemesis from bowel infarction may occur, the result of an accompanying systemic vasculitis.

The mode of progression of DM of childhood, like that of the adult form, is variable. In fulminant cases, the weakness appears rapidly, involving all the muscles including those of chewing, swallowing, talking, and breathing and leading to total incapacitation. Perforation of the gastrointestinal tract from bowel infarction may be the immediate cause of death, as it has been in two of our patients. In others, there is slow progression or arrest of the disease and, in a small number, there is a remission of weakness. Flexion contractures at the elbows, hips, knees, and ankles and subcutaneous calcification and ulceration of the overlying skin, with extrusion of calcific debris are manifestations in the late, untreated stages of the disease.

Systemic Autoimmune (Connective Tissue) Diseases With Polymyositis and Dermatomyositis

In both PM and DM, the inflammatory changes are often not confined to muscle but are associated with systemic autoimmune diseases such as rheumatoid arthritis, scleroderma, lupus erythematosus, or combinations thereof (mixed connective tissue disease); the same muscle changes are associated less often with the Sjögren syndrome. Conversely, in the aforementioned immune diseases, inflammatory muscle changes are frequently found but in only a limited number of muscles and often asymptotically. The incidence of these “crossover” or overlap cases cannot be stated with certainty. A true necrotizing-inflammatory myopathy has been reported in up to 8 percent of cases of lupus erythematosus (far higher than in our experience), and an even smaller proportion of cases of systemic sclerosis, rheumatoid arthritis, and Sjögren syndrome. The treatment of rheumatoid arthritis with d-penicillamine increases the incidence of, or perhaps independently precipitates, a myositis.

Also notable is the sporadic concurrence of myositis with other autoimmune diseases such as myasthenia gravis and Hashimoto thyroiditis and less often, with a monoclonal paraprotein in the blood; it is not clear whether these are coincidental, but it is likely that they reflect an underlying genetic propensity to autoimmune disease.

In the overlap syndromes that incorporate autoimmune disease and myositis, there is usually greater muscular weakness and atrophy than can be accounted for by the muscle changes alone. Inasmuch as arthritis or periarticular inflammation may limit motion because

of pain, result in disuse atrophy, and also at times cause a vasculitic polyneuropathy, the interpretation of diminished strength in these autoimmune diseases is not simple. Malaise, aches, and pains are common and attributable mostly to the systemic disease. Sometimes the diagnosis of myositis must depend on muscle biopsy, EMG findings, and measurements of muscle enzymes in the serum. In these complicated cases, myositis may accompany the connective tissue disease or occur many years later.

It is worth noting that PM may occur during pregnancy and that rarely the fetus is affected (most often the fetus and neonate are normal) with elevated CK levels for months postpartum (Messina et al).

Laboratory Diagnosis of PM and DM

In the majority of patients, serum levels of CK and other muscle enzymes, such as aldolase, are elevated. Serum CK levels tends to be higher in PM than in DM because of the widespread single-fiber necrosis in the former (as described in the following section on pathologic changes). However, in DM, if there are infarcts in muscle, CK levels will be moderately elevated as well. The sedimentation rate is normal or mildly elevated in both diseases.

It has been appreciated that some cases of PM and DM are associated with autoantibodies in the blood. Some of these are undoubtedly nonspecific markers of an autoimmune or inflammatory state, but others may be of pathogenetic significance or are markers for syndromes with multiorgan damage that extends beyond muscle. Tests for circulating rheumatoid factor or antinuclear antibody (ANA) are positive in fewer than half of cases. A high titer of ANA, in conjunction with elevated antiribonuclear antibodies, suggests the coexistence of systemic lupus or mixed connective tissue disease. It must be emphasized, however, that absent or low-titer ANA and a normal sedimentation rate do not exclude the diagnosis of PM, a fact that limits their diagnostic usefulness. Other antibodies can be found on occasion that are directed against constituents of a nucleolar protein complex (PM-Scl) and ribonucleoproteins (Ro/SS-A and La/SS-B).

Of greater interest are the findings that perhaps 20 percent of patients with PM and DM have antibodies against various cellular components of muscle, in particular, antibodies directed against cytoplasmic transfer ribonucleic acid (tRNA) synthetases (anti-Jo1), or against the tRNA itself. These are fairly specific to PM and, less frequently, to DM; they are found when the myositis is coupled with an expanded illness that involves other organs or connective tissues. The clinical disorders associated with these antibodies usually combine myositis with (1) interstitial lung disease but also (2) arthritis, (3) Raynaud syndrome, and (4) thickening of the skin of the hands (“mechanic’s hands”). Following from the designation of the main type of antibody, these have been termed *synthetase syndromes*. Furthermore, an unexpectedly high proportion of cases of PM and DM show myositis-specific antibodies that are directed against a cytoplasmic ribonucleoprotein complex (SRP), or against a protein complex that is a nuclear helicase (Mi-2). The former is found in approximately 10 percent of cases of PM, and of DM (and with inclusion

body myopathy; see further on), and in some series has carried a heightened risk of cardiac muscle inflammatory involvement. Although these various autoantibodies, with the possible exception of anti-Jo1, have not been especially useful as primary diagnostic tools, they do have a role in refining diagnosis. For example, a positive Jo1 antibody, although too uncommon to use as a screening test, precludes the diagnosis of inclusion body myopathy (which has been associated with a different set of autoantibodies as discussed further on) and its presence raises concern about the later development of interstitial lung disease. The presence of these antibodies also underscores the role for the humoral immune system in the pathogenesis of PM and raises opportunities for investigation discussed as follows.

Myoglobinuria can be detected in the majority of patients with most forms of myositis, particularly a necrotizing form, provided that a sensitive immunoassay procedure is used, but this test is not routinely performed.

The EMG is quite helpful in diagnosis but has been normal in a small proportion of our patients, even when many muscles are sampled. A typical "myopathic pattern is disclosed," that is, many abnormally brief action potentials of low voltage in addition to numerous fibrillation potentials, trains of positive sharp waves, occasional polyphasic units, and myotonic activity—all but the brief potentials possibly reflecting irritability of the muscle membranes (see Chap. 45). These findings are most apparent in weak muscles and are almost always seen when proximal weakness is well developed but they also may be observed in clinically unaffected areas. Indolent and chronic cases in which fibrosis of muscle and wasting have supervened may show polyphasic units that simulate denervation–reinnervation changes, juxtaposed with myopathic motor units. The EMG is also helpful in choosing a muscle for biopsy sampling but care must be taken not to obtain tissue from precisely the same site as a recent EMG needle insertion as a spurious histopathologic appearance of muscle damage may be obtained in this region (see the following text). Our approach has been to perform the needle EMG examination on one side of the body and biopsies on the other side.

As stated earlier, the ECG is abnormal in some cases and this finding may suggest the need for vigilance regarding cardiac symptoms and arrhythmias.

The results of magnetic resonance imaging (MRI) of muscle have been interesting and may aid the clinician in that abnormalities in T1, T2 and STIR signal intensity define regions of increased water content and inflammation and spectroscopic studies demonstrate regional deficits in energy production. Although MRI cannot at this time replace a biopsy for diagnosis, it can refine the distribution of lesions and aid in targeting the muscle biopsy, as well as provide a useful index of the efficacy of drug therapy. In some cases, MRI can distinguish IBM from either PM or metabolic muscle disease (see Lodi et al and also Dion et al).

Pathologic Changes in PM and DM

Because of the scattered distribution of inflammatory lesions and destructive changes, only part (or none) of the

complex of pathologic changes may be divulged in any single biopsy specimen. Because of this limitation, more than one site of biopsy or multiple samples through one incision is advisable.

The principal changes in idiopathic PM consist of widespread destruction of segments of muscle fibers with an inflammatory reaction, that is, phagocytosis of muscle fibers by mononuclear cells and infiltration with a varying number of lymphocytes and lesser numbers of other mononuclear and plasma cells. Evidence of regenerative activity of muscle, mainly in the form of proliferating sarcolemmal nuclei, basophilic (RNA-rich) sarcoplasm, and new myofibrils, is evident in damaged regions. Many of the residual muscle fibers are small, with increased numbers of sarcolemmal nuclei. Some of the small fibers are found in clusters, the result of splitting of regenerating fibers. Either the degeneration of muscle fibers or an infiltration of inflammatory cells may predominate in any given biopsy specimen, although both types of changes are in evidence at autopsy.

In a single section from a biopsy sample, there may be only necrosis and phagocytosis of individual muscle fibers without infiltrates of inflammatory cells, or the reverse may be observed. However, in serial sections, muscle necrosis is shown to be adjacent to inflammatory infiltrates. Repeated attacks of a necrotizing myositis exhaust the regenerative potential of the muscles so that fiber loss, fibrosis, and residual thin and large fibers in haphazard arrangement may eventually impart a dystrophic appearance. For all these reasons, the pathologic picture can be correctly interpreted only in relation to clinical and other laboratory data. Guidelines for the interpretation of the muscle biopsy reflecting these comments, a critical step in correct diagnosis of the inflammatory myopathies, are given in the review by Dalakas and Hohlfeld.

In DM, there are several other distinctive histopathologic changes. In contrast to the evident necrosis of single fibers of PM, DM is characterized by perifascicular muscle fiber atrophy (referring to changes at the periphery of a fascicle, for reasons noted below). Moreover, the inflammatory infiltrates in DM predominate in the perimysial connective tissue, whereas in PM they are scattered throughout the muscle and are most prominent in relation to the muscle fiber membrane and the endomysium. The muscle lesions in dermatomyositis of childhood are similar to those of the adult form, only greatly accentuated. In a biopsy sample, the diagnosis can be inferred from the perifascicular pattern of degeneration and atrophy of muscle fibers.

Even more distinctive of DM are microvascular changes in muscle. Endothelial alterations (tubular aggregates in the endothelial cytoplasm) and occlusion of vessels by fibrin thrombi may be appreciated, with associated zones of infarction. The same vascular changes underlie the lesions in the connective tissue of skin, subcutaneous tissue, and gastrointestinal tract when they are present. The perifascicular muscle fiber atrophy had in the past been attributed to an ischemic process set up by capillary occlusion, but recent evidence suggests otherwise (see Greenberg and Amato).

Etiology and Pathogenesis

PM and DM are idiopathic. All attempts to isolate an infective agent have been unsuccessful. Several electron microscopists observed virus-like particles in muscle fibers, but a causative role has not been proved. A polymyositic illness has not been induced in animals by injections of affected muscle as it has in models of several other inflammatory neurologic conditions. Nevertheless, the notion that an autoimmune mechanism is operative in PM and DM is supported by the association of these disorders with a number of the more clearly established autoimmune diseases enumerated earlier in this chapter. Further evidence of an autoimmune nature is given by the presence of specific autoantibodies in nearly half of cases, as also described earlier.

Immunopathologic studies have partially substantiated an autoimmune mechanism and suggested that PM and DM can be distinguished from one another on the basis of their immunopathologic characteristics. In DM, immune complexes, IgG, IgM, complement (C3), and membrane-attack complexes are deposited in the walls of venules and arterioles, indicating that the immune response is directed primarily against intramuscular blood vessels (Whitaker and Engel; Kissel et al). Such a response is lacking in PM (and in IBM, discussed further on). Engel and Arahata have demonstrated a difference between the two disorders on the basis of the subsets and locations of lymphocytes that make up the intramuscular inflammatory aggregates. However, the deposition of these complexes may be a secondary event as our colleagues Greenberg and Amato propose. In PM, there are a large number of activated T cells, mainly of the CD8 class, whereas B cells are sparse. Moreover, T cells, accompanied by macrophages, enclose and invade nonnecrotic muscle fibers. In DM, very few fibers are affected in this manner, and the percentage of B cells at all sites is significantly higher than it is in PM. Engel and Arahata interpreted these differences as indicating that the effector response in DM is predominantly humoral, whereas in PM the response is composed of cytotoxic T cells, clones of which have been sensitized to a yet undefined antigen on the muscle fiber.

Treatment

Most clinicians agree that corticosteroids (prednisone, 1 mg/kg, as a single daily dose orally, or intravenously) are a reasonable first line of therapy for both PM and DM. The response to treatment is monitored by careful testing of strength and measurement of CK (not by following the erythrocyte sedimentation rate [ESR]). In patients who respond, the serum CK decreases before the weakness subsides; with relapse, the serum CK rises before weakness returns. Once the CK level normalizes and strength improves, typically several weeks or longer, the dosage may be reduced gradually—by no more than 5 mg every 2 weeks—toward 20 mg daily. It is then appropriate to attempt to control the disease with an alternate-day schedule with double this amount (i.e., prednisone, 40 mg every other day) so as to reduce the side effects of the drug. After cautious reduction of prednisone over

a period of 6 months to 1 year or longer, the patient can usually be maintained on doses of 7.5 to 20 mg daily, with the aim of eventual discontinuation of the drug. Corticosteroids should not be discontinued prematurely, for the relapse that may follow is often more difficult to treat than the original illness.

In acute and particularly severe cases, treatment may be facilitated by the use initially of high-dose methylprednisolone (1 g infused over 2 h each day for 3 to 5 days). This form of treatment should be regarded as a temporary measure until oral prednisone becomes effective.

Alternatively, or sometimes in tandem with this approach, intravenous immunoglobulin (IVIg) or plasma exchanges may be instituted. In patients with DM who respond poorly to corticosteroids and other immunosuppressants or are severely affected early on, the addition of IVIg infusions often proves helpful, although several courses of treatment at monthly intervals may be required to achieve sustained improvement. In several controlled studies of small numbers of patients with DM, practically all showed improvement in muscle strength and in skin changes, and a reduction in CK concentration (see Dalakas; Mastaglia et al). PM has also been reported to respond favorably to treatment with IVIg, but the evidence is less certain. Further controlled studies are required to corroborate these reports and to establish, in both PM and DM, the optimal doses and modes of administration. It is noteworthy from our experience that IVIg has seldom been effective in PM or DM when used alone or as initial therapy. The proper use of these treatments in crossover cases with connective tissue disease has not been established.

Some patients who cannot tolerate, or are refractory to, prednisone may respond favorably to oral *azathioprine* with care being taken to avoid severe leukopenia. *Methotrexate* is currently favored by many groups over azathioprine as an adjunct to steroids (5 to 10 mg/week in 3 divided oral doses, increased by 2.5 mg/week, to a total dose of 20 mg weekly). Methotrexate or azathioprine should generally be given along with the lowest effective doses (15 to 25 mg) of prednisone. Although 1 study failed to show efficacy (Oddis et al), in cases that have been refractory to corticosteroids and methotrexate, we and our colleagues have had success rituximab intravenously, 750 mg/m², repeated in 2 weeks and sometimes required every 6 to 18 months. Some clinicians favor, from the beginning, a combination of prednisone in low dosage and one of these immunosuppressant drugs, and this approach is generally necessary when myocarditis or interstitial pneumonitis is coupled with DM. Mycophenolate mofetil has also been introduced and has allowed a reduction in steroid dose within several months in both PM and DM, according to a number of anecdotal reports, but has not proven clearly effective in a randomized trial; the reasons for this failure are being actively discussed and we have not abandoned its use. *Cyclosporine* has also been used in recalcitrant cases; it has few advantages over other immunosuppressant drugs and has a number of potentially serious side effects, including nephrotoxicity. *Cyclophosphamide*, which is a

useful drug in the treatment of Wegener granulomatosis, polyarteritis, and other vasculitides, is said to be of lesser value in PM, but it may be useful in refractory cases and has perhaps the highest toxicity of the immunosuppressive medications that are used for inflammatory myopathies; we no longer use it with any regularity.

Prognosis

Except for patients with malignancy, the prognosis in adult PM and DM is generally favorable. Only a small proportion of patients with PM succumb to the disease and then usually from a secondary pulmonary complication or from myocarditis as already mentioned. Several of our patients have had severe aspiration pneumonias as a result of their dysphagia. The period of activity of disease varies considerably but is typically 2 to 3 years in both the child and adult. As indicated earlier, the majority improves with corticosteroid therapy, but many are left with varying degrees of weakness of the shoulders and hips. Approximately 20 percent of our patients have recovered completely after steroid therapy and long-term remissions have been achieved after withdrawal of medication in about an equal number. The extent of recovery is roughly proportional to the acuteness and severity of the disease and the duration of symptoms prior to institution of therapy. Patients with acute or subacute PM in whom treatment is begun soon after the onset of symptoms have the best prognosis. In the series collected by DeVere and Bradley, in which patients were treated early, there was remission in more than 50 percent of cases, whereas Riddoch and Morgan-Hughes reported a far lower rate in patients who were treated more than 2 years after onset of the disease. Those patients who have come to our attention after a long period of proximal weakness and with substantial muscle atrophy have not recovered completely, although some improvement occurred over years.

Even in patients who have a coexistent malignancy, muscle weakness may lessen and serum enzyme levels decline in response to corticosteroid therapy, but weakness returns after a few months and may then be resistant to further treatment. As already stated, if the tumor is successfully removed, muscle symptoms may remit, but even this experience has not been uniform.

The overall mortality after several years of illness had in the past approximated 15 percent, being higher in childhood DM, in PM with connective tissue diseases, and, of course, when a malignancy is found. Recent figures give more optimistic results.

Inclusion Body Myositis

Inclusion body myositis (IBM) is the third major form of inflammatory myopathy and, depending on the care taken with histologic diagnosis, is the most common inflammatory myopathy in patients older than 50 years. Its defining features, intracytoplasmic and intranuclear inclusions, were first described in 1965 by Adams and colleagues, who also drew attention to a number of clinical attributes now considered characteristic. By 1994, only 240 sporadic cases had been recorded in the medical

literature (Mikol and Engel), but the diagnosis is now made so frequently that this low number almost certainly reflects the misidentification of IBM as PM in the past. Garlepp and Mastaglia concluded that more than one-third of cases of inflammatory myopathy, especially in men, are IBM. Moreover, the majority of myopathies in patients over 50 years, not attributable to medication toxicity, are due to IBM. A set of clinical and pathologic diagnostic criteria for the disease have been proposed by Griggs and coworkers and are useful for research purposes. A source of confusion has been the entirely separate entity of *inclusion body myopathy*, a largely hereditary, pauci-inflammatory process, and displays a different pattern of weakness from IBM. The myositis, as alluded to earlier, predominates in males (in a ratio of 3:1) and has its onset in middle or late adult life. Diabetes, any one of a variety of autoimmune diseases, and a relatively mild polyneuropathy are associated in approximately 20 percent of sporadic cases of IBM, but associations with malignancy or systemic autoimmune disease have not been established.

Clinical Manifestations

The illness is more variable but generally more focal in presentation than is PM and DM. It is characterized by a steadily progressive, painless muscular weakness and modest atrophy, which is usually distal in the arms and both proximal and distal in the legs. In approximately 20 percent of cases, the disease begins with focal weakness of the quadriceps, finger or wrist flexors, or lower leg muscles on one or both sides, and gradually spreads to other muscle groups after many months or years. Selective weakness of the flexor pollicis longus is a particularly characteristic pattern of involvement, and isolated quadriceps weakness or neck extensor weakness should also bring the diagnosis to mind, although IBM is not the exclusive cause of these patterns. In most patients, the deltoids are spared and the thumb flexors are weak, the opposite pattern to PM and DM. The tendon reflexes are normal initially but diminish in about half the patients, especially the knee jerks, as the disease progresses. Interestingly, the knee jerks may be depressed or lost even without much in the way of quadriceps weakness; this is not the case in PM, in which the reflexes are spared until the muscle is extremely weak. These clinical features are well displayed in the series reported by Amato and colleagues. Dysphagia is common (Wintzen et al). Selective or asymmetric involvement of distal muscles, when it occurs, erroneously suggests the diagnosis of motor neuron disease (the reflexes are not, however, enhanced as they are in ALS).

Laboratory and Muscle Biopsy Features

The CK is normal or slightly elevated, generally showing lower levels than in cases of PM with comparable amounts of weakness. EMG abnormalities are much like those found in PM, as discussed earlier. In addition, a small proportion of IBM patients display a more typically neuropathic EMG pattern, mainly with long-duration polyphasic potentials because of the chronicity of the

disease, in the distal limb muscles. However, the EMG changes tend to be restricted to weakened muscles, a distinction from ALS.

The diagnosis depends on the clinical features and is supported by the muscle biopsy. There are structural abnormalities of muscle fibers and inflammatory changes. The latter are identical to but usually of lesser severity than those observed in idiopathic PM. (The infiltrating cells are mainly T cells of the CD8 type.) The denominative finding is of intracytoplasmic, subsarcolemmal vacuoles and eosinophilic inclusions in both the cytoplasm and nuclei of degenerating muscle fibers. The vacuoles contain, and are rimmed by, basophilic granular material "rimmed vacuoles. Special stains, particularly Gomori trichrome on frozen sections, and extensive inspection of biopsy specimens are required to disclose the rimmed vacuoles, for they are infrequent, widely dispersed, and easily overlooked. The inclusions may be congophilic, and may stain for TDP-43, p62, SM1-31, and, particularly, beta amyloid. As noted in subsequent sections similar inclusions are found in a number of other muscle diseases and are not in and of themselves diagnostic, especially without the destructive and mildly inflammatory changes of IBM. Moreover, the clinical context of these other diseases usually causes little difficulty in identifying the inclusions as ancillary and minor abnormalities on the biopsy.

Of clinical utility has been the recent introduction of testing for the earlier mentioned cytosolic antibodies (anti-cN1; NT5C1A) that are found in two-thirds of patients with IBM. They appear to be specific and assist in particular by differentiating this disease from the other inflammatory myopathies and in its detection when there is an unusual pattern of weakness that is not typically of an inflammatory myopathy. Testing other antibodies such as anti-Jo is probably suited to confirming cases that have the elements of a larger syndrome that includes, for example, interstitial lung disease.

Ultrastructural studies show that the protein inclusions accumulate at or near foci of abnormal tubulofilamentous structures in both the nuclei and cytoplasm. The nature of these diverse changes is obscure. The tubulofilamentous inclusions suggested to earlier investigators a viral origin, but an agent has never been isolated and serologic studies have failed to substantiate an infectious causation.

Treatment

IBM has not responded in any consistent fashion to treatment with corticosteroids or other immunosuppressive drugs. Indeed, the disease should be suspected in recalcitrant cases of apparent PM. The level of CK and the degree of leukocyte infiltration of muscle often diminish with corticosteroid treatment despite a lack of clinical improvement. On this basis, Barohn and coworkers suggested that the inflammatory response is not a primary cause of muscle destruction. In a few cases there has been brief improvement in response to IVIg, especially in weakened muscles involved in swallowing, but the gains have been unsustainable and serial histopathologic

examinations have detected no change. Two controlled trials have failed to show a benefit of IVIg. Plasma exchange and leukocytapheresis have also been tried, with generally discouraging results.

The disease in most patients is relentlessly progressive over many years, sometimes very slowly, and no method of treatment has so far altered the long-term prognosis. Sometimes, the process remains fairly restricted in scope or severity for up to a decade, thereby creating less disability than in cases that become generalized.

Problems in Diagnosis of Inflammatory Myopathy

The main issue here is differentiation from inclusion body myopathy, a subject introduced in the next section. The specific problem of determining which patients with DM or PM should have an extensive evaluation for a systemic malignancy and for connective tissue disease has been partially settled. We have adopted the practice of careful inspection of the chest radiograph, routine blood tests and stool examination for blood for all patients, and of undertaking a more extensive evaluation in patients older than 55 years and in smokers of any age. The evaluation of patients over 55 and smokers includes chest and abdominal computed tomographic (CT) scans, colonoscopy, pelvic ultrasound, cancer antigen (CA)-125, carcinoembryonic antigen (CEA), as well as other tests. In patients with recent weight loss, anorexia, or other symptoms suggestive of malignancy, we have included upper endoscopy and resorted to a body positron emission tomography scanning.

In addition to these main issues of distinguishing PM and DM from IBM, currently aided by antibody testing for the latter, we call attention to the following problems that we have encountered in connection with *diagnosis*:

1. *The patient with proximal muscle weakness is incorrectly diagnosed as having progressive muscular dystrophy (actually, the opposite pertains more often).* Points in favor of myositis are (1) lack of family history (although many dystrophies have recessive inheritance); (2) older age at onset; (3) rapid evolution of weakness; (4) evidence, past or present, of other connective tissue diseases; (5) high serum CK values (again, can be high in certain dystrophies); (6) marked degeneration and regeneration in muscle biopsy; and, finally, if there is still doubt, (7) unmistakable improvement with corticosteroid therapy.
2. *The patient with a systemic autoimmune disease (rheumatoid arthritis, scleroderma, lupus erythematosus, Sjögren syndrome) is suspected of having PM in addition.* Pain in these conditions prevents strong exertion (algic pseudoparesis). Points against the coexistence of myositis are (1) the inability to document weakness out of proportion to muscle atrophy and the presence of pain on passive movement of the limbs; (2) normal EMG; (3) normal serum CK; and (4) normal muscle biopsy except possibly for areas of infiltration of chronic inflammatory cells in the endomyrial and perimyrial connective tissue (interstitial myositis).
3. *When muscle pain is a prominent feature, polymyalgia rheumatica must be differentiated.* This latter syndrome

is characterized by pain, stiffness, and tenderness in the muscles of the neck, shoulders, and arms, and sometimes of the hips and thighs; even passive motion of the limbs causes pain because of the periarticular locus of this disease. A high sedimentation rate, usually above 65 mm/h, is a diagnostic feature, but more typically the value is close to 100 mm/h, levels higher than in myositis. Biopsy of the temporal artery frequently discloses a giant cell arteritis. CK levels—and, of course, muscle biopsy—are normal. Rapid disappearance of pain with administration of small doses of prednisone is also diagnostic of polymyalgia rheumatica (see Chap. 11).

4. *The patient has restricted muscle weakness.* Weakness or paralysis of the posterior neck muscles, with inability to hold up the head, restricted bilateral quadriceps weakness, and other limited pelvic palsies are examples. Most often, the head-hanging or head-lolling syndrome proves to be caused by PM, and the other syndromes are caused by restricted forms of dystrophy or by motor neuron disease. IBM is the main alternative consideration in cases of neck or quadriceps weakness, particularly if the latter weakness is asymmetric; muscle enzymes in the serum are normal or slightly elevated. EMG and biopsy are helpful in diagnosis.
5. *The patient has diffuse myalgia and fatigability.* Most such patients have proved to be depressed and only rarely to have a myopathy. A few will be found to be caused by a toxic myopathy, particularly from one of the statin class of drugs. Hypothyroidism, McArdle disease, hyperparathyroidism, steroid myopathy, adrenal insufficiency, and early rheumatoid arthritis must be excluded by appropriate studies. Features that virtually exclude a myositis are (1) lack of reduced peak power of contraction and (2) normal EMG, serum enzymes, and muscle biopsy.
6. *Trichinosis, toxoplasmosis, HIV, and other infectious causes of myositis* can simulate acute immune myositis as described in the early parts of this chapter. Occasionally, the diagnosis of sarcoidosis is made from the muscle biopsy, but the myopathic features (weakness and pain) tend to be minor.

Other Inflammatory Myopathies

There are a large number of unrelated myositides and rare forms of focal myositis or relatively minor changes in muscle that occur in the course of inflammatory diseases of blood vessels or systemic infections and, curiously, with certain tumors such as thymoma. Most of these do not warrant extensive consideration and are described in detail in monographs devoted to muscle disease (see Banker). We are uncertain how to place the newly described and undoubtedly rare entity of myositis with abundant macrophage infiltration and aluminum hydroxide crystalline deposits. A type of fasciitis that is characterized by pronounced infiltration of macrophages has been related to vaccinations that contain the aluminum compound, but the myositis does not seem to be related to this aforementioned entity (see Bassez et al).

Three inflammatory myopathic diseases, however, are distinctive and of interest to neurologists: (1) eosinophilic myositis, fasciitis, and myalgia syndrome, (2) orbital myositis, and (3) sarcoidosis of muscle.

Eosinophilic Myositis and Fasciitis

This term has been applied to 4 overlapping clinical entities: (1) eosinophilic fasciitis, (2) eosinophilic monomyositis (sometimes multiplex), (3) eosinophilic PM, and (4) the eosinophilia-myalgia syndrome.

Eosinophilic Fasciitis This condition, mistakable for PM, was reported by Shulman in 1974. He described 2 men with a scleroderma-like appearance of the skin and flexion contractures at the knees and elbows associated with hyperglobulinemia, elevated sedimentation rate, and eosinophilia. Biopsy revealed greatly thickened fascia, extending from the subcutaneous tissue to the muscle and infiltrated with plasma cells, lymphocytes, and many eosinophils; the muscle itself appeared normal and the skin lacked the characteristic histologic changes of scleroderma. One of Shulman's patients recovered in response to prednisone.

The many reports that followed have substantiated and amplified Shulman's original description. The disease predominates in men in a ratio of 2:1. Symptoms appear between the ages of 30 and 60 years and are often precipitated by heavy exercise (Michet et al). There may be low-grade fever and myalgia followed by the subacute development of diffuse cutaneous thickening and limitation of movement of small and large joints. In some patients, proximal muscle weakness and eosinophilic infiltration of muscle can be demonstrated (Michet et al). Repeated examinations of the blood disclose an eosinophilia in most but not all patients. The disease usually remits spontaneously or responds well to corticosteroids. A small number relapse and do not respond to treatment and some have developed aplastic anemia and lympho- or myeloproliferative disease.

Eosinophilic Monomyositis Painful swelling of a calf muscle or, less frequently, some other muscle has been the chief characteristic of this disorder. Biopsy discloses inflammatory necrosis and edema of the interstitial tissues; the infiltrates contain large but variable numbers of eosinophils. The disorder was typified by 1 of our patients, a young woman who developed such an inflammatory mass first in 1 calf and, 3 months later, in the other. The response to prednisone was dramatic; the swelling and pain subsided in 2 to 3 weeks and her power of contraction was then normal. When the connective tissue and muscle are both damaged, a chaotic regeneration of fibroblasts and myoblasts may result, forming a pseudotumorous mass that may persist indefinitely.

Eosinophilic Polymyositis Layzer and associates described an eosinophilic disorder that they classified as "subacute polymyositis." Their patients were adults in whom predominantly proximal weakness evolved over several weeks. The features of the muscle disorder were typical of PM except that the inflammatory infiltration was predominantly eosinophilic and the muscles were swollen and painful. Moreover, the muscle disorder was part of a widespread systemic illness typical of the *hyper eosinophilic syndrome*. The systemic manifestations included a striking

eosinophilia (20 to 55 percent of the white blood cells), cardiac involvement (conduction disturbances and congestive failure), vascular disorder (Raynaud phenomenon, subungual hemorrhages), pulmonary infiltrates, strokes, anemia, neuropathy, and hypergammaglobulinemia. There was a favorable response to corticosteroids in 2 patients, but in a third the outcome was fatal in 9 months. Layzer and coworkers noted that a lack of necrotizing arteritis distinguished this process from polyarteritis nodosa and Churg-Strauss disease. No infective agent was isolated. An allergic mechanism seems possible, and in the present authors' view one cannot exclude an angitis as a cause of the muscle lesions.

The last two of these previously mentioned syndromes (eosinophilic monomyositis and polymyositis) have overlapping features as shown by Stark's cases, in which a monomyositis was accompanied by several of the systemic features described by Layzer and colleagues. An uncertain proportion of cases are attributable to mutations in CAPN3, the gene for calpain-3 (Krahn et al). Moreover, some cases of eosinophilic polymyositis without systemic features have been found to be limb-girdle muscular dystrophy 2A, also due to a calpain mutation (i.e., both are considered to be "calpainopathies"). Patients with the dystrophic process, who also have a peripheral eosinophilia, probably have eosinophilic myositis.

Eosinophilia-Myalgia Syndrome Beginning in 1980, sporadic reports documented a lingering systemic illness characterized by severe generalized myalgia and eosinophilia of the peripheral blood following the ingestion of contaminated L-tryptophan. In late 1989 and early 1990, an outbreak occurred of this eosinophilia-myalgia syndrome, as the illness came to be called. More than 1,200 cases were reported to the Centers for Disease Control and Prevention (Medsker) and we examined several of them. The outbreak was ultimately traced to the use of nonprescription L-tryptophan tablets used as a sleep aid supplied by a single manufacturer and contaminated by ethylidene-bis-tryptophan and methyltetrahydro-beta-carboline-carboxylic acid, both close chemical relatives of L-tryptophan (Mayeno et al, 1990, 1992).

The onset of the muscular illness was relatively acute, with fatigue, low-grade fever, and eosinophilia ($>1,000$ cells/mm³). Muscle pain and tenderness, cramps, weakness, paresthesias of the extremities, and induration of the skin were the main clinical features. A severe axonal neuropathy with slow and incomplete recovery was associated in some cases. Biopsies of the skin fascia, muscle, and peripheral nerve disclosed a microangiopathy and an inflammatory reaction in connective tissue structures; changes like those observed in scleroderma, eosinophilic fasciitis, and in the *toxic oil syndrome*. The latter syndrome, caused by the ingestion of contaminated rapeseed oil, occurred in an outbreak in Spain in 1981 and gave rise to a constellation of clinical and pathologic changes that were essentially identical to those caused by contaminated L-tryptophan (Ricoy et al; see also Chap. 46). The two toxins are also closely linked chemically and there have been other more limited outbreaks of the toxic neuropathy, usually from adulterated cooking oil.

The cutaneous lesions and eosinophilia of this syndrome responded to treatment with prednisone and other immunosuppressive drugs, but other symptoms persisted. Severe axonal neuropathy in our patients improved incompletely over several years, leaving one chair-bound with severe distal atrophic weakness after 15 years. Although no longer a problem that is likely to be seen by physicians, it serves as a model for future peculiar myopathic syndromes from adulterated drugs that otherwise would seem innocuous.

Acute Orbital Myositis

Among the many cases of orbital inflammatory disease (pseudotumor of the orbit and Tolosa-Hunt syndrome, as described in Chap. 14), there is a small group in whom the inflammatory process appears to be localized to the extraocular muscles. To this group, the term *acute orbital myositis* has been applied. The abrupt onset of orbital pain that is made worse by eye motion, redness of the conjunctiva adjacent to the muscle insertions, diplopia caused by restrictions of ocular movements, lid edema, and mild proptosis are the main clinical features and, admittedly, the distinctions from orbital pseudotumor are not clear. It may spread from one orbit to the other. The ESR is usually elevated and the patient may feel generally unwell, but only rarely can the ocular disorder be related to a systemic autoimmune disease or any other specific systemic disease. CT and MRI have proved to be particularly useful in demonstrating the swollen ocular muscles or muscle, and in separating orbital myositis from the other remitting inflammatory orbital and retroorbital conditions (Dua et al). As a rule, acute orbital myositis resolves spontaneously in a matter of a few weeks, although it may recur in the same or the opposite eye. Administration of steroids appears to hasten recovery.

Sarcoid Myopathy, Granulomatous Myositis, and Localized Nodular Myositis

There are undoubted examples of muscle involvement in patients with sarcoidosis, but they seem to be less frequent and less certain than would appear from the medical literature. In some cases, sarcoid myopathy becomes evident as a slowly progressive, occasionally fulminant, painless proximal or distal weakness. The CK levels are elevated. Muscle biopsy discloses numerous noncaseating granulomas. However, such lesions may also be found in patients with sarcoidosis who have no weakness. Treatment with moderate doses of corticosteroids (prednisone, 25 to 50 mg daily) is usually effective in symptomatic cases, but an additional immunosuppressive agent, such as cyclosporine, may have to be instituted if improvement is not evident in several weeks.

Much more puzzling have been cases of myopathy with the clinical features of idiopathic polymyositis and the presence of noncaseating granulomas in the muscle biopsy but with no evidence of sarcoidosis of the nervous system, lungs, bone, skin, or lymph nodes. Such cases call into question the validity of a muscle granuloma as a criterion of sarcoidosis, but the matter cannot be

settled until we have a better definitions and etiology for sarcoidosis. These cases are presently classified as *granulomatous myositis* and, if limited to one or a small group of muscles, *localized nodular myositis* (Cumming et al). In a syndrome described by Namba and colleagues, this type of myositis was combined with myasthenia gravis, myocarditis, and thyroiditis. The muscle process has, on a few occasions, also been associated with Crohn disease. Electron microscopy has disclosed muscle fiber invasion by lymphocytes, suggesting a cell-mediated immune reaction. Very rarely, a granulomatous myositis may complicate tuberculosis or syphilis.

THE MUSCULAR DYSTROPHIES

(Tables 48-1 through 48-3)

The muscular dystrophies are a group of progressive hereditary degenerative diseases of skeletal muscles. The intensity of the degenerative changes in muscle and the cellular response and nature of the regenerative changes distinguish the dystrophies histologically from other

diseases of muscle and also have implications regarding their pathogenesis. The category of more benign and relatively nonprogressive myopathies—each named from its special histopathologic appearance, such as central core, nemaline, mitochondrial, and centronuclear diseases—present greater difficulty in classification. Like the dystrophies, they are primarily diseases of muscle and are often hereditary in nature, but they are placed in a separate category because of a nonprogressive or slowly progressive course and their distinctive histochemical and ultrastructural features.

The current clinical classification of the muscular dystrophies is based mainly on the distribution of the dominant muscle weakness; however, several of the classical types have retained their eponymic designations: Duchenne, Becker, Emery-Dreifuss, Landouzy-Dejerine, Miyoshi, Welander, Fazio-Londe, and Bethlem are among the ones that still have utility in shorthand. To these are added myotonic dystrophy and a group of so-called congenital muscular dystrophies, usually severe in degree.

The extraordinary depth of information regarding the molecular nature of the dystrophies is one of the most gratifying developments of modern neuroscience.

Table 48-1

DUCHENNE/BECKER, EMERY-DREIFUSS, LIMB-GIRDLE, AND RELATED MAJOR MUSCULAR DYSTROPHIES

INHERITANCE TYPE	GENE OR CHROMOSOME	ONSET DECADE	CK ELEVATION	REGIONS AFFECTED
<i>X-linked recessive</i>				
Duchenne/Becker	Dystrophin	1st	10–50 ×	Proximal, then distal muscles Cardiac muscle
Emery-Dreifuss	Emerin	2nd–3rd	5 ×	Proximal muscles, joint contractures; cardiac arrhythmias
Scapuloperoneal	<i>FHL1</i>			Scapular-peroneal
<i>Autosomal dominant</i>				
LGMD 1A	Myotilin	3rd–4th	2 ×	Distal greater than proximal weakness, vocal cords, pharynx; allelic with myofibrillar myopathy
LGMD 1B	Lamin A/C	1st–2nd	3–5 ×	Resembles Emery-Dreifuss disease Proximal muscles and heart, joint contractures
LGMD 1C	Caveolin-3	1st	4–25 ×	Proximal muscles
LGMD 1D	6p	3rd–5th	2–4 ×	Proximal muscles; cardiomyopathy
LGMD 1E	Desmin	1st	NI	Proximal muscles
<i>Autosomal recessive</i>				
LGMD 2A	Calpain-3	1st–2nd	3–15 ×	Proximal and distal muscles
LGMD 2B	Dysferlin	2nd–3rd	10–50 ×	Proximal and distal muscles Allelic to Miyoshi myopathy
LGMD 2C–F	α , β , γ , δ -sarcoglycans	1st–3rd	5–40 ×	Phenotype of Becker dystrophy
LGMD 2G	Telethonin	2nd	3–17 ×	Proximal greater than distal muscles
LGMD 2H	<i>TRIM32</i>	1st–3rd	2–25 ×	Proximal greater than distal muscles
LGMD 2I	<i>FKRP</i>	1st–3rd	10–30 ×	Proximal greater than distal muscles FKRP defects also cause CMD
LGMD 2J	Titin	1st–3rd	2 ×	Proximal and sometimes distal muscles
LGMD 2M	<i>POMGNT1*</i>	Birth		Mutations also associated with muscle-eye-brain diseases

CK, creatine kinase; CMD, childhood muscular dystrophy; FKRP, fukutin-related protein; LGMD, limb-girdle muscular dystrophy; NI, normal.

Table 48-2

SELECTED MUSCULAR DYSTROPHIES*

TYPE	GENE OR CHROMOSOME	ONSET DECADE	CK ELEVATION	REGIONS AFFECTED
Myotonic dystrophy (DM1)	Expanded intronic CTG repeat in myotonin kinase	1st–2nd	1–2 ×	Distal weakness, myotonia, cataracts Testicular atrophy, balding, cardiac arrhythmias
Proximal myotonic myopathy (DM2)	Expanded intronic CCTG repeat in zinc finger protein	1st–2nd	1–2 ×	Resembles myotonic dystrophy with prominent proximal muscle weakness but no infancy onset; less facial weakness
Facioscapulohumeral dystrophy	Multigene dysregulation at 4q telomere	1st–4th	1–2 ×	Facial, scapular, anterior tibial muscles Hearing loss, ocular telangiectasias
Oculopharyngeal dystrophy	Exonic GCG expansion (alanine) in poly-A binding protein	6th–7th	1–2 ×	Oculopharyngeal and levator palpebrae muscles
Bethlem myopathy	Collagen VI, subunits α 1-3	1st–3rd	1–4 ×	Proximal weakness Contractures in fingers, elbows, knees May present as CMD
Myofibrillar myopathy	Myotilin, desmin, $\alpha\beta$ -crystallin	2nd–4th	1–5 ×	Allelic with LGMD-1A

*All inherited in an autosomal dominant pattern.

CCTG, cytosine, cytosine, thymine, guanidine; CMD, childhood muscular dystrophy; CTG, cytosine, thymine, guanidine; GCG, guanidine, cytosine, guanidine; LGMD, limb-girdle muscular dystrophy.

Table 48-3

DISTAL MUSCULAR DYSTROPHIES

INHERITANCE DISORDER	GENE OR PROTEIN DEFICIENCY	ONSET DECADE	CK ELEVATION	REGIONS AFFECTED
<i>Autosomal recessive</i>				
Miyoshi myopathy	Dysferlin	2nd–3rd	10–50 ×	Begins in gastrocnemius muscles, rarely, in anterior tibial muscles Identical genetic defects may cause LGMD-2B Involves multiple muscle groups, spares heart
Nonaka myopathy with rimmed vacuoles (familial IBM)	GNE kinase–epimerase UDP-N-acetylglucosamine-2-epimerase/N-mannosamine kinase	2nd–3rd	3–10 ×	Distal more than proximal weakness Quadriceps sparing Spares heart
<i>Autosomal dominant</i>				
Welander distal dystrophy	Unknown	4th–5th	2–3 ×	Weakness begins in hands Slow progression Spares cardiac muscle
Tibial muscular dystrophy	Titin	4th–8th	2–4 ×	Onset in tibial distribution No cardiac involvement
Scapuloperoneal dystrophy	X-linked (see Table 48-1)	3rd–6th	2–10 ×	Scapuloperoneal weakness Hyaline bodies in muscle Early onset of foot-drop
Desmin myopathy	Desmin	3rd–4th	2–3 ×	Onset of distal weakness, slowly progressive Cardiac arrhythmias (sometimes fatal)
Gower-Laing	MYHC-1 (MYH7)	2nd–3rd	3 ×	Anterior tibial (early foot-drop)
Markesbery-Griggs	ZASP	2nd–3rd	2 ×	Anterior tibial Cardiomyopathy common

IBM, inclusion body myopathy.

The majority of the dystrophies are caused by changes in structural elements of the muscle cell, mainly in its membrane, but other important mechanisms also are being identified, such as altered messenger RNA (mRNA). In keeping with the outlook expressed throughout the book, we adhere to a clinical orientation in describing the muscular dystrophies but make clear that treatment in the future could be determined based on understanding of molecular mechanisms. Each of the muscular dystrophies is described in accordance with this scheme.

The differentiation of dystrophic diseases of muscle from those secondary to neuronal degeneration was an achievement of neurologists of the second half of the nineteenth century. Isolated cases of muscular dystrophy had been described earlier, but no distinction was made between neuropathic and myopathic disease. In 1855, the French neurologist Duchenne described the progressive muscular atrophy of childhood that now bears his name. However, it was not until the second edition of his monograph in 1861 that the "hypertrophic paraplegia of infancy" was recognized as a distinct syndrome. By 1868 he was able to write a comprehensive description of 13 cases and recognized that the disease was muscular in origin and restricted to males. Gowers in 1879 gave a masterful account of 21 personally observed cases and called attention to the characteristic way in which such patients arose from the floor (Gowers sign). Erb, in 1891, crystallized the clinical and histologic concept of a group of diseases caused by primary degeneration of muscle, which he named *muscular dystrophies*. The first descriptions of facioscapulohumeral dystrophy were published by Landouzy and Déjerine in 1894; of progressive ocular myopathy by Fuchs in 1890; of myotonic dystrophy by Steinert and by Batten and Gibb in 1909; of distal dystrophy by Gowers in 1888, Milhorat and Wolff in 1943, Welander in 1951, and Miyoshi and colleagues in 1986; and of oculopharyngeal dystrophy by Victor and associates in 1962. References to these and other writings of historical importance can be found in the works of Kakulas and Adams, of Walton and colleagues, and of Engel and Franzini-Armstrong, and most recently of Amato and Russell.

In the more recent history of the dystrophies, the most notable event was the discovery by Kunkel, in 1986, of the dystrophin gene and its protein product. Since then there has been an extraordinary accumulation of molecular-genetic, ultrastructural, and biochemical information about the muscular dystrophies, which has greatly broadened our understanding of their mechanisms. It has also clarified a number of uncertainties as to their clinical presentations and has necessitated a revision of an older classification.

Duchenne Muscular Dystrophy

This is the most frequent and best known of the early-onset muscular dystrophies. It begins in early childhood and runs a relatively rapid, progressive course. The incidence is in the range of 13 to 33 per 100,000 yearly or about 1 in 3,300 live male births. There is a strong familial liability as the disease is transmitted as an X-linked

recessive trait, occurring almost exclusively in males. However, careful examination of the mothers of affected boys shows slight muscle involvement in as many as half of them, as pointed out by Roses and coworkers (a frequency higher than in our limited experience). Approximately 30 percent of patients have no family history of the disease and these represent spontaneous mutations.

Rarely, a severe proximal Duchenne-type muscular dystrophy occurs in young girls. This may have several explanations. The female may have only 1 X chromosome, as occurs in the Turner (XO) syndrome, and that chromosome carries the Duchenne gene, or the Lyon principle may be operative; that is, there is inactivation of the unaffected paternal X chromosome allowing expression of the mutated Duchenne protein from the maternal chromosome in a large proportion of embryonic cells (mosaicism). It so happens that most childhood dystrophies in girls prove to be of an entirely different type that is caused by an autosomal recessive mutation causing a limb-girdle dystrophy as discussed further on.

Clinical Features

Duchenne muscular dystrophy is usually recognized by the third year of life and almost always before the sixth year. Nearly half of children show evidence of disease before beginning to walk. Many of them are slightly backward in other ways (mild mental retardation) and the muscle weakness may at first be overlooked. A greatly elevated CK may be the clue. In another group of young children, an indisposition to walk or run normally at the expected time brings them to medical attention or, having achieved these motor milestones, they appear less active than expected and are prone to falls. Increasing difficulty in walking, running, and climbing stairs, excessive lumbar lordosis, and waddling gait become more obvious as time passes. The iliopsoas, quadriceps, and gluteal muscles are involved initially; then the pretibial muscles weaken (foot-drop and toe walking). Muscles of the pectoral girdle and upper limbs are affected after the pelvic ones; the serrati, lower parts of pectorals, latissimus dorsi, biceps, and brachioradialis muscles are affected, more or less in this order.

Enlargement of the calves and certain other muscles is progressive in the early stages of the disease but most of the muscles, even the ones that are originally enlarged, eventually decrease in size; only the gastrocnemii, and to a lesser extent the lateral vasti and deltoids, are consistently large and this peculiarity may attract attention before the weakness becomes evident. The enlarged muscles have a firm, resilient ("rubbery") feel and are slightly weaker and more hypotonic than healthy ones. Thus the muscle enlargement is a pseudohypertrophy. Rarely, all muscles are at first large and strong, even the facial muscles, as in one of Duchenne's cases (from the marble statue, Farnese Hercules); histologically, this is a true muscle hypertrophy.

Muscles of the pelvic girdle, lumbosacral spine, and shoulders become weak and wasted, accounting for certain clinical peculiarities. Weakness of abdominal

and paravertebral muscles accounts for a lordotic posture and protuberant abdomen when standing and the rounded back when sitting. Weakness of the extensors of the knees and hips interferes with equilibrium and with activities such as climbing stairs or rising from a chair or from a stooped posture. In standing and walking, the patient places his feet wide apart so as to increase his base of support. To rise from a sitting position, he first flexes his trunk at the hips, puts his hands on his knees, and pushes the trunk upward by working the hands up the thighs. In rising from the ground, the child first assumes a four-point position by extending the arms and legs to the fullest possible extent and then works each hand alternately up the corresponding thigh (the sign traditionally attached to Gowers' name). In getting up from a recumbent position, the patient turns his head and trunk and pushes himself sideways to a sitting position. S.A.K. Wilson used an alliterative phrase to describe the characteristic abnormalities of stance and gait: The patient "straddles as he stands and waddles as he walks." The waddle is the result of bilateral weakness of the gluteus medius. Many affected boys have a tendency to walk on their toes as a consequence of contractures in the gastrocnemii muscles. Calf pain is frequent. Weakening of the muscles that fix the scapulae to the thorax (serratus anterior, lower trapezius, rhomboids) causes winging of the scapulae, and the scapular angles can sometimes be seen above the shoulders when one is facing the patient.

Later, weakness and atrophy spread to the muscles of the legs and forearms. The muscles that are preferentially affected among these are the neck flexors, wrist extensors, brachioradialis, costal part of the pectoralis major, latissimus dorsi, biceps, triceps, and anterior tibial and peroneal muscles. The ocular, facial, bulbar, and hand muscles are usually spared, although weakness of the facial and sternocleidomastoid muscles and of the diaphragm occurs in the late stages of the disease. As the trunk muscles atrophy, the bones stand out like those of a skeleton. The space between the lower ribs and iliac crests diminishes with atrophy and weakness of the abdominal muscles.

The limbs are usually loose and slack, but as the disability progresses, fibrous contractures appear as a result of the limbs remaining in one position and the imbalance between agonists and antagonists. Early in the ambulatory phase of the disease, the feet assume an equinovarus position as a result of shortening of the posterior calf muscles, which act without the normal opposition of the pretibial and peroneal muscles. Later, the hamstring muscles become permanently shortened because of a lack of counteraction of the weaker quadriceps muscles. Similarly, contractures occur in the hip flexors because of the relatively greater weakness of hip extensors and abdominal muscles. This leads to a pelvic tilt and compensatory lordosis to maintain standing equilibrium. The consequences of these contractures account for the habitual posture of the patient with Duchenne dystrophy: lumbar lordosis, hip flexion and abduction, knee flexion, and plantar flexion. As they become severe, these contractures contribute importantly to the eventual loss of ambulation.

Scoliosis, as a result of unequal weakening of the paravertebral muscles, and flexion contractures of the forearms appear, usually after walking is no longer possible.

The tendon reflexes are diminished and then lost as muscle fibers disappear, the ankle reflexes being the last to go. The bones are thin and demineralized, and the appearance of ossification centers is delayed. Smooth muscles are spared, but the heart is affected by various types of arrhythmias. The ECG shows prominent R waves in the right precordial leads and deep Q waves in the left precordial and limb leads, the result of cardiac fiber loss and replacement fibrosis of the basal part of the left ventricular wall (Perloff et al).

Death is usually the result of pulmonary infections and respiratory failure and sometimes, of cardiac decompensation. Patients with Duchenne dystrophy usually survive until late adolescence, but not more than 20 to 25 percent live beyond the twenty-fifth year. The last years of life are spent in a wheelchair; finally the patient becomes bedfast.

Mild degrees of developmental delay, which is non-progressive, are observed in many cases. The average IQ is 85 and approximately one-quarter have an IQ below 70, but the range has been 40 to 130.

As mentioned earlier, Roses and colleagues have studied the female carriers of the disease (i.e., the mothers of affected boys) and described slight weakness and enlargement of the calves as well as elevated CK values and abnormalities of the electromyogram (EMG) and muscle biopsy, all slight in degree, in more than half; as mentioned, this is far higher than in our experience and that of our colleagues. A small number of female carriers manifest a moderate myopathy that may mimic limb-girdle dystrophy (see further on). The muscle fibers of such patients (referred to as *manifesting* or *symptomatic* carriers) show a mosaic immunostaining pattern mentioned earlier, some fibers containing dystrophin and others lacking it (Hoffman et al, 1988). This diagnostic information is particularly helpful in genetic counseling.

The serum CK values are 25 to 200 times normal, which, with the EMG and muscle biopsy findings, help exclude spinal muscular atrophy. The EMG shows fibrillations, positive waves, low-amplitude and brief polyphasic motor unit potentials, and, sometimes, high-frequency discharges. The female carrier may occasionally display the same abnormalities, but to a much milder degree. The molecular and genetic bases of the disease are discussed further on.

Becker Muscular Dystrophy

This milder dystrophy is closely related to the Duchenne type clinically, genetically, and ultrastructurally. It had long been noted that mixed with the Duchenne group were certain relatively benign cases. In 1955, Becker and Keiner proposed that the latter be separated as a distinct entity, now called Becker muscular dystrophy. The incidence is difficult to ascertain, but it has been estimated as 3 to 6 per 100,000 male births. Like the Duchenne form, it is an X-linked disorder, practically limited to males and transmitted by females. It causes weakness and hypertrophy in

the same muscles as Duchenne dystrophy, but the onset is much later (mean age: 12 years; range: 5 to 45 years). While boys with Duchenne dystrophy are usually dependent on a wheel-chair by early in the second decade, it is not uncommon for those with Becker dystrophy to walk well into adult life. In comparison to Duchenne dystrophy, those with Becker and intermediate types retain their ability to raise the head fully off the bed. We have, for example, encountered patients who served in the military with the disease undetected. If maternal uncles are affected by the disease and are still walking, the diagnosis is relatively easy. Mentation is usually normal and cardiac involvement is far less frequent than in Duchenne dystrophy, but there are cases that present with a cardiomyopathy and we have been made aware of 2 brothers who had cardiac transplantation before the disease was detected. Kuhn and associates have reported a genealogy in which early myocardial disease and cramping myalgia were prominent features.

Pathology of Duchenne and Becker Dystrophies

In the early stages of Duchenne dystrophy, the most distinctive features are prominent segmental degeneration and phagocytosis of single muscle fibers or groups of fibers and evidence of regenerative activity (basophilia of sarcoplasm, hyperplasia and nucleation of sarcolemmal nuclei, and the presence of myotubes and myocytes). The necrosis excites a regenerative or restorative process, which explains the forking of fibers and clustering of small fibers with prominent nuclei. The necrotic sarcoplasm and sarcolemma are removed by mononuclear phagocytic (macrophage) cells. There may also be a few T lymphocytes in the region, suggesting inflammation. There is a hyalinization of the sarcoplasm of many degenerating and nondegenerating fibers. In longitudinal sections these are seen as "contraction bands," expressive of the irritability of dystrophic muscle. This phenomenon may be present before there is any significant degree of degeneration and is more extensive in Duchenne than in any of the other dystrophies. Eventually, there are histologic changes that are common to all types of advanced muscular dystrophies: loss of muscle fibers, residual fibers of larger and smaller size than normal, all in haphazard arrangement, and the secondary reaction of an increase in lipocytes and fibrosis.

Hypertrophy of muscle is apparently the result of work-induced enlargement of the remaining sound fibers in the face of adjacent fiber injury. However, examples of true hypertrophy of entire muscles prior to the first sign of weakness also occur and are difficult to explain. In these cases, large fibers may be present when at most there are only a few degenerating fibers. The more common feature of pseudohypertrophy is a result of lipocytic replacement of degenerated muscle fibers, but in its earlier stages, the presence of many enlarged fibers may contribute to the enlargement of muscle. Thus a true hypertrophy appears to give way to pseudohypertrophy. In the late stage of the dystrophic process, only a few scattered muscle fibers remain, almost lost in a sea of fat cells. It is notable that the late, or burned-out, stage of chronic polymyositis resembles muscular dystrophy in that the fiber population is depleted, the residual fibers are of

variable size, and fat cells and endomysial fibrous tissue are increased; lacking only are the hypertrophied fibers of dystrophy. This resemblance confirms that many of the typical changes of muscular dystrophy are nonspecific, reflecting mainly the chronicity of the myopathic process.

Etiology of Duchenne and Becker Dystrophies

The most important development in our understanding of the Duchenne and Becker muscular dystrophies was the discovery by Kunkel of the mutation on the X chromosome and of its gene product, *dystrophin* (Hoffman et al, 1987). The protein is expressed in skeletal, cardiac, and smooth muscle, as well as in brain. To date, the dystrophin gene is the largest one known in humans, spanning more than 2 Mb of DNA. This is in part the explanation for the observation that one-third of affected boys have a spontaneous mutation in the gene. The biochemical assay of dystrophin and its histochemical demonstration near the sarcolemma have made possible the accurate diagnosis of the Duchenne and Becker phenotypes and have clarified the relationship between these two disorders. Whereas dystrophin is absent in patients with the Duchenne phenotype, it is present but structurally abnormal in the Becker type. Moreover, phenotypes that fall between the classic Duchenne and Becker forms exist and are characterized by a lower-than-normal amount of dystrophin. The Duchenne and Becker dystrophies and their intermediate forms are spoken of as *dystrophinopathies*.

A slightly different form of dystrophin, originating in a different part of the gene, is found in neurons of the cerebellum and brainstem and in astrocytes, Purkinje cells, and Schwann cells at nodes of Ranvier (Harris and Cullen). A deficiency of cerebral dystrophin may in some yet unexplained way account for the mild cognitive developmental delay. It will be interesting to learn how such a deficiency might impair brain development and whether there is any connection to some cases of mental deficiency without muscular dystrophy.

Figure 48-1 schematically represents the structural basis of the dystrophinopathies and certain of the limb-girdle and congenital dystrophies described further on. In normal skeletal and cardiac muscle, dystrophin is localized to the cytoplasmic surface of the sarcolemma, where it interacts with F-actin of the cytoskeleton (the filamentous reinforcing structure of the muscle cell). Dystrophin is also tightly bound to a complex of sarcolemmal proteins known as dystrophin-associated proteins (DAPs) and to dystrophin-associated glycoproteins (DAGs). Of special biologic importance in this complex are these proteins and a 156-kDa glycoprotein called *dystroglycan*. The latter actually lies just outside the muscle cell and links the sarcolemmal membrane to the extracellular matrix (the inner portion of the basement membrane) by binding with merosin, a subunit of laminin. The dystrophin-glycoprotein complex functions in this scheme as a transsarcolemmal structural link between the subsarcolemmal cytoskeleton and the extracellular matrix. Moreover, each of these membrane-binding proteins (adhalin, merosin, and laminin) is implicated in specific muscular dystrophies, as discussed later in this chapter.

Figure 48-1. The molecular organization of the dystrophin-glycoprotein complex in the membrane and sarcolemma and endoplasmic reticulum-Golgi apparatus. These proteins are related to Duchenne, limb-girdle, Miyoshi, and certain congenital dystrophies. Details in text.

The loss of dystrophin leads to a parallel loss of DAPs and to disruption of the dystroglycan-protein complex. This change renders the sarcolemma susceptible to breaks and tears during muscle contraction, a hypothesis proposed first by Mokri and Engel and entirely consistent with the ultrastructural abnormalities that characterize Duchenne dystrophy. These authors demonstrated defects of the plasma membrane (sarcolemma) in a large proportion of nonnecrotic hyalinized muscle fibers, allowing ingress of extracellular fluid and calcium. The entrance of calcium is speculated to activate proteases and to increase protein degradation. The membrane defects and the associated alterations in the underlying region of the fiber represent the earliest and most basic pathologic change in Duchenne dystrophy and account for the leakage into the serum of CK and other enzymes of muscle.

Diagnosis of Duchenne and Becker dystrophies

The identification of dystrophin has made possible a number of highly refined tests for the diagnosis of Duchenne and Becker dystrophies, as well as for the carrier state. Analysis of the dystrophin gene in DNA obtained from white blood cells or from 50 mg of skeletal muscle can demonstrate the gene mutations in Duchenne and Becker patients and discriminate between these diseases. Also, immunostaining of muscle for dystrophin makes possible the differentiation of Duchenne, Becker, the carrier state, and other muscle disorders. An alternative method, developed by Byers and colleagues, uses an ELISA to measure the dystrophin levels in muscle biopsy samples. This testing is a rapid and relatively inexpensive tool for establishing the diagnosis of Duchenne and Becker muscular dystrophies and distinguishing them from unrelated disorders.

Other Rarer Dystrophinopathies

Testing for the dystrophin protein has also brought to light several much rarer types of dystrophin abnormalities. One, described by Gospe and coworkers, takes the form of a familial X-linked *myalgic-cramp-myoglobinuric syndrome*, resulting from the deletion of the first third of the dystrophin gene. The muscle changes are mild and relatively nonprogressive. Another dystrophinopathy takes the form of an X-linked *cardiomyopathy* characterized by progressive heart failure in young persons without clinical evidence of skeletal muscle weakness; biopsy of skeletal muscle reveals reduced immunoreactivity to dystrophin (Jones and de la Monte). In yet another type, a glycerol-kinase deficiency is associated with varying degrees of adrenal hypoplasia, mental retardation, and myopathy.

Emery-Dreifuss Muscular Dystrophy

This is a highly diverse group of disorders that encompasses at least six different genetic types, the most common probably being an X-linked muscular dystrophy characterized by the special feature of muscle contractures. That process is relatively benign in comparison with the Duchenne dystrophy. It was described originally by Emery and Dreifuss and subsequently by Hopkins and by Merlini and their colleagues. The primary gene defect is a deficiency of the protein emerin, a constituent of the nuclear membrane, encoded by a gene on the X chromosome (Fig. 48-2). However, also described are autosomal dominant forms with mutations in the gene for laminin A/C (called LGMD 1B, obviously affecting both girls and boys), an additional X-linked form due to mutations in FHL-1 as well as sporadic and dominant mutations of other genes encoding for entirely disparate proteins. Making a complete understanding of this syndrome even more complex is the recent appreciation that many of cases have none of these mutations.

Figure 48-2. Expanded schematic of the nuclear and contractile proteins of the muscle. These proteins are referable to Emery-Dreifuss dystrophy and a number of the distal and the congenital dystrophies, as well as several of the limb-girdle dystrophies. Details in text.

The age of onset varies from childhood to late adolescence or adulthood. Weakness affects first the upper arm and pectoral girdle musculature and later the pelvic girdle and the distal muscles in the lower extremities. The distinguishing feature of the disease is the early appearance of contractures in the flexors of the elbow, extensors of the neck, and posterior calf muscles. Facial muscles are affected occasionally. There is no hypertrophy or pseudohypertrophy, and mentation is unaffected. However, severe cardiomyopathy with variable sinoatrial and atrioventricular conduction defects is a common accompaniment.

The course of the myopathy is generally benign, more like that of Becker dystrophy, but weakness and contractures are severe in some cases and sudden cardiac death is a not infrequent occurrence. For this reason, close monitoring by a cardiologist and the prophylactic insertion of a pacemaker at the appropriate time may be lifesaving.

The less common types of Emery-Dreifuss dystrophy, as mentioned, may have a *scapulo-peroneal* (*FHL-1* gene) or *humero-peroneal* (laminin mutation).

Facioscapulohumeral Muscular Dystrophy (Landouzy-Dejerine Muscular Dystrophy)

This is a slowly progressive dystrophy involving primarily the musculature of the face and shoulders, often with long periods of nearly complete arrest. The pattern of inheritance is usually autosomal dominant. Almost all are of the facioscapulohumeral muscular dystrophy 1 (FSHD1) type; 5 to 10 percent are designated FSHD2, for which the mutation has recently been identified. The clinical presentations are very similar.

Although less common than the Duchenne and myotonic dystrophies, FSHD is not rare (an estimated yearly incidence rate of 5:100,000) and we have seen 1 or more cases yearly. The age of onset is usually between 6 and 20 years, but cases beginning in early adult life are occasionally encountered. Weakness and atrophy of the involved muscles are the major physical findings; pseudohypertrophy occurs only rarely and is slight. As a rule, the first manifestations are difficulty in raising the arms above the head and winging of the scapulae, although bifacial weakness may have initially attracted attention, even in early childhood. There is involvement especially of the orbicularis oculi, the zygomaticus, and the orbicularis oris, whereas the masseters, as well as the temporalis, extraocular, pharyngeal, and respiratory muscles are spared. There is an inability to close the eyes firmly, to purse the lips, and to whistle; the lips have a peculiar looseness and tendency to protrude. The lower parts of the trapezius muscles and the sternal parts of the pectorals are almost invariably affected. By contrast, the deltoids may seem to be unusually large and strong, an appearance that may be mistaken for pseudohypertrophy. The advancing atrophic process involves the sternocleidomastoid, serratus magnus, rhomboid, erector spinae, latissimus dorsi, and eventually the deltoid muscles as well. The bones of the shoulders become prominent;

the scapulae are winged and elevated ("angel-wing" appearance), and the clavicles stand out. The anterior axillary folds slope down and out as a result of wasting of the pectoral muscles. Usually the biceps waste less than the triceps, and the brachioradialis muscles even less, so that the upper arm may be thinner than the forearm ("Popeye" effect). Pelvic muscles are involved later and to a milder degree, giving rise to a slight lordosis and pelvic instability. The pretibial muscles weaken, and foot-drop is added to the waddling gait. The Beever sign, an upward movement of the umbilicus on flexing the neck as a result of weakness of the lower abdominal muscles, is reportedly common (Awerbuch et al), but we have not seen it in early cases.

Initially, and even throughout the course, the muscular weakness may be asymmetrical (winging of only one scapula). Many of the patients with milder degrees of this form of dystrophy are unaware that they have the disease. This was true of nearly half of the large series of patients described by Tyler and Stephens in the Utah Mormon population. At any point, the disease may become virtually arrested. Nevertheless, 15 to 20 percent of patients eventually require a wheelchair (Tawil et al).

An interesting feature of this group of diseases is the occasional congenital absence of a muscle (amyoplasia of one pectoral, brachioradialis, or biceps femoris) or part of a muscle in patients who later develop the typical features of the disease. The external ocular muscles are known to occasionally become affected late in the illness. Although cardiac involvement is rare, in a few cases tachycardia, cardiomegaly, and arrhythmias have occurred. Mental function is normal. Serum CK values are normal or slightly elevated.

At a molecular level, FSHD1 has been found to have a consistent association with deletions of variable size on the tip of chromosome 4q. This disorder is a consequence of alterations of a noncoding portion of DNA. Deletions in a repeated segment interfere with the structure of chromatin and allow the expression of normally inactive genes such as *DUX4*. Only patients with an allele that contains a repeat segment FSHD2 (called D4Z4 repeats) are susceptible to the disease. An entirely different mutation in a gene that maintains the structural integrity of chromatin accounts for the less common FSHD2; this change results in hypomethylation of the D4Z4 segments (an epigenetic mechanism) and is therefore also dependent on the permissive repeat allele.

A variant in which only the shoulder and arm muscles are affected, sparing the face, and a form with bilateral foot-drop are known (Krasnianski et al). In some cases, usually with severe deletions at the FSH locus on chromosome 4, there is an early-onset, relatively rapid progression and an association with facial diplegia, sensorineural deafness, and, sometimes, exudative retinal detachment (Coats disease). Using fluorescein angiography, Fitzsimmons and others have found a variety of other retinal abnormalities: telangiectasia, occlusion, leakage, and microaneurysms; in the majority of cases, suggesting that these retinal abnormalities are an integral part of the disease. Less common manifestations of FSHD

include isolated scapular winging or other focal weakness such as foot drop, sparing of facial muscles, a variant with limb-girdle weakness, and rare instances of PEO.

Scapulo-peroneal Muscular Dystrophy

Beginning with Brossard in 1886, there were numerous reports of a distinctive pattern of progressive muscular weakness and wasting that involved the muscles of the neck, shoulders, and upper arms, and of the anterior tibial and peroneal groups, causing severe foot-drop. The nature of this disorder has been a matter of controversy, some writers claiming it to be a progressive muscular dystrophy and others, a muscular atrophy of spinal or neuropathic type. Probably both are correct in that either process can produce more or less the same pattern of weakness. Davidenkow, who wrote extensively on this subject, described a form of familial scapulo-peroneal weakness and atrophy associated with areflexia and distal sensory loss (a spinal-neuropathic form) that was later found to have a mutation in the desmin gene, and others have confirmed these findings (see discussions of Thomas et al [1972, 1975] and of Munsat and Serratrice). Nevertheless, Thomas and colleagues (1975) firmly established the existence of a purely myopathic form and the mutation is in the *FHL-1* gene on the X-chromosome (see Table 48-1). The onset of symptoms in their 6 patients was in early or middle adult life, with difficulty in walking because of bilateral foot-drop; symptoms referable to scapulo-humeral involvement came later. Progression was slow, and none of the patients became severely incapacitated.

Limb-Girdle Muscular Dystrophies (Scapulo-humeral and Pelvifemoral Muscular Dystrophies, Erb Dystrophy) (See Table 48-1)

There is a large group of patients with muscular dystrophy who do not fit into the Duchenne/Becker, facioscapulo-humeral, or scapulo-peroneal categories. Children of both sexes in this group lack the hypertrophy of calves and other muscles; adults with late-onset forms have either pelvic or shoulder girdle involvement or both, and their facial muscles are spared. Because Wilhelm Erb first called attention to these types of dystrophy, they were classified by Walton and Nattrass as the "limb-girdle dystrophies of Erb." This clinically based grouping has been problematic from the time it was proposed because, like the scapulo-peroneal group, it is heterogeneous, the only unifying feature being the presence of limb-girdle weakness with sparing of the facial muscles. The inheritance is variable, but the autosomal recessive forms are the most common. Either the shoulder girdle or pelvic girdle muscles may be first affected (traditionally these forms had been referred to as the Erb juvenile atrophic and Leyden-Möbius types, respectively). Weakness and atrophy may become evident during either late childhood or early adult life and spread from shoulders to hips or vice versa.

The status of this group of limb-girdle muscular dystrophies (LGMDs) as a clinical-genetic entity is being steadily revised. The delineation of the progressive spinal

muscular atrophies and the congenital and metabolic myopathies has considerably narrowed the category of limb-girdle dystrophies as originally described. During the past decade, with the application of molecular genetic techniques, progress in this direction has accelerated greatly. The now well-populated class of limb-girdle dystrophies is classified as LGMD1 for the autosomal dominant types, and LGMD2 for the recessive types, and further subclassified based on the specific genotype. At the time of this writing, at least 19 forms of autosomal recessive (LGMD type 2A-2S) and 6 forms of autosomal dominant (LGMD type 1A-1E) limb-girdle dystrophies have been defined, most with an identifiable mutation and a protein that in most cases is a constituent of the sarcolemmal, sarcomeric, or nuclear membrane structural protein (Bushby). The later the onset of these disorders, the more likely that the course will be benign. In these lesser-affected patients the EMG is myopathic and the CK values are only moderately elevated and may be normal. More severe cases can have greatly elevated CK levels. Cardiac involvement occurs but is infrequent (mainly in the group classified as myofibrillar dystrophies), and mental function is normal, but there are exceptions including in cases of laminin A/C mutations (type 1B), *FKRP* (fukutin-related protein mutation) mutations (type 2I), and in the sarcoglycanopathies.

This information is summarized in Table 48-2 and discussion of the better-characterized types follows.

Limb-Girdle Muscular Dystrophy 2I (Fukutin-Related Protein Mutation)

The discovery of the "fukutin-related protein" initially came about because mutant forms caused a severe congenital muscular dystrophy (CMD). It later became apparent that certain mutations also cause a common type of later onset limb-girdle dystrophy. As the designation "2" indicates, it is transmitted in an autosomal recessive manner. This is the most common form of limb-girdle dystrophy in patients of Northern European descent. In a series of 16 patients from 14 families, Poppe and colleagues characterized the main features as having an onset of proximal girdle weakness in the second to fourth decades of life (but as early as age 2 years). The majority of patients eventually had respiratory failure and several displayed varying degrees of congestive heart failure, features that also accompany some of the other limb-girdle dystrophies. In most other ways, this disease reflects the heterogeneity of clinical presentation of the other subtypes of limb-girdle disease. A period of stabilization lasting several to 35 years is common, followed by a decade or more of progression that eventually involves the shoulder muscles. Most patients, particularly those with later onset, remained able to walk into their forties. Other features are variable, for example, dysphagia and ptosis; however, distal weakness is not seen and intelligence is normal.

The defective *FKRP* gene is related in function to 4 other muscle genes in addition to fukutin (hence its name). All 5 of these genes are glycosyl transferases that attach sugar groups to proteins such as alpha-dystroglycan. The

severity of the clinical phenotype is inversely related to the levels of glycosylation of alpha-dystroglycan. Defects in any of the 5 genes can cause developmental lesions in the brain in addition to muscle disease, although those associated with FKRP mutations are less common and less severe.

Severe Childhood Autosomal Recessive Muscular Dystrophy (Sarcoglycanopathies; LGMD 2C, D, E, and F)

These entities comprise the best-defined group of limb-girdle dystrophy. Clinically they resemble severe Duchenne dystrophy in practically all respects, including the presence of calf hypertrophy, cardiomyopathy, and marked elevation of CK in the early stages of the illness. The obvious distinction from Duchenne dystrophy is the autosomal recessive pattern of inheritance (affection of both girls and boys in the same sibship). The largest and best-studied group of this severe, recessive pelvic-pectoral dystrophy (99 children in 28 families) has come from Tunisia (Ben Hamida et al). It also occurs commonly in other Arab countries and has been observed repeatedly in Brazil, but less so in Europe and North America.

The basic defect is in 1 of 4 dystrophin-associated glycoproteins (DAGs)— α -, β -, γ - and δ -sarcoglycan (see Fig. 48-1); α -sarcoglycan (designated 50 DAG) is also called adhalin, from the Arabic word *adhal*, meaning muscle. A primary deficiency of adhalin has been traced to a defective gene on chromosome 17q21 (Roberds et al). A primary defect in β -sarcoglycan (43 DAG) has been mapped to chromosome 4q12, of γ -sarcoglycan (35 DAG) to the pericentromeric region of chromosome 13q, and of δ -sarcoglycan (43 DAG) to chromosome 5q. Primary defects in 25 DAG may also lead to a deficiency of adhalin, but the latter is incomplete and represents a secondary effect, possibly explained by the proximity of the defective genes to the adhalin gene.

Because of clinical similarities, there may be difficulty in distinguishing limb-girdle dystrophies (formerly termed severe childhood autosomal recessive muscular dystrophy [SCARMD]) from a dystrophinopathy (except that the former occur in females). In addition to the difference in inheritance, they can be readily diagnosed by showing a loss of sarcolemmal immunostaining for any of the dystrophin-associated glycoproteins but with preservation of staining for dystrophin itself. However, it is not possible on clinical grounds to distinguish one sarcoglycanopathy from another; this can be accomplished only by specific immunostaining.

Autosomal Recessive Muscular Dystrophy (LGMD 2A and B; Calpain-3 and ANO-5 Mutations)

These forms of limb-girdle dystrophies have been described in large kindreds, in Indiana (among the Amish people), on the island of Réunion in the Indian Ocean, in Brazil, Great Britain, Italy and Spain, and elsewhere, affecting males and females equally. Both the shoulder and pelvic girdles are involved. The degree of weakness has varied considerably. In one form of the disease,

called LGMD2A, the abnormal gene codes for a calcium-activated neutral protease, or calpain (see Fig. 48-2). This “calpainopathy” is currently believed to account for approximately 40 percent of patients with LGMD. Frequently, and early in the course of disease, there are Achilles tendon contractures and very high serum CK levels (at least 10 times normal), features that may permit distinction from the sarcoglycanopathies.

Yet another fairly common recessive limb-girdle dystrophy of slow progression is caused by a mutation in the gene for the protein dysferlin, which localizes to the muscle fiber membrane. Noteworthy is the fact that this same protein is involved in the distal form of Miyoshi muscular dystrophy described further on. Early involvement of the gastrocnemius muscle (inability to walk on tiptoe) and extraordinarily high levels of CK, as in calpainopathy, are clues to the latter disease.

Autosomal Dominant Limb-Girdle Dystrophies (LGMD 1A-1E)

Several dystrophies with the LGMD phenotype are inherited as autosomal dominant traits. For example, LGMDA 1A is an autosomal dominant limb-girdle dystrophy of late onset that was described in a large North Carolina family (49 affected members in a pedigree of 218 persons). The mean age at onset was 27 years. Proximal leg weakness, with or without proximal arm weakness, and elevated CK values were the main clinical characteristics. Speer and colleagues have documented that the primary defect is in a gene encoding the protein *myotilin* (see Fig. 50-2). LGMDA 1A is allelic to a form of myofibrillar myopathy.

LGMD 1B is a dominantly inherited disorder arising from mutations in the gene encoding the nuclear membrane protein *lamin A/C* (see Fig. 50-2). Mercuri and colleagues note that the phenotypes of these mutations vary widely. The muscle disorders range from severe cases that mimic CMD to milder ones with features of limb girdle dystrophy or Emery-Dreifuss muscular dystrophy. The diverse, nonmuscular manifestations of *lamin A/C* mutations include a cardiomyopathy, a form of lipodystrophy, a syndrome of accelerated aging (Hutchinson-Gilford progeria), and a recessively inherited axonal neuropathy.

Progressive External Ophthalmoplegia (Kearns-Sayre Syndrome) (See also “Progressive External Ophthalmoplegia [PEO] and Kearns-Sayre Syndrome” in Chap. 37)

This has proved to be a confusing group of processes characterized by slowly progressive myopathy primarily involving and often limited to the extraocular muscles. Usually, the levators of the eyelids are the first to be affected, causing ptosis, followed by progressive balanced ophthalmoparesis. This disorder usually begins in childhood, sometimes in adolescence, and rarely in adult life (as late as 50 years).

Several types have been described. The most common one arises from either deletions or point mutations in mitochondrial DNA and are discussed in Chap. 37

with other metabolic disorders. However, when the foregoing progressive external ophthalmoplegia (PEO) categories are eliminated, there remains a distinctly different category of dominantly inherited PEO. Males and females are equally affected; the pattern of inheritance is autosomal dominant in some and recessive or uncertain in others. Once started, the disease progresses relentlessly until the eyes are motionless. Simultaneous involvement of all extraocular muscles permits the eyes to remain in a central position, so that strabismus and diplopia are uncommon (in rare instances, one eye is affected before the other). The pupillary responses and accommodation are normal. As the patient attempts to raise his eyelids and to see under them, the head is thrown back and the frontalis muscle is contracted, wrinkling the forehead (hutchinsonian facies). The eyelids are abnormally thin due to atrophy of the levator muscles. The orbicularis oculi muscles are frequently involved in addition to the extraocular muscles. Thus, in PEO, as in myasthenia gravis and myotonic dystrophy, there can be a characteristic combination of weakness of eye closure and eye opening, a combination that is nearly always myopathic. Other facial muscles, masseters, sternocleidomastoids, deltoids, or peronei are variably weak and wasted in approximately 25 percent of cases. The characteristic feature of PEO is that ptosis and ocular paralysis precede involvement of other muscles by many years.

Given that there is considerable clinical overlap between the mitochondrial syndrome and dominantly inherited PEO, it is not surprising that some of the dominantly inherited gene defects causing PEO result in disturbances in mitochondrial DNA. Mutations in three nuclear genes have been implicated. (These are *twinkle*, a mitochondrial DNA binding protein; *ANT1*, an adenine nucleotide transporter in the intermembrane space in the mitochondrion; and *POLG*, a subunit of the mitochondrial DNA polymerase.) There are also recessively inherited instances of familial PEO, one of which involves a nuclear gene.

Oculopharyngeal Dystrophy (See Table 48-2)

Oculopharyngeal dystrophy is inherited as an autosomal dominant trait and is unique in its late onset (usually after the forty-fifth year) and the restricted muscular weakness, manifest mainly as a bilateral ptosis and dysphagia. E.W. Taylor first described the disease in 1915 and assumed that it was caused by a nuclear atrophy (oculomotor-vagal complex). However, Victor and colleagues, in 1962, showed that the descendants of Taylor's cases had a late-life dystrophy (myopathic EMG and biopsy). One of the families described by Victor, Hayes, and Adams was subsequently traced by Barbeau through 10 generations to an early French-Canadian immigrant, who was the progenitor of 249 descendants with the disease. Other families showing a dominant (rarely recessive) pattern of inheritance and a number of sporadic cases have been observed in many parts of the world.

Difficulty in swallowing and change in voice are associated with slowly progressive ptosis. Swallowing becomes so difficult that food intake is limited, resulting in

cachexia, which can be ameliorated by cutting the cricopharyngeus muscles, or, if that fails, by a gastrostomy or nasogastric tube. Later in the disease, in some families the external ocular muscles and shoulder and pelvic muscles become weakened and atrophic to a varying extent. In the few autopsied cases, a loss of fibers of modest proportions was widespread in these and many other muscles. Rimmed vacuoles in the sarcoplasm and, by electron microscopy, intranuclear tubular filaments are characteristic but not specific histologic findings (these features are seen in other myopathies, particularly in inclusion body myositis). The brainstem nuclei and cranial nerves are normal. As in the other mild and restricted muscular dystrophies, the serum CK and aldolase levels are normal and the EMG is altered only in the affected muscles.

The gene product is a protein that binds to RNA (poly-A binding protein). The defect is an expansion of a string of alanines. Normally, there are 6 repeats; in dominantly inherited oculopharyngeal dystrophy, there are 8 to 13 repeats; in the recessively inherited form there are 7 repeats on each allele. Thus this represents one of the most subtle nucleotide expansion diseases yet discovered.

Myotonic Dystrophy Types 1 and 2

There are 2 types of myotonic dystrophies (DM1 and DM2/PROMM). Type 1 (DM1) is the most common adult muscular dystrophy. It was described in 1909 by Steinert, who considered it to be a variant of congenital myotonia (Thomsen disease; see Chap. 50) and in the same year by Batten and Gibb, who recognized it as a unique clinical entity.

DM1 is distinguished by an autosomal dominant pattern of inheritance with a high level of penetrance, special topography of the muscle atrophy, associated obvious myotonia, and occurrence of dystrophic changes in nonmuscular tissues (lens of eye, testicle and other endocrine glands, skin, esophagus, heart, and, in some cases, the cerebrum). Certain muscles, the levator palpebrae, facial, masseter, sternocleidomastoid, and forearm, hand, and pretibial muscles, are consistently involved in the dystrophic process. It is possible that Gowers' famous case of an 18-year-old youth with weakened and wasted anterior tibial and forearm muscles and sternocleidomastoids, in conjunction with paresis of the orbicularis and frontalis muscles, was an example of this disease.

Despite some clinical variability of myotonic dystrophy, the defective gene in the first type has been the same in every population that has been studied. At this locus on chromosome 19q there is a specific molecular defect, an unstable trinucleotide sequence (CTG) in the *DMPK* gene that is longer in affected individuals than it is in healthy siblings or unaffected subjects. Whereas healthy individuals will have 5 to 30 CTG repeats, patients with myotonic dystrophy have 50 to 2,000. Longer sequences are associated with more severe disease, and they increase in size through successive generations lead to earlier occurrence (genetic anticipation). The CTG repeats reside within the myotonin protein kinase gene. It is of considerable interest that these CTG repeating segments do not code

for a protein (i.e., they are intronic), quite unlike conditions such as Huntington disease in which the triplet expansion codes for amino acid sequences within a protein.

The milder type 2 myotonic dystrophy (DM2) is caused by an expanded triplet repeat in the *CNBP* gene on chromosome 3, as discussed further on under "Proximal Myotonic Myopathy (PROMM, DM2)." A critical element in the pathogenesis of this disease in both types is the intranuclear accumulation of the expanded RNA sequences; these disrupt the regulation of alternative splicing of mRNA and perturb the expression of many genes, thus the multiple systems affected clinically.

Clinical Features of DM1

In most instances of myotonic dystrophy, the weakness and muscular wasting do not become evident until early adult life, but they may present in childhood, usually with facial weakness and ptosis. Also, a severe *neonatal (congenital) form* of the disease is well known and is described separately further on.

In the common early adult form of the disease, the small muscles of the hands along with the extensor muscles of the forearms are often the first to become atrophied. In other cases, ptosis of the eyelids and thinness and slackness of the facial muscles may be the earliest signs, preceding other muscular involvement by many years. Atrophy of the masseters leads to narrowing of the lower half of the face, and the mandible is slender and malpositioned so that the teeth do not occlude properly. This, along with the ptosis, frontal baldness, and wrinkled forehead, imparts a distinctive physiognomy that, once seen, can be recognized at a glance ("hatchet" face). The sternocleidomastoids are almost invariably thin and weak and are associated with an exaggerated forward curvature of the neck ("swan neck"). Atrophy of the anterior tibial muscle groups, leading to foot-drop, is an early sign in some families.

Pharyngeal and laryngeal weakness results in a weak, monotonous, nasal voice. The uterine muscle may be weakened, interfering with normal parturition, and the esophagus is often dilated because of loss of muscle fibers in the striated as well as smooth muscle parts. Megacolon occurs in some patients. Diaphragmatic weakness and alveolar hypoventilation, resulting in chronic bronchitis and bronchiectasis, are common late features, as are cardiac abnormalities; the latter are most often a result of disease of the conducting apparatus, giving rise to bradycardia and a prolonged P-R interval. Patients with extreme bradycardia or atrial tachyarrhythmia or high degrees of atrioventricular block may die suddenly; for such individuals, insertion of a pacemaker is often recommended (Moorman et al; Groh et al). Mitral valve prolapse and left ventricular dysfunction (cardiomyopathy) are less frequent abnormalities. In this disorder, as in Emery-Dreifuss dystrophy, careful assessment by a knowledgeable cardiologist is required.

The disease progresses slowly, with gradual involvement of the proximal muscles of the limbs and muscles of the trunk. Tendon reflexes are lost or much reduced. Contracture is rarely seen, and the thin, flattened hands

are consequently soft and pliable. Most patients are confined to a wheelchair or bed within 15 to 20 years of the first signs, and death occurs before the normal age from pulmonary infection, heart block, or heart failure.

The phenomenon of *myotonia*, which expresses itself in prolonged idiomuscular contraction following brief percussion or electrical stimulation and in delay of relaxation after strong voluntary contraction, is the third striking attribute of the disease (the other two being the facial, ptotic, and limb weakness, and the cardiac-autoimmune features). Not as widespread or severe as in myotonia congenita, it is, nonetheless, easily elicited in the hands and tongue in almost all cases, and in the proximal limb muscles in half of the cases. Gentle movements do not evoke it (eye blinks, movements of facial expression, and the like are not impeded), whereas strong closure of the lids and clenching of the fist are followed by a long delay in relaxation.

Myotonia may precede weakness by several years. Indeed, Maas and Paterson have claimed that many cases diagnosed originally as myotonia congenita eventually proved to be examples of myotonic dystrophy. Of interest is the fact that in congenital or infantile cases of myotonic dystrophy, the myotonic phenomenon is not elicited until later in childhood, after the second or third year of life (see later). The child often becomes accustomed to the myotonia and does not complain about it. The relation of myotonia to the dystrophy is not direct. Certain muscles that show the myotonia best (tongue, flexors of fingers) are seldom weak and atrophic. Moreover, there may be little or no myotonia in certain families that show the other characteristic features of myotonic dystrophy. The muscle hypertrophy that is characteristic of myotonia congenita is not a feature of myotonic dystrophy.

The fourth major characteristic of the disease is the dystrophic change in nonmuscular tissues. The most common of these is lenticular opacities, found by slit-lamp examination in 90 percent of patients. At first dust-like, they then form small, regular opacities in the posterior and anterior cortex of the lens just beneath the capsule; under the slit lamp they appear blue, blue-green, and yellow, and are highly refractile. Microscopically, the crystalline material (probably lipids and cholesterol, which cause the iridescence) lies in vacuoles and lacunae among the lens fibers. In older patients, a stellate cataract slowly forms in the posterior cortex of the lens.

Mild to moderate degrees of developmental cognitive delay are common in DM1, and the brain weight in several of our patients was 200 g less than that in normal individuals of the same age. Late in adult life, some patients become suspicious, argumentative, and forgetful. In some families, a hereditary sensorimotor neuropathy may be added to the muscle disease (Cros et al). Other nonspecific abnormalities, such as hyperostosis of the frontal bones and calcification of the basal ganglia, both readily discerned by CT, seem to be more common in patients with myotonic dystrophy than they are in healthy persons.

Progressive frontal alopecia, beginning at an early age, is a characteristic feature in both men and women

with this disease. Testicular atrophy with androgenic deficiency, reduced libido or impotence, and sterility are additional frequent manifestations. In some patients gynecomastia and elevated gonadotropin excretion are found. Testicular biopsy shows atrophy and hyalinization of tubular cells and hyperplasia of Leydig cells. (Thus all the clinical characteristics of the Klinefelter syndrome may be present but without the "sex chromatin" mass [Barr body].) Ovarian deficiency occasionally develops in the female patient, but it is seldom severe enough to interfere with menstruation or fertility. The prevalence of clinical or chemical diabetes mellitus is slightly increased in patients with myotonic dystrophy, but an increased insulin response to a glucose load has proved to be a common abnormality. Numerous surveys of other endocrine functions have yielded little of significance.
