drug intoxication may obliterate reflex eye movements. Conversely, *certain structural lesions of the cerebral hemispheres are so diffuse as to produce a picture that simulates a metabolic disturbance*; TTP, fat embolism, vasculitis, intravascular lymphoma, acute disseminated encephalomyelitis, and the late effects of global ischemia–anoxia are examples of such states. At other times, they cause a diffuse encephalopathy with superimposed focal signs.

Unilateral cerebral infarction because of anterior, middle, or posterior cerebral artery occlusion produces no more than drowsiness, as a rule; however, with massive unilateral infarction as a result of carotid artery occlusion, coma can occur if extensive brain edema and secondary tissue shift develop. There are exceptional cases wherein stupor results from massive infarction of the dominant (left) hemisphere. Edema of a degree serious enough to compress the brainstem and cause coma seldom develops before 12 or 24 h. Rapidly evolving hydrocephalus causes smallness of the pupils, rapid respiration, extensor rigidity of the legs, Babinski signs, and sometimes a loss of eye movements.

Of course, diagnosis has as its prime purpose the direction of therapy. The treatable causes of coma are drug and alcohol intoxications, shock from infection, cardiac failure, or systemic bleeding, uremia, epidural and subdural hematomas, brain abscess, bacterial and fungal meningitis, diabetic acidosis or hyperosmolar state, hypoglycemia, hypo- or hypernatremia, hepatic coma, hypercalcemia, uremia, status epilepticus, Wernicke disease, Hashimoto encephalopathy, and hypertensive encephalopathy. Also treatable to a varying degree are cerebellar hemorrhages, which can be removed successfully; edema from massive stroke, which may be ameliorated by hemispherectomy; and hydrocephalus from any cause, which may respond to ventricular drainage.

Management of the Acutely Comatose Patient

Seriously impaired states of consciousness, regardless of their cause, are often fatal not only because they represent an advanced stage of many diseases but also because they add their own particular burdens to the primary disease. The physician's main objective, of course, is to find the cause of the coma and to treat it appropriately. It often happens, however, that the disease process is one for which there is no specific therapy; or, as in hypoxia or hypoglycemia, the acute, irreversible effects have already occurred before the patient comes to the attention of the physician. Again, the problem may be highly complex, for the disturbance may be attributable not to a single cause but to several factors acting in unison, no one of which could account for the total clinical picture. In certain circumstances two processes contribute to depressing consciousness, particularly head injury combined with drug or alcohol intoxication. In lieu of specific therapy, supportive measures must be used; indeed, the patient's chances of surviving the original disease often depend on the effectiveness of these general medical measures.

The successful management of the insensate patient requires the services of a well-coordinated team of nurses

and a physician. Necessary treatments must be instituted rapidly, even before all the diagnostic steps have been completed; diagnosis and treatment may have to proceed concurrently. The following is a brief outline of the principles involved in the treatment of such patients. The details of management of shock, fluid and electrolyte imbalance, and other complications that threaten the comatose patient (pneumonia, urinary tract infections, deep venous thrombosis, etc.) can be found in *Harrison's Principles of Internal Medicine*.

1. Shallow and irregular respirations, stertorous breathing (indicating obstruction to inspiration), and cyanosis require the establishment of a clear airway and delivery of oxygen. The patient should initially be placed in a lateral position so that secretions and vomitus do not enter the tracheobronchial tree. Secretions and vomitus should be removed by suctioning as soon as they accumulate; otherwise they will lead to atelectasis and bronchopneumonia. Arterial blood gases should be measured and further observed by monitoring of oxygen saturation. A patient's inability to protect against aspiration and the presence of either hypoxia or hypoventilation dictate the use of endotracheal intubation and a positive-pressure respirator.
2. The management of shock, if present, takes precedence over all other diagnostic and therapeutic measures.
3. Concurrently, an intravenous line is established and blood samples are drawn for determination of glucose, intoxicating drugs, and electrolytes and for tests of liver and kidney function. Naloxone, 0.5 mg, should be given intravenously if a narcotic overdose is a possibility. Hypoglycemia that has produced stupor or coma requires the infusion of glucose, usually 25 to 50 mL of a 50 percent solution followed by a 5 percent infusion; this must be supplemented with thiamine. A urine sample is obtained for drug and glucose testing. If the diagnosis is uncertain, both naloxone and the glucose-thiamine combination should be administered.
4. With the development of elevated intracranial pressure from a mass lesion, mannitol, 25 to 50 g in a 20 percent solution, should be given intravenously over 10 to 20 min and hyperventilation instituted if deterioration occurs, as judged by pupillary enlargement or deepening coma. Repeated CT scanning allows the physician to follow the size of the lesion and degree of localized edema and to detect displacements of cerebral tissue. With massive cerebral lesions, it may be appropriate to place a pressure-measuring device in the cranium of selected patients (see Chap. 35 for details of intracranial pressure monitoring and treatment).
5. A lumbar puncture should be performed if meningitis or subarachnoid hemorrhage is suspected on the basis of headache and meningismus (and fever in the case of infectious meningitis), keeping in mind the risks of this procedure and the means of dealing with them. A CT scan may have disclosed a primary

subarachnoid hemorrhage, in which case lumbar puncture is not necessary. In the case of meningitis, broad-spectrum antibiotics that penetrate the meninges should be instituted immediately, independent of the timing of the lumbar puncture. The choice of drug is then determined by the principles set forth in Chap. 32. If CSF pressure is greatly elevated when measured from a lumbar puncture that has been performed to diagnose bacterial meningitis, it has been recommended that the stylette should be left in the lumen of the needle, as little CSF should be withdrawn as is necessary for diagnostic purposes, and mannitol or hypertonic saline should be administered to lower the pressure.

6. Convulsions should be controlled by measures outlined in Chap. 16, usually by intravenous diazepam.
7. As indicated earlier, gastric aspiration and lavage with normal saline may be diagnostically and therapeutically useful in some instances of coma due to drug ingestion. Salicylates, opiates, and anticholinergic drugs (tricyclic antidepressants, phenothiazines, scopolamine), all of which induce gastric atony, may be recovered many hours after ingestion. Caustic materials should not be lavaged because of the danger of gastrointestinal perforation. The administration of activated charcoal is indicated in certain drug poisonings. Measures to prevent gastric hemorrhage and excessive gastric acid secretion are usually advisable.
8. The temperature-regulating mechanisms may be disturbed and extreme hypothermia or hyperthermia should be corrected. In severe hyperthermia, evaporative-cooling measures are indicated in addition to antipyretics.
9. The bladder should not be permitted to become distended; if the patient does not void, decompression should be carried out with an indwelling catheter. Needless to say, the patient should not be permitted to lie in a wet or soiled bed.
10. Diseases of the CNS may disrupt the control of water, glucose, and sodium. The unconscious patient can no longer adjust the intake of food and fluids by hunger and thirst. Both salt-losing and salt-retaining syndromes have been described with brain disease (see Chap. 27). Water intoxication and severe hyponatremia may of themselves prove damaging. If coma is prolonged, the insertion of a nasogastric tube will ease the problems of feeding the patient and maintaining fluid and electrolyte balance. It is quite acceptable to leave the tube in place for long periods. Otherwise, approximately 35 mL/kg of isotonic fluid should be administered per 24 h (5 percent dextrose in 0.45 percent saline with potassium supplementation unless there is brain edema, in which case the use of hypertonic normal saline is indicated).
11. Aspiration pneumonia is avoided by prevention of vomiting (gastric tube and endotracheal intubation), proper positioning of the patient, and restriction of

oral fluids. Should aspiration pneumonia occur, it requires treatment with appropriate antibiotics and aggressive pulmonary physical therapy. Oral decontamination with chlorhexidine is advised to reduce the incidence of ventilator-associated pneumonia.

12. Leg vein thrombosis, a common occurrence in comatose and hemiplegic patients, often does not manifest itself by obvious clinical signs. An attempt may be made to prevent it by the subcutaneous administration of heparin, 5,000 U q12h, or of low-molecular-weight heparin, and by the use of intermittent pneumatic compression boots. There are few absolute contraindications to the prophylactic use of low-dose anticoagulants such as heparin and enoxaparin.
13. If the patient is capable of moving, suitable restraints should be used to prevent him from falling out of bed and to avert self-injury from convulsions.
14. Regular conjunctival lubrication and oral cleansing should be instituted.

Prognosis of Coma (See also "Prognosis of Hypoxic-Ischemic Brain Injury" in Chap. 40.)

As a general rule, recovery from coma of metabolic and toxic causes is far better than from anoxic coma, with head injury occupying an intermediate prognostic position. Most patients who are initially comatose as a result of a stroke will die; subarachnoid hemorrhage in which coma is a result of hydrocephalus is an exception and those cases in which brain shift is relieved by craniectomy are also exceptions. In regard to all forms of coma, but particularly after cardiac arrest, if there are no pupillary, corneal, or oculovestibular responses within 1 day of the onset of coma, the chances of regaining independent function are practically nil (Levy et al). Other signs that predict a poor outcome are absence of corneal reflexes, eye-opening responses, atonia of the limbs at 1 and 3 days after the onset of coma, and absence of the cortical component of the somatosensory-evoked responses on both sides (see Booth et al for an analysis of prior studies and consult Chap. 40 for further details). It is the unfortunate survivor from this latter group who may remain in a vegetative state for months or years, breathing without aid and with preserved hypothalamopituitary functions. The frequency of vegetative state after head injury and the negligible chances of improvement if the condition persists for several months have already been discussed, and a discussion of the outcome of anoxic-ischemic coma can be found in Chap. 40. The novel perspectives that have been introduced by demonstrating residual and willful cognitive activity in survivors of traumatic brain injury have been discussed in an earlier section.

In all other cases, the nature of the underlying disease determines outcome; the reader should refer to the appropriate sections of this book for details.

Faintness and Syncope

The term *syncope* (Greek: *synkope*) literally means a “cessation,” a “cutting short,” or “pause.” Medically, it refers to an episodic loss of consciousness and postural tone and an inability to stand because of a diminished flow of blood to the brain. It is synonymous in everyday language with *fainting*. *Feeling faint* and a *feeling of faintness* are also commonly used terms to describe the loss of strength and other symptoms that characterize the impending or incomplete fainting spell. This latter state is referred to as *presyncope*. Relatively abrupt onset, brief duration, and spontaneous and complete recovery not requiring specific resuscitative measures are other typical features.

Faintness and syncope are among the most common of all medical problems. Practically every adult has experienced some presyncopal symptoms, if not a fully developed syncopal attack, or has observed such attacks in others. Description of these symptoms, as with other predominantly subjective states, is often ambiguous. The patient may refer to the experience as light-headedness, dizziness, a “drunk feeling,” a weak spell, or, if consciousness was lost, a “blackout.” Careful questioning may be necessary to ascertain the exact meaning the patient has given to these words. In many instances the nature of the symptoms is clarified by the fact that they include a sensation of faintness and then a momentary loss of consciousness, which is easily recognized as a faint, or syncope. This sequence also informs us that under certain conditions any difference between faintness and syncope is only one of degree. These symptoms must be clearly set apart from certain types of epilepsy, the other major cause of episodic unconsciousness, and from disorders such as cataplexy, transient ischemic attacks (TIAs), “drop attacks,” and vertigo, which are also characterized by episodic attacks of generalized weakness or inability to stand upright, but not by a loss of consciousness.

CAUSES OF EPISODIC FAINTNESS AND SYNCOPE

From a clinical perspective, syncope is essentially of three main types, all ultimately causing hypotension and each of which may lead to a temporary reduction in the flow of blood to the brain. The first, reflex withdrawal of vascular

sympathetic tone (vasodepressor effect), triggered by centrally mediated inhibition of the normal tonic sympathetic influences, is often associated with excessive vagal effect and bradycardia (vagal effect). The type associated with bradycardia is called *vasovagal syncope*, a special form of neurogenic, or *neurocardiogenic syncope*, by which is meant the withdrawal of sympathetic tone through a reflex neural mechanism. Neurocardiogenic syncope usually signifies that the inciting stimulus originates in neural receptors within the heart. Each may cause the common faint, the clinical details of which are described later.

The second is a failure of sympathetic innervation of blood vessels and of autonomically activated compensatory responses (reflex tachycardia and vasoconstriction), which occurs with assumption of the upright body position and leads to pooling of blood in the lower parts of the body—causing *orthostatic hypotension* and syncope. Typically, in individuals with these first two forms of syncope, there is no evidence of underlying cardiac disease.

Syncope of a third type is caused by a primary diminished cardiac output because of disease of the heart itself as in the Stokes-Adams bradyarrhythmia attack, severe aortic or subaortic stenosis, or ischemic heart disease. Greatly reduced blood volume from dehydration or blood loss usually causes only near syncope, but complete loss of consciousness may certainly occur in severe circumstances.

As a rough guide to the relative frequency of the various causes of syncope, the large amount of information from the Framingham Heart Study accumulated by Soteriades and colleagues can be taken as representative: the leading cause was vasovagal, a cardiac cause was established in about 10 percent; and orthostatic hypotension in another 10 percent. Also, 7 percent of cases were attributed to medications, mainly those that interfered with sympathetic tone, and remaining 40 percent could not be categorized.

The three main types of syncope as well as several others that cannot readily be classified within these categories can be further subdivided by their pathophysiologic mechanism, as follows:

- I. Neurogenic vasodepressor reactions
 - A. Elicited by *extrinsic signals* to the medulla from baroreceptors
 1. Vasodepressor (vasovagal)
 2. Neurocardiogenic

3. Carotid sinus hypersensitivity
4. Vaguglossopharyngeal
5. Severe pain, especially if arising in a viscera (bowel, ovary, testicle, etc.)
- B. Coupled with diminished venous return to the heart
 1. Micturitional
 2. Tussive
 3. Valsalva, straining, breathholding, weight lifting
 4. Postprandial
- C. Intrinsic and extrinsic psychic stimuli
 1. Fear, anxiety (presyncope is more common)
 2. Sight of blood
 3. Hysterical
- II. Failure of sympathetic nervous system innervation (postural–orthostatic hypotension)
 - A. Peripheral nervous system autonomic failure (peripheral neuropathy, autonomic neuropathy)
 1. Diabetes
 2. Pandysautonomia
 3. Guillain-Barré syndrome
 4. Amyloid neuropathy
 5. Surgical sympathectomy
 6. Antihypertensive medications and other blockers of vascular sympathetic innervation and presynaptic alpha agonists
 7. Pheochromocytoma
 - B. Central nervous system (CNS) autonomic failure
 1. Primary autonomic failure (idiopathic orthostatic hypotension)
 2. Multiple system atrophy (parkinsonism, ataxia, orthostatic hypotension)
 3. Lewy-body and Parkinson diseases
 4. Spinal cord trauma, infarction, and necrosis
 5. Centrally acting antihypertensive and other medications
- III. Reduced cardiac output or inadequate intravascular volume (hypovolemia)
 - A. Reduced cardiac output
 1. Cardiac arrhythmias
 - a. Bradyarrhythmias
 - i. Atrioventricular (AV) block (second and third degree) with Stokes-Adams attacks
 - ii. Ventricular asystole
 - iii. Sinus bradycardia, sinoatrial block, sinus arrest, sick sinus syndrome
 - b. Tachyarrhythmias
 - i. Episodic ventricular tachycardia
 - ii. Supraventricular tachycardia (infrequently causes syncope)
 2. Myocardial: angina, infarction, or severe congestive heart failure with reduced cardiac output
 3. Obstruction to left ventricular or aortic outflow: aortic stenosis, hypertrophic subaortic stenosis, Takayasu arteritis
 4. Obstruction to pulmonary flow: pulmonic stenosis, tetralogy of Fallot, primary pulmonary hypertension, pulmonary embolism
 5. Pericardial tamponade

B. Inadequate intravascular volume (hemorrhage); dehydration

- IV. Other causes of episodic faintness and syncope
 - A. Hypoxia
 - B. Severe anemia
 - C. Diminished CO₂ as a result of hyperventilation (faintness common, syncope rare)
 - D. Hypoglycemia (faintness frequent, syncope rare)
 - E. Anxiety (panic) attacks
 - F. Environmental overheating

This list of conditions causing faintness and syncope is deceptively long and involved, but the usual types are reducible to a few well-established mechanisms. So as not to obscure these mechanisms by too many details, only the varieties of fainting commonly encountered in clinical practice and those of particular neurologic interest are discussed below.

CLINICAL FEATURES OF SYNCOPE

The Common Faint (Vasodepressor Syncope)

This is the common faint, seen mainly in young individuals. A familial predisposition is well known (Mathias et al). The evocative factors are usually strong emotion, physical injury—particularly to viscera (testicles, gut)—or other factors (see below). As described earlier, the vasodilatation of adrenergically innervated “resistance vessels” is postulated to lead to a reduction in peripheral vascular resistance, but cardiac output fails to exhibit the compensatory rise that normally occurs in hypotension. Some physiologic studies suggest that the dilatation of intramuscular vessels, innervated by beta-adrenergic fibers, may be more important than dilatation of the splanchnic ones.

Skin vessels, in contrast, are constricted. Vagal stimulation may be superimposed either as a primary or a reactive phenomenon (hence the term *vasovagal*) causing bradycardia and leading possibly to a slight further drop in blood pressure. Other vagal effects are perspiration, increased peristaltic activity, nausea, and salivation. However, bradycardia probably contributes little to the hypotension and syncope. The term *vasovagal* was used originally by Thomas Lewis. As Lewis himself pointed out, atropine, “while raising the pulse rate up to and beyond normal levels during the attack, leaves the blood pressure below normal and the patient still pale and not fully conscious.”

The vasodepressor faint occurs (1) in normal health under the influence of strong emotion, particularly in some susceptible individuals (sight of blood or an accident) or in conditions that favor peripheral vasodilatation, e.g., hot, crowded rooms (“heat syncope”), especially if the person is hungry or tired or has had alcoholic drinks; (2) during a painful illness or after bodily injury (especially of the abdomen or genitalia), as a consequence of fright, pain, and other factors (where pain is involved, the vagal element tends to be more prominent in the genesis of the faint); and (3) during exercise in some sensitive persons (see further on).

The clinical manifestations of fainting attacks vary to some extent, depending on their mechanisms and the settings in which they occur. The most common types of faint—namely, *vasodepressor* and *vasovagal syncope*, conform more or less to the following pattern. In these types, which are taken in this section as one characteristic manifestation, the patient is usually in the upright position at the beginning of the attack, either sitting or standing. Certain subjective symptoms, the prodrome, mark the onset of the faint. The person feels queasy, is assailed by a sense of giddiness and apprehension, may sway, and sometimes develops a headache. What is most noticeable at the beginning of the attack is pallor or an ashen-gray color of the face; often the face and body become bathed in cool perspiration. Salivation, epigastric distress, nausea, and sometimes vomiting may accompany these symptoms, and the patient tries to suppress them by yawning, sighing, or breathing deeply. Vision may dim or close in concentrically, the ears may ring, and it may be impossible to think clearly (“grayout”). This serves to introduce the common faint that is known to all physicians and most laypersons.

The duration of the prodromal symptoms is variable from a few minutes to only a few seconds. If, during the prodromal period, the person is able to lie down promptly, the attack may be averted before complete loss of consciousness occurs; otherwise, consciousness is lost and the patient falls to the ground. The more or less deliberate onset of this type of syncope enables patients to lie down or at least to protect themselves as they slump. A hurtful fall is exceptional in the young, although an elderly person may be injured.

The depth and duration of unconsciousness vary. Sometimes the person is not completely oblivious to his surroundings; he may still hear voices or see the blurred outlines of people. More often there is a complete lack of awareness and responsiveness. The patient lies motionless, with skeletal muscles fully relaxed. Sphincteric control is maintained in nearly all cases. The pupils are dilated. The pulse is thin and slow or cannot be felt; or they may be tachycardic, the systolic blood pressure is reduced (to 60 mm Hg or less as a rule), and breathing may be almost imperceptible. It is the brief period of hypotension and cerebral hypoperfusion that is the hypifying feature of the various forms of syncope. The depressed vital functions, striking facial pallor, and unconsciousness almost simulate death.

Once the patient is horizontal, the flow of blood to the brain is restored. The strength of the pulse soon improves and color begins to return to the face. Breathing becomes quicker and deeper. Then the eyelids flutter and consciousness is quickly regained. However, should unconsciousness persist for 15 to 20 s, convulsive movements may occur. The term *convulsive syncope* has been used to describe this phenomenon, but it has also been used for an authentic seizure caused by a prolonged period of brain hypoxia. These movements, which are often mistaken for a seizure, usually take the form of brief, mild, clonic jerks of the limbs and trunk and twitchings of the face or a tonic extension of the trunk and clenching of the jaw. Occasionally, the extensor rigidity and jerking

flexor movements are more severe, but very rarely is there urinary incontinence or biting of the tongue, features that characterize a generalized tonic-clonic convulsion.

Gastaut and Fischer-Williams used the oculocardiac inhibitory reflex to study the pattern of electroencephalographic (EEG) changes in syncope. They found that the heightened vagal discharge produced by compression of the eyeballs (oculovagal reflex, a cause of syncope in acute glaucoma) could produce brief periods of cardiac arrest and syncope. This effect was produced in 20 of 100 patients who had a history of syncopal attacks. These investigators found that after a 7- to 13-s period of cardiac arrest, there was a loss of consciousness, pallor, and muscle relaxation and changes in EEG activity. Toward the end of this period, runs of bilaterally synchronous theta and delta waves appeared in the EEG, predominantly in the frontal lobes; in some patients there were one or more myoclonic jerks, synchronous with the slow waves. If the hypotension persisted beyond 14 or 15 s, the EEG became flat. This period of electrical silence lasted for 10 to 20 s and was sometimes accompanied by a generalized tonic spasm with incontinence. Following the spasm, heartbeats and large-amplitude delta waves reappeared, and after another 20 to 30 s, the EEG reverted to normal. It is noteworthy that rhythmic clonic seizures or epileptiform EEG activity was not observed at any time during the periods of cardiac arrest, syncope, and tonic spasm.

From the moment that consciousness is regained, there is a correct perception of the environment. Confusion, headache, and drowsiness, the common sequelae of a convulsive seizure, do not follow a syncopal attack. Nevertheless, the patient often feels weak and groggy after a vasodepressor faint and, by arising too soon, may precipitate another faint.

The clinical features of *cardiac* and *carotid sinus syncope* are in some ways the same as those described above except that the onset may be absolutely abrupt, without any warning symptoms, and is independent of the patient being in an upright posture. The clinical particulars of these and other forms of syncope are described further on.

Neurogenic Syncope

This term refers to all forms of syncope that result directly from the vascular effects of neural signals coming from the central nervous system. In essence, all the types of syncope in this category are “vasovagal,” meaning a combination of vasodepressor and vagal effects in varying proportions; the only differences are in the stimuli that elicit the reflex response.

A number of stimuli, mostly from the viscera but some of psychologic or emotional origin, are capable of eliciting this response, which consists of a reduction or loss of sympathetic vascular tone coupled with a heightened vagal activity. The nucleus of the tractus solitarius (NTS) in the medulla integrates these afferent stimuli and normal baroreceptor signals with the efferent sympathetic mechanisms that maintain vascular tone (see further on and Chap. 26).

Several lines of study suggest that there are disturbances of both sympathetic control of vascular tone and also of the responsiveness of baroreceptors in neurogenic syncope, but the precise mechanisms are unclear. By the use of microneurography, Wallin and Sundlof have demonstrated an increase in sympathetic outflow in peripheral nerves just prior to syncope, as would be expected; however, this activity then ceases at the onset of fainting. Unmyelinated (postganglionic sympathetic) fibers cease firing during vasovagal fainting at a point when the blood pressure falls below 80/40 mm Hg and the pulse, below 60. This would signify that there is an initial attempt to compensate for the falling blood pressure, following which there is a centrally mediated withdrawal of sympathetic activity. Which one of these mechanisms (perhaps both) is responsible for syncope is not clear. More recently, Bechir and colleagues showed that muscle sympathetic activity as assessed using microneurography is increased in the resting state in patients with orthostatic hypotension and, importantly, does not increase further with venous pooling (induced by lower-body negative pressure). Moreover, in the same patients, the response of the cardiac baroreceptors to pooling was significantly diminished. These data are only partially in agreement with those of Wallin and Sundlof, and they are not in accord with an initial increase in sympathetic activity prior to syncope.

There is agreement that peripheral vascular resistance is greatly reduced just prior to and at the onset of fainting. This drop in resistance has been attributed to an initial adrenergic discharge that, at high levels, causes a vasodilatation (rather than constriction) in intramuscular blood vessels. High levels of epinephrine and the vasodilating effects of nitric oxide acting on vascular endothelium, as well as greatly augmented levels of circulating acetylcholine during syncope, also have been invoked as additional or intermediary factors, but all remain speculative. In the current view, the drop in blood pressure is the result of a transient but excessive activity of sympathetic nerves that paradoxically leads to vascular dilatation in muscle and viscera from an imbalance between beta-adrenergic and alpha-adrenergic activity peripherally.

It has been further suggested, on the basis of reasonable but inconclusive physiologic evidence, that the early sympathotonic attempt to maintain blood pressure leads to overly vigorous contractions of the cardiac chambers and that this, in turn, acts as the afferent stimulus for withdrawal of sympathetic tone in common fainting (see "Neurocardiogenic Syncope," later).

Also of interest are abnormalities in the response to hypocarbia of patients who are prone to syncope. Norcliffe-Kaufmann and colleagues recorded a greater-than-normal reduction in cerebral blood flow velocity (gauged by transcranial Doppler) and an excessively reduced vascular resistance in the forearm in response to hypocarbia, and the opposite reactions to hypercarbia. They relate the degree of these changes to variations in orthostatic tolerance among patients and suggest that the two aforementioned changes relate to decreased cerebral blood flow that may engender syncope.

Neurocardiogenic Syncope

This entity, a component or perhaps a subtype of vasodepressor syncope, has received attention as a cause of otherwise unexplained fainting in healthy and athletic children and young adults. As mentioned earlier, it may be the final precipitant in the common vasodepressor faint, and the term is used synonymously with *vasovagal* or *vasodepressor syncope* by some authors.

Oberg and Thoren were the first to observe that the left ventricle itself can be the source of neurally mediated syncope in much the same way as the carotid sinus when stimulated, produces vasodilatation and bradycardia. During acute blood loss in cats, they noted a paradoxical bradycardia that was preceded by increased afferent activity in autonomic fibers arising from the ventricles of the heart, a reaction that could be eliminated by sectioning these nerves. This concept of the heart as the afferent source of vasodepressor reflexes had been suggested earlier by Bezold, as well as by Jarisch and Zoterman, and came to be known as the *Bezold-Jarisch reflex*. The inferoposterior wall of the left ventricle is the site of most of the subendocardial mechanoreceptors that are responsible for the afferent impulses to the nucleus tractus solitarius.

For this mechanism to become active, very vigorous cardiac contractions must occur in the presence of deficient filling of the cardiac chambers (hence "neurocardiogenic"). In the simple faint, an initial burst of sympathetic activity is thought to precipitate physiologic circumstances of excessive cardiac contraction. Echocardiographic findings of a diminished ventricular chamber size and vigorous contractions just prior to syncope support this notion (the "empty-heart syndrome"). The remaining baroreceptors in the aorta may be responsible for the increased afferent activity.

According to Kaufmann, a proclivity to primary neurocardiogenic syncope can be identified by the finding of delayed fainting when the patient is placed at a 60-degree upright position on a tilt table. After approximately 10 min of upright posture, the blood pressure drops below 100 mm Hg; soon thereafter, the patient complains of dizziness and sweating and subsequently faints. In contrast, patients with primary sympathetic failure will faint soon after upward tilting. Half of patients with unexplained syncope display a delayed tilt-table reaction, but it is also seen in 5 percent of controls (see "Tilt-Table Testing" further on). The value of isoproterenol as a cardiac stimulant and peripheral vasodilator to enhance the effect of upright posture and expose neurocardiogenic syncope during the tilt-table test is controversial.

Exercise-Induced Syncope

Aerobic exercise, particularly running, is known to induce fainting in some persons, a trait that may become apparent in late childhood or later and may be familial. There is nausea as well as other presyncopal symptoms; the faint can be avoided by discontinuing exercise or not exceeding a threshold of effort set by the patient himself. Such persons do not seem unduly sensitive to nonaerobic exercise and have no recognizable electrocardiographic or structural heart problems. They have a predilection to

faint with prolonged tilt-table testing and with isoproterenol infusion, suggesting that this represents a form of neurocardiogenic syncope. For this reason, these patients may benefit from beta-adrenergic-blocking drugs if given under careful supervision. As discussed further on, exercise can also precipitate syncope in patients with a number of underlying cardiac conditions (myocardial ischemia, long QT syndrome, aortic outflow obstruction, cardiomyopathy, structural chamber anomalies, exercise-induced ventricular tachycardia, and, less often, supraventricular tachycardias).

Athletes who faint unpredictably during exercise pose a particularly difficult problem. Obviously those found to have serious heart disease should give up competitive sports, but the majority has no demonstrable cardiac abnormality. Subjecting these patients to intense exercise and other testing sometimes fails to elicit the faints, but many have varying degrees of hypotension when subjected to prolonged head-up tilt, again suggesting that the cause of fainting is essentially neurocardiogenic (see above). Implanted cardiac pacemakers are not curative in these vasodepressor faints, as the main deficiency is in vascular resistance. Unless the results of tilt-table testing are unequivocal and reproducible, it is best to consider the more serious causes of exercise-induced syncope and to treat the patient appropriately.

Carotid Sinus Syncope

The carotid sinus is normally sensitive to stretch and gives rise to sensory impulses carried via the nerve of Hering, a tributary of the glossopharyngeal nerve, to the medulla. Massage of one of the carotid sinuses or of both alternately, particularly in elderly persons, causes (1) a reflex cardiac slowing (sinus bradycardia, sinus arrest, or even atrioventricular block)—the *vagal type* of response, or (2) a fall of arterial pressure without cardiac slowing—the *vasodepressor type* of response. Another (“central”) type of carotid sinus syncope was in the past ascribed to cerebral arteriolar constriction, but such an entity has never been validated.

Faintness or syncope because of carotid sinus sensitivity reportedly has been initiated by turning of the head to one side while wearing a tight collar or even by shaving over the region of the sinus. However, the absence of a history of such an association does not exclude the diagnosis. The attack nearly always occurs when the patient is upright, usually standing. The onset is sudden, often with falling. Small convulsive movements occur quite frequently in both the vagal and vasodepressor types of carotid sinus syncope. The period of unconsciousness in carotid sinus syncope seldom lasts longer than 30 s, and the sensorium is immediately clear when consciousness is regained. The majority of the reported cases have been in men.

In some circumstances, it is important to avoid compression of the carotid artery as an evocative test, particularly if a carotid bruit is heard over either carotid vessel. Moreover, carotid sinus compression for syncope testing should be conducted in controlled circumstances.

A number of other types of purely reflexive cardiac slowing can be traced to direct irritation of the vagus nerves (from esophageal diverticula, mediastinal tumors, gallbladder stones, carotid sinus disease, bronchoscopy,

and needling of body cavities). Here, the reflex bradycardia is more often of sinoatrial than atrioventricular type. Weiss and Ferris called such faints *vagovagal*.

Through a similar mechanism, tumors or lymph node enlargements at the base of the skull or in the neck that impinge on the carotid artery, as well as postradiation fibrosis, are capable of causing dramatic syncopal attacks, sometimes preceded by unilateral head or neck pain. Often the episodes are unpredictable, but some patients find that turning the head stimulates an attack. The mechanism in one of our patients with cervical adenopathy was primarily a vasodepressor response; patients with prominent bradycardia have generally had tumors that directly surrounded or infiltrated the glossopharyngeal and vagus nerves (Frank et al; see also MacDonald et al). If the tumor can be safely removed from the carotid region, the syncope often abates; in many cases, however, intracranial section of the ninth and upper rootlets of the tenth nerves on the side of the mass is necessary.

Syncope in Association With Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia typically begins in the sixth decade with paroxysms of pain localized to the base of the tongue, pharynx or larynx, tonsillar area, or an ear (see discussion in Chaps. 10 and 47). In only a small proportion of cases (estimated at 2 percent) are the paroxysms of pain complicated by syncope. Always the sequence is pain, then bradycardia, and, finally, syncope. Presumably the pain gives rise to a massive volley of afferent impulses along the ninth cranial nerve, activating the medullary vasomotor centers via collateral fibers from the nucleus of the tractus solitarius. An increase in parasympathetic (vagal) activity slows the heart. Wallin and colleagues demonstrated that, in addition to bradycardia, there is an element of hypotension caused by inhibition of peripheral sympathetic activity. Here, the effects of the bradycardia exceed those of the vasodepressor hypotension, sometimes to the point of asystole, reflecting the opposite relationship from that seen in most other types of syncope.

The medical treatment of this type of syncope parallels that of trigeminal neuralgia (which is associated in approximately 10 percent of cases, usually on the same side). Antiepileptic drugs and baclofen are helpful in reducing both the pain and syncope in some patients. Intracranial vascular decompression procedures involving small branches of the basilar artery that impinge on the ninth nerve are said to be useful, but such patients have not been extensively studied. Conventional surgical treatment, which consists of sectioning the ninth cranial nerve and upper rootlets of the tenth, has proved to be effective in intractable cases.

The same mechanism is probably operative in so-called *deglutitional syncope*, in which consciousness is lost during or immediately after a forceful swallow. The administration of anticholinergic drugs (propantheline 15 mg tid) has abolished these attacks (Levin and Posner).

Micturition Syncope

This infrequent condition is usually seen in men, sometimes in young adults but more often in the elderly, who

arise from bed at night to urinate. The syncope occurs at the end of micturition or soon thereafter, and the loss of consciousness is abrupt, with rapid and complete recovery. Several factors are probably operative. A full bladder causes reflex vasoconstriction; as the bladder empties, this gives way to vasodilatation, which, combined with an element of postural hypotension, might be sufficient to cause fainting in some individuals. Vagally mediated bradycardia and, in some cases, a mild Valsalva effect may also be factors, and alcohol ingestion, hunger, fatigue, and upper respiratory infection are common predisposing factors. Moreover, the use of alpha-adrenergic blockers for bladder outlet obstruction in men may contribute to the situation. In some instances, especially in the elderly, the nocturnal faint has caused serious head injury.

Tussive and Valsalva Syncope

Syncope as a result of a severe paroxysm of coughing was first described by Charcot in 1876. Affected patients are usually heavyset males who smoke and have chronic bronchitis. Occasionally, the problem occurs in children, particularly following paroxysmal coughing spells of pertussis and laryngitis. After sustained hard coughing, the patient suddenly becomes weak and may lose consciousness momentarily. This is mainly attributable to the greatly elevated intrathoracic pressure, which interferes with venous return to the heart. Increased cerebrospinal fluid (CSF) pressure and diminished P_{CO_2} , with resultant cerebral vasoconstriction, are possibly contributing factors.

Powerful efforts to exhale against a closed glottis (as occurs in tussive syncope) are referred to as the *Valsalva maneuver*. The unconsciousness that results from *breathholding spells* in infants is probably based on this mechanism as well; the so-called pallid attacks in infants probably represent reflex vasodepression. Also, the loss of consciousness that occurs during competitive weight lifting (“weight lifters’ blackout”) is mainly the effect of a Valsalva maneuver, added to which are the effects of vascular dilatation produced by squatting and hyperventilation. Lesser degrees of this phenomenon (faintness and light-headedness) often follow other kinds of strenuous activity, such as unrestrained laughing, straining at stool, heavy lifting, underwater diving, or effortful trumpet playing. Rarely, a brief faint may occur in each of these circumstances.

Syncope may occur occasionally in the course of prostatic or rectal examination, but there is only pallor and bradycardia unless the patient stands immediately (prostatic syncope). A Valsalva effect and reflex vagal stimulation appear to be contributing factors. *Postprandial hypotension* may occasionally lead to syncope in elderly persons, in whom impaired baroreflex function cannot compensate for pooling of blood in splanchnic vessels.

Sympathetic Nervous System Failure

Orthostatic Hypotension

This type of syncope is the result of orthostatic loss of blood pressure. It affects persons whose adrenergic innervation to the blood vessels is defective or, of course, those who are hypovolemic. The patient with autonomic

failure, on assuming an upright position, shows a steady decline in blood pressure that begins almost immediately and, if not checked, declines to a level at which the cerebral circulation cannot be supported. This rapid effect and the slow decline in pressure are quite different from the situation in neurocardiogenic syncope, in which there is a delayed but then rapid onset of hypotension.

These conditions are easily understood if one keeps in mind that, on assuming the erect posture, the pooling of blood in the lower parts of the body is normally prevented by (1) reflex arteriolar and arterial constriction, through alpha- and beta-adrenergic effector mechanisms; (2) reflex acceleration of the heart by means of aortic and carotid reflexes, as described earlier; and (3) muscular activity, which improves venous return. Lipsitz has pointed out that aging is associated with a progressive impairment of these compensatory mechanisms, thus rendering the older person especially vulnerable to syncope. However, even in some younger persons, after the blood pressure has fallen slightly and stabilized at a lower level, the compensatory reflexes may also fail suddenly, with a precipitant drop in blood pressure.

With few exceptions (see Chap. 26), peripheral autonomic failure includes an element of vagal dysfunction that precludes the development of a compensatory tachycardia because vagal tone has already been maximally reduced, and also contrary to what happens in vasodepressor syncope, there tend to be no autonomic responses such as pallor, sweating, nausea, or release of norepinephrine.

Postural syncope occurs under a wide variety of clinical conditions: (1) in otherwise normal individuals who, in certain circumstances, experience an excess centrally mediated sympathetic discharge, as described earlier under vasodepressor syncope, or the simple faint; (2) as part of a chronic, probably degenerative central nervous system syndrome known as idiopathic orthostatic hypotension or primary autonomic insufficiency and with a variety of central nervous system degenerations of the basal ganglia that have autonomic failure as a parallel pathology (multiple system atrophy, Parkinson disease, Lewy-body disease); (3) after a period of prolonged illness with recumbency, especially in elderly individuals with poor muscle tone; (4) in association with diseases of the peripheral nerves that involve autonomic nerve fibers—diabetes, tabes dorsalis, amyloidosis, Guillain-Barré syndrome, a primary idiopathic autonomic neuropathy, pandysautonomia, and several other polyneuropathies, all of which interrupt vasomotor reflexes; (5) in patients receiving L-dopa, dopamine agonists, antihypertensive agents, and certain sedative and antidepressant drugs; (6) in spinal cord transection above the T6 level, particularly in the acute stage; (7) in patients with hypovolemia, (8) in pheochromocytoma, in which repeated exposure to catecholamines leads to desensitization of alpha receptors on resistance blood vessels.

The diagnosis of orthostatic hypotension from autonomic failure is established by measuring the blood pressure in the supine and then in the standing position and noting a substantial drop accompanied by symptoms of dizziness or syncope. It should be emphasized that the

bedside testing of orthostatic blood pressure is best performed by having the patient stand quickly and taking readings immediately and again at 1 min and at 3 min, rather than using the lying-sitting-standing sequence.

Orthostatic hypotension involves the failure to maintain blood pressure in the upright posture. The maintenance of blood pressure during various levels of activity and with postural changes depends on pressure-sensitive receptors (baroreceptors) in the aortic arch and carotid sinus and mechanoreceptors in the walls of the heart. These receptors, which are the sensory nerve endings of the glossopharyngeal and vagus nerves, send afferent impulses to the vasomotor centers in the medulla, more specifically the NTS. Axons from the NTS project to the reticular formation of the ventrolateral medulla, which in turn, sends fibers to the intermediolateral cell column of the spinal cord, thereby controlling vasomotor tone in skeletal muscles, skin, and the splanchnic bed. A diminution of sensory impulses from baroreceptors increases the flow of excitatory signals, which raise the blood pressure and cardiac output, thus restoring cerebral perfusion. This subject is discussed further in relation to the regulation of blood pressure in Chap. 26.

Postural Orthostatic Tachycardia Syndrome

As described by Low and colleagues, postural orthostatic tachycardia syndrome (POTS) consists of intolerance of the standing position accompanied by tachycardia up to 120 beats per minute or more, but *without* orthostatic hypotension. Dyspnea, fatigue, and tremulousness and a complaint of "dizziness" accompany the assumption of an upright posture, and the same constellation of symptoms may be brought out by upright tilting. There is a frequent association with longer term fatigue and with exercise intolerance. The situation is comparable to orthostatic intolerance in the chronic fatigue and postviral syndromes, with which POTS shares many features. An impairment of cerebral autoregulation has been hypothesized; others consider the condition to be a limited form of dysautonomia. The component of the syndrome that simulates anxiety makes it difficult in some cases to differentiate the anticipation of symptoms from a genuine form of autonomic dysfunction.

Goldstein and associates compared a cohort of POTS patients with a group that experienced recurrent postural near-syncope and found that in the former group there was increased myocardial epinephrine release from intact cardiac sympathetic nerves. The basis for this is not known, although the researchers did exclude the possibility of defects in the cardiac norepinephrine transporter membrane and in norepinephrine synthesis.

Primary Autonomic Insufficiency (Idiopathic Orthostatic Hypotension)

This presents in two forms. In one, there is a selective degeneration of neurons in the sympathetic ganglia with denervation of smooth muscle vasculature and adrenal glands. The pathology has not been fully delineated, but lesions in other parts of the nervous system are not evident. In the second type, there is a degeneration of preganglionic neurons in the lateral columns of gray

matter in the spinal cord, leaving postganglionic neurons isolated from spinal control. The latter lesion is often associated with degeneration of other systems of neurons in the CNS, particularly the basal ganglia but also the cerebellum. These processes are subsumed under the term *multiple system atrophy*, as discussed in Chap. 39. Parkinson disease and Lewy-body dementia may be associated with the same type of central loss of sympathetic neurons, but orthostatic hypotension and a variety of other features of autonomic insufficiency are early, more pronounced, and progressive in multiple system atrophy than in the other diseases named. Most of the dopaminergic drugs used in the treatment of Parkinson disease can exaggerate the hypotension. There are cases in which neuronal degeneration is limited to the sympathetic neurons of the intermediolateral cell columns—the Shy-Drager syndrome. All of these forms of degenerative disease have their onset in adult life, and the associated hypotension and syncope are usually part of a more widespread autonomic dysfunction that includes other features such as a fixed cardiac rate, vocal cord paralysis, a loss of sweating in the lower parts of the body, redness of the digits, atonicity of the bladder, constipation, and impotence.

Syncope of Cardiac Origin

This is caused by a sudden reduction in cardiac output, usually because of an arrhythmia. Normally, a heart rate as low as 35 to 40 beats per min or as high as 150 beats per min is well tolerated, especially if the patient is recumbent. Changes in heart rate beyond these extremes impair cardiac output and may lead to syncope. Upright posture, anemia, and coronary, myocardial, and valvular disease all render the individual more susceptible to these alterations in heart rate and rhythm. Detailed discussions of the various valvular and myocardial abnormalities and arrhythmias that may compromise cardiac output and lead to syncope are to be found in the articles by Lipsitz, and by Kapoor and colleagues.

Cardiac syncope occurs most frequently in patients with *complete atrioventricular block* and a heart rate of 40 beats or less per minute (Stokes-Adams attacks, or Adams-Stokes-Morgagni syndrome). The block may be persistent or intermittent; it is often preceded by fascicular or second-degree heart block. Ventricular arrest of 4 to 8 s, if the patient is upright, is enough to cause syncope; if the patient is supine, the asystole must last 12 to 15 s. After asystole of 12 s, according to Engel, the patient turns pale and becomes momentarily weak or may lose consciousness without warning; this may occur regardless of the position of the body. If the duration of cerebral ischemia exceeds 15 to 20 s, there are a few clonic jerks. With still longer asystole, the clonic jerks merge with tonic spasms and stertorous respirations and the ashen-gray pallor gives way to cyanosis, incontinence, fixed pupils, and bilateral Babinski signs. As heart action resumes, the face and neck become flushed. The report of this sequence of signs by a dependable observer helps to distinguish syncope from epilepsy. In cases of even more prolonged asystole (4 to 5 min), or if the patient is trapped in an upright or seated position for briefer

periods, there may be cerebral injury caused by a combination of hypoxia and ischemia. Coma may persist or may be replaced by confusion and other neurologic signs. Focal ischemic changes, often irreversible, may then be traced to the fields of occluded atherosclerotic cerebral arteries or the border zones between the areas of supply of major arteries. Cardiac faints of the Stokes-Adams type may recur several times a day. The heart block is usually intermittent at first, and between attacks the electrocardiogram (ECG) may show only evidence of heart disease. A continuous ECG using a Holter monitor or telemetry is then needed to demonstrate the arrhythmia (see further on).

Less easily recognized are faintness and syncope caused by *dysfunction of the sinus node*, and manifested by marked sinus bradycardia, sinoatrial block, or sinus arrest ("sick sinus syndrome"). The nodal block results in prolonged atrial asystole. Supraventricular tachycardia or atrial fibrillation may occur, alternating with sinus bradycardia (bradycardia-tachycardia syndrome).

Tachyarrhythmias alone are less likely to produce syncope. Certainly, intermittent ventricular fibrillation can cause fainting, and supraventricular tachycardias with rapid ventricular responses (usually over 180 beats per minute) cause syncope when sustained, predominantly in patients who are upright at the time. The *long QT syndrome* is a rare familial condition in which syncope and ventricular arrhythmias are prone to occur. Mutations in at least six different genes encoding cardiac sodium and potassium channels cause this syndrome. Another inherited syndrome with right bundle branch block and ST-segment elevation in the right precordial leads is known to cause syncope and even sudden death (Brugada syndrome). Some patients with mitral valve prolapse seem disposed to syncope and presyncope and an inordinate number are also said to have panic attacks but these associations, like others with mitral valve prolapse, have never been adequately settled.

Aortic stenosis or *subaortic stenosis* from cardiomyopathy often sets the stage for exertional syncope, because cardiac output cannot keep pace with the demands of exercise. Primary pulmonary hypertension and obstruction of right ventricular outflow (pulmonic valvular or infundibular stenosis) or intracardiac tumors may also be associated with exertional syncope. Syncope may also be a manifestation of large pulmonary embolism. Vagal overactivity may be a factor contributing to the syncope in these conditions as well as in the syncope that may accompany acute aortic outflow obstruction. Tetralogy of Fallot is the congenital cardiac malformation that most often leads to syncope. Other cardiac causes are listed in the classification given at the opening of this chapter.

Syncope Associated With Cerebrovascular Disease

It is now widely appreciated that syncope is not a manifestation of conventional cerebrovascular disease (see further on for discussion and the problem of "drop attacks" that do not have loss of consciousness as a feature).

Specifically, syncope does not occur as a manifestation of TIAs that are confined to the territory of the internal carotid arteries and it is rare, if ever, that pure syncopal attacks occur with vertebralbasilar ischemia (see further on). Cases of syncope that do occur are usually associated with multiple occlusions of the large arteries in the thorax or neck. The main examples are found in patients with the aortic-arch syndrome (Takayasu disease) in which the brachiocephalic, common carotid, and vertebral arteries have become narrowed. Physical activity may then critically reduce blood flow to the upper part of the brainstem, causing abrupt loss of consciousness. Stenosis or occlusion of vertebral arteries and the "subclavian steal syndrome" are other examples of cerebrovascular diseases that may cause syncope under the special circumstance of overuse of an arm (see Chap. 34). Fainting also occurs occasionally in patients with congenital anomalies of the upper cervical spine (Klippel-Feil syndrome) or cervical spondylosis, in which the vertebral circulation is compromised. Head turning may then cause vertigo, nausea and vomiting, visual scotomas and, finally, unconsciousness.

Cerebral Hemorrhage and Syncope

The onset of a subarachnoid hemorrhage may be signaled by a syncopal episode, often with transient apnea. Because the bleeding is arterial, there is a momentary cessation of cerebral circulation as the levels of intracranial pressure and blood pressure approach one another. Unless there has been vomiting, a complaint of headache immediately preceding the syncope, or the discovery of severe hypertension or stiff neck when the patient awakens, the diagnosis may not be suspected until a CT scan or lumbar puncture is performed.

An associated problem, with which we have had numerous unsatisfactory encounters, is posed by the patient who falls suddenly forward, striking the head without apparent cause, has headache, and is found to have bifrontal hematomas and subarachnoid blood on CT. These cases highlight the difficulty of distinguishing a primary aneurysmal subarachnoid hemorrhage from an accidental fall or syncope with secondary frontal brain contusions; in almost every case, we have felt obliged to perform some form of cerebral angiography to exclude an anterior communicating artery aneurysm, but we have rarely found one.

Fainting in Hysteria

Hysterical fainting is rather frequent and usually occurs under dramatic circumstances (Chap. 51). The evident lack of change in pulse, blood pressure, or color of the skin or any outward display of anxiety distinguishes it from the vasodepressor faint. Irregular jerking movements and generalized spasms without loss of consciousness or change in the EEG are typical features (Linzer et al, 1992). The diagnosis is based on these negative findings in a person who exhibits the general personality and behavioral characteristics of hysteria. Several interesting instances of mass faintness and syncope of hysterical type have been described—for example, in school marching bands (R.J. Levine).

Syncope of Unknown Cause

Finally, after careful evaluation of patients with syncope and the exclusion of the many forms of the condition described earlier, there remains a significant proportion (one-third to one-half, according to Kapoor and 40 percent in the earlier-noted Framingham Heart Study) in which a cause for the syncope cannot be ascertained. The question of whether a single positive tilt-table test signifies that a prior episode of syncope was neurocardiogenic is not resolved; this obviously has a bearing on the proportion of cases that remain without a diagnosis. If the episodes are repetitive and erratically spaced, a cardiac arrhythmia, intraventricular conduction defect, or seizure should be sought by use of prolonged cardiac rhythm monitoring and conduction studies as well as long-term EEG recordings.

DIFFERENTIAL DIAGNOSIS

Anxiety Attacks and the Hyperventilation Syndrome

These are probably the most important diagnostic considerations in unexplained faintness without syncope. The light-headedness of anxiety and hyperventilation are frequently described as a feeling of faintness, but a loss of consciousness does not follow (see Linzer et al, 1990). Such symptoms are not accompanied by facial pallor or relieved by recumbency. The diagnosis is made on the basis of the associated symptoms, the absence of laboratory and tilt-table abnormalities, and the finding that part of the attack can be reproduced by having the patient hyperventilate. The symptoms produced in this way mimic the persistent or episodic dizziness that accompanies anxiety and panic states (Chap. 15). When anxiety attacks are combined with a Valsalva effect or prolonged standing, fainting may occur. The relationship of anxiety-panic to the previously described postural orthostatic tachycardia syndrome is uncertain.

Hypoglycemia

In diabetics and nondiabetics, hypoglycemia may be an obscure cause of episodic weakness and very rarely of syncope. With progressive lowering of blood glucose, the clinical picture is one of hunger, trembling, flushed facies, sweating, confusion, and, finally, after many minutes, seizures and coma. The diagnosis depends largely on the history, the documentation of reduced blood glucose during an attack, and reproduction of the patient's spontaneous attacks by an injection of insulin or hypoglycemia-inducing drugs (or ingestion of a high-carbohydrate meal in the case of reactive hypoglycemia).

Acute Blood Loss

Acute hemorrhage, usually within the gastrointestinal tract, is a cause of weakness, faintness, or even unconsciousness when the patient stands suddenly. The cause (gastric or duodenal ulcer is the most common) may remain inevent until the passage of black stools.

Drop Attacks

This term has been applied to falling spells that occur without warning and *without* loss of consciousness or postictal symptoms. The patient, usually elderly, suddenly falls down while walking or standing, rarely while stooping. The knees inexplicably buckle. There is no dizziness or impairment of consciousness, and the fall is usually forward, with scuffing of the knees and sometimes the nose. The patient, unless obese, is able to right himself and to rise immediately and go his way, quite embarrassed. There may be several attacks during a period of a few weeks and none thereafter. The interval EEGs and ECGs are normal. One potential mechanism is a lapse of tone in leg muscles during the silent phase of an unnoticed myoclonic or asterixis jerk. Primary orthostatic tremor (see Chap. 4) has a similar appearance. Drop attacks also occur in acute hydrocephalus, and with the Chiari malformation, and these patients, although conscious, may not be able to arise for several hours. Rare instances of Ménière disease, in which the patient is suddenly thrown to the ground ("otolithic catastrophe of Tumarkin," see "Ménière Disease and Other Forms of Labyrinthine Vertigo" in Chap. 15) may be mistaken for a syncopal or drop attack, but only briefly, until vertigo becomes prominent.

Drop attacks as defined above are usually without an identifiable mechanism, requiring no treatment if cardiologic studies are normal. On uncertain grounds, they are often attributed to brainstem ischemia. In only about one-quarter of such cases, according to Meissner and coworkers, can an association be made with cardiovascular or cerebrovascular disease to which treatment should be directed.

Orthopedic surgeons and rheumatologists are familiar with knee-buckling attacks, which they attribute to arthritic or tendinous disorders of the knee. Painful impulses arising in and around the knee could result in brief reflex silence of the antigravity muscles (primarily the quadriceps), producing a phenomenon akin to asterixis. Greenwood and Hopkins long ago proposed this mechanism. Although brief periods of silence have been recorded in the quadriceps muscles of patients with drop attacks, the reflex mechanism and its relationship to knee pain is speculative. This problem is also taken up in Chap. 7.

Seizures and Syncope

In epilepsy, whether major or minor, the arrest in consciousness is almost instantaneous and, as revealed by the EEG, is accompanied by a paroxysm of electrical activity occurring simultaneously in all of the cerebral cortex and thalamus. There are a number of important clinical distinctions between epileptic and syncopal attacks. The epileptic attack may occur day or night, regardless of the position of the patient; syncope rarely appears when the patient is recumbent, the only common exception being the Stokes-Adams attack. The patient's color usually does not change at the onset of an epileptic attack; pallor is an early and almost invariable finding in most types of syncope except those

caused by chronic orthostatic hypotension or hysteria, and it precedes unconsciousness. If an aura is present, it rarely lasts longer than a few seconds before consciousness is abolished. The onset of syncope is usually more gradual, and the prodromal symptoms are quite distinctive and different from those of seizures. In general, injury from falling is more frequent in epilepsy than in syncope, because protective reflexes are instantaneously abolished in the former. (Nevertheless, cardiogenic syncope is an important cause of hurtful falls, especially in the elderly.) The return of consciousness is slow in epilepsy, prompt in syncope; mental confusion, headache, and drowsiness are common sequelae of seizures, and physical weakness with clear sensorium, of syncope (a brief period of grogginess may follow vasodepressor syncope). Biting of the tongue is well known, albeit not always present in convulsion; it is exceptional in syncope. Repeated spells of unconsciousness in a young person at a rate of several per day or month are much more suggestive of epilepsy than of syncope.

Tonic spasm of muscles with upturning of the eyes is a prominent and often initial feature of epilepsy, but also occurs in the course of a faint and cannot be depended upon to make the distinction between the 2 processes. Urinary incontinence is a frequent occurrence in epilepsy, but it need not occur during an epileptic attack and may occasionally occur with syncope, so that it also cannot be used as a means of separating the disorders.

The EEG may be helpful in differentiating syncope from epilepsy. In the interval between epileptic seizures, the EEG, particularly if repeated once or twice, shows some degree of abnormality in 50 to 75 percent of cases, whereas it should be normal between syncopal attacks. Sometimes one must resort to continuous EEG monitoring by tape recording or telemetry to clarify the situation (this can be combined with continuous ECG recording). Another useful laboratory marker of a seizure, especially if unwitnessed, is an elevation of the serum creatine kinase (CK) concentration; such a finding occurs only infrequently in the rare case of syncope associated with extensive muscle trauma. Elevated prolactin levels have not proved discriminating enough for routine use in separating seizure from syncope but remain useful in distinguishing both of these from other causes of loss of consciousness, particularly hysteria, in which such elevations do not occur.

No single criterion will absolutely differentiate epilepsy from syncope, but taken as a group and supplemented by the EEG, these criteria usually enable one to distinguish the 2 conditions.

Cardiovascular structures represented in the insular cortex may give rise to seizures that produce cardiac arrhythmias, leading in turn to syncope. As a rule, seizures arising from the left insula prolong the QT interval and increase sympathetic tone, thereby lowering the threshold for ventricular arrhythmia, whereas those arising from the right insula shorten the QT interval and increase parasympathetic tone, thereby increasing the risk of vagally mediated syncope. *Sympathetic storms* may arise from the brain in circumstances of generalized injury (e.g., trauma, subarachnoid hemorrhage, infarction, or intracerebral hemorrhages). When severe,

this sympathetic hyperactivity can cause an acute left ventricular apical cardiomyopathy that causes syncope.

SPECIAL METHODS OF EXAMINATION

In patients who complain of recurrent faintness or syncope but do not have a spontaneous occurrence while under observation, an attempt to reproduce attacks may prove to be of great assistance in diagnosis. Here it is important to recall that normal persons can faint if made to squat and overbreathe and then to stand erect and hold their breath (especially if the Valsalva maneuver is added). Prolonged standing at attention in the heat often causes even well-conditioned soldiers to faint, as does compression of the chest and abdomen while holding one's breath, as in the parlor trick of adolescents ("fainting lark").

When an anxiety state is accompanied by faintness, the pattern of symptoms can often be reproduced by having the subject hyperventilate—that is, breathe rapidly and deeply for 2 to 3 min. This test may also be of therapeutic value, because the underlying anxiety tends to be lessened when the patient learns that the symptoms can be produced and alleviated at will simply by controlling breathing.

Most patients with tussive syncope cannot reproduce an attack by the Valsalva maneuver but can sometimes do so by voluntary coughing, if severe enough. Another useful procedure is to have the patient perform the Valsalva maneuver for more than 10 s (thus trapping blood behind closed valves in the veins) while the pulse and blood pressure are measured (see "Tests for Abnormalities of the Autonomic Nervous System" in Chap. 26).

In each of the aforementioned instances, the crucial point is not whether symptoms are produced but whether they reproduce the exact pattern of symptoms that occurs in the spontaneous attacks.

Other conditions in which the diagnosis is clarified by reproducing the attacks are carotid sinus hypersensitivity (massage of one or the other carotid sinus) and orthostatic hypotension (observations of pulse rate, blood pressure, and symptoms in the recumbent and standing positions or, even better, with the patient on a tilt table).

The measurement of beat-to-beat variation in heart rate is a simple but sensitive means of detecting vagal dysfunction, as described in Chap. 26 but its role in the evaluation of syncope has not been established.

Careful, continuous monitoring of the ECG in the hospital or by using a portable (Holter) recorder may determine whether an arrhythmia is responsible for the syncopal episode. A continuous cardiac loop ECG recorder (which continually records and erases cardiac rhythm) permits prolonged (a month or longer) ambulatory monitoring at reasonable cost. The diagnostic yield from loop recording is modestly greater than that from Holter monitoring (Linzer et al, 1990).

Tilt-Table Testing

Upright tilting on a tilt table may cause, within seconds, up to 20 or 25 mm Hg drop in systolic blood pressure and

5 to 10 mm Hg in diastolic pressure in normal individuals, usually with only minor symptoms. In response, the heart rate rises 5 to 15 beats per minute.

There are 2 types of abnormal response to upright tilting: (1) early hypotension (occurring within moments of tilting) that slowly progresses with continued upright posture; this signifies inadequate sympathetic tone and baroreceptor function; and (2) a delayed (up to several minutes) hypotension that appears abruptly at the end of that period and indicates a neurocardiogenic mechanism.

The normal response to a 60- to 80-degree head-up tilt after approximately 10 min is a transient drop in systolic blood pressure (5 to 15 mm Hg), a rise in diastolic pressure (5 to 10 mm Hg), and a rise in heart rate (10 to 15 beats per minute). Hypotension and fainting after tilting for this duration, a positive test, as already emphasized, is taken as a proclivity to neurocardiogenic fainting and at least an ostensible explanation for the problem. However, because it occurs in a proportion of individuals who have never fainted; it is not to be taken as incontrovertible evidence that a recent spell is explained by this mechanism. Although controversial, in some circumstances the infusion of the catecholamine isoproterenol (1 to 5 mcg/min for 30 min during head-up tilt) may be a more effective means of producing hypotension (and syncope) than the standard tilt test alone (Almquist et al; Waxman et al). While it brings out more cases of neurocardiogenic syncope, some of these are false positives.

TREATMENT OF SYNCOPE

Patients seen during the preliminary stages of fainting or after they have lost consciousness should be placed in a position that permits maximal cerebral blood flow, i.e., with head lowered between the knees if sitting, or, far preferably, in the supine position with legs elevated. All tight clothing and other constrictions should be loosened and the head and body positioned so that the tongue does not fall back into the throat and the possible aspiration of vomitus is avoided. Nothing should be given by mouth until the patient has regained consciousness. The patient should not be permitted to rise until the sense of physical weakness and the appearance of pallor have passed and he should be watched carefully for a few minutes after arising.

As a rule, the physician sees the patient after recovery from the faint and is asked to explain why it happened and how it can be prevented in the future. One should think first of those causes of fainting that constitute a therapeutic emergency. Among them are massive internal hemorrhage and myocardial infarction, and cardiac arrhythmias. In an elderly person, a sudden faint without obvious cause must always arouse the suspicion of a complete heart block or other cardiac arrhythmia.

The prevention of fainting depends on the mechanisms involved. In the usual vasodepressor faint of adolescents—which tends to occur in circumstances favoring vasodilatation (warm environment, hunger, fatigue, alcohol intoxication) and periods of emotional

excitement—it is enough to advise the patient to avoid such circumstances and to maintain adequate hydration. In postural hypotension, patients should be cautioned against arising suddenly from bed. Instead, they should first exercise the legs for a few seconds, then sit on the edge of the bed and make sure they are not light-headed or dizzy before starting to walk. Standing for prolonged periods can sometimes be tolerated without fainting by crossing the legs forcefully. The same regimen suffices for cases of syncope from deconditioning. Alternatives should be found for medications that are conceivable causes of orthostasis. Beta-adrenergic blocking agents, diuretics, antidepressants, and sympatholytic antihypertensive drugs are the common culprits.

In the syndrome of chronic orthostatic hypotension, from central or peripheral sympathetic failure, special mineralocorticoid preparations—such as fludrocortisone acetate (Florinef) 0.05 to 0.4 mg/d in divided doses—and increased salt intake to expand blood volume are helpful. The alpha₁-agonist midodrine, beginning with 2.5 mg every 4 h and slowly increasing the dose to 5 mg every 4 to 6 h, has been used successfully in several studies, but this medication has the potential to worsen the situation and must be used with care. Domperidone may be helpful in patients with parkinsonism. Sleeping with the head posts of the bed elevated on wooden blocks 8 to 12 in high and wearing a snug elastic abdominal binder and elastic stockings are measures that often prove helpful. Tyramine and monoamine oxidase inhibitors have given limited relief in some cases of Shy-Drager syndrome, and beta blockers (propranolol or pindolol) and indomethacin (25 to 50 mg tid) in others. These and other approaches that have proved useful in treating orthostatic hypotension are reviewed by Mathias and Kimber. Anticholinesterase drugs such as pyridostigmine are entering a phase of popularity for the treatment of many forms of orthostatic hypotension (Singer and colleagues).

Neurally mediated syncope (neurocardiogenic or vasodepressor syncope), identified largely by the clinical circumstances and by tilt-table testing, may be prevented by the use of beta-adrenergic blocking agents. Our colleagues in cardiology have recently favored acebutolol 400 mg daily, in part because of its partial alpha-adrenergic activity, which raises baseline blood pressure, but atenolol 50 mg may be as effective. The anticholinergic agent disopyramide has also been used (Milstein et al). Several other drugs (e.g., ephedrine, metoclopramide, dihydroergotamine) have been variably successful in individual patients, but their utility as standard medications remains to be established; the beta-blocking agents are generally preferred.

The treatment of carotid sinus syncope involves, first of all, instructing the patient in measures that minimize the hazards of a fall (see below). A loose collar should be worn, and the patient should learn to turn his whole body, rather than the head alone, when looking to one side. Atropine or one of the sympathomimetic group of drugs may be used, respectively, in patients with pronounced bradycardia or hypotension during attacks. If atropine is not successful, and it is certainly not practical for any

period of time, and the syncopal attacks are incapacitating, the insertion of a dual-chamber pacemaker should be considered. Radiation or surgical denervation of the carotid sinus had apparently yielded favorable results in some patients, but it is no longer practiced. Vagovagal attacks usually respond well to an anticholinergic agent (propranolol, 15 mg tid). Syncope arising from glossopharyngeal neuralgia tends to benefit from medications that reduce the incidence of episodes, such as gabapentin.

In the elderly person, a faint carries the additional hazard of a fracture or other trauma as a consequence of the fall. Therefore the patient subject to recurrent syncope

should cover the bathroom floor and bathtub with mats and have as much of his home carpeted as is feasible. Especially important is the floor space between the bed and the bathroom, because this is the route along which faints in elderly persons most commonly occur. Outdoor walking should be on soft ground rather than hard surfaces, and the patient should avoid standing still for prolonged periods, which is more likely than walking to induce an attack. Padded hip protectors, now available as a commercial product, should be considered in elderly patients at risk of recurrent falls of any kind but evidence of their effectiveness in large populations is so far, lacking.

Sleep and Its Abnormalities

Sleep, that familiar yet inexplicable condition of repose in which consciousness is in abeyance, is obviously not abnormal, yet it is appropriately considered in connection with abnormal phenomena because there are a number of interesting and common irregularities of sleep, some of which approach serious extremes. Furthermore, a number of neurological conditions have special types of sleep disruption as common features. The psychologic and physiologic benefits of sleep are of paramount importance, and it is increasingly recognized that disruption of sleep increases the risks for a number of medical diseases, including stroke, hypertension, and coronary disease. Everyone, of course, has had a great deal of personal experience with sleep, or lack of it, and has observed people in sleep, so it requires no special knowledge to understand something about this condition or to appreciate its importance to health and well-being.

Physicians are frequently consulted by patients who suffer from some derangement of sleep. Most often, the problem is one of sleeplessness, but sometimes it concerns excessive sleepiness or some peculiar phenomenon occurring in connection with sleep. Certain points concerning normal sleep and the sleep-wake mechanisms are worth reviewing, as familiarity with them is necessary for an understanding of disorders of sleep. A great deal of information about sleep and sleep abnormalities is now available as a result of the development of the subspecialty of sleep medicine, and the creation of centers for the diagnosis and treatment of sleep disorders.

Most disorders of sleep can be readily recognized if one attends closely to the patient's description of the disturbance. Only complex or odd cases or those requiring the documentation of apneic episodes or seizures, and other motor disorders during sleep, need study in special sleep laboratories.

PHYSIOLOGY OF SLEEP AND SLEEP-WAKE MECHANISMS

Sleep represents one of the basic 24-h (circadian) rhythms, traceable through all mammalian, avian, and reptilian species. The neural control of circadian rhythms is thought to reside in the ventral-anterior region of the

hypothalamus, more specifically, in the suprachiasmatic nuclei. Lesions in these nuclei result in a disorganization of the sleep-wake cycles as well as of the rest-activity, temperature, and feeding rhythms. Chapter 27 describes the ancillary role of melatonin and the pineal body in modulating this cyclic activity. There is also an important dimension of a homeostatic drive to sleep as the day wears on. This modulates the circadian rhythm independent of light entrainment of the circadian rhythm and makes the workday possible.

Effects of Age

Observations of the human sleep-wake cycle show it to be closely age linked. The newborn baby sleeps from 16 to 20 h a day, and the child, 10 to 12 h. Total sleep time drops to 9 to 10 h by mid-adolescence and to about 7 to 7.5 h during young adulthood. A gradual decline to about 6.5 h develops in late adult life. However, there are wide individual differences in the length and depth of sleep, apparently as a result of genetic factors, early life conditioning, the amount of physical activity, and psychologic states.

The pattern of sleeping, which is adjusted to the 24-h day, also varies in the different epochs of life. The circadian rhythm, with predominance of daytime wakefulness and nighttime sleep, begins to appear only after the first few weeks of postnatal life of the full-term infant; as the child matures, the morning nap is omitted, then the afternoon nap; by the fourth or fifth year, sleep becomes consolidated into a single long nocturnal period. (Actually, a large part of the world's population continues to have an afternoon nap, or siesta, as a lifelong sleep-wake pattern.) Fragmentation of the sleep pattern begins in late adult life. Over ensuing years, night awakenings tend to increase in frequency, and the daytime waking period may be interrupted by episodic sleep lasting seconds to minutes (microsleep), as well as by longer naps. From about 35 years of age onward, women tend to sleep slightly more than men.

Stages of Sleep

Seminal contributions to our understanding of the physiology of sleep were made by Loomis and associates and

by Aserinsky, Dement, and Kleitman through electroencephalographic analysis and clinical observation. As a result of their studies, five stages of sleep, representative of two alternating physiologic mechanisms, have been defined. In each stage, the electrical activity of the brain occurs in organized and recurring cycles, referred to as the *architecture of sleep*. As the electrophysiologic stages of sleep progress, sleep becomes deeper, meaning that arousal requires a more intense stimulus. These findings put to rest the antiquated ideas that sleep is a purely passive state and reflects fatigue and reduction in environmental stimuli.

Relaxed wakefulness with the eyes closed is accompanied in the electroencephalogram (EEG) by posterior alpha waves of 9 to 11 Hz (cycles per second) and intermixed low-voltage fast activity of mixed frequency. Except for the facial muscles, the electromyogram (EMG) is silent when the patient is sitting or lying quietly. With drowsiness, as the first stage of sleep sets in, the eyelids begin to droop, the eyes may rove slowly from side to side, and the pupils become smaller. As the early stage of sleep evolves, the muscles relax and the EEG pattern changes to one of progressively lower voltage and mixed frequency with a loss of alpha waves; this is associated with slow, rolling eye movements and is called *stage 1 sleep*. As this changes into *stage 2 sleep*, 0.5- to 2-s bursts of biparietal 12- to 14-Hz waves (sleep spindles) and intermittent high-amplitude, central-parietal sharp slow-wave complexes appear (vertex waves) (Fig. 19-1).

The American Academy of Sleep Medicine (AASM) recommends the following staging: stage W (wakefulness), stage N1 (non-REM sleep, or NREM 1, formerly stage 1), stage N2 (NREM 2, formerly stage 2), stage N3 (NREM 3, combining former stages 3 and 4—or slow-wave sleep), and stage R (rapid eye movement [REM] sleep). The essential difference between this new nomenclature and the one formerly used by neurologists is that stage N3 now represents *slow-wave sleep*, replacing stage 3 and stage 4 sleep, composed of an increasing proportion of high-amplitude delta waves (0.75- μ V, 0.5- to 2-Hz) in the EEG (Table 19-1). If the eyelids are raised gently, the globes are usually seen to be exotropic and the pupils are even smaller than before, but with retained responses to light. An additional stage of the sleep cycle, which follows the others intermittently throughout the night, is associated with further reduction in muscle tone except in the extraocular muscles and with bursts of rapid eye movement; thus the term *REM sleep* designates this stage. The EEG becomes desynchronized, i.e., it has a low-voltage, high-frequency discharge pattern. The first three stages of sleep are called *nonrapid eye movement (NREM) sleep* or *synchronized sleep*; the last stage, in addition to REM sleep, is variously designated as *fast-wave, nonsynchronized, or desynchronized sleep*. Figure 19-2 illustrates these features.

In the first portion of a typical night's sleep, the normal young and middle-aged adult passes successively through stages N1, N2, N3, and R (REM) sleep. After about 70 to 100 min, a large proportion of which consists

Figure 19-1. Conventional EEG (30 mm/s) of a young healthy woman in stage 2 (N2) sleep showing vertex waves (*large arrows*) and sleep spindles (*small arrows*), best seen in the central regions.

Table 19-1

AMERICAN ACADEMY OF SLEEP MEDICINE (AASM) SLEEP SCORING SYSTEM

AMERICAN ACADEMY OF SLEEP MEDICINE	FORMER NOMENCLATURE	EEG CHARACTERISTICS	BEHAVIORAL STATE
W	—	Posterior reactive alpha rhythm	Awake
N1	Stage 1	Diffuse theta and loss of alpha	Drowsy
N2	Stage 2	Sleep spindles and K complexes	Light sleep
N3	Stages 3 and 4	High-voltage theta and delta activity	Deep sleep
R	REM	Diffuse theta	Predominance of dreaming (see text)

Figure 19-2. Representative polysomnographic recordings from adults in the awake state and various stages of sleep. Recordings are made at conventional sleep laboratory speed of 10 mm/s (i.e., at the paper speed of one-third standard clinical EEG recordings). *A. Upper tracings:* Awake state (with eyes closed). Alpha rhythms are prominent in EEG. Normally active chin EMG. *B. Middle tracings:* Stage 1 (N1) sleep. Onset of sleep is defined by the diminished amplitude of alpha waves in the occipital EEG channel (“flat” appearance). *C. Lower tracings:* Stage 2 (N2) sleep, characterized by appearance of high-amplitude single-complex (K) waves and bursts of 13- to 16-Hz waves (sleep spindles) on a background of low frequency. *D. Upper tracings:* Stage 3 (N3) sleep. Appearance of high-voltage slow (delta) waves. *E. Middle tracings:* Deepest stage of N3 sleep, with predominant delta-wave activity occupying 50 percent of a 30-s tracing. *F. Lower tracings:* Rapid eye movement (REM) sleep, characterized by episodes of REM and occasional muscle twitches in an otherwise flat chin EMG. *Technical Note:* Four sites from the same montage are illustrated in each recording: C₃/A₂, left central to right mastoid; O₂/A₁, right occipital to left mastoid; ROC/A₁, right outer canthus to left mastoid; LOC/A₂, left outer canthus to right mastoid. A chin EMG tracing is added to each recording. (Adapted with permission from Butkov N. *Atlas of Clinical Polysomnography*. Vol 1. Synapse Media, Medford, OR, 1996.)

Figure 19-2. (Continued)

of stage N3 sleep, the first REM period occurs, usually heralded briefly by a transient increase in body movements and a shift in the EEG pattern from that of stage N3 to stage N2. This NREM-REM cycle is repeated at about the same interval four to six times during the night, depending on the total duration of sleep. The first REM period may be brief; the later cycles have less stage N3 sleep or none at all. In the latter portion of a night's sleep, the cycles consist essentially of two alternating stages—REM sleep and stage N2 (spindle-K-complex) sleep.

The relation of dreaming to these sleep stages is described further on.

Newborn full-term infants spend approximately 50 percent of their sleep in the REM stage (although their EEG and eye movements differ from those of adults). The newborn sleep cycle lasts about 60 min (50 percent REM, 50 percent NREM, generally alternating through a 3- to 4-h interfeeding period); with age, the sleep cycle lengthens to 90 to 100 min. Approximately 20 to 25 percent of total sleep time in young adults is spent in REM sleep,

Figure 19-3. Sleep architecture, or sleep cycles. REM sleep (darkened areas) occurs cyclically throughout the night at intervals of approximately 90 min in all age groups. REM sleep shows little variation in the different age groups, whereas stage 4 sleep decreases with age. Stages 3 and 4 are now considered N3. (Redrawn by permission from Kales, Kales, and Soldatos.)

3 to 5 percent in stage N1, 50 to 60 percent in stage N2, and 10 to 20 percent in stage N3 combined. The amount of sleep in N3 decreases with age, and persons older than 70 years of age have virtually no very deep slow-wave sleep (Fig. 19-3). The 90- to 100-min cycle is fairly stable in any one person and is believed to continue to operate to a less-perceptible degree during wakefulness in relation to a number of other cyclic phenomena, such as core body temperature, gastric motility, hunger, urinary output, alertness, and capacity for cognitive activity.

Physiologic Changes and Dreaming in NREM and REM Sleep

A comparison of the physiologic changes in NREM and REM sleep is of interest. The change in the EEG pattern has already been indicated. Cortical neurons tend to discharge in synchronized bursts during NREM sleep and in nonsynchronized bursts during wakefulness. In REM sleep, the EEG pattern is generally asynchronous as well. Much of the night's complex visual dreaming has been

found to occur in the REM period, with the qualifications noted below, and dreams are recalled most consistently if the subject is awakened during this time. It is important to point out, however, that dreaming activity is reported by subjects awakened from NREM sleep, although less consistently. Because the time spent in NREM is so much greater than that in REM, approximately 20 percent of dreaming occurs outside of REM periods but REM sleep nonetheless maintains a special relationship to dreaming.

Subjects are easily aroused from REM sleep, but arousing a person during stage N3 is more difficult; full arousal may take minutes or more, during which time the subject may be slightly disoriented and confused (for which reason, physicians called at night should, if possible, avoid making complex medical decisions during this brief period).

As mentioned above, tonic muscle activity is minimal during REM sleep, although small twitches in facial and digital muscles (hand and foot) can still be detected. Eye movements of REM sleep are conjugate and occur in all directions (horizontal more than vertical). They can be appreciated through the closed eyelids. Gross body movements occur every 15 min or so in all stages of sleep but are maximal in the transition between REM and NREM sleep, at which time the sleeping person changes position, usually from side to side (most people sleep on their sides).

On closer study, REM sleep has been found to have phasic and tonic components. In addition to the rapid eye movements, phasic phenomena include activation of the sympathetic nervous system with attendant alternate dilation and constriction of the pupils and fluctuation of the blood pressure, heart rate, and respiration. The phasic activities are related to bursts of neuronal activity in the pontine, vestibular, and median raphe nuclei and are conducted through the corticobulbar and corticospinal tracts. In the nonphasic periods of REM sleep, alpha and gamma spinal neurons are inhibited, the H responses diminish (see Chap. 45), and the tendon and postural and flexor reflexes diminish or are abolished. This flaccidity and atonia, which are prominent in the abdominal, upper airway, and intercostal muscles, may compromise breathing during REM sleep and pose a threat to infants with respiratory difficulty and to adults who are obese or have respiratory difficulty as a result of kyphoscoliosis, muscular dystrophy, hypoplastic or otherwise compromised airways, and neuromuscular paralyses (see Guilleminault and Dement).

It has long been known that body temperature falls slightly during sleep; however, if sleep does not occur, there is still a drop in body temperature as part of the circadian (24-h) temperature pattern. This reduction in temperature is also independent of the 24-h recumbency-ambulatory cycle. During sleep, the decline in temperature occurs mainly during the NREM period, and the same is true of the heartbeat and respiration, both of which become slow and more regular in this period. Cerebral blood flow and oxygen consumption in muscle diminish during NREM sleep and increase during REM sleep. Also, cerebral blood flow and metabolism are markedly reduced across the entire brain during deep

NREM sleep; however, during REM sleep, metabolism and blood flow are restored to the levels of the waking state (Madsen and Vorstrup). Presumably, as a result of increased blood flow, intracranial pressure rises during REM sleep.

Urine excretion decreases during sleep and the absolute quantity of sodium and potassium that is eliminated also decreases; however, urine specific gravity and osmolality increase, presumably because of increased antidiuretic hormone excretion, and reabsorption of water. Parasympathetic outflow is activated periodically in REM sleep; sympathetic activity is suppressed. It has also been recognized that there is a drop in blood pressure and heart rate during slow-wave sleep and the loss of this dip, for example as a result of sleep apnea, has been associated with daytime hypertension and increased risk for cardiovascular events. As mentioned, in phasic REM sleep, there is an increase in sympathetic tone. Breathing is more irregular, and heart rate and blood pressure fluctuate. Penile erections appear periodically, usually during REM periods.

A number of endocrine changes also have a regular relationship to the sleep-wake cycle. During the first 2 h of sleep, there is a surge of growth hormone secretion, mainly during slow-wave sleep. In men, there tends to be a single peak, whereas women have a multiple episodes of increased secretion. This feature persists through middle and late adult life and then disappears. The secretion of cortisol and particularly of thyroid-stimulating hormone peaks at the onset of sleep. High concentrations of cortisol are also characteristically found on awakening. Melatonin, elaborated by the pineal gland, is produced at night and ceases upon retinal stimulation by sunlight (see Chap. 27). Prolactin secretion increases during the night in both men and women, the highest plasma concentrations being found soon after the onset of sleep. Secretion of prolactin is influenced by sleep stages. Circadian mechanisms and the stages of sleep alter testosterone secretion and are therefore disrupted by sleep disorders, especially in younger individuals. Also, an increased sleep-associated secretion of luteinizing hormone occurs in pubertal boys and girls.

Neurophysiology of Sleep and Dreaming

Hobson originally proposed that the basic oscillation of the sleep cycle is the result of reciprocal interaction of excitatory and inhibitory neurotransmitters. Single-cell recordings from the pontine reticular formation suggest that there are two interconnected neuronal populations whose levels of activity fluctuate periodically and reciprocally. During wakefulness, according to this conceptualization, the activity of aminergic (inhibitory) neurons is high; because of this inhibition, the activity of the cholinergic neurons is low. During NREM sleep, aminergic inhibition gradually declines and cholinergic excitation increases; REM sleep occurs when the shift is complete. It is likely that these monoaminergic neuronal circuits are modulated by input from hypocretin (also called orexin)-secreting neurons of the hypothalamus, but the details of this control system are not entirely known. Hypocretin, a peptide that assumes great importance in the pathophysiology of narcolepsy, is discussed further on.

A refinement of these views has elaborated the complex interaction of specially functioning nuclei in the hypothalamus, pons, and basal forebrain. Reciprocal connections among these areas, modulated by input from regions of the brain that sense environmental conditions, allow the organism to adapt sleep cycles to its needs and to external circumstances. The suprachiasmatic nucleus (SCN) of the hypothalamus has no direct influence on the sleep cycle but does integrate ambient light cues, and thereby affects various circadian rhythms, including sleep, as discussed in Chap. 27. Experiments in animals and analyses of cases of von Economo encephalitis (that caused a pathologic sleep syndrome) have indicated that the ventrolateral preoptic nucleus of the hypothalamus (VLPO) sends fibers to all the other major cell groups of the hypothalamus and brainstem that are engaged in arousal. Damage to the VLPO results in pathologic wakefulness, and the virtual absence of sleep. The SCN has only minimal projections to the VLPO and to orexin-containing neurons (see further on), but it does strongly innervate the subparaventricular zone (SPZ) and the dorsomedial hypothalamic nuclei. The last of these areas integrates feeding, temperature, light, and other cues from SPZ and SCN. The brain contains a three-stage pathway for the control of the sleep rhythm.

The above-described interconnections and the action of the integrated system that causes the sleep state have been summarized by Saper and colleagues and schematically in Fig. 19-4, taken from their publication. The current conceptualization is one of an unstable “flip-flop” switch that depends on mutual inhibition of the monoaminergic system and the VLPO. The state of the switch is indirectly stabilized by the orexin neurons. In this model, the awake state is maintained by monoaminergic activity (locus ceruleus, tuberomammillary nucleus [TMN], and the raphe nuclei) that inhibits the VLPO. Sleep occurs when the VLPO is activated, which reciprocally removes the tonic inhibitory action of the monoaminergic system. The orexin neurons act through the monoaminergic system as a stabilizing influence to prevent rapid transitions from one state to the other.

Apart from the overall diurnal sleep cycle, evidence from animal studies suggests that the physiologic mechanisms and transitions between NREM and REM sleep are governed by the pontine reticular formation and are influenced by acetylcholine. *Cholinergic neurons* are found in two major loci in the parabrachial region of the dorsolateral pontine tegmentum—in the pedunculopontine group of nuclei and the lateral dorsal tegmental group. The cholinergic cell groups project rostrally, but the precise anatomy of this projection system has not been defined. Cells from these groups make up parts of the ascending reticular activating system.

Despite the heuristic value of Hobson's reciprocal interaction hypothesis, some of its features remain controversial. Although it is generally agreed that cholinergic mechanisms selectively promote REM sleep, and its components—rapid eye movements, absence of activity in the antigravity muscles (i.e., atonia), and desynchronized EEG—the role of amines has been more difficult to establish. Thus, lesions of the locus ceruleus and raphe

Figure 19-4. Schematic representation of the “flipflop” mechanism of transition between sleep and waking, which is determined by the state of activity of the ventrolateral preoptic nucleus (VLPO). *A.* During wakefulness, the monoaminergic nuclei (LC, locus ceruleus; TMN, tuberomammillary nucleus; raphe nuclei) inhibit the VLPO, thereby relieving the inhibition of the monoaminergic cells, and that of the orexin (ORX) neurons. Because the VLPO neurons do not have orexin receptors, orexin serves to reinforce the monoaminergic tone, rather than directly inhibiting the VLPO. *B.* During sleep, firing of VLPO neurons inhibits the monoaminergic cell groups, thereby relieving their own inhibition. This inhibits the orexin neurons, further preventing monoaminergic activation that might interrupt sleep. The mutual inhibition between the VLPO and the monoaminergic cell groups forms a flip-flop switch, which produces sharp transitions in state, but is relatively unstable. The addition of the orexin neurons stabilizes the switch. (Reproduced with permission from Saper, Scammell, and Lu.)

nuclei, which contain neurons rich in norepinephrine, do not greatly alter REM sleep. Nevertheless, a considerable body of pharmacologic data suggests that a decrease in monoamines causes an increase in REM activity and vice versa. Insofar as the bulk of cholinergic and aminergic neurons are found in the pedunculo pontine group of nuclei, Shiromani and colleagues have suggested that interaction between these neurons occurs in the region of the pedunculo pontine nuclei rather than in the medial pontine reticular formation, as suggested by Hobson and associates.

Solms (1995, 1996) and others have questioned the traditional view that dreaming and REM sleep are obligately or even closely connected and has presented an alternative model. Among patients with cerebral lesions that eliminate or disrupt REM sleep, he cites several cases in which dreaming was retained. Conversely, in 9 of his patients with basal forebrain (frontal) lesions, dreaming was lost, at least for a time, while REM periods remained undisturbed through the night. This same observation had been made in patients who had prefrontal leukotomies. Solms has proposed that the dopaminergic systems in the basal forebrain areas elicit or modulate dreaming. This view is supported by reports of diminished dreaming in patients being treated with dopaminergic blockers and the enhancement of dreaming reported by patients taking L-dopa or dopamine agonists. Notable in this regard is the fact that major intracortical dopaminergic pathways originate in the frontal lobes.

In regard to the neurophysiology of the EEG and sleep rhythms, much has been gleaned from intracellular recordings in animals. As with the earlier-described anatomic and neurochemical data, the degree to which similar electrophysiologic changes are reflected in humans is not known. Most of the integrated rhythms of sleep that are recorded at the surface of the brain, including the background activity of slow-wave sleep and the faster and more synchronized sleep spindles and vertex waves, have their origins in the thalamus. Steriade and colleagues have performed a substantial amount of the modern work in this area and summarize it in their review. They make clear that these complex EEG rhythms, while apparent in nascent form in certain isolated neurons, are oscillations that arise from integrated ensembles of cells, with the thalamus as a nexus. It is evident that there is as yet no agreement concerning the integration of all these brainstem and thalamic-hypothalamic mechanisms in the production of sleep or of dreams.

The Function of Sleep and Dreams

These questions have been pondered endlessly by physiologists and psychiatrists (and philosophers). Parkes has reviewed the main theories—body restitution, facilitation of motor function, consolidation of learning and memory—and tends to agree with the ungrammatical

but unambiguous conclusion of Popper and Eccles that “Sleep is a natural repeated unconsciousness that we do not even know the reason for.” There is no convincing proof, for example, of the popular notion that we stabilize learned material while asleep, nor can one logically entertain the notion that the function of sleep is to produce dreams, at least until the utility and meaning of dreams become known.

Regarding neurophysiologic changes during dreaming, Braun and colleagues used positron emission tomography (PET) to study REM sleep; they observed selective activation of the extrastriate visual cortices and limbic-paralimbic regions, with attenuation of activity in the primary visual cortex and frontal association areas. Based on these and similar studies, several authors have speculated that the suppression of frontal lobe activity during dreaming, at a time when visual association areas and their paralimbic connections are activated, might explain the uncritical acceptance of the bizarre visual content, the disordered temporal relationships, and the heightened emotionality that characterize dreams. This would be in keeping with Hobson’s view of dreams as a form of delirium that is appealing to us. As an alternative that links dreams to inherent meaning for the individual, Solms suggested that activation of frontal dopaminergic systems during dreaming, the same pathways that participate in most biologic drives, implies that dreams express latent wishes and drives—a psychoanalytical interpretation expressed by Freud in his book *The Interpretation of Dreams*.

The Effects of Sleep Deprivation

Deprived of sleep, experimental animals will die within a few weeks, no matter how well they are fed, watered, and housed (Rechtschaffen et al), but whether a similar degree of sleep deprivation leads to death in humans is unknown. Nevertheless, humans beings deprived of sleep do suffer a variety of very unpleasant symptoms quite distinct from the effects of the usual types of insomnia.

Despite many studies of the deleterious emotional and cognitive effects of sleeplessness, we still know little about them. If deprived of sleep (NREM and REM) for periods of 60 to 200 h, human beings experience increasing sleepiness, fatigue, irritability, and difficulty in concentration. Performance of skilled motor activities also deteriorates; if the tasks are of short duration and slow pace, the subject can manage them, but if speed and perseverance are demanded, he cannot. Self-care is neglected, incentive to work wanes, sustained thought and action are interrupted by lapses of attention, judgment is impaired, and the subject becomes decreasingly inclined to communicate. With sustained deprivation, sleepiness becomes increasingly more intense, momentary periods of sleep (“microsleep”) become more intrusive, and the tendency to all types of accidents becomes more marked. Eventually, subjects fail to perceive inner and external experiences accurately and to maintain their orientation. Illusions and hallucinations, mainly visual and tactile ones, intrude into consciousness and become more persistent as the period of sleeplessness is

prolonged. This may be a component of the decompensation of individuals with bipolar psychiatric disease, sometimes triggering manic episodes.

Neurologic signs of sleep deprivation include a mild and inconstant nystagmus, impairment of saccadic eye movements, loss of accommodation, exophoria, a slight tremor of the hands, ptosis of the eyelids, expressionless face, and thickness of speech, with mispronunciations, and incorrect choice of words. The EEG shows a decrement of alpha waves, and closing of the eyes no longer generates alpha activity. The seizure threshold is reduced, and seizure foci in the EEG may be activated. Rarely and probably only in predisposed persons, loss of sleep provokes a psychotic episode (2 to 3 percent of 350 sleep-deprived patients studied by Tyler); however, many sleep specialists dispute the production of psychosis.

During recovery from prolonged sleep deprivation, the amount of sleep obtained is never equal to the amount lost. This is probably a result of the intrusion of brief sleep periods during the waking state and represents a sizable amount of time if summated (it is virtually impossible to deprive a human being or animal totally of sleep). When falling asleep after a long period of deprivation, the subject rapidly enters N3 (NREM) sleep, which continues for several hours at the expense of N2 and REM sleep. But by the second recovery night, REM sleep rebounds and exceeds that of the predeprivation period. N3 seems to be the most important sleep stage in restoring the altered functions that result from prolonged sleep deprivation.

The effects of differential REM sleep deprivation are more difficult to interpret than the effects of total or near-total deprivation. Some subjects in whom REM sleep is prevented night after night show an increasing tendency to hyperactivity, emotional lability, and impulsivity—a state that has been compared to the heightened activity, excessive appetite, and hypersexuality of animals deprived of REM sleep. However, in humans, monoamine inhibitors are able to completely suppress REM sleep for months to years without obvious harm. Differential deprivation of NREM sleep (N3) leads, instead, to hyporesponsiveness and excessive daytime sleepiness as noted.

Because the need for sleep varies considerably from person to person, it is difficult to decide what constitutes sleep deprivation. Certain individuals apparently function well on 4 h or even less of sleep per 24-h period, and others, who sleep long hours, claim not to obtain maximum benefit from it.

SLEEP DISORDERS

Insomnia

The term *insomnia* signifies a chronic inability to sleep despite adequate opportunity to do so; it is used popularly to indicate any impairment in the duration, depth, or restorative properties of sleep. There may be difficulty in falling asleep or remaining asleep, awakening may come too early, or there may be a combination of

these complaints. Precision as to what constitutes pathologic insomnia is impossible at the present time because of our uncertainty as to the exact amounts of sleep required, and the role of sleep in the economy of the human body. All that can be said is that some form of sleeplessness is a frequent complaint (20 to 40 percent of the population) and is more prominent in the elderly and in women. Only a small proportion of persons who perceive their sleep to be inadequate seek professional help or use sleeping pills, according to Mellinger and colleagues.

Two general classes of insomnia can be recognized—one in which there appears to be a primary abnormality of the normal sleep mechanism, and another in which the sleep disturbance is secondary to, or perhaps more accurately comorbid with, a medical or psychological disorder. Polysomnographic studies have defined yet another subgroup who actually sleep enough, but who perceive their sleep time to be shortened or disrupted (“paradoxical insomnia”).

Primary Insomnia

This term is reserved for the condition in which nocturnal sleep is disturbed for prolonged periods and none of the symptoms of anxiety, depression, pain, or other psychiatric or medical diseases can be invoked to explain the sleep disturbance. In some patients, like those described by Hauri and Olmstead, the disorder is lifelong. Unlike the rare individuals who seem to be satisfied with 4 h or even less of sleep a night, insomniacs suffer the effects of partial sleep deprivation and resort to medications, alcohol, and their lives come to revolve around sleep to such an extent that they have been called “sleep pedants” or “sleep hypochondriacs.” Although statements on the quantity and quality of sleep given by insomniacs are often not to be taken as entirely valid, Rechtschaffen and Monroe have confirmed that most of them do, indeed, sleep for shorter periods, move and awaken more often, spend less time in N3 sleep than normal persons, and show a heightened physiologic arousal. Personality inventories have disclosed a high incidence of psychological disturbances in this group, but whether these are cause or effect is not clear.

Furthermore, a category of “conditioned,” or “psychophysiological” insomnia has been denominated, in which a situational trigger for insomnia has ceased, but the sleep disorder persists. Although insomniacs, regardless of the cause, tend to exaggerate the amount of sleep lost, primary insomnia should be recognized as an entity and not passed off as a neurotic quirk.

Secondary Insomnia

This common type of insomnia, which is often transitory, can be ascribed to pain or some other recognizable bodily disorder, such as drug or alcohol abuse or, most commonly, to anxiety, worry, or depression. Of the medical disorders conducive to abnormal wakefulness, certain ones stand out—pain in the joints or in the spine, abdominal discomfort from peptic ulcer and carcinoma, pulmonary and cardiovascular insufficiency, and the nocturia engendered by prostatism. The “restless legs” syndrome

and periodic leg movements of sleep are not considered in this category and have their own physiology, phenomenology, and treatment.

Restless Legs Syndrome, Periodic Leg Movements of Sleep, and Related Disorders

The disorder known as the *restless legs syndrome* may regularly delay the onset of sleep and usually occurs in its early stages. Ekbom called it *asthenia crurum parasthetica* and also, *anxietas tibiaram*. This disorder is surprisingly prevalent, affecting more than 2 percent of the population. The patient may complain of unpleasant aching and drawing sensations in the calves and thighs, often associated with creeping or crawling feelings; other descriptions have included “worms,” “internal itch,” and “coldness,” and the legs may feel tired, heavy, and weak. The symptoms are provoked by rest, and rapidly, but temporarily, relieved by moving the legs. An urge to move the legs can be suppressed voluntarily for a brief period but is ultimately irresistible. Moving the limbs alleviates the sensation briefly. It is interesting that a small proportion of patients have similar symptoms in the arms after many years of symptoms. There may be variants of nocturnal restlessness in other parts of the body such as the abdomen, as suggested by Pérez-Díaz and colleagues. Their patients described an unpleasant abdominal musculature restlessness that required movement for relief and was eliminated with dopamine agonists.

Fatigue worsens restless legs syndrome, and there is a tendency for it to be worse in warm weather. In a few patients, mainly older ones with a severe form of the nighttime disorder, these movements and an associated myoclonus spill over into wakefulness and are accompanied by restlessness, foot spasms, foot stamping, body rocking, and marching that are only partly under voluntary control. The daytime phenomena may require several medications used simultaneously for control.

The syndrome is idiopathic and persists for years. Iron-deficiency anemia and low ferritin levels are associated with the syndrome in many instances, as is thyroid disease, pregnancy, and certain drugs, such as antidepressants and antihistamines. Occasionally, it is a prelude to a peripheral neuropathy, particularly in relation to uremia. Also, reduced levels of iron in the cerebrospinal fluid (CSF) have been found with restless legs syndrome and with periodic limb movements of sleep (see below). The basis for this relationship is not well defined, but it makes it advisable to check for reduced iron stores and anemia in most patients. One hypothesis is that a disturbance of iron storage in the basal ganglia causes a decrement in dopamine binding by dopamine receptors and transporters, as has been described in studies using PET and single-photon emission tomography (SPECT) scans. Another potential relationship, unproved, is that iron is a cofactor for the enzyme, tyrosine hydroxylase, which is required to produce dopamine.

A closely related disturbance is *periodic leg movements of sleep*. Like the restless legs syndrome, it may result in sleep deprivation and daytime somnolence or, more often, in disturbance of a bed partner. However, the

diagnosis of periodic leg movements depends on finding them during polysomnographic recordings, whereas restless leg syndrome is identified on clinical grounds. Originally described as “nocturnal myoclonus,” periodic leg movements are slower than myoclonic jerks. They consist of a series of repetitive movements of the feet and legs occurring every 20 to 90 s for several minutes to an hour; mainly the anterior tibialis is involved, with dorsiflexion of the feet and big toes, sometimes followed by flexion of the hip and knee. The movements are similar to the triple-flexion (Babinski) response, which can be elicited in normal sleeping persons. These movements produce frequent microarousals or, if severe and periodic, full arousals. The patient, usually unaware of these sleep-related movements at the time they occur, is told of them by a bed mate or suspects their occurrence from the disarray of the bedclothes. Periodic leg movement is closely associated with the restless legs syndrome and many sleep specialists consider it an integral part of the syndrome, but it also occurs independently with narcolepsy, sleep apnea, following the use of tricyclic and serotonin reuptake inhibiting antidepressants, L-dopa, and withdrawal from anticonvulsants and sedative-hypnotic drugs. Approximately eighty percent of individuals with restless leg syndrome will display periodic leg movements, but the opposite is not the case, as only twenty to thirty percent of patients with periodic leg movements have restless leg syndrome.

A seminal genetic finding by Stefansson and colleagues derived from several populations, including the homogenous Icelandic, is that a nucleotide variant in a short segment of chromosome 6p is associated with periodic leg movements of sleep. This was found to hold in those with and without restless legs syndrome. If nothing else, as pointed out by the authors, this establishes that periodic limb movements are a distinct entity as defined in the era of genomics. The biologic significance and frequency in other populations of this variant is not yet known. Nonetheless, we continue to be impressed at the frequent concurrence of the two conditions and several shared underlying conditions such as iron deficiency, and treatments that are effective in both.

Treatment

A search for iron deficiency, and its correction if present, is indicated in almost all cases. A large number of symptomatic medications have proved helpful in the treatment of both the restless legs syndrome and periodic leg movements. As a first choice, many practitioners favor treatment with dopamine agonists such as pramipexole (0.25 to 0.75 mg) or ropinirole (0.5 to 1.5 mg), either one taken 1.5 to 2 h before bedtime. Long-acting combinations of L-dopa/carbidopa (12.5/50 or 25/100 mg dose) taken at bedtime have also been successful, but L-dopa, and sometimes the dopamine agonists, causes some patients to develop the movements earlier, i.e., in the daytime, which become more intense and spread to other body parts. A longer acting dopamine agonist, rotigotine patch is available to treat patients who have this augmentation phenomenon. The latter is also helpful for periodic leg movements.

A major problem, recently recognized, is one of “augmentation,” or enhancement of the restless leg syndrome with the long-term use of this class of drugs. This is less prominent with some of the other numerous drugs that have been effective including gabapentin, pregabalin, clonazepam (0.5 to 2.0 mg), temazepam (30 mg), taken 30 min before retiring and extended release gabapentin which are available to minimize the augmentation phenomenon. Other drugs—e.g., baclofen, opioids, carbamazepine seem to be helpful in certain patients, but they are infrequently required. The lengthy list of medications that have been effective is given in Earley’s review. It is sometimes useful to give a medication in 2 divided doses, the first early in the evening, and the second just before sleep or, in severe cases, during the night by setting an alarm clock before the anticipated time of symptoms.

Other Causes of Secondary Insomnia

Among the secondary insomnias, those caused by some type of *psychologic disturbance* are particularly common. Domestic or business worries may keep the patient’s mind in turmoil (situational insomnia). A strange bed or unfamiliar surroundings may prevent drowsiness and sleep. Under these circumstances, the main difficulty is in falling asleep, with a tendency to sleep late in the morning. These facts emphasize that conditioning and environmental factors (social and learned) are normally involved in readying the mind and body for sleep.

Illnesses in which anxiety and fear are prominent symptoms also result in difficulty in falling asleep and in light, fitful, or intermittent sleep. Disturbing dreams are frequent in these situations and may awaken the patient. Exceptionally, a patient may even try to stay awake in order to avoid them. In contrast, *depressive illness* produces early morning waking and inability to return to sleep; the quantity of sleep is reduced, and nocturnal motility is increased. REM sleep in depression, although not always reduced, comes earlier in the night. If anxiety is combined with depression, there is a tendency for both the above patterns to be observed. Yet another common pattern of disturbed sleep can be discerned in individuals who are under great tension and worry or are overworked and tired out. These people sink into bed and sleep through sheer exhaustion, but they awaken early with their worries and are unable to get back to sleep.

Chronic and even short-term use of alcohol, barbiturates, and certain nonbarbiturate sedative-hypnotic drugs markedly reduces REM sleep as well as stages 3 and 4 of NREM sleep (N3). Following withdrawal of these drugs, there is a rapid and marked increase of REM sleep, sometimes with vivid dreams and nightmares. “Rebound insomnia,” a worsening of sleep compared with pretreatment levels, has also been reported upon discontinuation of short-half-life benzodiazepine hypnotics, notably triazolam (Gillin et al) and including the newer sleep agents mentioned below. Furthermore, a form of drug-withdrawal or rebound insomnia may actually occur during the same night in which the drug is administered. The drug produces its hypnotic effect in the first half of the night and a worsening of sleep during the latter half of the night, as the effects of the drug

wear off; the patient and the physician may be misled into thinking that these latter symptoms require more of the hypnotic drug or a different one. Alcohol taken in the evening acts in the same way. Rebound insomnia must be distinguished from the early morning awakening that accompanies anxiety and depressive states.

A wide variety of other pharmacologic agents may give rise to sporadic or persistent disturbances of sleep. Caffeine-containing beverages, corticosteroids, bronchodilators, central adrenergic-blocking agents, amphetamines, certain “activating” antidepressants such as fluoxetine, and cigarettes are the most common offenders. Others are listed in the extensive review of Kupfer and Reynolds.

Acroparesthesias, a predominantly nocturnal tingling and numbness of the fingers and palms caused by tight carpal ligaments (carpal tunnel syndrome), may awaken the patient at night (see further on, under “Sleep Palsies and Acroparesthesias”). *Cluster headaches* characteristically awaken the patient within 1 to 2 h after falling asleep (see Chap. 10 for a fuller discussion). In a few patients, cluster headaches occur only during or immediately after the REM period.

The sleep rhythm is totally deranged in acute confusional states and especially in delirium, and the patient may doze for only short periods, both day and night, the total amount and depth of sleep in a 24-h period being reduced. Frightening hallucinations may prevent sleep. The senile patient tends to catnap during the day and to remain alert for progressively longer periods during the night, until sleep is obtained in a series of short naps throughout the 24 h; the total amount of sleep may be increased or decreased.

Treatment of Insomnia

In general, a sedative-hypnotic drug for the management of insomnia should be prescribed only as a short-term aid during an illness or some unusual circumstance, i.e., for acute insomnia. For patients who have difficulty falling asleep, a quick-acting, fairly rapidly metabolized hypnotic is useful. The most commonly used medications are the benzodiazepine receptor agonists, which act on the gamma-aminobutyric acid (GABA)-A receptor complex. In the past, benzodiazepines were popular but these have been replaced by newer nonbenzodiazepine receptor agonists with shorter half-lives and fewer side effects (e.g., zolpidem, zaleplon, and eszopiclone). Patients who do not respond to these medications may be given an intermediate-duration benzodiazepine such as temazepam. Hypnotic use is inadvisable during pregnancy and should be used cautiously in patients with alcoholism or advanced renal, hepatic, or pulmonary disease, and should be avoided in patients with sleep apnea syndrome.

Melatonin (3 to 12 mg) has reportedly been as effective as the sedative-hypnotics and may cause fewer short-term side effects, but both of these statements are difficult to confirm. Melatonin has a short half-life, and it has only weak hypnotic effect. Therefore, for sleep rhythm disturbances, it is ideally taken three to four hours before sleep time. Amitriptyline (25 to 50 mg at bedtime) appears to be a sleep-enhancing drug even in those who are not anxious or depressed. Tolerance develops to the drug, and there are

morning side effects so the drug may find its best use in patients who are taking it for alternative reasons such as headache or depression. Some practitioners indicate that it may also worsen restless leg or periodic leg movement disorders. When pain is a factor in insomnia, the sedative may be combined with a suitable analgesic. Nonprescription drugs containing diphenhydramine (Benadryl), valerian, or doxylamine, which are minimally or not at all effective in inducing sleep, may impair the quality of sleep and lead to drowsiness the following morning.

The chronic insomniac who has no other symptoms should be discouraged from using sedative drugs. The solution of this problem is rarely to be found in medication. One should search out and correct, if possible, any underlying situational or psychologic difficulty, using medication only as a temporary measure. Patients should be encouraged to regularize their daily schedules, including their bedtimes, and to be physically active during the day but to avoid strenuous physical and mental activity before bedtime. It has been suggested that illumination from broad-spectrum light (television) in the late evening is detrimental. Dietary excesses must be corrected, and all nonessential medications interdicted. Coffee and alcohol should be avoided at night, if not throughout the day. A number of simple behavioral modifications may be useful, such as using the bedroom only for sleeping, arising at the same time each morning regardless of the duration of sleep, avoiding daytime naps, and limiting the time spent in bed strictly to the duration of sleep. A helpful approach is to lessen the patient’s concern about sleeplessness by pointing out that he will always get as much sleep as needed and that there is pleasure to be derived from staying awake and reading, or viewing a movie.

Disorders of Sleep Related to Neurologic Disease

Many neurologic conditions seriously derange the total amount and patterns of sleep (see Culebras). Lesions in the upper pons, near the locus ceruleus, are particularly prone to do so. Markand and Dyken have described the most substantial of these, pontine infarction with involvement of the tegmental raphe nuclei. The clinical abnormality took the form of diminished NREM sleep and near abolition of REM sleep lasting for weeks or months. Bilateral lacunar infarctions in the pontine tegmentum, demonstrable by MRI, also appear to be the basis of some instances of the so-called REM sleep behavior disorder (Culebras and Moore) described further on with the other parasomnias. Bilateral paramedian thalamic infarctions are a potent cause of hypersomnia, the result of disruption of both arousal mechanisms and NREM sleep (Bassetti et al).

Medullary lesions may affect sleep by altering automatic ventilation; the most extreme examples occur with bilateral tegmental lesions that may completely abolish breathing during sleep (“Ondine’s curse,” as described in Chap. 26). Lesser degrees of tegmental damage—as might occur with Chiari malformations, unilateral medullary infarction, syringobulbia, or poliomyelitis—may cause sleep apnea, and daytime drowsiness. Patients with

large hemispheric strokes may also be left with daytime lethargy on the basis of inversion of sleep–wake rhythm. Certain instances of mesencephalic infarction that are characterized by vivid visual hallucinations (peduncular hallucinosis) may be associated with disruption of sleep.

von Economo encephalitis, now an extinct illness, was usually associated with a hypersomnolent state but caused persistent insomnia in some instances. The latter was related to a predominance of lesions in the anterior hypothalamus and basal frontal lobes, in distinction to hypersomnia, which was related to lesions mainly in dorsal hypothalamus and subthalamus. This subject and other forms of hypersomnia are elaborated further on under “Pathologic Excessive Sleep (Hypersomnia).”

A remarkable illness, termed *fatal familial insomnia*, was initially described by Lugaresi and colleagues. This disorder, with onset in middle age and a clinical course of 7 to 36 months, is characterized by a virtual incapacity to sleep and to generate EEG sleep patterns. The cerebral changes consist mainly of profound neuronal loss in the anterior or anteroventral, and mediadorsal thalamic nuclei. These cases apparently represent a usually familial form of prion disease similar to diseases that cause subacute spongiform encephalopathy and Gerstmann-Sträussler-Scheinker disease (see Chap. 33). Interestingly, the alcoholic form of the Korsakoff amnesic state, associated with less severe lesions in the same thalamic nuclei, is also characterized by a sleep disturbance, taking the form of an increased frequency of intermittent periods of wakefulness (Martin et al). When carefully sought, similar sleep–wake disturbances have been found in sporadic Creutzfeldt-Jakob-prion disease (Landolt et al).

Major *head injury* is an important cause of sleep disturbance. The abnormalities, which may persist for months or years, consist mainly of a decrease in stages 1 and 2 sleep, and less than the expected amounts of REM sleep and dreaming. Some patients in the persistent vegetative state show a cycle of changes in the EEG, progressing from a picture of abortive spindles and K complexes with cyclic alterations in respiration and pupil size to the acquisition of a more normally structured sleep activity. This sequence usually presages the change from a state of coma to one of minimally conscious state (Chap. 17). Organized sleep activity is absent in virtually all types of coma that are the result of anatomic damage to the brain. An exception, albeit a semantic one, occurs in the unusual condition known as “spindle coma,” in which persistent coma, and the electrographic features of sleep coexist. This particular combination of events has been described after head trauma, and rarely, in association with profound metabolic encephalopathies. Despite what appears to be a genuine comatose state (not simply hypersomnolence) from a lesion of the reticular-activating system, the EEG displays frequent spindle activity and vertex waves, attesting to the integrity of thalamocortical pathways for sleep activity (see Nogueira de Melo et al).

Migraine, cluster headaches, and paroxysmal hemiparesis all have been linked to certain sleep stages and are discussed in Chap. 10 in relation to other forms of “hypnic headaches.” A variety of sleep disturbances may accompany brain tumors or follow surgical resection of

an intracranial tumor. These include excessive daytime sleepiness, sleep apnea, and, rarely, nocturnal epilepsy. The location of the lesion, rather than the tumor type, is predictive of such a disturbance; thus, tumors affecting the hypothalamus, and pituitary are associated with excessive daytime drowsiness, whereas medullary lesions cause respiratory disturbances that may affect sleep (Rosen et al). A symptomatic form of narcolepsy is associated with tumors located adjacent to the third ventricle, and midbrain (see below). Schwartz and associates reported transient cataplexy (see further on) following surgery for a craniopharyngioma, but a delirious state has been more common in a few cases for which we have been consulted.

However, it is the disturbed sleep patterns in patients with Alzheimer disease, Huntington chorea, olivopontocerebellar degeneration, and progressive supranuclear palsy that have attracted the most attention by neurologists (Parkes). Dreaming is also absent in some of these conditions. The peculiarities of sleep in *Parkinson disease* have been extensively studied. Many patients in the early stages of the disease complain of fragmented and unrestful sleep, particularly in the early morning hours; some advanced cases have pathologic insomnia, and this is influenced also by medications used to treat the disease and by deep brain stimulation (see Chap. 39 for a discussion of the nonmotor effects of Parkinson disease). The loss of natural body movements and the alerting effects of L-dopa contribute to the insomnia. The directly acting dopaminergic agonist drugs used for the treatment of Parkinson disease may have the side effect of a pronounced and often rapid daytime sleepiness; however, a similar problem arises in some patients with advancing disease alone.

In striatonigral degeneration (multiple system atrophy), Lewy-body disease, and other parkinsonian syndromes, there is often a characteristic REM sleep disorder, in which the patient moves and speaks violently and aggressively during dreaming. This “REM sleep behavior disorder” does not reflect the personality of the patient or his behavior in the daytime. The majority of patients are able to recall their dream and report that it involved escaping or protecting another person from harm. In these degenerative conditions that affect the basal ganglia the sleep disturbances may precede other symptoms or be an essential part of the illness (see later in this chapter and Chap. 39).

Disorders of Sleep Associated with Changes in Circadian Rhythm

Sleep is also disturbed and diminished when the normal circadian rhythm of the sleep–wake cycle is exogenously altered. This is observed most often in shift workers, who periodically change their work schedule from day to night, and as a result of transmeridianal air travel—i.e., jet lag (Baker and Zee). Eastbound travelers fall asleep late and face an early sunrise. The consequent fatigue is a product of both sleep deprivation and a phase change required by changing time zones. A review of the subject can be found by Sack. One antidote is to reset one’s watch on the plane and conform to the routine of the

destination—i.e., to stay awake all day until the usual evening hour for sleep—and to take a short-acting sedative at bedtime. Melatonin is also used for this purpose, and a meta-analysis by Herxheimer and Petrie of four trials suggests it is slightly effective. These measures facilitate the resetting of the circadian rhythm. Westbound travelers face a late sunset and a long night's sleep and adjust more readily to resetting of the circadian rhythm than do those traveling east. Exposure to light during the extended day is helpful in entraining the sleep cycle; this adjustment is also accomplished more easily when traveling west than east. Shifting of the circadian rhythm in animals suggests that brief exposure to light at crucial times effectively resets the sleep-wake cycle; apparently, the period just before 4 A.M. is a nodal time for susceptibility to this phase change. The sleep problems caused by shift work are more complicated (see Monk).

The *delayed-sleep-phase syndrome* is a chronic inability to fall asleep and to arise at conventional clock times. Sleep onset is delayed until 3 to 6 A.M.; the subject then sleeps normally until 11 A.M. to 2 P.M. An imposed sleep period from 11 P.M. to 7 A.M. leads to a prolonged sleep latency and daytime sleepiness. By contrast, the *advanced-sleep-phase syndrome* is characterized by an early evening sleep onset (8 to 9 P.M.) and early morning awakening (3 to 5 A.M.). Simply delaying the onset of sleep usually fails to prevent early morning awakening. This pattern is not uncommon among healthy elderly persons (and also among college students), in whom it should probably not be defined as an insomnia syndrome. Still other persons show a completely *irregular sleep-wake pattern*; sleep consists of persistent but variable short or long naps throughout the night and day, with a nearly normal 24-h accumulation of sleep.

Parasomnic Disturbances and Isolated Sleep Symptoms

Although new classifications have rearranged the nosology of these phenomena, included under this title are several diverse disorders: somnolescent starts, sensory paroxysms, nocturnal paroxysmal dystonia, sleep paralysis, night terrors and nightmares, somnambulism, and REM sleep behavior disorder.

Somnolescent (Sleep, Hypnic, Myoclonic) Starts

As sleep comes on, certain motor centers may be excited to a burst of insubordinate activity. The result is a sudden "start" or myoclonic bodily jerk of large amplitude, which rouses the incipient sleeper. It may involve one or both legs or the trunk, less often, the arms. If the start occurs repeatedly during the process of falling asleep and is a nightly event, it may become a matter of great concern to the patient. The starts are more apt to occur in individuals in whom the sleep process develops slowly; they are especially frequent under conditions of tension and anxiety. Polysomnographic recordings have shown that these bodily jerks occur at the moment of falling asleep or during the early stages of sleep. Sometimes they appear as part of an arousal response to a faint external

stimulus and are then associated with a frontal K complex in the EEG. These bodily jerks are not variants of epilepsy.

A small proportion of otherwise healthy infants exhibit rhythmic jerking of the hands, arms, and legs or abdomen, both at the onset and in the later stages of sleep (*benign neonatal myoclonus*). The movements begin in the first days of life and disappear within months. There may be a familial tendency toward these movements. Coulter and Allen differentiate this state from myoclonic epilepsy and neonatal seizures by the absence of EEG changes, and its occurrence only during sleep.

Sensory Sleep Paroxysms

Sensory centers may be disturbed in a similar way to the earlier-described sleep starts, either as an isolated phenomenon or in association with motor phenomena. The patient, dropping off to sleep, may be roused by a sensation that darts through the body, a sudden flash of light, or a sudden crashing sound or thunderclap of head pain—cephalgia fugax, or "the exploding head syndrome" (Pearce). Sometimes there is a sensation of being turned or lifted, and dashed to the ground; conceivably, these are sensory paroxysms involving the labyrinthine-vestibular mechanism. Though obvious causes for concern by patients, these sensory paroxysms are benign.

Nocturnal Frontal Lobe Epilepsy

Numerous forms of epilepsy become more prominent during sleep as noted in a later section and in Chap. 16 on epilepsy. However, one isolated seizure disorder is characterized by paroxysmal bursts of generalized choreoathetic, ballistic, and dystonic movements occurring during NREM sleep (Lugaresi et al, 1986). Sometimes the patient appears awake and has a fearful or astonished expression, or there are repetitive utterances and an appearance of distress, similar to what is seen in night terrors, the main differential diagnosis discussed further on. The attacks may begin at any age, affect both sexes, and are usually nonfamilial. Two forms of this disorder have been recognized: in one, the attacks last 60 s or less; they may be diurnal as well as nocturnal; some patients in addition have epileptic seizures of the more usual type; and all respond to treatment with carbamazepine. The studies of Tinuper and coworkers, using prolonged video-EEG monitoring, indicate that these brief attacks of nocturnal paroxysmal dystonia may actually be epileptic seizures of frontal lobe origin. In a second and more rare type, the attacks are longer lasting (2 to 40 min). Ictal and interictal EEGs during wakefulness and sleep are normal, and these attacks do not respond to anticonvulsants of any type. Except for the lack of familial incidence and occurrence only during sleep, the disorder is very much the same as the "familial paroxysmal dystonic choreoathetosis" described by Lance (see "Paroxysmal Choreoathetosis and Dystonia" in Chap. 4).

Sleep Paralysis

Curious paralytic phenomena, referred to as *pre- and post-dormital paralyses*, may occur in the transition from the sleeping to the waking state. Sometimes in the morning and less

frequently when falling asleep, otherwise healthy persons—though awake, conscious, and fully oriented—are seemingly unable to activate their muscles. Respiratory and diaphragmatic function and eye movements are usually unaffected, although a few patients have reported a sensation of being unable to breathe. They lie as though still asleep, with eyes closed, and may become quite frightened while engaged in a struggle for movement. They have the impression that if they could move one muscle, the paralysis would be dispelled instantly, and they would regain full power. It has been stated that the slightest stimulus, such as the touch of a hand or calling the patient's name, will abolish the paralysis. Sleep deprivation is a common precipitant to the syndrome.

Such attacks are also observed in patients with narcolepsy (discussed later in this chapter) and with the hypersomnia of the pickwickian syndrome and other forms of sleep apnea. Some cases are familial.

The weakness or paralysis is thought to be a dissociated form of the atonia of REM sleep. Usually, the attacks are brief (minutes or less); if they occur in isolation and only on rare occasions, they are of no special significance. If frequent, as in narcolepsy, they can be prevented by the use of tricyclic antidepressants, particularly clomipramine, which has serotonergic activity.

Night Terrors and Nightmares

The night terror (*pavor nocturnus*) is mainly a problem of childhood. It usually occurs soon after falling asleep, during stage 3 or 4 sleep. The child awakens abruptly in a state of intense fright, screaming or moaning, with marked tachycardia (150 to 170 beats/min) and deep, rapid respirations. Children with night terrors are often sleepwalkers as well, and both kinds of attack may occur simultaneously. The entire episode lasts only a minute or two, and in the morning the child recalls nothing of it or only a vague unpleasant dream. It has been suggested that night terrors and somnambulism represent impaired or partial arousal from deep sleep, as EEGs taken during such episodes show a waking type of mixed frequency and alpha pattern. Children with night terrors and somnambulism do not show an increased incidence of psychologic abnormalities and tend to outgrow these disorders. The persistence of such problems into adult life, however, has, in a small number of cases, been associated with psychopathology (Kales et al). It has been found that diazepam, which reduces the duration of the deep stages of sleep, will prevent night terrors. Selective serotonin reuptake inhibitors have also been used successfully, especially when night terrors are associated with sleepwalking. Frequent night terrors have reportedly been eliminated by having parents awaken the child for several successive nights, just prior to the usual time of the attack or at the first sign of restlessness and autonomic arousal (Lask).

Frightening dreams or nightmares are far more frequent than night terrors and affect children and adults alike. They occur during periods of normal REM sleep and are particularly prominent during periods of increased REM sleep (REM rebound) following the withdrawal of alcohol or other sedative-hypnotic drugs that had suppressed

REM sleep chronically. Autonomic changes are slight or absent, and the content of the dreams can usually be recalled in considerable detail. Some of these dreams (e.g., the ones occurring in the alcohol-withdrawal period) are so vivid that the patient may later have difficulty in separating them from reality; indeed, they may merge with the hallucinations of delirium tremens. Nightmares are of little significance as isolated events. Fevers dispose to them, as do conditions such as indigestion and the reading of bloodcurdling stories or exposure to terrifying movies or television programs before bedtime (truly). Some patients report nightmares and extremely vivid dreams when first taking certain medications such as beta blockers and, particularly in our experience, L-dopa. We have also consulted on a few patients who complained of almost nightly nightmares and concurrent severe headaches, but without apparent depression or other psychiatric illness; the nature of their problem was obscure. Persistent nightmares may be a pressing medical complaint and are often accompanied by other behavioral disturbances or anxieties.

Childhood Somnambulism and Sleep Automatism

This condition occurs far more commonly in children (average age: 4 to 6 years) than in adults, and is often associated with nocturnal enuresis and night terrors, as indicated above. It is estimated that 15 percent of children have at least one episode of sleepwalking, and that 1 in 5 sleepwalkers has a family history of this disorder. Motor performance and responsiveness during the sleepwalking incident vary considerably. The most common behavioral abnormality is for a patient to sit up in bed or on the edge of the bed without actually walking. When walking about the house, he may turn on a light or perform some other familiar act. There may be no outward show of emotion, or the patient may be frightened (night terror), but the frenzied, aggressive behavior of some adult sleepwalkers, described below, is rare in the child. Usually the eyes are open, and such sleepwalkers are guided by vision, thus avoiding familiar objects; the sight of an unfamiliar object may awaken them. Sometimes they make no attempt to avoid obstacles and may injure themselves. If spoken to, they make no response; if told to return to bed, they may do so, but more often they must be led back. Sometimes they repeatedly mutter strange phrases or perform certain repetitive acts, such as pushing against a wall or turning a doorknob back and forth. The episode lasts for only a few minutes, and the following morning, they usually have no memory of it, or only a fragmentary recollection.

A popular belief is that the sleepwalker is acting out a dream. The observations of sleep laboratories are entirely at variance with this view, as somnambulism has been found to occur almost exclusively during deeper stages of NREM sleep (stage N3) and during the first third of the night when dreaming is least likely to occur. In fact, the entire nocturnal sleep pattern of such individuals does not differ from normal. Also, there is no evidence that somnambulism is a form of epilepsy. It is probably allied to talking in one's sleep, although the two conditions

seldom occur together. Sleepwalking must be distinguished from fugue states and ambulatory automatisms of complex partial seizures discussed in Chap. 16.

The major consideration in the treatment of childhood somnambulism is to guard patients against injury by locking doors and windows, removing dangerous objects from the patients' usual routes of march, having them sleep on the ground floor, etc. Children usually outgrow this disorder; parents should be reassured on this score and disabused of the notion that somnambulism is a sign of psychiatric or any other disease.

Somnambulism in Adults

The onset of sleepwalking or night terrors for the first time in adult life is most unusual, and, in an occasional case, may suggest the presence of psychiatric disease or drug intoxication. Almost always, the adult sleepwalker has a history of sleepwalking as a child, although there may have been a period of freedom between the childhood episodes and their reemergence in the third and fourth decades. Adult somnambulism also occurs during N3 of NREM sleep, but unlike the childhood type, is not confined to the earlier part of the night. If one extends the category of somnambulism to all forms of nocturnal wandering, it seems to be remarkably common, with a lifetime prevalence of 29% of U.S. adults according to the survey by Ohayon and colleagues.

Somnambulism in the adult, as in the child, can be a purely passive event unaccompanied by fear or other signs of emotion. More frequently, however, the attack is characterized by frenzied or violent behavior associated with fear and tachycardia, like that of a night terror and sometimes with self-injury. Very rarely, crimes have reportedly been committed during sleepwalking, but the authors are skeptical that organized and planned sequential activity is possible. The finding of normal sleep patterns on polysomnography distinguishes these attacks from complex partial seizures. They can be eliminated or greatly reduced by the administration of clonazepam (0.5 to 1.0 mg) at bedtime. Some patients respond better to a combination of clonazepam and phenytoin or to flurazepam (Kavey et al).

An associated but unclassifiable disorder is "sleep eating" in which the individual seeks out mainly carbohydrates and is only aware of their actions on the following morning when they see the mess they have left. Also, in the provocatively named "sexomnia," the individual, male or female, engages in sexual activity, sometimes forcefully, and has no recollection of the events. The status of these syndromes as authentic parasomnias is unclear.

REM Sleep Behavior Disorder

This is a recognized parasomnic disorder, occurring in adult life, most commonly in older men without a history of childhood sleepwalking. It is characterized by attacks of vigorous, agitated, and often dangerous motor activity accompanied by vivid dreams (Mahowald and Schenck). The characteristic features are angry speech with shouting, violent activity with injury to self and bed mate, a very high arousal threshold, and the variable but sometimes detailed recall of a nightmare of being attacked and

fighting back or attempting to flee. The episodes vary in frequency in affected individuals, occurring once every week or two or several times nightly. The episodes, which occur *exclusively during REM sleep*, usually in the second half of the night, are out of keeping with the patient's waking personality. Polysomnographic recordings during these episodes have disclosed augmented muscle tone but no seizure activity.

The rare appearance of this disorder with pontine infarctions has been mentioned earlier in the chapter. However, in a series of 93 cases of REM sleep behavior disorder reported by Olson and colleagues, more than half were associated with some other neurologic disorder, in particular Parkinson disease, multiple system atrophy, and Lewy-body dementia, but in other series, with a number of degenerative and varied neurologic conditions. A more systemic polysomnographic examination of 457 patients with Parkinson disease by Sixel-Döring and colleagues found REM sleep behavior disorder in 46%. Viewed from another perspective, Postuma and coworkers have reported that one-quarter of individuals with idiopathic REM sleep disorder later developed a neurodegenerative disorder, similar to or slightly lower than other series. These observations have led to the suggestion that this disorder is an early manifestation of a degenerative brain disease characterized by the deposition of alpha-synuclein in certain neuronal systems, as summarized by Boeve and associates.

The episodes can be suppressed by the administration of clonazepam in doses of 0.5 to 1.0 mg at bedtime and by melatonin, 3 to 12 mg. The advantage of the latter is that sleep apnea is not affected as it is with benzodiazepines. Discontinuation of medication, even after years of effective control, has resulted in relapse. Antidepressants are said to exacerbate the disorder with the possible exception of bupropion.

The patient and family should probably be advised about safety including removal of weapons, sharp objects and try to insure spousal safety by this and by means of sleeping in another room.

Nocturnal Epilepsy (See also Chap. 16)

It has long been known that seizures, both convulsive and nonconvulsive, often occur during sleep, especially in children. This is such a frequent occurrence that the practice of inducing sleep has been adopted as an activating EEG procedure to obtain confirmation of epilepsy. Seizures may occur soon after the onset of sleep or at any time during the night, but mainly in stages 1 and 2 of NREM sleep or, rarely, in REM sleep. They are also common during the first hour after awakening. On the other hand, deprivation of sleep may be conducive to a seizure.

Sleeping epileptic patients may attract attention to their seizures by a cry, violent motor activity, unusual but stereotyped actions, such as sitting up and crossing the arms over the chest, the adoption of a "fencing" posture, or labored breathing. After the tonic-clonic phase, patients become quiet and fall into a state resembling deep sleep, but they cannot be aroused from it for some

minutes or longer. If the nocturnal seizure is unobserved, the only indication of it may be disheveled bedclothes, a few drops of blood on the pillow from a bitten tongue, wet bed linen from urinary incontinence, or sore muscles. Or the occurrence of a seizure may be disclosed only by confusion, muscle soreness, or headache, the common aftermaths of a major generalized seizure. Rarely, a patient may die in an epileptic seizure during sleep, sometimes from smothering in the bed clothes or aspirating vomitus or for some obscure reason (possibly respiratory or cardiac dysrhythmia). Epilepsy occasionally occurs in conjunction with night terrors and somnambulism; the question then arises whether the latter disorders represent postepileptic automatisms. Usually no such relationship is established. EEG studies during a nocturnal period of sleep are most helpful in such cases. Measurement of serum creatine kinase concentration in the hours following an event may distinguish seizure from night terrors, and the other described sleep-related motor behaviors.

Pathologic Excessive Sleep (Hypersomnia)

Encephalitis lethargica, or von Economo "epidemic encephalitis," the remarkable illness that appeared on the medical horizon as a pandemic following World War I, provided some of the most dramatic instances of pathologic somnolence. Protracted sleep lasting for days to weeks was such a prominent symptom of this disease that it was called *sleeping sickness* (a term also applied to African trypanosomiasis, as noted below). The patient appeared to be in a state of continuous sleep, or *somnolence*, and could be kept awake only by constant stimulation. Although the infective agent of von Economo disease was never isolated, the pathologic anatomy was fully disclosed by many excellent studies, all of which demonstrated a destruction of neurons in the midbrain, subthalamus, and hypothalamus. Patients who survived the acute phase of the illness often had difficulty in reestablishing their normal sleep-wake rhythm. As the somnolence disappeared, some patients exhibited a reversal of the normal pattern, tending to sleep by day, and stay awake at night; many of them also developed a parkinsonian syndrome months or years later. The hypersomnia was possibly related to destruction or functional paralysis of dopamine-rich neurons in the substantia nigra, resulting in overactivity of the raphe (serotonergic) neurons.

Hypersomnia is also a manifestation of *trypanosomiasis*, the common cause of *sleeping sickness* in Africa, and of other diseases localized to the mesencephalon, and the floor and walls of the third ventricle. Small tumors in this area have been associated with arterial hypotension, diabetes insipidus, hypo- or hyperthermia, and protracted somnolence lasting many weeks. Such patients can be aroused; but if left alone, they immediately fall asleep. Traumatic and vascular lesions and other diseases affecting the mesencephalon may have a similar effect.

Sleep drunkenness is the name given to a special form of hypersomnia, characterized by a failure of the patient to attain full alertness for a protracted period after awakening. Unsteadiness, drowsiness, disorien-

tation, and automatic behavior are the main features. This disorder is usually associated with idiopathic hypersomnia, and sometimes with sleep apnea or other forms of sleep deprivation, but often no such connection can be discerned, in which case a motivational factor should be suspected.

An interesting type of transient unresponsiveness in elderly patients, as described by Haimovic and Beresford, has been in our experience akin to a deep sleep, but the EEG has not shown sleep patterns.

Kleine-Levin Syndrome

Kleine in 1925 and Levin in 1936 described an episodic disorder characterized by somnolence and overeating. For days or weeks, the patients, mostly adolescent boys, sleep 18 h or more a day, awakening only long enough to eat and attend to toilet needs. They appeared dull, often confused, and restless, and were sometimes troubled by hallucinations. In the series of 18 cases collected by Critchley, the age range was from puberty to 45 years. There may be a brief prodromal period of inertia and drowsiness. The duration of nocturnal sleep may be greatly prolonged, or, as in our patients referred to below, they may sleep for days on end. Food intake during and around the period of hypersomnia may exceed three times the normal (bulimia) and occurs almost compulsively during brief periods of semiwakefulness; to a variable extent, there are other behavioral changes such as social withdrawal, negativism, slowness of thinking, incoherence, inattentiveness, and disturbances of memory. The somnolence has been well studied by modern laboratory methods; except for the total duration of sleep, the individual components of the NREM and REM cycles are normal. Between episodes these patients are behaviorally and cognitively normal.

The basis of this condition has never been clarified. A psychogenic mechanism has been proposed, without foundation in our opinion. The syndrome usually disappears during adulthood, and there is limited pathologic material (see further discussion in the context of hypothalamic syndromes in Chap. 27). A series of 108 cases reviewed by Arnulf and colleagues frame the clinical features; a predominance of males, higher C-reactive protein than controls, and a history of early childhood developmental problems. There was no human leukocyte antigen (HLA) clustering, but children of Jewish heritage were overrepresented. We have cared for a sibling pair who had the illness into young adulthood (Katz and Ropper). The case reported by Carpenter and coworkers, in which an acute and chronic inflammation in the medial thalamus, but not the hypothalamus, was found, must be questioned as representative of the idiopathic adolescent condition. Their patient was a man 39 years of age who had episodes of diurnal drowsiness, hyperphagia (intermittently relieved by methylphenidate), and hypersexuality over a period of months. In some patients with this disorder, schizophrenic and sociopathic symptoms have been recorded between attacks, raising doubt as to whether all the reported cases are of the same type. We have seen variants of this syndrome manifesting

themselves in drowsiness and extreme inactivity lasting for a few weeks, then with a complete return to normalcy. In two of our patients, the use of serotonergic antidepressants lengthened the interval between episodes.

No consistent change in the level of hypocretin (orexin) has been found in the spinal fluid, as occurs in narcolepsy (see further on), and the two disorders are distinct. In one typical case, there was pronounced hypoperfusion of the left medial temporal lobe both during and between attacks, but the interpretation of this finding is unclear (Portilla et al).

No treatment has been consistently effective (e.g., antidepressant drugs), but some of the stimulants that are used for the treatment of narcolepsy may be useful (see further on).

Finally, it should be mentioned that sleep laboratories now recognize a form of *idiopathic hypersomnia* in which there are repeated episodes of drowsiness throughout the day. This condition is discussed further on, in relation to the diagnosis of narcolepsy, with which it is most often confused.

A related disorder has been described of “menstrual related hypersomnia” that has a cyclic catamenial nature.

Sleep Apnea and Excessive Daytime Sleepiness

Excessive daytime sleepiness is a common complaint in general medical practice (Table 19-2). Certainly, the most frequent causes are inadequate sleep and the use of any one of the large variety of medications that are not

prescribed primarily for their sedative effect. Abuse of alcohol and illicit drugs should also be included in this category. Most conditions associated with severe fatigue produce daytime sleepiness and a desire to nap. A notable medical cause is infectious mononucleosis but many other viral infections have the same effect. Certain chronic neurologic conditions can produce fatigue and sleepiness, multiple sclerosis being the outstanding example. Among general medical conditions, hypothyroidism and hypercapnia must always be considered when daytime sleepiness is a prominent feature. One must not overlook the possibility that excessive daytime drowsiness is the result of repeated episodes of sleep apnea, discussed below, or the disruption of nocturnal sleep by disorders such as the restless legs syndrome.

As mentioned above, REM sleep is characterized by irregular breathing, and this may include several brief periods of apnea up to 10 s in duration. Such apneas and those occurring at the onset of sleep are not in themselves considered to be pathologic. In some individuals, however, sleep-induced apneic periods are particularly frequent and prolonged (> 10 s) and such a condition is responsible for a variety of clinical disturbances in children and adults. This pathologic form of sleep apnea may be the result of a reduction of respiratory drive (so-called central apnea), an obstruction of the upper airway, or a combination of these two mechanisms.

Sleep-Disordered Breathing

Obstructive Sleep Apnea Apnea of the *obstructive type* in which the posterior pharyngeal muscles collapse and narrow the upper airway is far more common than the central variety. Obstructive apnea is associated with obesity and also accompanies acromegaly, hypothyroidism or myxedema, micrognathia, and myotonic dystrophy. In children, more than in adults, adenotonsillar hypertrophy may be a factor. Instances occur as a result of neuromuscular diseases that weaken the posterior pharyngeal musculature; motor neuron disease is the most common example of this group. Obstructive sleep apnea is characterized by noisy snoring of a cyclic type. After a period of regular albeit noisy breathing, there occurs a waning of breathing efforts; then, despite repeated inspiratory efforts, airflow ceases. Following a prolonged period of apnea (10 to 30 s or even longer), the patient makes a series of progressively greater breathing efforts until breathing resumes, accompanied by very loud snorting sounds and a brief arousal.

Obstructive sleep apnea occurs during both REM and NREM sleep. The upper respiratory muscles (genioglossus, geniohyoid, tensor veli palatini, and medial pterygoid) normally contract just before the diaphragm contracts, resisting the collapse of the oropharynx. If the airway is obstructed or the muscles are weakened and then go slack, the negative intrathoracic pressure causes narrowing of this passage. Sedative medications, alcohol intoxication, excessive tiredness, a recent stroke, head trauma or other acute neurologic disease, and primary pulmonary disease may all exaggerate obstructive sleep apnea, particularly in the obese patient with a tendency to snore.

Table 19-2

CAUSES OF DAYTIME SLEEPINESS

1. Medications (including many types of sedatives, tranquilizers, anticonvulsants, antihistaminics, antidepressants, β -adrenergic blockers, and atropinic drugs), L-dopa and dopaminergic agonists, abuse of alcohol and illicit drugs
2. Acute medical illness of the mononucleosis type, including mundane respiratory and gastrointestinal infections
3. Postsurgical, postconcussive, and postanesthetic states

10. Narcolepsy-cataplexy
11. Idiopathic hypersomnia

Hypoxia or perhaps other stimuli induce an arousal response, either a lightening of sleep or a very brief awakening, which is followed by an immediate resumption of breathing. The patient quickly falls asleep again and the sequence is repeated, several hundred times a night in severe cases, greatly disrupting the sleep pattern and reducing the total sleep time. Paradoxically, these patients are very difficult to rouse at all times during the night.

Obstructive sleep apnea is predominantly a disorder of overweight, middle-aged men and usually presents as *excessive daytime sleepiness*, a complaint that is sometimes mistaken for narcolepsy (see below). Other patients, usually those with the much-less-common central form of apnea, complain mainly of a disturbance of sleep at night, or insomnia, which may be incorrectly attributed to anxiety or depression. The occurrence of an obstructive sleep apnea is accompanied after a period of weeks or months by progressive hemoglobin oxygen desaturation, hypercapnia and hypoxia, a transient increase in systemic and pulmonary arterial pressures, and sinus bradycardia or other arrhythmias. Morning headache, inattentiveness, grogginess, and decline in school or work performance are other symptoms attributable to sleep apnea. Ultimately, systemic and pulmonary arterial hypertension, cor pulmonale, polycythemia, and heart failure may develop. When combined with obesity, these symptoms have been referred to as the “pickwickian syndrome,” so named by Burwell and coworkers, who identified this clinical syndrome with that of the extraordinarily sleepy, red-faced, fat boy described by Dickens in *The Pickwick Papers*.

The full-blown syndrome of obstructive sleep apnea is readily recognized by the features of daytime sleepiness, loud snoring, and the typical habitus of affected individuals. However, in patients who complain only of excessive daytime sleepiness or insomnia, the diagnosis may be elusive and require all-night polysomnographic sleep monitoring.

Central Sleep Apnea This disorder has been observed in patients with a variety of severe and life-threatening lower brainstem lesions—bulbar poliomyelitis, lateral medullary infarction, spinal (high cervical) surgery, syringobulbia, brainstem encephalitis, as well as with striatonigral degeneration, Creutzfeldt-Jakob disease, anoxic encephalopathy, and olivopontocerebellar degeneration. When a unilateral lesion (e.g., infarction) of the medulla is the cause, there is almost always involvement of crossing fibers between respiratory nuclei (see discussion in Chap. 26).

In addition to these symptomatic forms of sleep apnea, there is a disorder referred to as *primary*, or *idiopathic, hypoventilation syndrome* (“Ondine’s curse,” as described in Chap. 26). This last term is now applied to many forms of total loss of automatic breathing, especially during sleep. Awakenings during the night are frequent, usually after an apneic period, and insomnia is a common complaint. Snoring is mild and intermittent. In the few autopsied cases of congenital central hypoventilation of childhood, Liu and colleagues found the external arcuate nuclei of the medulla to be absent,

and the neuron population in the medullary respiratory areas to be depleted.

Complex sleep apnea, or “treatment emergent central sleep apnea,” occurs most often in patients with cardiovascular conditions, particularly congestive heart failure, wherein, after sleep apnea is treated with positive airway pressure, central apnea emerges.

Treatment The approach is governed by the severity of symptoms and the predominant type of apnea, central or obstructive. In the treatment of *obstructive apnea*, continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BIPAP) is the most useful measure. These therapies are delivered by a tight-fitting nasal mask that is worn at night and connected to a pressure-cycled ventilator that is triggered by the patient’s breath. The increased airway pressure maintains patency of the naso- and oropharynx, thereby reducing the obstruction. A nasal device that passively resists nasal collapse by providing expiratory resistance is used by some specialists for mild sleep apnea. All of these approaches have a level of discomfort that is not tolerable to some patients.

Patients benefit from losing weight, lateral positioning during sleep, and avoidance of alcohol and other sedative drugs. Surgical correction of an upper airway defect may be helpful, but it is difficult to predict which patients will benefit. There are no clear guidelines for procedures such as uvulopalatopharyngoplasty and related surgeries or uvulectomy and tonsillectomy except in children. These may obliterate snoring more than it ameliorates the sleep apnea. Oral alignment devices that are produced by dentists, aimed at advancing the mandible, have been helpful to some patients, especially for those who cannot tolerate positive pressure.

Those few patients with the most severe hypersomnia and cardiopulmonary failure who cannot tolerate nocturnal positive pressure ventilation require tracheostomy and nocturnal respirator care. (See Parkes for a fuller account of therapeutic measures.) Some patients with non-obstructive apnea may also benefit from nighttime treatment with CPAP, but the results are far less consistent than with the obstructive type.

In *central apnea*, any underlying abnormality, such as congestive heart failure or nasal obstruction, should, of course, be treated insofar as possible. Where no underlying cause can be found, one of several medications—acetazolamide, medroxyprogesterone, protriptyline, and particularly clomipramine—may be helpful in the short run (Brownell et al). However, drug treatment has proven generally unsatisfactory. Low-flow oxygen may also be useful in reducing central sleep apnea.

Narcolepsy and Cataplexy

This clinical entity has long been known to the medical profession. Gélinau gave it the name *narcolepsy* in 1880, although several authors had described the recurring attacks of irresistible sleep even before that time. Gélinau had also mentioned that the sleep attacks were sometimes accompanied by falls (“astasia”), but it was Loewenfeld, in 1902, who first recognized the common association between the sleep attacks and the

temporary paralysis of the somatic musculature during bouts of laughter, anger, and other emotional states; this was referred to as cataplectic inhibition by Henneberg (1916), and later as cataplexy by Adie (1926). The term *sleep paralysis*—used to designate the brief, episodic loss of voluntary movement that occurs during the period of falling asleep (hypnagogic, or predormital) or less often when awakening (hypnopompic, or postdormital)—was introduced by S.A. Kinnier Wilson in 1928. Actually, Weir Mitchell had described this latter disorder in 1876, under the title of *night palsy*.

Sometimes sleep paralysis is accompanied or just preceded by vivid and terrifying hallucinations (*hypnagogic hallucinations*), which may be visual, auditory, vestibular (a sense of motion), or somatic (a feeling that a limb or finger or other part of the body is enlarged or otherwise transformed). These four conditions—narcolepsy, cataplexy, hypnagogic paralysis, and hallucinations—constitute a clinical tetrad. Wilson has reviewed the historical aspects and early accounts of this subject. The most important observations regarding the pathophysiology of this process have been special relationship to a disordered pattern of REM sleep, and the more recent finding of abnormalities in hypothalamic substances that induce sleep, as discussed below.

Clinical Features

This syndrome is encountered regularly by neurologists; Daly and Yoss recorded about 100 new cases a year at the Mayo Clinic. Dement and colleagues have estimated the prevalence at 50 to 70 per 100,000 in the San Francisco and Los Angeles areas. Men and women are affected equally. Several papers have found an epidemiologic relationship to just preceding outbreaks of H1N1 pandemics and the vaccine (see Ham et al and Dauvilliers et al).

As a rule, narcolepsy has a gradual onset between the ages of 15 and 35 years; in fully 90 percent of narcoleptics, the condition is established by the 25th year of life. Narcolepsy is usually the first symptom, less often cataplexy, and rarely sleep paralysis. The essential disorder is one of frequent attacks of irresistible sleepiness. Several times a day, usually after meals or while sitting in class or in other boring or sedentary situations, the affected person is assailed by an uncontrollable desire to sleep. The eyes close, the muscles relax, breathing deepens slightly, and by all appearances, the individual is dozing. A noise, a touch, or even the cessation of the lecturer's voice is enough to awaken the patient. The periods of sleep rarely last longer than 15 min unless the patient is reclining, when he may continue to sleep for an hour or longer. At the conclusion of a nap, the patient feels somewhat refreshed. It should be emphasized that there are many narcoleptics who tend to be pervasively drowsy throughout the day. What distinguishes the typical narcoleptic sleep attacks from commonplace postprandial drowsiness and napping is the frequent occurrence of the former (two to six times every day as a rule), their irresistibility, and their occurrence in unusual situations, as while standing, eating, or carrying on a conversation. Blurring of vision, diplopia, and ptosis may attend the drowsiness and may bring the patient first to an ophthalmologist.

In addition to episodes of outright sleep, narcoleptics, like other very drowsy persons, may experience episodes of automatic behavior and amnesia. Initially the patient feels drowsy and may recall attempts to fight off the drowsiness, but gradually he loses track of events. The patient may continue to perform routine tasks automatically but does not respond appropriately to a new demand or answer complex questions. Often there is a sudden burst of words, without meaning or relevance to what was just said. Such an outburst may terminate the attack, for which there is complete or nearly complete amnesia. In many respects, the attacks resemble episodes of nocturnal sleepwalking. Such attacks of automatic behavior and amnesia are common, occurring in more than half of a large series of patients with narcolepsy-cataplexy (Guilleminault and Dement). Affected patients are frequently involved in driving accidents, even more frequently than epileptics.

Nocturnal sleep is often disrupted and reduced in amount. The number of hours in a 24-h day spent in sleep by the narcoleptic is no greater than that of a normal individual. Narcoleptics have an increased incidence of sleep apnea and periodic leg and body movements, but not of somnambulism.

Approximately 70 percent of narcoleptics first seeking help will report having some form of cataplexy, and about half of the remainder will develop cataplexy later in life. *Cataplexy* refers to a sudden loss of muscle tone brought on by strong emotion—that is, circumstances in which hearty laughter or, more rarely, excitement, surprise, anger, or intense athletic activity cause the patient's head to fall forward, the jaw to drop, the knees to buckle, even with sinking to the ground—all with perfect preservation of consciousness. Cataplectic attacks occur without provocation in perhaps 5 percent of cases. The attacks last only a few seconds or a minute or two and are of variable frequency and intensity. In most of our patients, they have appeared at intervals of a few days or weeks. Exceptionally, there are many attacks daily and even status cataplecticus, in which the atonia lasts for hours. This is more likely to happen at the beginning of the illness or upon discontinuing tricyclic medication.

Most attacks of cataplexy are partial (e.g., only a dropping of the jaw or “weakening of the knees”). Wilson found that the tendon reflexes were abolished during the attack. Pupillary reflexes are absent in some cases.

Rarely, cataplexy precedes the advent of sleep attacks, but usually it follows them, sometimes by many years. Sleep paralysis and hypnagogic hallucinations together are stated to occur in about half the patients. Of course, hypnagogic paralysis and hallucinations occur in otherwise normal persons, and normal children, especially when tickled, may laugh to the point of cataplexy. About 10 percent of persons with sleep attacks indistinguishable from those of narcolepsy have none of the associated phenomena (“independent narcolepsy”), and in these cases, REM periods are not found consistently at the onset of sleep (see further on).

Once established, narcolepsy and cataplexy usually continue for the remainder of the patient's life. The degree of sleepiness rarely lessens, although cataplexy,

sleep paralysis, and hallucinations improve or disappear with age in about one-third of patients who have those features (Billiard and Cadilhac). No other condition is consistently associated with narcolepsy-cataplexy, and none develops later.

Cause and Pathogenesis

A familial component has been recognized for years; the risk of narcolepsy in a first-degree relative of an affected individual is 1 to 2 percent, more than 25 times that in the general population. As reviewed by Chabas and colleagues, important insights into the pathogenesis have come from studies of recessively inherited narcolepsy in three species of dogs, in which mutations have been identified in a gene encoding a receptor for the protein hypocretin (Lin et al). These studies implicate the peptide hypocretin in the control of sleep. The hypocretins were thought in the past to regulate feeding behavior and energy metabolism; indeed, they were also designated "orexins," from the Greek word for appetite. In mice, inactivation of two hypocretin receptors reproduces narcolepsy. In both humans and animals, hypocretin-containing neurons in the hypothalamus send projections widely through the brain and particularly to structures implicated in control of sleep as discussed earlier and shown in Fig. 19-4: the locus ceruleus (noradrenergic), the tuberomammillary nucleus (histaminergic), the raphe nucleus (serotonergic), and the ventral tegmental area (dopaminergic).

A number of compelling observations implicate hypocretin and its receptors in human narcolepsy. First, a narcoleptic patient has been described with a mutation in the gene encoding human hypocretin. Second, hypocretin-secreting neurons are depleted in the brains of human narcoleptics, and CSF hypocretin levels are reduced or absent in affected patients. In some studies, the absence of CSF hypocretin distinguished narcoleptic individuals from patients with other categories of sleep disorders.

Perhaps surprisingly, several lines of evidence suggest an autoimmune causation for narcolepsy. For example, it has long been known that there is an almost universal association with specific alleles of the histocompatibility antigen HLA-DQ (B1-0602) (Neely et al; Kramer et al). Therapeutic approaches to narcolepsy based on a presumed autoantibody have also been developed as noted below. Because the mode of inheritance of narcolepsy is not clearly mendelian (Kessler et al), it has been proposed that the disease reflects a genetic predisposition, possibly with a superimposed autoimmune reaction that impairs the function of hypocretin neuronal systems or damages the neurons that secrete the peptide.

Finally, the approximate similarities to the post infectious sleep states of von Economo encephalitis and, as provocatively, the aforementioned increased incidence of narcolepsy after outbreaks of H1N1 respiratory infection, or after administration of the vaccine, implicates an infectious or post infectious inflammatory cause, ostensibly affecting the hypothalamic nuclei (Dauvillers et al, 2010).

As mentioned earlier, a *secondary or symptomatic narcolepsy* syndrome on occasion results from cerebral

trauma, multiple sclerosis, craniopharyngioma, or other tumors of the third ventricle or upper brainstem, head trauma, or a sarcoid granuloma within the hypothalamus (Servan et al).

Our understanding of narcolepsy was greatly advanced by the demonstration by Dement and his group that this disorder is associated with a reversal in the order of the two states of sleep, with REM rather than NREM sleep occurring at the onset of the sleep attacks. Not all the sleep episodes of the narcoleptic begin with REM sleep, but almost always a number of sleep attacks with such an onset can be identified in narcoleptic-cataplectic patients in the course of a polysomnographic sleep study. The hypnagogic hallucinations, cataplexy, and sleep-onset paralysis (caused by inhibition of anterior horn cells) all coincide with the REM period. These investigators have also shown that the night sleep pattern of patients with narcolepsy-cataplexy may begin with a REM period. This may occur in normal subjects, though infrequently and usually with severe sleep deprivation. Furthermore, the nocturnal sleep pattern is altered in narcoleptics, who have frequent body movements and transient awakenings and a decrease in sleep stage N3, as well as in total sleep duration. Another important finding in narcoleptics is that *sleep latency* (the interval between the point when an individual tries to sleep and the point of onset of EEG sleep patterns), measured repeatedly in diurnal nap situations, is greatly reduced. Thus, narcolepsy is not simply a matter of excessive diurnal sleepiness (essential daytime drowsiness) or even a disorder of REM sleep but a generalized disorganization of sleep-wake function.

Diagnosis

The greatest difficulty in diagnosis relates to the problem of separating narcolepsy from the daytime sleepiness of sedentary, obese adults who, if unoccupied, doze readily after meals, while watching television or in the theater. Many of these patients prove to have obstructive sleep apnea. Excessive daytime somnolence, easily mistaken for narcolepsy, may also attend heart failure, hypothyroidism, excessive use of soporific, other medications including antihistamines, use of alcohol, cerebral trauma, and certain brain tumors (e.g., craniopharyngioma; see Table 19-2). A more serious form of recurrent daytime sleepiness, referred to as *independent narcolepsy* or *essential narcolepsy*, is described further on. However, both of these forms of daytime drowsiness are isolated disturbances, lacking the other disturbances of sleep and motor activity that characterize the narcolepsy syndrome. The brief attacks of automatic behavior and amnesia of the narcoleptic must be distinguished from hysterical fugues and complex partial seizures.

Cataplexy must also be distinguished from syncope, drop attacks (Chap. 17), and atonic seizures; in atonic seizures, consciousness is temporarily abolished. The careful documentation of narcolepsy by laboratory techniques is imperative when the diagnosis is in doubt, in part because of the potential for abuse of stimulant drugs used for treatment. Overnight polysomnography followed by a standardized multiple sleep latency test,

in which the patient is afforded opportunities for napping at 2-h intervals, permit the quantification of drowsiness and increase the probability of detecting short-latency REM activity (within 15 min from the onset of each sleep period). According to some investigators, a reduced level (below 110 pg/mL) of hypocretin in the spinal fluid is virtually diagnostic of narcolepsy in the proper clinical circumstances (see Mignot et al). We would comment, however, that it is not necessary to resort to any of these studies in clinically typical cases.

Treatment

No single therapy will control all the symptoms. Narcolepsy responds best to (1) strategically placed 15- to 20-min naps (during lunch hour, before or after dinner, etc.); (2) the use of stimulant drugs—modafinil, dextroamphetamine sulfate, or methylphenidate hydrochloride to heighten alertness; and (3) antidepressants (sertraline, venlafaxine, protriptyline, imipramine, or clomipramine) for control of cataplexy. All these drugs are potent suppressants of REM sleep. Monoamine oxidase (MAO) inhibitors also inhibit REM sleep and can be used if they are tolerated. Modafinil (200 mg daily, up to 600 mg in divided doses) may prove to be the safest of the stimulants (Fry), but experience with this agent is still being acquired. Methylphenidate, because of its prompt action and relative lack of side effects, is also widely used. It is usually given in doses of 10 to 20 mg tid on an empty stomach. Alternatively, amphetamine 5 to 10 mg may be given 3 to 5 times a day; this is ordinarily well tolerated and does not cause wakefulness at night. Pemoline, a potent stimulant (50 to 75 mg daily) is no longer available in the United States because of potential hepatic toxicity. The tricyclic antidepressants had been used to reduce cataplexy, but they have been overtaken by selective serotonin reuptake inhibitors such as sertraline and by norepinephrine reuptake inhibitors such as venlafaxine. Sodium oxybate, whose active agent is gamma-hydroxybutyrate, is also beneficial for cataplexy and narcolepsy in many individuals.

The combined use of these stimulant and tricyclic antidepressant drugs is often indicated. A problem with the stimulant drugs is the development of tolerance over a 6- to 12-month period, which requires the switching and periodic discontinuation of drugs. Excessive amounts of amphetamines may induce a schizophreniform psychosis. The stimulant drugs and the tricyclic antidepressants increase catecholamine levels; their chronic administration may produce hypertension.

An entirely different approach, based on a presumed autoimmune attack on hypothalamic neurons, has introduced immune globulin infusions in early cases of narcolepsy. This must still be considered preliminary but the results are interesting (see Dauvilliers et al, 2004).

Narcoleptics must be warned of the dangers of falling asleep and lapses of consciousness while driving or during engagement in other activities that require constant alertness. The earliest feeling of drowsiness should prompt the patient to pull off the road and take a nap. Long-distance driving should probably be avoided completely.

Idiopathic Hypersomnia (Essential Narcolepsy; NREM Narcolepsy)

As has been indicated, recurrent daytime sleepiness may be the presenting symptom in a number of varied disorders other than narcolepsy. When chronic daytime sleepiness occurs repeatedly and persistently without known cause, it is classified as essential or idiopathic hypersomnia. Roth distinguishes this state from narcolepsy on the basis of longer and unrefreshing daytime sleep periods, deep and undisturbed night sleep, difficulty in awakening in the morning or after a nap ("sleep drunkenness"), all of these occurring in the absence of REM-onset sleep and cataplexy. Admittedly, this condition proves difficult to distinguish from narcolepsy unless laboratory studies exclude the latter, and even then, there is overlap between the two syndromes (Bassetti and Aldrich). Treatment, however, is the same as that for narcolepsy. Idiopathic hypersomnia, as defined in this manner, proves to be a rare syndrome once narcolepsy, and all other causes of daytime sleepiness have been excluded.

Pathologic Wakefulness

This state, as remarked earlier, has been induced in animals by lesions in the tegmentum (median raphe nuclei) of the pons. Comparable states are known to occur in humans but are rare. Asomnia in hospital practice is a result of delirium of any type, including delirium tremens and drug-withdrawal states. Drug-induced psychoses and mania may induce a similar state. We have seen a number of patients with a delirious hyperalertness lasting a week or more after temporofrontal cerebral contusions or in association with a hypothalamic lymphoma. None of the various treatments we have tried has been successful in suppressing this state. It was transitory in the traumatic cases.

Additional Syndromes Occurring during Sleep

Sleep Palsies and Acroparesthesias

Several paresthetic disturbances, sometimes distressing in nature, may arise during sleep. Everyone is familiar with the phenomenon of an arm or leg "falling asleep." Immobility of the limbs and maintenance of uncomfortable postures, without any awareness of them, permit undue pressure to be applied on peripheral nerves (especially the ulnar, radial, and peroneal). Pressure of the nerve against the underlying bone may interfere with intraneural function in the compressed segment of nerve. Sustained pressure may result in a sensory and motor paralysis—sometimes referred to as *sleep or pressure palsy*. Usually, this condition lasts only a few hours or days, but if compression is prolonged recovery may be delayed. Deep sleep or a stupor, as in alcohol intoxication or anesthesia, renders patients especially liable to pressure palsies merely because they are not able to heed the discomfort of a sustained unnatural posture.

Acroparesthesias are frequent in adult women and are not unknown in men. The patient, after being asleep

for a few hours, is awakened by numbness or a tingling, prickling, "pins-and-needles" feeling in the fingers, and hands. There are also aching, burning pains or tightness, and other unpleasant sensations. With vigorous rubbing or shaking of the hands or extension of the wrists, the paresthesia subsides within a few minutes, only to return later or upon first awakening in the morning. At first, there is a suspicion of having slept on an arm, but the frequent bilaterality of the symptoms and their occurrence regardless of the position of the arms dispels this notion. Usually the paresthesia is in the distribution of the median nerves, and almost invariably proves to be caused by carpal tunnel syndrome.

Bruxism

Nocturnal grinding of the teeth, sometimes diurnal as well, occurs at all ages and may be as distressing to the bystander as it is to the patient. It may also cause serious dental problems unless the teeth are protected in some way. There are many hypothetical explanations, all without proof. Stress is most often blamed, and claimants point to EMG studies that show the masseter and temporalis muscles to be excessively contracted. When present in the daytime, it may also represent a fragment of segmental dystonia or tardive dyskinesia.

Nocturnal Enuresis (See also Chap. 26)

Nocturnal bedwetting with daytime continence is a frequent disorder during childhood, which may persist into adult life. Approximately 1 of 10 children 4 to 14 years of age is affected, boys more frequently than girls (in a ratio of 4:3); even among adults (military recruits), the incidence is 1 to 3 percent. The incidence is much higher if one or both parents were enuretic. Although the condition was formerly thought to be psychogenic, the studies of Gastaut and Broughton revealed a peculiarity of bladder physiology. The intravesicular pressure periodically rises to much higher levels in the enuretic than in normal persons, and the functional bladder capacity of the enuretic is smaller than normal. This suggests a maturational failure of certain modulating nervous influences.

An enuretic episode is most likely to occur 3 to 4 h after sleep onset, and usually, but not necessarily, in stages 3 and 4 sleep. It is preceded by a burst of rhythmic delta waves associated with a general body movement. If the patient is awakened at this point, he does not report any dreams. Imipramine (10 to 75 mg at bedtime) has

proved to be an effective agent in reducing the frequency of enuresis. A series of training exercises designed to increase the functional bladder capacity and sphincter tone may also be helpful. Sometimes all that is required is to proscribe fluid intake for several hours prior to sleep and to awaken the patient and have him empty his bladder about 3 h after going to sleep. One interesting patient, an elderly physician with lifelong enuresis, reported that he had finally obtained relief (after all other measures had failed) by using a nasal spray of an analogue of antidiuretic hormone (desmopressin) at bedtime. This has now been adopted for the treatment of intractable cases. Diseases of the urinary tract, diabetes mellitus or diabetes insipidus, epilepsy, sleep apnea syndrome, sickle cell anemia, and spinal cord or cauda equina disease must be excluded as causes of symptomatic enuresis.

Relation of Sleep to Medical Illnesses

The high incidence of thrombotic stroke that is apparent upon awakening, a phenomenon well known to neurologists, has been studied epidemiologically by Palomaki and colleagues. These authors have summarized the evidence for an association between snoring, sleep apnea, and an increased risk for stroke. As already mentioned, cluster headache and migraine have an intricate relationship to sleep, the former almost always occurring during or soon after the first REM period, and the latter often curtailed by a sound sleep.

Patients with coronary arteriosclerosis may show electrocardiogram (ECG) changes during REM sleep, and nocturnal angina has been recorded at this time. Snoring is strongly associated with chronic hypertension. Asthmatics frequently have their attacks at night, but not concomitantly with any specific stage of sleep; they do have a decreased amount of stage N3 sleep and frequent awakenings, however. Patients with hypothyroidism have shown a decrease of stages N3 sleep, and a return to a normal pattern when they become euthyroid. Demented patients generally exhibit reduced amounts of REM and slow-wave sleep, as do children with Down syndrome, phenylketonuria, and other forms of brain damage. Alcohol, barbiturates, and other sedative-hypnotic drugs that suppress REM sleep produce extraordinary excesses of REM during withdrawal periods. This may, in part, account for the hyperactivity and confusion, and perhaps the hallucinosis, seen in withdrawal states.

Derangements of Intellect, Behavior, and Language Caused by Diffuse and Focal Cerebral Disease

CHAPTER 20 **Delirium and Other Acute Confusional States**

CHAPTER 21 **Dementia, the Amnesic Syndrome, and the Neurology of Intelligence and Memory**

CHAPTER 22 **Neurologic Disorders Caused by Lesions in Specific Parts of the Cerebrum**

CHAPTER 23 **Disorders of Speech and Language**

Physicians sooner or later discover, through clinical experience, the need for special competence in assessing the mental faculties of their patients. They must be able to observe with objectivity the patient's attention, intelligence, memory, judgment, mood, character, and other attributes of cognitive performance, and personality in much the same fashion as they observe the patient's movements, gait, and reflexes. The systematic examination of these intellectual and affective functions permits the physician to reach conclusions regarding the patient's mental status and its relationship to his illness. Without such data, there are likely to be errors in the diagnosis and treatment of the patient's neurologic, general medical, and psychiatric disease.

The content of this section will be more clearly understood if a few of the introductory remarks to the later section on psychiatric diseases are anticipated here. The main thesis of the neurologist is that mental and physical functions of the nervous system are simply two aspects of the same neural process. Mind and behavior both have their roots in the self-regulating, goal-seeking activities of the organism, the same ones that provide impulse to all forms of mammalian life. But the prodigious complexity of the human brain permits, to an extraordinary degree, the solving of difficult problems, the capacity for remembering past experiences, and casting them in a symbolic language that can be written and read, and the planning for events that have yet to take place. The constant but sometimes meandering internal verbal experience of this ideation during waking was aptly named "stream of thought" by William James. Somehow there emerges in the course of these complex cerebral functions a continuous awareness of one's self, and the operation of one's psychic processes. It is this continuous inner consciousness of one's self, of one's past experiences, and of ongoing cognitive activities that might be called *mind*. Whether this is an emergent property of various mental functions or simply their representation cannot be answered, but any separation of the mental from the observable behavioral aspects of cerebral function is probably illusory. Biologists and psychologists have reached this view by placing all known activities of the nervous system (growth, development, behavior, and mental function) on a continuum and noting the inherent purposiveness and creativity common to all of them. The physician is persuaded of the truth of this view through daily clinical experience, in which every possible aberration of behavior and intellect appears at some time or other as an expression of cerebral disease. Furthermore, in many brain diseases, one witnesses parallel disorders of the patient's behavior and a dissolution or distortion of the introspective awareness of his own mental capacities.

The reader will find that Chaps. 20 and 21 are concerned with common disturbances of the sensorium and of cognition, which stand as cardinal manifestations of cerebral diseases. The most frequent of these are delirium and other acute confusional states, as well as disorders of learning, memory, and other intellectual functions. A consideration of these abnormalities leads naturally to an examination of the symptoms that result from focal cerebral

lesions, which are discussed in Chap. 22, and of derangements of language, which are discussed in Chap. 23. As emphasized in those chapters, even these disturbances fall between the readily localizable functions of the cerebrum and those that can be assigned only broadly to large regions or systems of the brain.

Because the psychiatric causes of disordered thinking and behavior have special qualities that make them separable from most of the conditions considered in the next several chapters, they are discussed in Chaps. 51 to 53 at the end of the book, rather than here.

Delirium and Other Acute Confusional States

The striking event in which a patient with previously intact mentality becomes acutely confused is observed almost daily on the medical, surgical, and emergency wards of a general hospital. Occurring, as it often does, during an infection with fever or in the course of a toxic or metabolic disorder (such as renal or hepatic failure) or as an effect of medication, drugs, or alcohol, it never fails to create grave problems for the physician, nursing personnel, and family. The physician has to cope with the problem of diagnosis, often without the advantage of a lucid history, and any program of therapy is constantly impeded by the patient's inattention, agitation, sleeplessness, and inability to cooperate. Nurses are burdened with the need to provide satisfactory care and a safe immediate environment for the patient, and at the same time, maintain a tranquil atmosphere for other patients. The family must be supported as it faces the frightening specter of a deranged mind with peculiar behaviors and all it signifies.

These difficulties are magnified when the patient arrives in the emergency ward, having behaved in some irrational way, and the clinical analysis must begin without knowledge of the patient's background and underlying medical illnesses. It is our view that such patients should be admitted to a general medical or neurologic ward. Transfer of the patient to a psychiatric service is undertaken only if the behavioral disorder proves impossible to manage on a general hospital service.

DEFINITION OF TERMS

The definition of normal and abnormal states of mind is difficult because the terms used to describe them have been given so many different meanings in both medical and non-medical writings. Compounding the difficulty is the fact that the pathophysiology of the confusional states and delirium is not fully understood, and the definitions depend to some extent on their clinical causes and relationships, with all the imprecision that this entails. The following nomenclature has proved useful to us and is employed in this and subsequent chapters.

Confusion is a general term denoting the patient's incapacity to think with customary speed, clarity, and coherence. Its most conspicuous attributes are impaired attention

and power of concentration, disorientation—which may be manifest or is demonstrated only by direct questioning—an inability to properly register immediate events and to recall them later, a reduction in the amount and a disruption in the quality of all mental activity, including the normally constant inner ideation and sometimes, by the appearance of bewilderment. Thinking, speech, and the performance of goal-directed actions are impermanent or abruptly arrested by the intrusion of irrelevant thoughts or distracted by the slightest external stimulus. Reduced perceptiveness and accompanying visual and auditory illusions or hallucinations and paranoid delusions (psychosis) are variable features that may be appended to the picture.

These psychologic disturbances may appear in many contexts. Confusion, as defined in this way, is an essential ingredient of the state called *delirium* (discussed further on), in which agitation, hallucinations, and sometimes tremulousness accompany the confusional state. Also, as pointed out in Chap. 17, a confusional state may appear at any stage in the evolution and resolution of a number of diseases that lead to drowsiness, stupor, and coma—typically in the metabolic encephalopathies but also in diseases affecting those parts of the brain that maintain normal arousal.

Confusion is also a characteristic feature of the chronic syndrome of *dementia*, where it is the product of a progressive failure of cognition, language, memory, and other intellectual functions; there it is the long-standing and progressive nature of the mental confusion that differentiates dementia from the acute confusional and delirious states that carry quite different implications. Finally, intense emotional disturbances, of either *manic* or *depressive* type, may interfere with attentiveness and coherence of thinking and thereby produce an apparent confusional state.

Special restricted forms of what could be called confusion appear as a result of certain focal cerebral lesions, particularly of the frontal, parietal, and temporal lobe association areas. Then, instead of a global inattention and incoherence, there are specific and circumscribed syndromes, such as unilateral neglect of self or of the environment, inability to identify persons or objects, and sensorimotor defects as described in Chap. 22. Yet another special form of confusion arises as a result

of disordered language function, which also alters the stream of thought; this aphasia is a consequence of lesions in the language areas of the left temporal lobe. These are considered separately in Chap. 23.

The many mental and behavioral aberrations that are seen in confused patients, and their occurrence in various combinations and clinical contexts, make it unlikely that all forms of confusion derive from a single elementary psychologic abnormality such as a disturbance of attention. While attention is near the core of confusion, phenomena as diverse as drowsiness and stupor, hallucinations and delusions, disorders of perception and registration, impersistence and perseveration, and so forth are not easily reduced to a disorder of one psychologic or physiologic mechanism. It seems more likely to us that a number of separable disorders of function are involved. Indeed, one view of the confusional state that we find attractive conceptualizes confusion as a loss of the integrative functions among all the elementary and localizable cerebral functions such as symbolic language, memory retrieval, and apperception (the interpretation of primary perceptions). All of these are included under the rubric of *the confusional state*, for want of a better term.

We reserve the term *delirium* to denote a special agitated type of confusional state. In addition to many of the negative elements of incoherent thinking mentioned above, delirium is characterized by a prominent disorder of perception; hallucinations and vivid dreams; a kaleidoscopic array of strange and absurd fantasies and delusions; inability to sleep; a tendency to twitch, tremble, and convulse; and intense fear or other emotional reactions. Delirium is distinguished not only by extreme inattentiveness but also by a state of heightened alertness—i.e., an increased readiness to respond to stimuli—and by overactivity of psychomotor and autonomic nervous system functions, sometimes striking in degree. Implicit in the term *delirium* are its nonmedical connotations as well—namely, intense agitation, or frenzied excitement, and trembling. This distinction between delirium and other acute confusional states is not universally accepted. Many authors attach no particular significance to the autonomic and psychomotor overactivity and the hallucinatory and dream-like features of delirium, or to the underactivity and somnolence that characterize most other confusional states. All such states are categorized together as we continue to find it useful to set delirium apart from other nondescript confusional states because the two conditions are manifestly different and tend to occur in different clinical contexts. Nevertheless, implicit in both designations is the idea of an acute, transient, and usually completely reversible disorder.

An impairment of memory is often included among the symptoms of delirium and other confusional states. Registration and recall are indeed greatly impaired in the states under discussion, but they are affected in proportion to the degree of inattention and the inability to register new material. The term *amnesia*, however, refers more precisely to an isolated loss of past memories as well as to an inability to form new ones, despite an alert state of mind and normal attentiveness. Amnesia further

presupposes an ability of the patient to grasp the meaning of what is going on around him. The failure in the amnesic state is one of retention, recall, and reproduction and must be distinguished from states of drowsiness, acute confusion, and delirium, in which information and events seem never to have been adequately perceived and registered in the first place. In both a confusional state and in amnesia, the patient will be left with a permanent gap in memory for his acute illness.

In a similar way, the term *dementia* (literally, an undoing of the mind) denotes a deterioration of all intellectual or cognitive functions with little or no disturbance of consciousness or perception. Implied in dementia is the idea of a gradual degradation of mental powers in a person who formerly possessed a normal mind. *Amentia*, by contrast, indicates a congenital feeble-mindedness more commonly referred to as *mental retardation*, or more properly, *developmental cognitive delay*. Dementia and amnesia are discussed more explicitly in Chap. 21.

OBSERVABLE ASPECTS OF BEHAVIOR AND INTELLECT IN CONFUSION, DELIRIUM, AMNESIA, AND DEMENTIA

The intellectual, emotional, and behavioral activities of the human organism are so complex and varied that one may question the feasibility of using derangements of these activities as reliable indicators of cerebral disease. Certainly they do not have the same tangibility and ease of anatomic and physiologic interpretation as sensory and motor paralysis or aphasia. Yet one observes patterns of disturbed higher cerebrocortical function with such regularity as to make them clinically useful in identifying certain diseases. Some of these disturbances gain specificity because they are combined in certain ways to form syndromes.

The components of mentation and behavior that lend themselves to bedside observation and examination are (1) the processes of attention; (2) perception and apperception (awareness and interpretation of sensory stimuli); (3) the capacity to memorize and recall events of the recent and distant past; (4) the ability to think and reason; (5) temperament, mood, and emotion; (6) initiative, impulse, and drive; (7) social behavior; and (8) insight. Of these, the first two are *sensory*, the third and fourth are *cognitive*, the fifth is *affective*, the sixth is *conative* or volitional, the seventh refers to the patient's relationships with those around him, and the last refers to the patient's capacity to assess his own functioning. Each component of behavior and intellect has its objective side, expressed in the behavioral responses produced by certain stimuli, and its subjective side, expressed in the thinking and feeling described by the patient in relation to the stimuli. Less accessible to the examiner, but nevertheless possible to study by questioning of the patient, are the memories, planning, and other psychic activities that continuously occupy the mind of an alert person. They, too, are disordered or quantitatively diminished by cerebral disease.

Disturbances of Attention

Critical to clear thinking is a process of maintaining awareness of one or a limited number of external stimuli or internal thoughts for a fixed period of time and to simultaneously disregard the numerous distracting sensations and ideas that constantly bombard the nervous system. Without this ability to focus or “pay attention” and have an “attention span,” a coherent stream of thought or action is not possible. The undue interruption of these activities by the intrusion of other thoughts or actions is termed *inattention*, or *distractibility*. Two essential components are embodied in the attention mechanism: one, a continuous state of alertness that is normally present throughout waking life (and underlies self-awareness); the other, a process of selecting from the myriad sensations and thoughts those that are relevant to the immediate situation to the exclusion of others.

The confused patient may demonstrate inattention in almost every task undertaken. If the degree of confusion is slight, the patient may report a difficulty with concentration. If severe, there is a parallel lack of insight and the problem is evident by observing easy distractibility by ambient stimuli and by imperistence and perseveration in conversation and motor tasks. Restated, attention has such a pervasive effect on all other aspects of mental performance that it is often difficult to determine whether the confused patient also has primary disorders of memory, executive, or visuospatial function. Indeed, retentive memory may be severely reduced in confusional states. Furthermore, the ability to carry out a series of actions or mental operations wherein one is required to hold in memory the result of the previous operation (“working memory”) is intimately tied to attention and is particularly prone to disruption in confusional states.

The general ability to persist in a motor or mental task emphasizes an executive side of attention, but here one encounters a problem because the term *attention* has been applied to a number of seemingly different mental activities. One can view attention as a separate and unique cerebral function or simply a way of referring to the persistence or imperistence of any activity. We would argue that the entire cerebrum participates in attentiveness and the frontal and perhaps the parietal lobes are responsible for directing its content, but that the thalamocortical system is in a special way responsible for its raw maintenance. Mesulam, who has thought substantially about this problem, considers the frontal and parietal lobes to be at the nexus of an “attentional matrix”; in his model, the prefrontal, parietal association, and limbic cortices direct and modulate attention in an executive manner. Certainly, the temporal lobes and other regions are involved as well.

Attention to a particular sensory modality requires the participation of the sensory cortex, which must simultaneously initiate the perceptive and apperceptive processes discussed later. What are called “modality” and “domain-specific” attentions (for example, face or object recognition) are more complex, and disorders of these functions result in unique types of inattention, such as agnosia and anosognosia (lack of recognition of a part of

the body, as discussed in Chap. 22). These are not derived from the all-encompassing loss of attention that is part of general confusional states but can instead be viewed as highly restricted forms of disruption of insight.

Disturbances of Perception

The process of acquiring through the senses a knowledge of the world or, of one’s self by cohering what is experienced into apperception, involves much more than the simple sensory process of being aware of the attributes of a stimulus. New visual stimuli, for example, activate the striate cortex and visual association areas, wherein are probably stored the coded past representations of these and similar classes of stimuli. Recognition involves the reactivation of this system by the same or similar stimuli at a later time. Essential elements in the perceptual process are the maintenance of attention, the selective focusing on a stimulus, elimination of all extraneous stimuli, and identification of the stimulus by recognizing its relationship to remembered experience.

The perception of stimuli undergoes predictable derangement in disease. Most often there is a reduction in the number of perceptions in a given unit of time and a failure to synthesize them properly and to relate them to the ongoing activities of the mind. Or, there may be inattentiveness and fluctuations of attention, distractibility (pertinent and irrelevant stimuli having equal value), and inability to concentrate and persist in an assigned task. This often leads to disorientation in time and place. Qualitative changes also appear, mainly in the form of sensory distortions, causing misinterpretations of environmental stimuli (illusions) and misidentifications of persons; these, at least in part, form the basis of hallucinatory experience in which the patient reports and reacts to environmental stimuli that are not evident to the examiner. There is an inability to perceive simultaneously all elements of a large complex of stimuli, a defect that has been termed “failure of subjective organization.” These major disturbances in the perceptual sphere, traditionally referred to as “clouding of the sensorium,” are characteristic of delirium, and other confusional states.

More specific partial losses of perception are manifest in the “neglect syndromes.” The most dramatic examples are observed with right parietal lesions, which render a patient unaware of the left half of his body and the environment on the left side. There are numerous other examples of focal cerebral lesions that disturb or distort sensory perceptions, each subject to neurologic testing; these are discussed in Chap. 22. Their close connection to spatial experience makes them understandable as alterations of apperception in the spatial-sensory sphere.

Disturbances of Memory

The retention of learned information and experiences is involved in all mental activities. Memory may be arbitrarily subdivided into several parts: (1) registration; (2) fixation, mnemonic integration, and retention; (3) recognition and recall; and (4) reproduction. As stated above, there is a failure of learning and memory in patients with

impaired perception and attention because the material to be learned was never registered and assimilated in the first place. In almost all circumstances, the formation of new memories and the ability to recall old ones are disturbed in tandem.

In the *Korsakoff amnesic syndrome*, newly presented material appears to be correctly registered but cannot be retained for more than a few minutes (*anterograde amnesia*, or failure of learning). In this syndrome, there is always an associated defect in the recall and reproduction of memories that had been formed several days, weeks, or even years before the onset of the illness (*retrograde amnesia*). The fabrication of stories, called *confabulation*, constitutes a third feature of the syndrome but is neither specific nor invariably present. Intact retention with failure of recall (retrograde amnesia without anterograde amnesia) when it is severe and extends to all events of past life and even personal identity, is usually a manifestation of hysteria or malingering. Certain other characteristic defects occur in almost all memory disorders, for example, the relative retention of older memories in preference to newer ones (Ribot's rule). Chapter 22 discusses this subject more fully.

Disturbances of Thinking

Thinking, the highest order of intellectual activity, remains the most elusive of all mental operations. If by thinking one means the selective ordering of symbols for learning, organizing information, and problem solving, as well as the capacity to reason and form sound judgments, then the working units of this type of mental activity are words and numbers. The substitution of words and numbers for the objects for which they stand (symbolization) is a fundamental part of the process. These symbols are formed into ideas or concepts, and the arrangement of new and remembered ideas into certain orders or relationships constitutes an intricate part of thought, presently beyond the scope of analysis. Reference is made further on to Luria's analysis of the steps involved in problem solving in connection with frontal lobe function, but actually, as he points out, the whole cerebrum is implicated in all forms of thinking. In a general way, one may examine thinking in terms of its speed and efficiency, ideational content, coherence and logical relationships of ideas, and the quantity and quality of associations to a given idea. Feelings and behaviors engendered by an idea are more in the realm of emotion and affect. Aphasic disturbances are uncommon in global confusional and delirious states, but Geschwind has emphasized misnaming as an important feature among the "nonaphasic disorders of speech" in these conditions. Spontaneous speech is normal, but there may be slight inaccuracies in repetition that are most likely the result of inattention rather than a focal cerebral lesion.

Disorders of thinking are quite prominent in delirium and other confusional states, in mania, dementia, and schizophrenia. In confusional states of all types, the organization of thought processes is disrupted, with fragmentation, repetition, and perseveration; this is spoken of as an "incoherence of thinking." Derangements

of thinking may also take the form of a flight of ideas; patients move too readily from one idea to another, and their associations are numerous, and loosely linked. This is a common feature of hypomanic and manic states, and of some schizophrenic psychoses. The opposite condition, poverty of ideas, is characteristic both of depressive illnesses, in which it is combined with gloomy thoughts, of schizophrenia, and of dementing diseases, in which it is part of a reduction of all inner psychic intellectual activity. This overall reduction in thought and action is the most prominent feature of diseases that damage the frontal lobes.

A related condition of slowed thought, or *bradyphrenia*, is comparable to the bradykinesia of extrapyramidal disorders. The two often coexist and the patient, for example with Parkinson's disease, can articulate that thinking is so slow as to be virtually blocked. The content of thought is not much altered, but it may be rendered almost useless when slowed to this degree. The outward manifestation of bradyphrenia is what one would expect, a delay in response and slowness in gathering one's thoughts to express ideas.

Thinking may be distorted in such a way that ideas are not checked against reality. When a false belief is maintained in spite of convincing evidence to the contrary, the patient is said to have a *delusion*. This abnormality is common to several illnesses, particularly bipolar, schizophrenic, and paranoid states, as well as the early stages of dementia. Often the story related by the patient has internal logic but is patently absurd. Psychotic patients may believe that ideas have been implanted in their minds by some outside agency, such as the internet, radio, television, or atomic energy; these thought control or "passivity feelings" are highly characteristic of schizophrenia, and sometimes of manic episodes. Also diagnostic of some forms of schizophrenia are distortions of logical thought, such as gaps in sequential thinking, intrusion of irrelevant ideas, and condensation of associations. Chapter 53 discusses these aspects of psychoses.

Disturbances of Emotion, Mood, and Affect

The emotional life of the patient is expressed in a variety of ways. It is widely appreciated that there are marked individual differences in basic temperament in the normal population; throughout their lives some persons are cheerful, gregarious, optimistic, and free from worry, whereas others are just the opposite. The state of emotionality, and changes that are uncharacteristic to the individual lend themselves to observation and have clinical significance. Furthermore, some inherent personality traits may precede the development of overt mental disease. For example, the volatile, cyclothymic person is said to be liable to bipolar disease, and the suspicious, withdrawn, introverted person to schizophrenia and paranoia, but there are frequent exceptions to these statements.

Strong, persistent emotional states, such as fear and anxiety, may occur as reactions to life situations and are accompanied by numerous derangements of visceral function. If excessive, prolonged, and disproportionate to

the stimulus, they are usually manifestations of an anxiety state or depression. In depression, almost all stimuli also tend to enhance the somber mood of unhappiness. Affective displays that are excessively labile and poorly controlled or uninhibited are a common manifestation of many cerebral diseases, particularly those involving the corticopontine and corticobulbar pathways. This disorder constitutes part of the syndrome of spastic bulbar (pseudobulbar) palsy, as discussed in Chap. 25, but it may occur independently of any problem with brainstem function. Affect being the external appearance of emotional life, the pseudobulbar state is characterized by a relative disconnection between the patient's reported emotional feelings and the outward display, most often being in the same general direction, but excessive in appearance. Conversely, all emotional feeling and expression may be lacking, as in states of profound apathy or depression. Or excessive cheerfulness may be maintained in the face of serious, potentially fatal disease or other adversity—a pathologic *euphoria*. Finally, a patient's emotional responses may be inappropriate to the stimulus, e.g., a depressing or morbid thought may seem amusing and be attended by a smile, a bizarre affective state as in schizophrenia.

Temperament, mood, and other emotional experiences are evaluated by observing the patient's behavior and appearance while questioning him about his feelings. For these purposes, it is convenient to divide emotionality into *mood* and *affect*. By mood is meant the prevailing internal emotional state of an individual. By contrast, *affect* (or *feeling*) refers to the outward emotional reactions evoked by a thought or an environmental stimulus. As such, it is the observable aspect of emotion. Emotionality may only be inferred from a person's affect and any more accurate assessment of the emotional state is made largely by the patient's self-report. It may be cheerful and optimistic or gloomy and melancholic. The patient's language (e.g., the adjectives used), facial expression, attitude, posture, and speed of movement reflect prevailing mood. These distinctions are at times rather tenuous, but they are clinically valuable because pathologic processes may dissociate the two to an extreme degree, as mentioned above. Chapter 25 more fully discusses the emotional disturbances relating to neurologic disease and Chap. 57 addresses depression.

Disturbances of Impulse (Conation) and Activity

Reference was made in Chaps. 3 and 4 to weakness, akinesia, and bradykinesia as manifestations of corticospinal and extrapyramidal disease. Disorders of these parts of the motor system interfere with voluntary or automatic movements, much to the distress of the patient. But motility and activity can be impaired in more general ways in which the overall tone of the motor system is enhanced or diminished. One such disorder is a lack of *conation*, or *impulse*. These terms designate that the basic biologic urges, driving forces, or purposes by which every organism is motivated to achieve an endless series of objectives. Indeed, motor activity is ostensibly a necessary

and satisfying objective in itself, for few individuals can remain still for long before they become fidgety or doodle, and the severely retarded apparently obtain gratification from certain rhythmic movements, such as rocking, head banging, and hand flapping. These are all presumed to be driven by mental impulses. As discussed in Chap. 6, tics and compulsions apparently also represent the fulfillment of some psychic urge.

It is our impression that a quantitative reduction in spontaneous activity, i.e., in the amount of activity per unit of time, is one of the most frequent manifestations of cerebral disease. An important aspect of this state, called *abulia* is the concomitant reduction and prominent delay in producing movement, speech, ideation, and emotional reaction (apathy). The terms bradyphrenia, and "psychomotor retardation," referred to above may be a related or perhaps identical phenomena. With certain cerebral diseases the disinclination to move and act may reach an extreme degree, to a point where a person who is wide awake and perceptive of the environment does not speak or move for weeks on end (akinetic mutism). Such patients seem indifferent to what is happening around them, and unconcerned about the consequences of their inactivity.

Abulia and akinetic mutism must be distinguished from two allied states, *catatonia* and the *psychomotor retardation* of depression. Kahlbaum, who first used the term *catatonia* in 1874, described it as a condition in which the patient sits or lies silent and motionless, with a staring countenance, completely without volition and without reaction to sensory impressions. Sometimes there is resistance to the examiner's efforts to move the patient, or the patient repeats certain movements or phrases hour after hour. If the limbs are moved passively, they may retain their new position for a prolonged period (*flexibilitas cerea*, or "waxy flexibility"), but more often there is no actual motor rigidity except that of voluntary resistance, termed *paratonia*. Profound depression or other psychosis is the usual cause of catatonia. The psychomotor retardation of depression and catatonia may be so profound that the patient makes no attempt to help himself in any way and ultimately starves unless fed with a nasogastric tube.

Less easy to understand is a form of "lethal catatonia," originally described by Stauder, in which the completely inert catatonic patient develops a high fever, collapses, and dies. In some respects, this state resembles the neuroleptic malignant syndrome, an idiosyncratic consequence of intoxication with neuroleptic drugs. In abulia, catatonia, and depression, the mind is usually sufficiently alert to record events and later to recount them, which differentiates these states from stupor. But this distinction is not always valid, for we have seen catatonic schizophrenic and greatly slowed depressive patients who could not recall what had happened during the period of illness.

Pathologic degrees of motor or mental restlessness and hyperactivity represent the opposite extreme from abulia. *Akathisia* refers to constant restless movements and inability to sit still; in some patients, this is a consequence of the prolonged use of phenothiazines, butyrophenones, newer antipsychosis drugs, and L-dopa, but it is also seen

in agitated depressions. Hyperactivity-inattention disorders describe yet another form of excessive motor activity that usually accompanies an attention deficit syndrome of children, mostly boys (attention-deficit hyperactivity disorder [ADHD]). In the manic form of bipolar disease (and to a lesser extent in hypomania), continuous activity and insomnia are added to the flight of ideas and the euphoric (although somewhat irritable) mood. Following certain cerebral diseases, notably some forms of encephalitis and during recovery from traumatic lesions of the frontal lobes, the patient may remain in a state of constant uncontrollable and sometimes destructive activity. Kahn referred to this state as “organic drivenness.”

Disorders of Social Behavior

Behavioral disturbances are common manifestations of all delirious–confusional states, particularly those of toxic–metabolic origin, but also those caused by more obvious structural disease of the brain. The patient may be completely indifferent to all persons around him, or the opposite, when any approach may excite anger and aggressive action. Family members may be treated with disrespect, regarded with suspicion, or falsely accused of harming the patient, stealing his possessions, or trying to poison him. The embarrassment consequent to urinating in public or soiling the bed may be absent and, particularly in men, there may be lewd behavior toward the opposite sex. In its most extreme form, usually seen in the later stages of dementing diseases, irascible behavior degenerates to kicking, screaming, biting, spitting, and an aversion to being touched, making it entirely impossible to approach the patient. These aspects of disordered mental function are the most alarming to the family and are difficult to manage in the hospital. Previously upstanding, socially appropriate, and abstemious persons may lose all regard for their actions and become profligate, gamblers, or alcoholics. In cases of damage to the frontal lobes, even beyond a neglect for social conventions, there is an indifference to others and to the consequences of the patient’s actions on other members of society.

In contrast, docility and amiable social behavior characterize certain conditions such as Down and Williams syndromes, and social indifference and a lack of ability to interpret the emotional state of others are major features of autism (see “Delirium” later on).

Loss of Insight

The state of being aware of the nature and degree of one’s deficits and their consequences becomes manifestly impaired or abolished in relation to many cerebral diseases, not just those of the frontal lobes. Lack of insight is a far more complex phenomenon than the operational definition given above suggests. In particular, there are many restricted forms of unawareness of gross neurologic deficits. These are the *agnosias*, discussed in Chap. 22. Patients with these diseases rarely seek advice or help for their illnesses; instead, the family usually brings the patient to the physician. And, after the diagnosis has

been made, the loss of insight may be reflected in a lack of compliance with planned therapy. It follows that diseases that produce abnormalities of insight also reduce the patient’s capacity to make accurate introspections concerning his psychic function.

CONFUSIONAL SYNDROMES

To summarize, the entire group of acute confusional and delirious states is characterized principally by an alteration of consciousness and by prominent disorders of attention and perception, which interfere with the speed, clarity, and coherence of thinking, the formation of memories, and the capacity for performance of self-directed and commanded activities. Three major clinical syndromes can be recognized. One is an *acute confusional state* in which there is manifest reduction in alertness and psychomotor activity. A second syndrome, already alluded to as a special form of confusion, *delirium*, is marked by overactivity, sleeplessness, tremulousness, and prominence of vivid hallucinations, sometimes with excessive sympathetic activity. These two illnesses tend to develop acutely, to have multiple causes and, except for a few cerebral diseases, to remit within a relatively short period of time of days to weeks, leaving the patient without residual damage. The third syndrome is one in which a confusional state occurs in persons with an underlying chronic cerebral disease, particularly a dementia. Such cerebral disease may be focal or diffuse. Dr. Raymond Adams had designated this disposition to a superimposed acute confusional state in the context of dementia as a *beclouded dementia* but the term, while very apt, seems not to have caught on.

From the neurologic perspective, the generic term *psychosis* applies to states of confusion in which elements of hallucinations, delusions, and disordered thinking comprise the prominent features. An important point to be made here is that psychoses typically leave the sensorium relatively unclouded and allow for normal attentions and high-level performance of many mental tasks. These syndromes and some aspects of psychotic confusion are elaborated below.

Characteristically, these abnormalities *fluctuate in severity*, typically being worse at night (“sundowning”). In the mildest form, the patient appears alert and may even pass for normal; only the failure to recollect and accurately reproduce happenings of the past few hours or days reveals the subtle inadequacy of his mental function. The more obviously confused patient spends much of his time in idleness, and what he does may be inappropriate and annoying to others. Only the more automatic acts and verbal responses are performed properly, but these may permit the examiner to obtain a number of relevant replies to questions about age, occupation, and residence. Orientation to the date, day of the week, and place is imprecise, often with the date being off by several days, the year being given as several years or one decade previous, or with the last two numbers transposed, e.g., 2015 given as 2051. Such patients may, before

answering, repeat every question that is put to them, and their responses tend to be brief and mechanical. It is difficult or impossible for them to sustain a conversation. Their attention wanders and they constantly have to be brought back to the subject at hand. They may even fall asleep during the interview, and if left alone are observed to sleep more hours each day than is natural or to sleep at irregular intervals.

As the confusion deepens, conversation becomes more difficult, and at a certain stage these patients no longer notice or respond to much of what is happening around them. Questions may be answered with a single word or a short phrase, spoken in a soft tremulous voice or whisper, or the patient may be mute. Asterixis is a common accompaniment if a metabolic or toxic encephalopathy is responsible for the confusional state. In the most advanced stages of the illness, confusion gives way to stupor and, finally, to coma (see Chap. 17). With improvement

in the underlying condition, they may pass again through the stages of stupor and confusion in the reverse order. All this informs us that at least one category of confusion is but a manifestation of the same disease processes that affect awakens and alertness and, in their severest form, cause coma.

Etiology

Table 20-1 lists some of the many causes of this common type of confusional state. The most frequent in general practice are drug intoxications and endogenous metabolic encephalopathies, mainly electrolyte and water imbalance (hypo- and hypernatremia, hyperosmolarity), hypercalcemia, disorders of acid-base balance, renal and hepatic failure, hyper- and hypoglycemia, febrile and septic states ("septic encephalopathy" discussed further on), and chronic cardiac and pulmonary insufficiency.

Table 20-1

CLASSIFICATION OF DELIRIUM AND ACUTE CONFUSIONAL STATES

I. Acute confusional states associated with psychomotor underactivity

- A. Associated with a medical or surgical disease (no focal or lateralizing neurologic signs; cerebrospinal fluid [CSF] clear)
 1. Metabolic disorders (hepatic stupor, uremia, hypo- and hypernatremia, hypercalcemia, hypo- and hyperglycemia, hypoxia, hypercapnia, porphyria, and some endocrinopathies)
 2. Infectious illnesses (pneumonia, endocarditis, urosepsis, peritonitis, and other illnesses causing bacteremia and septicemia—septic encephalopathy)
 3. Congestive heart failure
 4. Postoperative and posttraumatic states
- B. Associated with drug intoxication (no focal or lateralizing signs; CSF clear): opiates, anticholinergics, barbiturates and other sedatives, trihexyphenidyl, corticosteroids, anticonvulsants, L-dopa, dopaminergic agonists, serotonergic antidepressants
- C. Associated with diseases of the nervous system (with focal or lateralizing neurologic signs or CSF changes)
 1. Cerebrovascular disease, tumor, abscess (especially of the right parietal, left temporal and occipital, and inferofrontal lobes)
 2. Subdural hematoma
 3. Meningitis
 4. Encephalitis
 5. Cerebral vasculitis (e.g., granulomatous, lupus)
 6. Hypertensive encephalopathy
 7. Postconvulsive state

II. Delirium

- A. In a medical or surgical illness (no focal or lateralizing neurologic signs; CSF usually clear)
 1. Pneumonia
 2. Septicemia and bacteremia (septic encephalopathy)
 3. Postoperative and postconcussive states
 4. Thyrotoxicosis and corticosteroid excess (exogenous or endogenous)
 5. Infectious fevers such as typhoid, malaria
- B. In neurologic disease that causes focal or lateralizing signs or changes in the CSF
 1. Vascular, neoplastic, or other diseases, particularly those involving the temporal lobes and upper part of the brainstem
 2. Concussion and contusion (traumatic delirium)
 3. Meningitis of acute purulent, fungal, tuberculous, and neoplastic types (Chap. 32)
 4. Encephalitis from viral (e.g., herpes simplex, infectious mononucleosis), bacterial (mycoplasma), and other causes (Chaps. 32 and 33)
 5. Subarachnoid hemorrhage
- C. Abstinence states, exogenous intoxications, and postconvulsive states (signs of other medical, surgical, and neurologic illnesses absent or coincidental)
 1. Withdrawal of alcohol (delirium tremens), barbiturates, and nonbarbiturate sedative drugs, following chronic intoxication (Chaps. 42 and 43)
 2. Drug intoxications: scopolamine, amphetamine, cocaine, and other drugs, particularly hallucinogens, phencyclidine, etc.
 3. Postconvulsive delirium

III. Psychosis, particularly with manic characteristics

IV. Confusional states caused by focal cerebral lesions (see Chap. 22)

- V. **Beclouded dementia**, i.e., dementing or other brain disease in combination with infective fevers, drug reactions, trauma, heart failure, or other medical or surgical diseases

Diffuse or multifocal disease of the cerebral hemispheres is another class of transient or persisting confusional states. Concussion and seizures, especially petit mal or psychomotor status, and certain focal (e.g., right parietal and temporal) cerebral lesions may also be followed by a period of confusion. Focal lesions, most often infarctions but also hemorrhages, of the right cerebral hemisphere may evoke an acute confusional state. Such syndromes have been described with strokes mainly in the territory of the right middle cerebral artery (Mesulam et al; Caplan et al; Mori and Yamadori); usually the infarcts have involved the posterior parietal lobe or inferior frontostriatal regions, but they have also occurred with strokes in the territory of one posterior cerebral artery. A variety of more generalized or multifocal cerebral diseases may be associated with transient or persistent confusional states. Among these are meningitis, encephalitis, thrombotic thrombocytopenic purpura (TTP), disseminated intravascular coagulation, tumors, subdural hematoma, and cranial trauma.

A more restricted group of focal cerebral diseases, including drug and alcohol withdrawal and systemic infections cause delirium, as discussed below.

Pathophysiology of Confusional States

All that has been said on this subject in Chap. 17 regarding coma is applicable to at least one subgroup of the confusional states. In most cases, no consistent pathologic change is found because the abnormalities are metabolic and subcellular. As discussed in Chap. 2, the electroencephalogram (EEG) is almost invariably abnormal in even mild forms of this syndrome, in contrast to delirium, where the changes may be relatively minor. Bilateral high-voltage slow waves in the range of 2 to 4 per second (delta) or 5 to 7 per second (theta) are the usual findings with confusion. These changes surely reflect one aspect of the central problem—the diffuse impairment of the cerebral mechanisms governing alertness and attention and the property of coherence imparted by these functions. If only metaphorically, this mental incoherence and the disorganized thinking and behavior of the confusional states reflect the loss of integrated activity of all of the associative regions of the cortex as mentioned earlier in the chapter.

Delirium

This is best depicted in the patient undergoing withdrawal from alcohol after a sustained period of intoxication. The symptoms usually develop over a period of 2 or 3 d. The first indications are difficulty in concentration, restless irritability, increasing tremulousness, and insomnia. There may be momentary disorientation, an occasional inappropriate remark, or transient illusions or hallucinations.

These initial symptoms rapidly give way to a clinical picture that is one of the most colorful in medicine. The patient is inattentive and unable to perceive the elements of his situation. He may talk incessantly and incoherently, and look distressed and perplexed; his expression may

be in keeping with vague notions of being annoyed or threatened by someone. From his manner and the content of speech, it is evident that he misinterprets the meaning of ordinary objects and sounds, misidentifies the people around him, and is experiencing vivid visual, auditory, and tactile hallucinations, often of a most unpleasant type. At first the patient can be brought into touch with reality and may identify the examiner and answer other questions correctly; but almost at once he relapses into a preoccupied, confused state, giving incorrect answers and being unable to think coherently. As the process evolves, the patient cannot shake off his hallucinations and is unable to make meaningful responses to the simplest questions and is profoundly distracted and disoriented. Sleep is impossible or occurs only in brief naps. Speech is reduced to unintelligible muttering.

The signs of overactivity of the autonomic nervous system, more than any others, distinguish delirium from other confusional states. Tremor of fast frequency and jerky restless movements are practically always present and may be violent. The face is flushed, the pupils are dilated, and the conjunctivae are injected; the pulse is rapid, blood pressure elevated, and the temperature may be raised. There is excessive sweating. Most of these signs are reflections of overactivity of the sympathetic nervous system.

The most certain indication of the subsidence of the attack is the occurrence of lucid intervals of increasing length and sound sleep. Recovery is usually complete. In retrospect, the patient has only a few vague memories of his illness or none at all. Single seizures may punctuate the syndrome at any time, including before its development.

Fragments of the full syndrome are common. Brief disorientation, isolated hallucinations, or restlessness with mild hypersympathetic features all occur in withdrawal states, febrile illnesses, and with various intoxications.

The brains of patients who have died in delirium tremens without associated disease or injury usually show no pathologic changes of significance. Intoxication with a number of medications, particularly those with atropinic effects, and certain abused drugs, such as the hallucinogens, causes a delirious state. Delirium may also occur in association with a number of recognizable cerebral diseases, such as viral (herpes) encephalitis or meningoencephalitis, Wernicke disease, cerebral trauma, cerebral hemorrhage after surgery for craniopharyngioma or other tumors in the same region, or multiple embolic strokes caused by subacute bacterial endocarditis, cholesterol or fat embolism, or following cardiac or other surgery. An unusual type arises in young women with ovarian teratomas and circulating antibodies against the NMDA receptor.

The topography of the lesions in most of the deliriums that are symptomatic of underlying destructive processes is of interest; they tend to be localized in the rostral midbrain and hypothalamus or in the temporal lobes, where they involve the reticular activating and limbic systems. Involvement of the hypothalamus perhaps accounts for the autonomic hyperactivity that characterizes delirium in some cases of cerebral disease and the autoantibody condition. That these are not the only sites implicated is emphasized by the observations that an

acute agitated delirium has occurred, albeit infrequently, with lesions involving the fusiform and lingual gyri and the calcarine cortex (Horenstein et al); the hippocampal and lingual gyri (Medina et al); or the middle temporal gyrus (Mori and Yamadori).

Electrical stimulation studies of the human cerebral cortex during surgical exploration and studies by positron emission tomography (PET) have emphasized the importance of the temporal lobe in the genesis of complex visual, auditory, and olfactory hallucinations. Subthalamic and midbrain lesions may give rise to visual hallucinations that are not unpleasant and are accompanied by good insight ("peduncular hallucinosis" of Lhermitte). For reasons not easily explained, with pontine-midbrain lesions, there may be unformed auditory hallucinations.

The EEG in delirium may show symmetrical mild generalized slow activity in the range of 5 to 10 per second. In milder degrees of delirium, there is usually no abnormality at all; this is in stark contrast to the generalized slowing and disruption of EEG activity that accompany most other forms of confusion in proportion to the severity of the clinical state.

Analysis of the conditions conducive to delirium suggests several physiologic mechanisms. Alcohol and sedative drugs are known to have a strong depressant effect on certain regions of the central nervous system; presumably, the disinhibition and overactivity of these parts after withdrawal of the drug are the basis of delirium. Another mechanism is operative in the case of bacterial infections with sepsis and poisoning by certain drugs, such as atropine and scopolamine, in which visual hallucinations are a prominent feature. Here the delirious state probably results from the direct action of the toxin or chemical agent on the same parts of the brain. It has long been suggested that some persons are much more liable to delirium than others, but there is reason to doubt this. Many years ago, Wolff and Curran showed that randomly selected persons developed delirium if the causative mechanisms were strongly operative. This is not surprising, for any normal person may, under certain circumstances, experience phenomena akin to those of delirium. A healthy person can be induced to hallucinate by being isolated for several days in an environment free of sensory stimulation (sensory deprivation). A relationship of delirium to dream states has also been postulated; both are characterized by a loss of appreciation of time, a richness of visual imagery, indifference to inconsistencies, and "defective reality testing." Formulations in the field of dynamic psychiatry seem more reasonably to explain the topical content of delirium than its occurrence. Wolff and Curran, having observed the same content in repeated attacks of delirium from different causes, concluded that the content depends more on the age, gender, intellectual endowment, occupation, personality traits, and past experiences than on the cause of the delirium.

Confusional States and Delirium Induced by Medications (See also Chap. 43)

In considering the pathophysiology of delirium and confusion, it must be again emphasized that drug

intoxication—predominantly with drugs prescribed by physicians—is among the most common causes in practice. The most distinctive syndromes are those from drugs that have direct or indirect anticholinergic properties. The delirium associated with these agents is centrally mediated but may be accompanied by peripheral anticholinergic manifestations. This point is critical in the differential assessment of agitated confusional states because other compounds, particularly serotonergic agents used to treat depression, also can produce delirium. Thus, in addition to confusion, toxic levels of anticholinergic compounds typically cause dry skin, dry mouth, diminished bowel motility, and urinary hesitancy, if not frank retention. (The clinical maxim that applies is "red as a beet, dry as a bone, blind as a bat, hot as a hare, and mad as a hatter.") The last part of this mnemonic has been also attached to the dementia of mercury intoxication [see Mintzer and Burns].) By contrast, in the toxic serotonergic syndrome associated with excessive doses of the newer antidepressant drugs, salivation is normal, sweating is increased, and the gut is hyperactive; diarrhea is common. Moreover, the deep tendon reflexes may be exaggerated, and there may be clonus and myoclonus as described by Birmes and associates. Drugs with dopaminergic activity used in the treatment of Parkinson disease are notorious for the induction of confusion or delirium, but it appears that the underlying disease provides an important substrate. Allied compounds with sympathomimetic actions such as cocaine and phencyclidine produce a hallucinatory delirium and yet others with different pharmacologic properties such as glutaminergic activity may result in a variety of delirious fragments or pure hallucinosis. Another entity that arises in this context is the neuroleptic malignant syndrome, a state associated with an agitated confusion followed by stupor. However, the characteristic features in neuroleptic malignant syndrome (NMS) are progressive muscle rigidity and evidence of myonecrosis as indicated by elevations of the serum creatine kinase; usually there is in addition some elevation of body temperature. The clinical examination and a thorough history aid greatly in determining which category of drug is implicated.

Diffuse Cerebral and Dementing Disease Complicated by Confusional States

Physicians are all too familiar with the situation of an elderly patient who enters the hospital with a medical or surgical illness or begins a prescribed course of medication and displays a newly acquired mental confusion. Presumably, the liability to this state is determined by pre-existing brain disease, most often Alzheimer disease but sometimes Parkinson disease, multiple small deep cerebral infarctions, or another dementing process, which may or may not have been obvious to the family before. All the clinical features that one observes in the acute confusional states may be present, but their severity varies greatly. Confusion may be reflected only in the patient's inability to relate the history of the illness sequentially, or it may be so severe that the patient is virtually non compos mentis.

Although almost any complicating illness may bring out a confusional state in an elderly person, the most

common are febrile infectious diseases; trauma, notably concussive brain injuries; surgical operations, general anesthesia and pre- and postoperative medication; even small amounts of pain or sedative medications used for any cause; and congestive heart failure, chronic respiratory disease, and severe anemia, especially pernicious anemia. With regard to medications, those with atropinic effects have the highest tendency to cause confusion, but others, even seemingly innocuous ones, may do the same (e.g., histamine blockers used to reduce gastric acid, anti-convulsants, corticosteroids, and L-dopa as mentioned earlier and described in Chap. 39).

Very often, it is difficult to determine which of several possible factors is responsible for the patient's confusion, and often there may be more than one. In a cardiac patient, for example, fever, hypoxia or hypercarbia, one or more drugs, and electrolyte imbalance each may contribute.

Infectious and Postoperative Confusional States

In the instance of fever and confusion, particularly in the elderly person, the problem of "septic encephalopathy" is offered as an explanation, but it may simply be a rephrasing of the well-known problem of infection such as pneumonia leading to a global confusion or delirium. Young has called attention to the high frequency of this disorder in critically ill patients, 70 percent of their bacteremic patients, and its accompaniment by a polyneuropathy in a high proportion of cases. Paratonic rigidity of the limbs (an oppositional action on the patient's part that is proportioned to the effort of the examiner in moving the limbs) is an almost universal accompaniment; according to these authors, focal cerebral or cranial nerve signs are not encountered. All other potential causes of a confusional state must, of course, be excluded before attributing the state to an underlying infection. The EEG is slowed in approximation to the level of consciousness, but it shows mild changes even in the bacteremic patient who is fully alert. The spinal fluid is normal or has a slightly elevated protein concentration. While there is no doubt that young and healthy patients may become confused when affected with high fever and overwhelming infections such as pneumonia, most cases of septic encephalopathy are of the "beclouded dementia" type in the older patient. The point made by Young is that subtle degrees of confusion are ubiquitous with serious infections of many varieties. Among the most perplexing cases of this type have been healthy older persons we have observed who acquired an agitated delirium following spinal column infection after surgery. The delirium ceased within hours of drainage of an abscess. The older literature contains similar examples with closed space infection in other locations. The chapter by Young can be consulted for an exposition of the various theories of pathogenesis of this state. High fever itself (above 40.6°C [105°F]) is probably an adequate explanation for confusion in some cases. A similar global confusional state occurs in patients with severe burns (burn encephalopathy).

All that has been stated above is true of the patient with a nondescript *postoperative confusional state*, in which

a number of factors, such as fever, infection, dehydration, and drug and anesthetic effects, are implicated. In a study of 1,218 postoperative patients by Moller and colleagues, older age was by far the most important factor associated with persistent confusion after an operation; but a number of other factors—including the duration of anesthesia, need for a second operation soon after the first, postoperative infection, and respiratory complications—were also predictive of mental difficulty in the days after the procedure. Unacknowledged alcoholism and withdrawal effects undoubtedly cause the same problem quite often on surgical services (see also "Stroke with Cardiac Surgery" in Chap. 34).

When such patients recover from the medical or surgical illness, they usually return to their premorbid state, though their shortcomings, now drawn to the attention of the family and physician, are far more obvious than before. For this reason, families will date the onset of a dementia to the time of the medical illness or surgical procedure, and continue to minimize the previous gradual decline in cognition. In other cases, however, the acute medical illness seemingly marks the beginning of a persistent decline in mental clarity that over time can be identified as a dementing illness. A related problem that has recently come under study is persistent cognitive loss after critical illness. The rates of this irreversible change are apparently high, up to one-quarter of severely ill patients in some series, but accurate estimates are difficult to obtain because of the lack of pre-illness psychometric testing.

Nonconvulsive status epilepticus

This problem has attracted increasing attention in the past decades as a cause of otherwise obscure confusional states. It is discussed in Chaps. 16 and 17, but here we only comment that the process may be portrayed clinically only because of small myoclonic twitches or eyelid fluttering. The only certain way to arrive at, or exclude the diagnosis is with EEG monitoring for more than the usual 30 minute recording if possible. One suspects nonconvulsive seizures particularly in known epileptics, septic patients, and in certain medical diseases such as TTP.

Schizophrenic or Bipolar Psychosis During a Medical or Surgical Illness

A small proportion of psychoses of schizophrenic or bipolar type first become manifest during an acute medical illness or following an operation or parturition and need to be distinguished from an acute confusional state. Rarely, a catatonic state will make its first appearance in these circumstances. A causal relationship between the psychosis and medical illness is sought but cannot be established. The psychosis may have preceded the medical illness but was not recognized. The diagnostic study of the psychiatric illness must then proceed along the lines suggested in Chaps. 52 and 53. Close observation will usually disclose a clear sensorium and relatively intact memory, features that permit differentiation from an acute confusional or delirious state or dementia.

CLASSIFICATION AND DIAGNOSIS OF ACUTE CONFUSIONAL STATES

The syndromes themselves and their main clinical causes are the only satisfactory basis for classification until such time as their actual causes and pathophysiology are discovered (Table 20-1).

The first step in diagnosis is to recognize that the patient is confused. This is obvious in most cases but, as pointed out earlier, the mildest forms, particularly when some other alteration of personality is prominent, may be overlooked. Sometimes, the patient's attention can be best engaged by whispering rather than shouting or using a conversational amplitude of voice. A subtle disorder of orientation may be betrayed by an incorrect response regarding dates (off by more than one day of the month or day of the week), or in misnaming the hospital. The ability to retain a span of digits forward (normally 7) and backward (normally 5), spelling a word such as *world* or *earth* forward and then backward, reciting the months of the year in their reverse order, and serial subtraction of 3's from 30 or 7's from 100 are useful bedside tests of the patient's capacity for attentiveness and sustained mental activity, though some of these presuppose that the patient is literate or has a knowledge of mathematics. Another is the efficiency in performing dual tasks such as tapping alternately with each hand while reading aloud. Memory of recent events is one of the most delicate tests of adequate mental function and is readily accomplished by having the patient relate the details of entry to the hospital; examinations undertaken in the previous days; naming the president, vice president; and summarizing major current events, as outlined in Chap. 21. Errors in performance should not be minimized or attributed to age, for they may presage serious upcoming problems during the hospitalization.

Once it is established that the patient is confused, the differential diagnosis must be made between an acute confusional state associated with psychomotor underactivity, delirium, a beclouded dementia, and a confusional state that complicates focal cerebral disease. This is done by taking into account the degree of the patient's alertness, wakefulness, psychomotor and hallucinatory activity, and disturbances of memory and impulse, as well as the presence or absence of asterixis or myoclonus or signs of overactivity of the autonomic nervous system and of generalized or focal cerebral disease. In the neurologic examination, particular attention should be given to the presence or absence of focal neurologic signs and to asterixis, myoclonus, and seizures.

In the chronically demented patient, there are usually a number of "frontal release" signs, such as picking at the bedsheets and clothes, grasping, groping, sucking, and paratonic rigidity of the limbs. However, some demented patients are as bewildered as those with confusional psychosis, and the two conditions are distinguishable only by differences in their mode of onset and chronicity. This suggests that the affected parts of the nervous system may be the same in both conditions.

At times, a left hemispherical lesion causing a mild Wernicke's aphasia resembles a confusional state in that the stream of speech and thought are incoherent. The prominence of paraphasias and neologisms in spontaneous speech, difficulties in auditory comprehension, and normal nonverbal behavior mark the disorder as aphasic in nature. However, a problem with naming may be more common in non-aphasic global confusional states, as alluded to earlier in the chapter and emphasized in a brief piece by Geschwind. Spontaneous speech in these circumstances is unaffected.

The distinction between an acute confusional state and dementia is difficult at times, particularly if the mode of onset and the course of the mental decline are not known. The patient with an acute confusional state is said to have a "clouded sensorium" (an ambiguous term referring to a symptom complex of inattention, disorientation, perhaps drowsiness, and an inclination to inaccurate perceptions and sometimes to hallucinations and delusions), whereas the patient with dementia usually has a clear sensorium.

As indicated earlier, schizophrenia and bipolar psychosis can usually be separated from the confusional states by the presence of a clear sensorium and relatively intact memory function.

Once a case has been appropriately classified, it is important to determine its clinical associations as outlined in Table 20-1.

A thorough medical and neurologic examination, CT or MRI, and—in cases with fever or with no other apparent cause—blood count, chest X-ray, and lumbar puncture should be performed. The medical, neurologic, and laboratory findings (including measurements of Na, Ca, CO₂, blood urea nitrogen [BUN], NH₃, calcium, glucose, PAO₂, PCO₂, "toxic screen") determine the underlying disease and its treatment, and they also give information concerning prognosis. An approach to the laboratory tests that are useful in revealing the common conditions that give rise to the confusional state when the cause is not self-evident from the history and physical examination is given in Table 20-2; but as always, the choice of tests is governed by the clinical circumstances.

Table 20-2

AN APPROACH TO THE LABORATORY EVALUATION OF THE ACUTELY CONFUSED PATIENT

- I. Afebrile, no meningismus, and no focal neurologic signs
 - A. Endogenous metabolic disorders: glucose, sodium, calcium, BUN, PAO₂, PCO₂, NH₃, T₄, and special tests in particular circumstances (for porphyria, Hashimoto thyroid disease, etc.)
 - B. Exogenous toxic state: toxicologic screening of blood and urine
- II. Febrile or signs of meningeal irritation
 - A. Systemic infection: complete blood count, chest radiograph, urine analysis and culture, blood cultures, erythrocyte sedimentation rate
 - B. Meningitis and encephalitis: lumbar puncture
- III. Focal neurologic signs or seizures
 - A. CT scan or MRI
 - B. EEG

CARE OF THE DELIRIOUS AND CONFUSED PATIENT

These details are of the utmost importance. It has been estimated that 20 to 25 percent of medically ill hospital inpatients will experience some degree of confusion; moreover, elderly patients who are delirious have a significant level of mortality, variously estimated at 22 to 76 percent according to Weber and colleagues. Optimal care begins with the identification of individuals at risk for delirium, including those who have an underlying dementia, preexisting medical illnesses, or a history of alcoholism or serious depression. Furthermore, delirium is more common in males and, not surprisingly, is more likely when sensory function is already impaired (loss of vision and hearing) (Burns et al; Weber et al).

The primary effort is directed toward elimination of the underlying medical problem, particularly to discontinuing offending drugs or toxic agents. Other important objectives are to quiet the agitated patient and protect him from injury. A nurse, attendant, or member of the family should be with a seriously confused patient if this can be arranged. A room with adequate natural lighting will aid in creating a diurnal rhythm of activity and reduce "sundowning." It is often better to let an agitated patient walk about the room than to restrain him in bed, which may increase his fright or excitement and cause him to struggle to the point of exhaustion, collapse, or self-harm. The less-active patient can be kept in bed by side rails, wrist restraints, or a restraining sheet or vest. Sensitive explanations of these restraints to the family should be made in terms that emphasize the patient's health and safety. The fully awake but mildly confused patient should be permitted to sit up or walk about part of the day unless the primary disease contraindicates this.

All drugs that could possibly be responsible for the acute confusional state or delirium should be discontinued if this can be done safely. These include sedating, antianxiety, narcotic, anticholinergic, antispasticity, and corticosteroid medications, L-dopa, metoclopramide, and cimetidine, as well as antidepressants, antiarrhythmics, antiepileptics, and antibiotics. Despite the need to be sparing with medications in these circumstances, haloperidol, quetiapine, and risperidone are helpful in calming the severely agitated and hallucinating patient, but

they too should be used in the lowest effective doses. An exception is alcohol or sedative withdrawal, in which chlorthalidopoxide or other diazepamines are favored by most physicians (see Chap. 42). In delirious patients, the purpose of sedation is to assure rest and sleep, avoid exhaustion, and facilitate nursing care, but one must be cautious in attempting to suppress delirium completely. Warm baths were also known in the past to be effective in quieting the delirious patient, but hospitals no longer have facilities for this valuable method of treatment.

It would seem obvious that attempts should be made to preempt the problem of confusion in the hospitalized elderly patient. Inouye and colleagues devised an intervention program that includes frequent reorientation to the surroundings with signs, verbal reminders, and a clock; mentally stimulating activities; ambulation several times a day or similar exercises when possible; and attention to providing visual and hearing aids in patients with these impairments. They recorded a 40 percent reduction in the frequency of a confusional illness in comparison to patients who did not receive this type of organized program. Preventive strategies of the type they outline are most important in the elderly, even those without overt dementia, but a routine plan is advisable so that nurses and ancillary staff are able to apply them consistently.

Finally, the physician should be aware of the benefit of many small therapeutic measures that allay fear and suspicion and reduce the tendency to hallucinations. The room should be kept dimly lighted at night, and, if possible, the patient should not be moved from one room to another. Every procedure should be explained to the patient, even such simple ones as the taking of blood pressure or temperature. It may be some consolation and also a source of professional satisfaction to remember that most confused and delirious patients recover if they receive competent medical and nursing care (and are almost always amnesic for the ordeal). The family may be reassured on this point but forewarned that improvement may take several days or weeks and that episodes of confusion may be exposing an underlying dementia. They must also understand that the patient's abnormal behavior is not willful but rather symptomatic of a transitory brain disease. (See also Chaps. 42 and 43 for specific aspects of management of delirium due to withdrawal of alcohol and other sedative-hypnotic drugs.)

Dementia, the Amnesic Syndrome, and the Neurology of Intelligence and Memory

Increasingly, as the number of elderly in our population rises, the neurologist is consulted because an otherwise healthy person begins to fail mentally and loses his capacity to function effectively at work or in the home. This may indicate the development of a degenerative brain disease, a brain tumor, multiple strokes, chronic subdural hematomas, drug intoxication, chronic meningoencephalitis (such as caused by HIV or syphilis), normal-pressure hydrocephalus, or a depressive illness. Formerly, when there was little that could be done about these clinical states, no great premium was attached to diagnosis. But there are now effective means of treating several of these conditions, and in some instances, of restoring the patient to normal mental competence. Moreover, diagnostic technologies allow earlier recognition of the underlying pathologic process, thus improving the chances of recovery or of preventing the disease's progression.

The definitions of normal and abnormal states of mind were considered in Chap. 20, where it was pointed out that the term *dementia* denotes a persistent deterioration of intellectual or cognitive function with little or no disturbance of consciousness or perception. In current neurologic parlance, the term is used to designate a syndrome of failing memory and impairment of other intellectual functions as a result of chronic progressive degenerative disease of the brain. Such a definition may be too narrow. The term more accurately includes a number of closely related syndromes characterized not only by intellectual deterioration but also by certain behavioral abnormalities and changes in personality. Furthermore, dementia can be the result of a static encephalopathy such as head trauma or cerebral anoxia or of a progressive degenerative disease, but it differs from "encephalopathy" in its chronicity. Thus, it is not possible to determine if a confused, amnesic person is demented until some time has passed and the deficits have perished. Encephalopathies, by contrast, are largely reversible.

Beyond the need to properly define these terms, the two entities have different causes. There are several states of dementia of differing causes and mechanisms and that a degeneration of certain systems of cerebral neurons, albeit common, is only one of the many types. Thus, it is more correct to speak of the *dementias* or the *dementing diseases*.

To understand the phenomenon of intellectual deterioration, it is helpful to have some idea of how intellectual

functions, particularly intelligence and memory, are normally organized and sustained, and the manner in which deficits in these functions relate to diffuse and focal cerebral lesions. The neurology of intelligence is considered in this chapter as a prelude to a discussion of the dementias and the neurology of memory.

INTELLIGENCE

Intelligence, or intelligent behavior, has been variously defined as a "general mental efficiency," as "innate cognitive ability," or as "the aggregate or global capacity of an individual to act purposefully, to think rationally, and to deal effectively with his environment" (Wechsler) in other words, the capacity to have ideas and reason about them. It is global because it characterizes an individual's behavior as a whole; it is an aggregate in the sense that it is composed of a number of independent and qualitatively distinguishable cognitive abilities. This topic should be of interest to neurologists because intelligence is disturbed by many disorders of the brain but cannot be easily attributed to any cerebral region or particular cognitive function. In the dementias and in developmental delays, intelligence is affected in a way that cannot be explained except by some global aspect of brain function.

As every educated person knows, intelligence has something to do with normal cerebral function. It is also apparent that the level of intelligence differs widely from one person to another, and members of certain families are exceptionally bright and intellectually accomplished, whereas members of other families are just the opposite. If properly motivated, intelligent children excel in school and score high on intelligence tests. Indeed, the first intelligence tests, devised by Binet and Simon in 1905, were for the purpose of predicting scholastic success. The term *intelligence quotient*, or *IQ*, was introduced by the German psychologist Stern and used by Terman in 1916 for the development of intelligence testing. It denotes the figure that is obtained by dividing the subject's mental age (as determined by the Binet-Simon scale) by his chronological age (up to the 14th year) and multiplying the result by 100. The IQ correlates, but only broadly, with achievement in school and eventual success in professional work. IQ increases with age up to the 14th to 16th years

and then remains stable, at least until late adult life. At any given age, a large sample of normal children attains test scores of a normal, or gaussian, distribution.

The original studies of pedigrees of highly intelligent and mentally less-able families, which revealed a striking concordance between parent and child, lent support to the idea that intelligence is to a large extent inherited. However, it became evident that the tests were also greatly influenced by the environment in which the child was reared. Moreover, tests were less reliable in identifying talented children who were not offered optimal opportunities. This led to the widespread belief that intelligence tests are only achievement tests and that environmental factors fostering high performance are the important factors determining intelligence.

Neither of these views is likely to be entirely correct. Studies of monozygotic and dizygotic twins raised in the same or different families have put the matter in a clearer light. Identical twins reared together or apart are more alike in intelligence than nonidentical twins brought up in the same home (see reviews of Willerman, of Shields, and of Slater and Cowie). A study of elderly twins by McClearn and colleagues has shed further light on the issue; even in twins who were older than 80 years of age, a substantial part (an estimated 62 percent) of cognitive performance could be accounted for by genetic traits. These findings suggest that life experience alters intelligence, but in only a limited way. There can be little doubt, therefore, that genetic endowment is the more important factor—a view that was championed by Piercy and more recently by Herrnstein and Murray. However, there is also evidence that early learning modifies the level of ability that is finally attained. The latter should be looked upon not as the sum of genetic and environmental factors but as the product of the two. More importantly, it is generally appreciated that nonscholastic achievement or success is governed by factors other than intellectual ones, such as curiosity, a readiness to learn, interest, persistence, sociability, and ambition or motivation—factors that vary considerably from person to person and are not measured by tests of intelligence.

As to the genetic mechanisms involved in the inheritance of intelligence, a limited amount is known. There is an excess of males with mental retardation, and there are several well-characterized syndromes in which the inheritance of mental retardation is X-linked as described in Chaps. 28 and 38. Also notable is the somewhat different patterns of subtest performance between males and females (males perform better on subtests of spatial ability and certain mathematical tasks). Males may be more likely to be affected by advantageous or aberrant genes on a single X chromosome, whereas females benefit from the mosaic provided by two X chromosomes. In some families, high intelligence segregates to certain individuals through an X-linked pattern. Further study will determine the validity of this view and its contribution to our understanding of what will certainly prove to be a polygenic inheritance of intellectual traits.

One would think that neurologic structure and function would correlate in some way with intelligence, but

with the exception of the pathologically developmentally delayed (Chaps. 28 and 38), such an association has been difficult to document. Brain weight and the complexity of the convolitional pattern are not correlated with intelligence—despite popular notions to the contrary, including a widely criticized analysis of the brain of Albert Einstein. (In regard to Einstein's brain, Witelson and colleagues proposed that an enlarged inferior parietal lobule, a crossmodal association area, accounted for his visuospatial and mathematical genius, but this has been disputed.) Only laboratory measures of vigilance and facility of sensory registration (speed of motor responses/reaction time and rapid recognition of differences between lines, shapes, or pictures) have a definite but still modest correlation with IQ. However, it is of interest that morphometric features of the regions of the cortex that are presumed to underlie IQ and verbal skills, such as the frontal and language areas, show a heritable component when measured on high-resolution MRI scans in twins (see Thompson et al).

As to psychologic theories of intelligence, several have traditionally been held at different historical periods. One is the two-factor theory of Spearman, who noted that all the separate tests of cognitive abilities correlated with each other, suggesting that a general factor (*g factor*) enters into all performance. Because none of the correlations between subtests approached unity, he postulated that each test measures not only this general ability (commonly identified with intelligence) but also a subsidiary factors specific to the individual tests, which he designated the *s factors*. A second theory, the multifactorial theory of Thurstone, proposed that intelligence consists of a number of primary mental abilities, such as memory, verbal facility, numerical ability, visuospatial perception, and capacity for problem solving, all of them more or less equivalent. These primary abilities, although correlated, are not subordinate to a more general ability. For Eysenck, intelligence exists in three forms: biologic (the genetic component), social (development of the genetic component in relation to personal relationships), and a number of specific abilities subject to measurement by psychometric tests.

Thurstone's multifactorial theory of intelligence has been periodically resurrected, most recently by Gardner who recognizes six categories of high-order cerebral ability but restates them in more modern terms: linguistic (encompassing all language functions); musical (including composition and performance); logical-mathematical (the ideas and works of mathematicians); spatial (including artistic talent and the creation of visual impressions); bodily-kinesthetic (including dance and athletic performance); and the personal (consciousness of self and others in social interactions). He refers to each of these as *intelligences*, defined as the ability to solve problems or resolve difficulties and to be creative within the particular field. Several lines of evidence are marshaled in support of this parceling of separable skills and abilities: (1) each may be developed to an exceptionally high level in certain individuals, constituting virtuosity or genius; (2) each can be destroyed or spared in isolation as a

consequence of a lesion in a certain part of the nervous system; (3) in certain individuals, i.e., in prodigies, special competence in one of these abilities is evident at an unusually early age; (4) in the autism spectrum, one or more of these abilities may be selectively spared or developed to an abnormally high degree (*idiot savant*). Each of these entities appears to have a genetic basis in so far as musical, artistic, mathematical, and athletic ability often runs in families, but their full development is influenced by environmental factors.

There are only limited data regarding the highest levels of intelligence identified as genius. Terman and Ogden's longitudinal study of 1,500 California school children who were initially tested in 1921 supported the idea that an extremely high IQ predicted future scholastic accomplishments (though not necessarily occupational and life success). On the other hand, most individuals recognized as geniuses have been especially skilled in one domain—such as painting, linguistics, music, chess, or mathematics—and such “domain genius” is not necessarily predicated on high IQ scores, although certain individuals display crossmodal superiorities—particularly in mathematics and music.

Chapter 28 discusses the developmental aspects of intelligence in detail. One of the leading theories has been that of Piaget, who proposed that this is accomplished in discrete stages related to age: sensorimotor, from 0 to 2 years; preconceptual thought, from 2 to 4 years; intuitive thought, from 4 to 7 years; concrete operations (conceptualization), from 7 to 11 years; and, finally, the period of “formal operations” (logical or abstract thought), from 11 years on. This scheme implies that the capacity for logical thought, developing as it does according to an orderly timetable, is coded in the genes. Surely, one can recognize these states of intellectual development in the child, but Piaget's theory has been criticized as being too anecdotal and lacking the quantitative validation that could be derived only from studies of a large normal population. Furthermore, it does not take into account an individual's special abilities, which do not usually develop and reach their maximum at the same time as the more general intellectual capacities.

One would suppose that in neurology, where one is exposed to so many diseases affecting the cerebrum, it might be possible to verify one of these several theories of intelligence and to determine the anatomy of this cognitive entity. Presumably, the *g* factor of intelligence would be maximally impaired, by diffuse lesions, in proportion to the mass of brain involved, an idea expressed by Lashley as the “mass-action principle.” Indeed, according to Chapman and Wolff, there is a correlation between the volume of brain tissue lost and a general deficit of cerebral function. Others disagree, claiming that no universal psychologic deficit can be linked to lesions affecting particular parts of the brain. Probably the truth lies between these two divergent points of view. According to Tomlinson and colleagues, who studied the effects of vascular lesions in the aging brain, lesions that involve more than 50 mL of tissue cause some general reduction in performance, especially in speed and capacity to solve problems. Piercy, on the other hand, found correlations

only between specific intellectual deficits and lesions of particular parts of the left and right hemispheres. These problems are discussed in Chap. 22. It is surprising that lesions of the frontal lobes, and particularly the prefrontal regions, which so profoundly disorder planning and “executive” functions, do not measurably affect IQ except in subtests specific to these skills.

The authors conclude from experience and from evidence provided by neurologic studies that intelligence is a combination of multiple primary abilities, each of which seems to be inherited and each of which has a separate but as yet poorly delineated anatomy. Yet we would disagree with both Thurstone and Gardner that these special abilities are of equivalent weight with regard to what is generally considered as “intelligence.” When viewed in the light of the classics of literature, history, and science, we attach a disproportionate importance to some of them, namely linguistic and mathematical, and perhaps spatial–dimensional, abilities. These are integral to ideation and problem solving and are largely absent in the developmentally delayed and lost early in dementing diseases. To the extent that facility with general mental performance, that requiring the manipulation of abstract symbols and thoughts, marks an individual as “intelligent” and that these correlate with each other, we find Spearman's *g* factor to be a credible but not completely satisfying concept for intelligence.

Neurologic data certainly do not exclude the possibility of a general factor for intelligence—one that is unavoidably measured in many different tests of cerebral functions. It is expressed in thinking and abstract reasoning and is operative only if the connections between the frontal lobes and other parts of the brain are intact. Attention, drive, and motivation are noncognitive psychologic attributes of fundamental importance, the precise anatomy and physiology of which remain to be identified but are largely generated in the frontal and prefrontal region. It is also possible, if not likely, that the associative areas of the cerebrum are engaged in the apperception of sensory experiences and their manipulation in symbolic form. This applies equally to the ability to relate thoughts to each other and to stored concepts, but here, memory plays a central role. We view memory and capacity to learn as a separate cognitive entity, with its own neuroanatomic localizations. The interrelationships between some of these special abilities had been thoughtfully analyzed by Luria (see the section on frontal lobes in Chap. 22). An account of the subject of IQ and intelligence can also be found in the monograph by Mackintosh.

An even more complex problem arises in the neurologic analysis of the highest human achievement and the method of human advancement, namely creativity. In some ways, creativity is tied to special skills along the lines of Gardner's modality-based intelligence, particularly as it relates to artistic work, but the brain structures involved in aesthetics and abstraction are entirely obscure, as Zeki points out. Some insight is gained from the fact that intelligence and problem-solving ability are innately but only roughly tied to creativity and that there are congenital absences and deficiencies of appreciation

of visual, artistic, or mathematical skills. The capacity to be creative may be inhibited by other functions of the brain, as exposed in the case described by Seeley and colleagues of a woman with frontotemporal dementia whose artistic abilities emerged as her facility with language deteriorated. But, as pointed out in the following chapter, traits such as creativity almost certainly do not reside in a particular lobe or structure of the brain and may depend on the overdevelopment of certain associative areas, as well as on frontal lobe drive and, of course, are fully manifest only by educational exposure.

THE NEUROLOGY OF DEMENTIA

Dementia is a syndrome consisting of a loss of several separable but overlapping intellectual abilities and presents in a number of different combinations. These constellations of intellectual deficits constitute the pre-eminent clinical abnormalities in several cerebral diseases and are sometimes virtually the only abnormalities. Table 21-1 lists the most common types of dementing diseases and their relative frequency.

What is noteworthy about the figures in this table is the apparently high level of accuracy of diagnosis. Rather consistently, postmortem examination confirms that the accuracy of the clinical diagnosis of Alzheimer disease is in excess of 80 percent when rigid research criteria are used (Table 21-2). Of course, the high frequency of this

Table 21-1

THE COMMON TYPES OF DEMENTING DISEASES AND THEIR APPROXIMATE FREQUENCIES

DEMENTING DISEASE	RELATIVE FREQUENCY, %
Cerebral atrophy, mainly Alzheimer but including Lewy-body, Parkinson, frontotemporal, and Pick diseases	50
Multiinfarct dementia	10
Alcoholic dementia	7
Intracranial tumors	5
Normal-pressure hydrocephalus	5
Huntington chorea	2
Chronic drug intoxications	3
Miscellaneous diseases (hepatic failure; pernicious anemia; hypo- or hyperthyroidism; dementias with amyotrophic lateral sclerosis, amyloid angiopathy, neurosyphilis; Creutzfeldt-Jakob disease; multiple sclerosis; chronic epilepsy)	6
Cerebral trauma	2
AIDS dementia	2
Pseudodementias (depression, hypomania, schizophrenia, hysteria, undiagnosed)	8

disease in the older population makes the likelihood of correct diagnosis higher. In most cases, the degenerative diseases can be differentiated by one or two characteristic clinical features, but these distinctions may be difficult to discern early in the disease process. In particular, a proportion of patients thought to have Alzheimer disease are found to have another type of degenerative cerebral atrophy, such as Lewy-body disease, progressive supranuclear palsy, Huntington disease, Parkinson disease, corticobasal degeneration, Pick disease, or one of the frontotemporal lobar degenerative diseases (all described in Chap. 39). Or such patients have one of a variety of other processes, such as multiinfarct dementia or hydrocephalus alone or in combination with one of the other disorders. Of special importance is the fact that approximately 10 percent of patients who are referred to a neurologic center with a question of dementia prove to have a potentially reversible psychiatric or metabolic disorder. Emphasized again are the group of nonprogressive dementias that are the lasting result of a monophasic injury to the brain and do not appear in Table 21-2.

In the following pages, we consider the prototypic dementing syndromes. They are observed most frequently with degenerative diseases of the brain (Chap. 39) and less often as part of other categories of disease (vascular, traumatic, infectious, demyelinating), which are considered in their appropriate chapters.

Mild Cognitive Impairment and Early Dementia

It has become apparent that many individuals have memory complaints that are mild and do not interfere with daily functioning but are still disproportionate for the patient's age and education. It is often difficult to differentiate this less-intrusive problem, which may be a result of the normal process of aging, from dementia. The former condition has been called *mild cognitive impairment*,

age-associated memory impairment, and, in the past, *benign senescent forgetfulness*, as discussed in Chap. 29. When other aspects of mental functioning are affected, terms such as *aging-associated cognitive decline* are used. Defining the boundaries of such a condition has proved problematic, and determining the risk of progression to a dementing illness that does interfere with daily function, even more so. There is a further problem introduced by the premise that highly intelligent individuals would have to decline considerably on intelligence and memory tests to be identified as being below certain age-adjusted norms. However, a notion has evolved in which Alzheimer disease and mild cognitive impairment exist in a spectrum (see Petersen), and one of the main values to identifying such patients in a presymptomatic period of Alzheimer disease is the potential for early institution of treatment.

In most studies, 10 to 20 percent per year of such affected patients with mild cognitive decline will be found to have later acquired Alzheimer disease. A number of factors have been identified as associated with a progression to a state of indisputable dementia. These include elevated blood pressure, changes in the cerebral white matter on MRI, abnormality of gait, and—perhaps not surprisingly—certain biologic markers that are connected to Alzheimer disease. Other factors for the development of dementia, particularly the level of prior education and maintenance of an active mental life, have been studied in relation to Alzheimer disease (C.F. Willis et al) and are discussed in that section of Chap. 39.

At the moment, the clinician must simply counsel caution and reassurance in advising patients with mild memory impairment, and exclude treatable causes. Nonetheless, if the symptoms are progressive or begin to interfere in any consistent way with other mental functions or with the performance of daily activities, a dementing illness is likely.

Dementia Caused by Degenerative Diseases

The earliest signs of dementia caused by degenerative disease may be so subtle as to escape the notice of the most discerning physician. An observant relative of the patient or an employer may become aware of a certain lack of initiative or lack of interest in work, a neglect of routine tasks, or an abandonment of pleasurable pursuits. Initially, these changes may be attributed to depression, fatigue, or boredom in retirement. More often, gradual development of forgetfulness is the most prominent early symptom. Proper names are no longer remembered and cannot be recalled with time, to a far greater extent than can be attributed to “mild cognitive impairment.” Difficulty in balancing a checkbook and making change becomes evident. The purpose of an errand is forgotten, appointments are not kept, and recent conversations or social events have been overlooked. The patient may ask the same question repeatedly over the course of a day, having failed to retain the answers that were previously given.

Later, it becomes evident that the patient is easily distracted by every passing incident. He no longer finds it possible to think about or discuss a problem with customary clarity or to comprehend all aspects of complex

situations. The ability to make proper deductions and inferences from given premises are greatly reduced. One feature of a situation or some relatively unimportant event may become a source of unreasonable concern or worry. Tasks that require several steps cannot be accomplished, and all but the simplest directions cannot be followed. The patient may get lost, even along habitual routes of travel. Day-to-day events are not recalled, and perseveration or imperistence in speech, action, and thought becomes evident.

In yet other instances, an early abnormality may be in the nature of emotional instability, taking the form of unreasonable outbursts of anger, easy tearfulness, or aggressiveness. A change in mood becomes apparent, deviating more toward depression than elation. Apathy is common. Some patients are irascible; a few are cheerful and facetious. The direction of the mood change is said to depend on the patient’s previous personality rather than on the character of the disease, but one can think of glaring exceptions from clinical experience. Excessive lability of affect may also be observed—for example, easy fluctuation from laughter to tears on slight provocation.

A considerable group of patients come to the physician with physical complaints, the most common being dizziness, a vague mental “fogginess,” and nondescript headaches. The patient’s inability to give a coherent account of his symptoms bears witness to the presence of dementia. Sleep disturbances, especially insomnia, are prominent in some cases and a particular disorder relating to the acting out of dreams during REM sleep marks some of the degenerative dementia. Sometimes the mental failure is brought to light more dramatically by a severe confusional state attending a febrile illness, a concussive head injury, an operative procedure, or the administration of some new medicine, as discussed below and in Chap. 20. As noted there, the family almost uniformly, but mistakenly, dates an abrupt onset of dementia to the time of the intercurrent illness.

Loss of social graces and indifference to social customs may occur, but usually later in the course of illness. Judgment becomes impaired, early in some, late in others. At certain phases of the illness, suspiciousness or frank paranoia may develop. Although more typical of advanced cases, on occasion the first indication of an oncoming dementia is the expression of paranoia—for example, relating to being robbed by employees or to the infidelity of a spouse. When the patient’s condition is probed by an examination, there are no signs of depression, hallucinations, or illogical ideas, but memory and problem solving are found to be deficient. The troublesome paranoid ideas then persist throughout the illness. Also more typical of late disease but an early feature of certain degenerative dementias, visual and auditory hallucinations, sometimes quite vivid in nature, may be added. Wandering, pacing, and other aimless activities are common in the intermediate stage of the illness, while other patients sit placidly for hours. By this point, these patients have little or no realization of the changes occurring within themselves; i.e., they lack insight into the problem.

As the condition progresses, all intellectual faculties become impaired; but in the most common degenerative

diseases, memory is most affected. Deference to a spouse or child when the patient is unable to answer the examiner's questions is characteristic. Up to a certain point in the illness, memories of the distant past are relatively well retained at a time when more recently acquired information has been lost (Ribot's law). Eventually, patients also fail to retain remote memories, to recognize their relatives, and even to recall the names of their children.

Apraxias and agnosias are early and prominent in one special group of degenerative conditions, occurring only later in Alzheimer disease. These defects may alter the performance of the simplest tasks, such as preparing a meal, setting the table, or even using the telephone or a knife and fork, dressing, or walking. Or, language functions are impaired almost from the beginning of certain forms of dementia. Lost in these cases is the capacity to understand nuances of the spoken and written word, as are the suppleness and spontaneity of verbal expression. Vocabulary becomes restricted and conversation is rambling and repetitious. The patient gropes for proper names and common nouns and no longer formulates ideas with well-constructed phrases or sentences. Instead, there is a tendency to resort to clichés, stereotyped phrases, and exclamations, which hide the underlying defect during conversation. Paraphasias and difficulty in comprehending complex conversations become prominent. Subsequently, more severe degrees of aphasia, dysarthria, palilalia, and echolalia may be added to the clinical picture. As pointed out by Chapman and Wolff, there is loss also of the capacity to express feelings, to suppress impulses, and to tolerate frustration and restrictions.

However, several clinical variants of dementia in which memory is relatively spared have long been recognized, and in recent years three of them—frontotemporal dementia (Pick disease), primary progressive aphasia, and semantic dementia—have been subsumed under the summary term *frontotemporal lobar degeneration*. Several consensus statements on the clinical diagnostic criteria for these syndromes have been published, although not all writings on this subject are in agreement (see Morris).

The most common clinical syndrome in this group is characterized by features that would be expected of degeneration of the frontal lobes: early personality changes, particularly apathy or disinhibition, euphoria, perseveration in motor and cognitive tasks, ritualistic and repetitive behaviors, and laconic speech leading to mutism—all with relative preservation of memory, orientation, and visuospatial capability. With anterior temporal lobe involvement, hyperorality, excessive smoking, or overeating occur, and there may be added anxiety, depression, and anomia. Diminished capacity for abstraction, attention, planning, and problem solving may be observed as the degenerative process continues. These are subsumed under the term *disorders of "executive functions."* To these features in some patients is added a parkinsonian syndrome.

In the advanced stages of some dementias, restraining the patient leads to disagreeable behavior, petulance, agitation, shouting, and whining. Well known to physicians is nighttime confusion and inversion of the normal sleep pattern, as well as increased confusion and restlessness in the

early evening ("sundowning"), as described in Chap. 20. Any febrile illness, drug intoxication, anesthesia, surgery, or metabolic upset is poorly tolerated, leading to severe confusion and even stupor—an indication of the precarious state of cerebral compensation.

It would be an error to think that the abnormalities in the degenerative dementing diseases are confined to the intellectual sphere. The patient's appearance and the physical examination yield highly informative data. The first impression is often revealing; the patient may be unkempt and unbathed. He may look bewildered, as though lost, or his expression may be vacant, and he does not maintain a lively interest or participate in the interview. There is a kind of psychic inertia. Movements may be slightly slow, sometimes suggesting an oncoming parkinsonian syndrome.

Sooner or later, gait is characteristically altered in many of the dementias (Chap. 7). Passive movements of the limbs encounter a fluctuating resistance or paratonia (*gegenhalten*). Mouthing movements and a number of abnormal reflexes—grasping and sucking (in response to visual as well as tactile stimuli), inability to inhibit blink on tapping the glabella, snout reflex (protrusion of the lips in response to perioral tapping), biting or jaw clamping (bulldog) reflex, corneomandibular reflex (jaw clenching when the cornea is touched), and palmental reflex (retraction of one side of the mouth and chin caused by contraction of the mentalis muscle when the thenar eminence of the palm is stroked)—all occur with increasing frequency in the advanced stages of the dementia. Many of these abnormalities are considered to be motor disinhibitions that appear when the premotor areas of the brain are involved.

In the very later stages, physical deterioration is inexorable. Food intake, which may be increased at the onset of the illness, sometimes to the point of gluttony, is in the end reduced, with resulting emaciation. Finally, these patients remain in bed most of the time, oblivious of their surroundings, and succumb at this stage to pneumonia or some other intercurrent infection. Some patients, should they not die in this way, become virtually decorticate—totally unaware of their environment, unresponsive, mute, incontinent, and adopting a posture of flexion. They lie with their eyes open but do not look about. Food and drink are no longer requested but are swallowed if placed in the patient's mouth. The term *persistent vegetative state* is appropriately applied to these patients, although it was originally devised to describe patients in this inert state after cardiac arrest or head injury. Occasionally, diffuse choreoathetotic movements or random myoclonic jerking can be observed, and seizures occur in a few advanced cases. Pain or an uncomfortable posture goes unheeded. The course of the prototype of dementia, Alzheimer disease, extends for 5 to 10 years or more from the time that the memory defect becomes evident. The clinical course of advanced dementia has been studied by Mitchell and colleagues in nursing homes. Those who acquired pneumonia, a febrile episode or an eating disorder, not surprisingly, had high rates of mortality, approaching half, in the subsequent 6 months.

Naturally, every case does not follow the exact sequence outlined here. Often, a patient is brought to the physician because of an impaired facility with language. In other patients, impairment of memory with relatively intact reasoning power may be the dominant clinical feature in the first months or even years of the disease; or low impulsivity (apathy and abulia) may be the most conspicuous feature, resulting in obscuration of all the more specialized higher cerebral functions. Gait disorder, although usually a late development, may occur early, particularly in patients in whom the dementia is associated with or superimposed on frontal lobe degeneration, Parkinson disease, normal pressure hydrocephalus, cerebellar ataxia, or progressive supranuclear palsy. Insofar as the types of degenerative disease do not affect certain parts of the brain equally, it is not surprising that their symptomatology varies. Moreover, frank psychosis with delusions and hallucinations may be woven into the dementia and are particularly characteristic of certain diseases such as Lewy-body dementia. Chapter 39 discusses these variations and others more fully.

The aforementioned alterations of intellect and behavior are the direct consequence of neuronal loss in certain parts of the cerebrum. In other words, the symptoms are the primary manifestations of neurologic disease. However, some symptoms are secondary; i.e., they may represent the patient's reactions to his mental incapacity. For example, a demented person may seek solitude to hide his affliction and thus may appear to be asocial or apathetic. Again, excessive orderliness may be an attempt to compensate for failing memory; apprehension, gloom, and irritability may reflect a general dissatisfaction with a necessarily restricted life. According to Goldstein, who has written about these "catastrophic reactions," as he calls them, even patients in a state of fairly advanced deterioration are still capable of reacting to their illness and to persons who care for them.

In the early and intermediate stages of the illness, special neuropsychologic tests aid in the quantitation of some of these abnormalities, as indicated in the later part of this chapter.

Subcortical Dementia and Dementias Associated With Diseases of the Basal Ganglia

McHugh, who introduced the concept of subcortical dementia, pointed out that the cognitive decline of certain predominantly basal ganglionic diseases—such as progressive supranuclear palsy, Huntington chorea, and Parkinson disease—is different in several respects from the cortical dementia of Alzheimer disease. In addition to the obvious disorders of motility and involuntary movements, there are degrees of mild forgetfulness, slowed thought processes, lack of initiative, and depression of mood. Relatively spared, however, are vocabulary, naming, and praxis. By contrast, the "cortical dementias" (exemplified by Alzheimer disease) are distinguished by more severe disturbances of memory, language, and calculation, prominent signs of apraxia and agnosia, and impaired capacity for abstract thought.

The pathologic changes underlying the subcortical dementias predominate in the basal ganglia, thalamus, rostral brainstem nuclei, and mostly, in the ill-defined projections in the white matter from these regions to the cortex, particularly of the frontal lobes; however, it would be overly simplistic to attribute the dementia to changes in these areas. One of the problems with the concept of subcortical dementia is the name itself, implying as it does that symptoms of dementia are ascribed to lesions confined to subcortical structures. Anatomically, none of the neurodegenerative dementias is strictly cortical or subcortical. The attribution of dementia to subcortical gliosis, for example, has almost always proved to be incorrect; invariably there are cortical neuronal changes as well. In a similar way, the changes of Alzheimer disease may extend well beyond the cerebral cortex, involving the striatum, thalamus, and even cerebellum. Also, functionally, these lesions produce their effects by interrupting neural links to the frontal and other parts of the cerebral cortex. Similar ambiguity arises when one considers the dementias caused by Lewy-body disease (probably second in frequency only to Alzheimer disease) and by normal-pressure hydrocephalus; here there are parkinsonism and dementing features that could be construed as both cortical and subcortical in nature.

Certain authors, notably Mayeux and Stern and their colleagues as well as Tierney and coworkers, have been critical of the concept of subcortical dementia. They argue that the distinctions between cortical and subcortical dementias are not fundamental and that any differences between them are probably attributable to differences in the relative severity of the dementing processes. Nonetheless, a number of studies do indeed indicate that the constellations of cognitive impairments in the two groups of dementias differ along the lines indicated earlier (see Pillon et al). And, the clinical distinction between cortical and subcortical dementia based on a relative sparing of core cortical functions is very useful.

Pathogenesis of Dementia

Attempts to relate the impairment of general intellectual function to lesions in certain parts of the brain or a particular pathologic change have been largely unsuccessful. Lashley's concept of loss of intelligence in proportion to brain damage has already been mentioned. This is not to say that certain parts of the cognitive apparatus are not localizable. It is the integrated capacity to think that defies easy attribution to a part of the brain. Two types of difficulty have obstructed progress in this field. First, there is the problem of defining and analyzing the nature of the intellectual functions as already discussed. Second, the pathologic anatomy of the dementing diseases is often so diffuse and complex that it cannot be fully localized and quantitated.

As described in Chap. 22, certain portions of the intellectual ensemble are controlled by circumscribed regions of the cerebrum. Memory impairment, which is a central feature of some dementias, may occur with extensive disease in several different parts of the cerebrum, but the integrity of certain discrete parts of the

diencephalon and inferomedial parts of the temporal lobes is fundamental to memory. In a similar way, impairment of language function is associated specifically with disease of the dominant cerebral hemisphere, particularly the perisylvian parts of the frontal, temporal, and parietal lobes. Loss of capacity for reading and calculation is related to lesions in the posterior part of the left (dominant) cerebral hemisphere; loss of use of tools and imitation of gestures (apraxias) is related to loss of tissue in the dominant parietal region. Impairment in drawing or constructing simple and complex figures with blocks, sticks, picture arrangements, etc., is observed with parietal lobe lesions, more often with right-sided (nondominant) than with left-sided ones. And problems with modulation of behavior and stability of personality are generally related to frontal lobe degeneration. Thus, the clinical picture resulting from cerebral disease depends in part on the extent of the lesion, i.e., the amount of cerebral tissue destroyed, and in part on the region of the brain that bears the brunt of the pathologic change.

Dementia of the degenerative types is related to obvious structural diseases of the cerebral cortex but the diencephalon and, as mentioned earlier, the basal ganglia are also implicated. Rarely, purely thalamic degenerations may be the basis of a dementia because of the integral relationship of the thalamus to the cerebral cortex, particularly as regards memory. Even when a particular disease disproportionately affects one part of the cerebrum, additional areas are often implicated and contribute to the mental decline. One such important example is found in Alzheimer disease, in which the main site of damage is in the hippocampus, but degeneration of the cholinergic nuclei of the basal frontal region, which project to the hippocampus, greatly augments the deterioration in memory function. Indeed, replacement of this lost cholinergic influence is one of the main approaches to the treatment of the disease.

Arteriosclerotic cerebrovascular disease, which pursues a different course than the neurodegenerative diseases, results in multiple foci of infarction throughout the thalami, basal ganglia, brainstem, and cerebrum, including the motor, sensory, and visual projection areas as well as the association areas. There is no evidence, however, that arteriosclerosis *per se*, without vascular occlusion and infarction, is a cause of progressive dementia as was thought in previous decades. Undoubtedly, the cumulative effects of recurrent strokes impair the intellect. Usually, but not always, the stroke-by-stroke advance of the disease is apparent in such patients (multi-infarct dementia). More uncertain in our opinion is the notion that a decline in mental function can be attributed to periventricular white matter changes (leukoaraiosis), which are observed on CT and MRI scans of many elderly patients and are presumed to be ischemic in nature (see review of van Gijn). Also, the construct that small strokes exaggerate or in some way biologically produce an Alzheimer neuropathologic process has been uncritically accepted in some quarters. The two processes do seem to coincide more often than chance. The special problem of arteriosclerotic or multi-infarct dementia is discussed in Chap. 34 on cerebrovascular disease.

The lesions of *severe cerebral trauma*, if they result in dementia, are found in the cerebral convolutions (mainly frontal and temporal poles), corpus callosum, and thalamus. In some cases, there is widespread degeneration of the deep cerebral hemispheres, because of a mechanical disruption of the deep white matter termed *axonal shearing*. Most traumatic lesions that produce dementia are quite extensive, making localization difficult. Our own experience suggests that the thalamic lesions are critical, but many authorities view the axonal shearing lesions as the primary cause of traumatic dementia. The special problem of chronic traumatic encephalopathy is addressed in Chap. 35.

Mechanisms other than the overt destruction of brain tissue may operate in some cases of dementia. *Chronic hydrocephalus*, regardless of cause, is often associated with a general impairment of mental function. Compression of the cerebral white matter is probably the main factor, but this has not been settled. The extrinsic compression of one or both of the cerebral hemispheres by *chronic subdural hematomas* may have the same effect. A *diffuse inflammatory process* is at least in part the basis of dementia in syphilis, cryptococcosis, other chronic meningitides, and viral infections such as HIV encephalitis, herpes simplex encephalitis, and subacute sclerosing panencephalitis; presumably, there is a loss of some neurons and an inflammatory derangement of function in the neurons that remain. The prion diseases (e.g., Creutzfeldt–Jakob disease) cause a diffuse loss of cortical neurons, replacement gliosis, and spongiform change and produce special patterns of cognitive dysfunction.

The adult forms of *leukodystrophy* (Chap. 37) also give rise to a dementing state, generally a “subcortical” syndrome with prominent frontal lobe features. Or extensive lesions in the white matter may be the result of advanced multiple sclerosis, progressive multifocal leukoencephalitis, or some of the vascular dementias already mentioned (Binswanger disease and CADASIL [cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy]). Last, several of the metabolic and toxic disorders discussed in Chaps. 37, 40, and 43 may interfere with nervous function over a period of time and create a clinical picture similar, if not identical, to that of one of the dementias. One must suppose in those cases that the altered biochemical environment has affected neuronal function.

Classification of the Dementing Diseases

Conventionally, the dementing diseases have been classified according to cause if known, to the pathologic changes, or more recently, to a genetic mutation. Another, more practical approach, which follows logically from the method by which much of the subject matter is presented in this book, is to divide the diseases into three categories on the basis of the neurologic signs and associated clinical and laboratory signs of medical disease: (1) dementia with medical disease, (2) dementia that is accompanied by other prominent neurologic signs, and (3) dementia as the sole or predominant feature of the illness (Table 21-3). Once it has been determined that the patient suffers from a dementing illness, it must then be decided from

Table 21-3

BEDSIDE CLASSIFICATION OF THE DEMENTIAS

- I. Diseases in which dementia is associated with clinical and laboratory signs of other medical diseases
 - A. AIDS–HIV infection
 - B. Endocrine disorders: hypothyroidism, Cushing syndrome, rarely hypopituitarism, Hashimoto encephalopathy
 - C. Nutritional deficiency states: Wernicke–Korsakoff syndrome, subacute combined degeneration (vitamin B₁₂ deficiency), pellagra
 - D. Chronic meningoencephalitis: general paresis, meningovascular syphilis, cryptococcosis
 - E. Hepatolenticular degeneration—familial (Wilson disease) and acquired
 - F. Chronic drug and environmental intoxications (including CO poisoning)
 - G. Prolonged hypoglycemia or hypoxia
 - H. Paraneoplastic “limbic” encephalitis
 - I. Heavy metal exposure: arsenic, bismuth, gold, manganese, mercury
 - J. Dialysis dementia (now rare)
- II. Diseases in which dementia is associated with other neurologic signs but not with obvious medical diseases
 - A. Invariably associated with other neurologic signs
 1. Huntington chorea (choreoathetosis)
 2. Multiple sclerosis, Schilder disease, adrenal leukodystrophy, and related demyelinating diseases (spastic weakness, pseudobulbar palsy, blindness)
 3. Lipid-storage diseases (myoclonic seizures, blindness, spasticity, cerebellar ataxia)
 4. Myoclonic epilepsy (diffuse myoclonus, generalized seizures, cerebellar ataxia)
 5. Subacute spongiform encephalopathy; Creutzfeldt–Jakob disease; Gerstmann–Sträussler–Scheinker disease (prion, myoclonic dementias)
 6. Cerebrocerebellar degeneration (cerebellar ataxia)
 7. Cerebrobasal ganglionic degenerations (apraxia-rigidity)
 8. Dementia with spastic paraplegia
 9. Progressive supranuclear palsy (falls, vertical gaze palsy)
 10. Parkinson disease
 11. Amyotrophic lateral sclerosis (ALS) and ALS–Parkinson-dementia complex
 12. Other rare metabolic diseases, including polyglucosan disease and leukodystrophies
 - B. Often associated with other neurologic signs
 1. Multiple thrombotic or embolic cerebral infarctions and Binswanger disease
 2. Brain tumor (primary or metastatic) or abscess
 3. Brain trauma, such as cerebral contusions, midbrain hemorrhages, chronic subdural hematoma
 4. Lewy-body disease (parkinsonian features)
 5. Communicating, normal-pressure, or obstructive hydrocephalus (usually with ataxia of gait)
 6. Progressive multifocal leukoencephalitis
 7. Marchiafava–Bignami disease (often with apraxia and other frontal lobe signs)
 8. Granulomatous and other vasculitides of the brain
- III. Diseases in which dementia is usually the only evidence of neurologic or medical diseases
 - A. Alzheimer disease
 - B. Pick disease
 - C. Some cases of AIDS
 - D. Progressive aphasia syndromes
 - E. Frontotemporal and “frontal lobe” dementias associated with tau deposition, Alzheimer change, or with no specific pathologic alteration
 - F. Degenerative disease of unspecified type

Note. The special clinical features and morbid anatomy of these many dementing diseases are discussed in appropriate chapters throughout this book, particularly Chap. 39 on degenerative disorders, Chaps. 37 and 41 on metabolic and nutritional disturbances, and Chap. 33 on chronic infections.

the medical, neurologic, and ancillary data into which category the case fits. This classification may at first seem somewhat dated and not based on newer genetic and molecular models, but it is likely to be more useful to the student or physician who must confront the many diseases that cause dementia.

Differential Diagnosis

Although dementia per se does not indicate a particular disease, certain combinations of symptoms and neurologic signs are more or less characteristic and may aid in diagnosis. The age of the patient, the mode of onset of the dementia, its clinical course and time span, the associated neurologic signs, and the accessory laboratory data constitute the basis of differential diagnosis. It must be admitted, however, that some of the rarer types of degenerative brain disease are at present recognized mainly by pathologic examination or genetic testing. The correct diagnosis of treatable forms of dementia—subdural hematoma, certain brain tumors, chronic drug intoxication, normal-pressure hydrocephalus, HIV (reversible to some extent), neurosyphilis, cryptococcosis, pellagra, vitamin B₁₂ and thiamine deficiency states, hypothyroidism, and other metabolic and endocrine disorders—is, of course, of greater practical importance than the diagnosis of the untreatable ones. Also important is the detection of a *depressive illness*, which may masquerade as dementia, and chronic intoxication with drugs or chemical agents, both of which are treatable.

The first task in dealing with this class of patients is to verify the presence of intellectual deterioration and personality change. *It may be necessary to examine the patient serially before one is confident of the clinical findings and their chronicity.* A mild aphasia from a focal brain lesion must not be mistaken for dementia. Aphasic patients appear uncertain of themselves, and their speech may be incoherent. Careful attention to the patient’s language performance will lead to the correct diagnosis in most instances. It is a clinical truism that the abrupt onset of mental symptoms points to a delirium or other type of acute confusional state or to a stroke; inattention, perceptual disturbances, and often drowsiness are conjoined (Chap. 20). Also, progressive deafness or loss of sight in an elderly person may sometimes be misinterpreted as dementia.

There is always a tendency to assume that mental function is normal if a patient complains only of anxiety, fatigue, insomnia, or vague somatic symptoms, and to label the patient as anxious. This will be avoided if one keeps in mind that these disorders rarely have their onset in middle or late adult life.

Clues to the diagnosis of *depression* are the presence of frequent sighing, crying, loss of energy, psychomotor underactivity or its opposite, agitation with pacing, persecutory delusions, persistent hypochondriasis, and a history of depression in the past and in the family. Although depressed patients may complain of memory failure, scrutiny of their complaints will show that they can usually remember the details of their illness and that little or no qualitative change in other intellectual

functions has taken place. Their difficulty is either a lack of energy and interest or preoccupation with personal worries and anxiety, which prevents the focusing of attention on anything except their own problems. Even during mental tests, their performance may be impaired by “emotional blocking,” in much the same way as the worried student blocks during an examination (“experiential confusion”). When such patients are calmed by reassurance and encouraged to try harder, their mental function improves, indicating that intellectual deterioration has not occurred. Conversely, it is helpful to remember that demented patients rarely have sufficient insight to complain of mental deterioration; if they admit to poor memory, they do so without conviction or full appreciation of the degree of their disability. The physician must not rely on the patient’s statements alone in gauging the efficiency of mental function and should seek corroboration from family members. Yet another problem is that of the impulsive, cantankerous, and quarrelsome patient who is a constant source of distress to employer and family. Such changes in personality and behavior (as, for example, in Huntington disease) may precede or mask early intellectual deterioration.

The neuropsychiatric symptoms associated with metabolic, endocrine, or toxic disorders (e.g., Cushing syndrome, vitamin B₁₂ deficiency, hypercalcemia, uremia) may present difficulties in diagnosis because of the wide variety of clinical pictures by which they manifest themselves. Drowsiness or stupor and asterixis are the surest signs of a metabolic or drug-induced encephalopathy, but they are not always present. Psychosis with hallucinations and a great deal of fluctuation in behavior also bespeak an exogenously caused confusional state, with the exception that Lewy-body dementia also has these characteristics. Whenever any such metabolic or toxic disorder is suspected, a thorough review of the patient’s medications is crucial. Medications with atropinic activity, for example, can produce an apparent dementia or worsen a structurally based dementia, as discussed in Chap. 20. Occupational exposure to toxins and heavy metals should also be explored, but this is an infrequent cause of dementia; therefore, slight or even moderately elevated levels of these chemicals in the blood should be interpreted cautiously. It is also useful to keep in mind that seizures are not a usual component of the degenerative dementias; when they are present, they generally do not appear until a very late stage.

Once it is decided that the patient suffers from a dementing condition, the next step is to determine by careful physical examination, whether there are other neurologic signs or indications of a particular medical disease. This enables the physician to place the case in one of the three aforementioned categories in the bedside classification (see above and Table 21-3).

Experienced neurologists recognize that certain leading neurologic features are indicative of particular degenerative dementias. For example, prominent and early parkinsonian signs such as bradykinesia, tremor, and shortened gait step are parts of the subcortical dementias of Lewy body and Parkinson diseases. Rigidity of the limbs and apraxia may have a similar clinical appearance

but point to corticobasal degeneration as the cause of mental decline. An early aphasia or visuospatial difficulty that is manifest as either geographic confusion or difficulty with drawing, copying, and recognizing faces and objects are characteristic of a focal degeneration of the parietal or inferior temporal lobes. Involuntary movements such as choreoathetosis, dystonia, ataxia, and myoclonus are each signs of particular degenerative disorders that include Huntington disease, acquired and inherited hepatocerebral degenerations, and prion disorder, all of which are discussed in later chapter. Frequent falls and a disorder of vertical eye movements are the core components of progressive supranuclear palsy that often has an attendant dementia. In the nondegenerative categories of dementia, spasticity and Babinski signs are typical of vascular dementias.

Ancillary examinations—such as CT, MRI, electroencephalography (EEG), lumbar puncture, measurement of blood urea nitrogen, as well as serum concentrations of calcium and electrolytes, and liver function tests—should be carried out in appropriate cases. Brain MRI and CT are of major importance in objectifying hydrocephalus, lobar atrophy, cerebrovascular disease, tumor, and subdural hematoma. Testing for syphilis, vitamin B₁₂ deficiency, and thyroid function is also done in many clinics almost as a matter of routine because the tests are simple and the dementias they cause are reversible. These are supplemented in individual circumstances by serologic testing for HIV infection, measurement of copper and ceruloplasmin levels (Wilson disease), heavy metal concentrations in urine or tissues, serum cortisol levels, and drug toxicology screening. The final step is to determine, from the total clinical picture, the particular disease within any one category.

THE AMNESIC SYNDROME (KORSAKOFF SYNDROME) (See also Chap. 41)

The terms listed above are used interchangeably to designate a unique disorder of cognitive function in which memory and learning are deranged almost in isolation from all other components of mentation and behavior. The amnesic state, as originally defined by Ribot, possesses two salient features that may vary in severity but are always conjoined: (1) an impaired ability to recall events and other information that had been firmly established before the onset of the illness (*retrograde amnesia*) and (2) an impaired ability to acquire new information, i.e., to learn or to form new memories (*anterograde amnesia*). This duality inspired the White Queen, one of Lewis Carroll’s characters, to quip, “It’s a poor sort of memory that works only backwards.” In other words, the functions of memory and learning are inseparable. A third feature of the Korsakoff syndrome, contingent upon retrograde amnesia, is impaired temporal localization of past experience. Other cognitive functions, particularly the capacity for concentration, spatial organization, and visual and verbal abstraction, which depend little or not at all on memory, are usually not affected. Equally important in

the definition of the *Korsakoff syndrome*, or *amnesic state* (these terms are preferable to the older term, *Korsakoff psychosis*), is this integrity of certain aspects of behavior and mental function.

In order to establish the presence of the Korsakoff syndrome, the patient must be awake, attentive, and responsive—capable of perceiving and understanding the written and spoken word, of making appropriate deductions from given premises, and of solving such problems as can be included within his forward memory span. These features are of particular diagnostic importance because they help to distinguish the Korsakoff amnesic state from a number of other disorders in which the basic defect is not in memory but in some other abnormality—e.g., impairment in attention and perception (as in the delirious, confused, or stuporous patient), in loss of personal identity (as in the hysterical patient), or in volition (as in the apathetic or abulic patient with frontal lobe disease or depression).

Immediate recall, a function of *working memory*, allows the patient with Korsakoff syndrome to repeat a string of digits, but this is more a measure of attention and registration. Remote memory is relatively less affected than recent memory (the Ribot rule, as discussed later).

Confabulation

The creative falsification of memory in an alert, responsive individual is often included in the definition of the Korsakoff amnesic state but is not a requisite for diagnosis. It can be provoked by questions as to the patient's recent activities. The replies may be recognized as partially remembered events and personal experiences that are inaccurately localized in the past and related with no regard to their proper temporal sequence. Less frequent in Korsakoff syndrome, but more dramatic, is a spontaneous recital of personal experiences, many of which are fantasies. These two forms of confabulation have been referred to as "momentary" and "fantastic". In the patients with the alcoholic Korsakoff syndrome studied by Victor and Adams, fantastic confabulation was observed mainly in the initial phase of the illness, in which it could be related to a state of profound general confusion. In the chronic, stable stage of the illness, confabulation was rarely elicitable irrespective of how

broadly this symptom was defined. Confabulation therefore is not an obligate feature of the Korsakoff syndrome.

Neuropsychology of Memory

Memory function obeys certain neurologic laws. As memory fails, it first loses its hold on recent events. The extent in time of retrograde amnesia is generally proportionate to the magnitude of the underlying neurologic disorder. Early life memories are better preserved and often have been integrated into habitual responses; nevertheless, with natural aging, there is also a gradual loss of early life memories. In transitory amnesias (e.g., concussive head injury), memories are recovered in reverse order: first the remote and then the more recent. The enduring aspect of early life memories in contrast to more recently experienced and learned material, a restatement of the Ribot law, is apparent in both normal adults and in demented patients. As quoted by Kopelman, Ribot in 1882 stated: "The progressive destruction of memory follows a logical order—a law—it begins at the most recent recollections which, being rarely repeated and having no permanent associations, represent organization in its feeblest form."

In the further analysis of the Korsakoff amnesic syndrome, it is necessary to consider the proposition that memory is not a unitary function, but takes several forms. One practical classification that adheres broadly to current ideas in the field is shown in Fig. 21-1 and Table 21-4. An initial separation is made between the aforementioned immediate recall and the other types of memory. Short-term memory is exemplified by the common daily acts of hearing a phone number and retaining it to be able to walk across a room and dial the phone; or, performing a series of mental calculations that requires holding an intermediate sum briefly in mind; all the numbers are soon forgotten. Long-term memory can be viewed from the perspective the individual's awareness of the learning of new material (explicit memory), or not being conscious of the event of acquiring memory (implicit memory). Functions such the acquisition of physical skills (such as driving a car or playing tennis) are implicit memories termed procedural memory. Classic conditioning is considered another type of implicit memory.

Explicit memory subsumes what most persons consider to be memory and learning, that is, the ability to retain and recount events that were consciously experienced by

Figure 21-1. Schematic definitions of memory systems (see text). (From Budson and Price with permission.)

Table 21-4

NEUROPSYCHOLOGIC CATEGORIES OF MEMORY

	IMMEDIATE RECALL	WORKING MEMORY	LONG-TERM MEMORY			
			EXPLICIT		IMPLICIT	
			SEMANTIC	EPISODIC	PROCEDURAL	VISUAL
Function	Repetition	Short-term recall of objects, plans, names, sequencing	Recall for facts and their relationships	Recall for temporally organized events	Operational recall (“how to do”)	Recall of visual representations
Conscious access	Yes	Yes	Yes	Yes	Usually	No
Anatomic regions involved	Perisylvian cortex of dominant hemisphere	Prefrontal cortex, medial temporal lobes, dorsomedial thalamus	Anterior, inferior temporal lobes; frontal lobes	Association cortex	Premotor and motor cortex, basal ganglia, cerebellum	Occipital lobes
Conditions that disturb memory	Agitation, confusion (impaired attention)	Wernicke–Korsakoff syndrome, herpes encephalitis, infarction of hippocampi, dorsomedial thalamus	AD, frontotemporal dementia, encephalitis, chronic toxins, tumors	Hippocampal infarction, alcoholic Korsakoff syndrome, AD and other CNS degenerative disorders, encephalitis, chronic toxic exposure, tumors	AD and other CNS degenerative disorders, encephalitis, chronic toxic exposure, tumors	AD, other CNS degenerative disorders, encephalitis, tumors

AD, Alzheimer disease; CNS, central nervous system.

the person, including the time and general circumstances of the acquisition (episodic, or autobiographical memory). *Semantic memory*, the learning of the nature of the environment and factual knowledge (such as the shape and color of a lion) is also a type of explicit memory but the event of acquiring the memory cannot be recalled. A patient with virtually no capacity to learn any newly presented information can nonetheless still acquire some simple manual and pattern-analyzing skills. Moreover, having acquired these skills, the patient may have no memory of the circumstances in which they were acquired. The learning of simple mechanical skills has been referred to as *procedural memory*, in distinction to learning new data information. Cohen and Squire have described this dichotomy as “knowing how” as opposed to “knowing that.”

As confirmation of the separation of episodic from semantic memory functions, Gadian and colleagues have described young patients who showed severe impairments of episodic memory with relative preservation of semantic memory that was attributable to hypoxic-ischemic injury (bilateral hippocampal atrophy) sustained early in life. Here, again, the subject matter most relevant to amnesia involves episodic, or autobiographical, memory. The same occurs in early Alzheimer disease and herpes simplex encephalitis.

A pervasive problem with these terms is the lack of uniformity in defining the terms of memory. To Tulving, whose writings on this subject are recommended, the term *episodic* denotes a memory system for dating personal experiences and their temporal relationships; *semantic* memory is one’s repository of perceptual and factual knowledge, which makes it possible to comprehend

language and make inferences. This hardly constitutes a novel concept; Korsakoff himself clearly recognized that certain aspects of mental function (among them those now being defined as semantic memory) remain intact, despite the profound impairment of episodic memory. Damasio has introduced yet another set of terms—*generic* in place of semantic and *contextual* for episodic. To Damasio, generic memory denotes the basic properties of acquired information, such as its class membership and function; he makes the point that in the amnesic syndrome, this component of declarative memory remains intact and only the contextual component is impaired.

The full significance of these categorizations is still being explored. The categorical purity of semantic memory is open to question, as is the notion of a strict dichotomy between semantic and episodic memory. Most importantly, a separate anatomic basis for these systems of memory has not been clearly established (see below). Further interesting derivative issues regarding the neuropsychology of memory in relation to brain diseases can be found in the review by Kopelman. Among these is the degree to which a disparity between retrograde and anterograde memory can be detected in certain diseases. He also points out nicely the subtle distinctions between recall and memory by recognition.

Neuropsychologists have further subdivided memory and suggested that there are corresponding anatomic regions for specific categories (see Table 21-4). Some of these more complex subtypes have been alluded to above and others are simply restatements of the act of registration. Furthermore, it is not surprising that the participation of certain areas of the brain not primarily

involved in memory function, particularly the language and visuospatial areas, is required for the performance of certain memory tasks. Among the special modules of memory, the notion of a *working memory* has both clinical and neuropsychologic credibility. This relates to the capacity to register and attend to a task, and there is little question that it is a measurable form of memory. Several regions of the brain must be active during tasks of working memory, including the hippocampi and dorsal thalamus, but lesions of the dorsolateral prefrontal cortex most specifically impair the skill. The original work of Goldman-Rakic may be referred to for discussion of the mechanisms that underlie working memory.

Finally, there are reasons, based mainly on the neuro-anatomic and functional imaging studies discussed later, to view episodic memory for spatial and topographic information in a particular way. Certainly the recollection of personally experienced events can be dissociated to some degree from the memory of the topographic arrangement of the scene in which these memories were formed, but often these two elements are inextricably bound in one experience. More salient may be a disproportionate degradation of learned topographic and directional information compared to learned semantic material; such a dissociation can be found, but only in relative terms, in patients who have injuries to their right hippocampus, whereas semantic material is dependent more on the left hippocampus (see later).

Anatomic Basis of the Amnesic Syndrome

Two anatomic structures are of central importance in memory function: the diencephalon (specifically the medial portions of the dorsomedial and adjacent midline nuclei of the thalamus) and the hippocampal formations of the medial temporal lobes including their associated structures (dentate gyrus, hippocampus, parahippocampal gyrus, subiculum, and entorhinal cortex). Discrete bilateral lesions in these two main regions derange memory and learning disproportionate to all other cognitive functions, and even a unilateral lesion of these structures, especially of the dominant hemisphere, can produce a lesser degree of the same effect. The clinical-anatomic relationships that bear on this subject are discussed in detail by Aggleton and Saunders and in the monograph on Wernicke-Korsakoff syndrome by Victor et al.

While central to memory function, these are not the only regions engaged in the formation and retrieval of memory. A severe but less-enduring defect in memory is observed with damage of the anterior septal gray matter; a cluster of midline nuclei at the base of the frontal lobes, just below the interventricular septum and including the septal nucleus, nucleus accumbens, diagonal band of Broca; and paraventricular hypothalamic gray matter. The case of infarction of this region reported by Phillips and colleagues confirms the participation of this region in memory formation and retrieval. The amnesic syndrome, usually not permanent, that follows a ruptured anterior communicating aneurysm is a consequence of disruption of these nuclei. These septal nuclei have connections with the hippocampus through the precommissural fornix and

with the amygdala through the diagonal band. Again, what is most remarkable about this basal frontal amnesic syndrome is its initial severity lasting for weeks to months and the potential for almost complete recovery.

Observations of human disease have confirmed the fundamental importance of the diencephalic-hippocampal structures in all memory function. The difficulty of evaluating memory function in monkeys has been largely overcome by use of the "delayed nonmatching-to-sample task," which is essentially a refined test of recognition memory and is impaired both in patients with the amnesic syndrome and in monkeys with lesions of the mediodorsal nuclei of the thalamus and inferomedial temporal cortical regions (Mishkin and Delacour). Using this method and several others that simulate a restricted form of human amnesia, Zola-Morgan and colleagues have shown that bilateral lesions of the hippocampal formation cause an enduring impairment of memory function. Lesions confined to the fornices or mammillary bodies and stereotaxic lesions of the amygdala that spared the adjacent cortical regions (entorhinal and perirhinal cortices) failed to produce a memory defect. However, lesions that were restricted to the perirhinal and entorhinal cortex (Brodmann areas 35 and 36) and the closely associated parahippocampal cortex did cause a persistent memory defect, presumably by interrupting the major afferent pathways conveying cortical information to the hippocampus. Lesions of the anteromedial parts of the diencephalon, which receive and send fibers to the amygdala and hippocampus, similarly abolished memory function.

A body of work using functional neuroimaging also addresses the anatomic mechanisms of memory function. It has been found that the hippocampal formations are consistently engaged during memory acquisition and retrieval tasks. In addition, Maguire's group found a differential activation of the right side during recall of topographic spatial information and the left side for autobiographical memory. Their clever use of London taxi drivers as subjects for imaging studies has further suggested that the volume of the right hippocampus is larger in subjects who have more experience navigating the arcane streets of London. An asymmetrical representation of certain modalities of memory is in keeping with limited clinicopathologic studies of patients who have undergone temporal lobectomy on one side.

These observations in aggregate confirm that integrity of the hippocampal formations and the medial-dorsal nuclei of the thalamus are essential for normal memory and learning. Interestingly, there are only sparse direct anatomic connections between these two regions. The importance assigned to the hippocampal formations and medial thalamic nuclei in memory function does not mean that the mechanisms governing this function are confined to these structures or that these parts of the brain form a "memory center." It informs us only that these are the sites where the smallest lesions have the most devastating effects on memory and learning. Normal memory function, as emphasized, involves many parts of the brain in addition to diencephalic-hippocampal structures. The aforementioned basal frontal nuclei that project to the hippocampi are an example.

It is also clear that particular lesions of the neocortex may cause impairment of specific forms of memory and learning. Thus, a lesion of the dominant temporal lobe impairs the ability to remember words (loss of explicit semantic memory), and a lesion of the inferior parietal lobule undermines the recognition of written or printed words as well as the ability to relearn them (alexia). The dominant parietal lobe is related to recollection of geometric figures and numbers; the nondominant parietal lobe, to visuospatial relations; the inferoposterior temporal lobes, to the recognition of faces; and the dominant posterofrontal region, to acquiring and remembering motor skills and their affective associations. Whether these are truly forms of memory, or whether these regions of cortex must be entrained in order to retrieve and "experience" the memory, is philosophical. Taken to its extremes, aphasia from a left temporal perisylvian lesion (Wernicke's aphasia) could be viewed as an amnesia for language, and parietal lesions that cause ideomotor apraxia could be taken to represent a loss of memory for these previously learned acts. What remains inviolate is that the integrity of both the hippocampal-thalamic system and the appropriate cortical region is required for memory as we refer to it in this chapter, but only the former is integrated into all modalities of learning and retrieval.

It is a remarkable feature of the Korsakoff amnesic state that no matter how severe the defect in memory may be, it is never complete. Certain past memories can be recalled, but imperfectly and with no regard for their normal temporal relationships, giving them a fictional quality and explaining many instances of confabulation. Another noteworthy fact is that long-standing social habits, automatic motor skills, and memory for words (language) and visual impressions (visual or pictorial attributes of persons, objects, and places) are unimpaired. Long periods of repetition and usage may have made these implicit or procedural memories virtually automatic; they no longer require the participation of the diencephalic-hippocampal structures that were necessary to learn them originally. All of this suggests that these special memories, or coded forms of them, through a process of relearning and habituation, come to be stored or filed in other regions of the brain; i.e., they acquire a separate and autonomous anatomy that may be regional, cellular, or subcellular.

Several fundamental questions concerning the amnesic syndrome remain unanswered. Not known is how a disease process, acting over a brief period of time, not only impairs all future learning but also wipes out portions of a vast reservoir of past memories that had been firmly established for many years before the onset of the illness. Most likely, it is not the memories themselves that are obliterated but the mechanism required to access them.

One of the most provocative new observations regarding memory has been the enhancement of performance by electrical stimulation of the entorhinal area in individuals with epilepsy. The study by Suthana and colleagues is one of several demonstrating this effect in an improved ability to retain topographic-spatial landmarks

in a simulated exercise. At a minimum, these findings confirm the critical role of parahippocampal regions (perforant pathways) in forming and stabilizing memories, in these cases, the major source of afferent input to the hippocampus.

This begs the fascinating question of "what is a memory?" Current notions suggest that no single hippocampal neuron, for example, embodies a memory but that the connections between an ensemble of neurons in the medial temporal lobes and modality-specific neurons in the associative cortices are, in fact, the memory. Strengthening synaptic connections among this network serves to establish the memory. This may occur through long-term potentiation, as the work of Kandel has emphasized in experimental models. It is not clear if a hippocampal neuron is the trigger to the memory ensemble or the entirety of hippocampal system serves a generic role in cohering all memories. The cellular mechanisms involved in learning and the formation of memories are only beginning to be understood. Whether physiologic phenomena such as long-term potentiation or anatomic changes in the dendritic structure of neurons are at the center of memory storage is not known; certainly both are likely to be involved. The neurochemical systems that are activated during formation and recall of memory are also obscure. Kandel has provided a detailed review of information on this subject. The anatomic and physiologic mechanisms that govern immediate registration, which remains intact in even the most severely damaged patients with the Korsakoff amnesic syndrome has not been fully deciphered.

Other psychologic features of human memory that must be accounted for by any model purporting to explain this function are the importance of cueing in eliciting learned material and the imprecision of past memories, allowing for unwitting embellishment and false recollection, to the point of fabrication. The latter aspect has been a topic of considerable importance in children who have (or have not) been subjected to sexual abuse and in adults and children whose memories of past abuse have been suggested by the examiners (see Schacter).

The separate roles of the thalamus, the hippocampi, and the frontal lobes in memory and the differences in the nature of the amnesia resulting from damage at each site remain to be clarified. That isolated thalamic lesions, without implicating medial temporal areas, can cause a Korsakoff syndrome is evident from the experience with alcoholism and stroke. Graff-Radford and colleagues have found that with purely thalamic lesions, as appreciated by imaging studies, anterograde learning is more affected than retrograde recall; but comparing these functions quantitatively is difficult. Kopelman, in reviewing his own studies and those of others, concludes that the differences are subtle and pertain mostly to temporal ordering and the modality of information, which is degraded more with diencephalic-temporal lesions than with frontal lobe damage.

Each of the amnesic states listed in Table 21-5 is considered at an appropriate point in subsequent chapters of this book. The only exception is the striking syndrome of *transient global amnesia*, the nature of which is not certain.

Table 21-5

CLASSIFICATION OF THE AMNESIC STATES

- I. Amnesic syndrome of sudden onset—usually with gradual but incomplete recovery
 - A. Bilateral or left (dominant) hippocampal infarction because of atherosclerotic-thrombotic or embolic occlusion of the posterior cerebral arteries or their inferior temporal branches
 - B. Bilateral or left (dominant) infarction of anteromedial thalamic nuclei
 - C. Infarction of the basal forebrain due to occlusion of anterior cerebral–anterior communicating arteries
 - D. Subarachnoid hemorrhage (usually rupture of anterior communicating artery aneurysm)
 - E. Trauma to the diencephalic, inferomedial temporal, or orbitofrontal regions
 - F. Cardiac arrest, carbon monoxide poisoning, and other hypoxic states (hippocampal damage)
 - G. Following prolonged status epilepticus
 - H. Following delirium tremens
- II. Amnesia of sudden onset and short duration
 - A. Temporal lobe seizures
 - B. Postconcussive states
 - C. Transient global amnesia
 - D. Hysteria
- III. Amnesic syndrome of subacute onset with varying degrees of recovery, usually leaving permanent residua
 - A. Wernicke–Korsakoff syndrome
 - B. Herpes simplex encephalitis
 - C. Tuberculous and other forms of meningitis characterized by a granulomatous exudate at the base of the brain
- IV. Slowly progressive amnesic states
 - A. Tumors involving the floor and walls of the third ventricle and limbic cortical structures
 - B. Alzheimer disease (early stage) and other degenerative disorders with disproportionate affection of the temporal lobes
 - C. Paraneoplastic and other forms of immune “limbic” encephalitis

It cannot be included with any assurance with the epilepsies or the cerebrovascular diseases or any other category of disease and is therefore considered here.

TRANSIENT GLOBAL AMNESIA

This was the name applied by Fisher and Adams to a particular transient type of memory disorder that they observed in more than 20 middle-aged and elderly persons. The condition was characterized by an episode of amnesia and bewilderment lasting for several hours. The symptoms had their basis in an amnesia for events of the recent past coupled with an ongoing anterograde amnesia. During the attack, there is no impairment in the state of consciousness, no other sign of confusion, and no overt seizure activity; personal identification is intact, as are motor, sensory, and reflex functions. The patient’s behavior is normal except for a very characteristic incessant, repetitive questioning about his immediate circumstances—usually of the identical question over and over at intervals of 20 to 60 seconds after a response to the query has been given by the examiner (e.g., “What am I doing here?”; “How did we get here?”). Unlike psychomotor epilepsy, the patient

is alert, in contact with his surroundings, and capable of high-level intellectual activity and language function during the attack. As soon as the episode has ended, no abnormality of mental function is apparent except for a permanent gap in memory for the period of the attack itself and for a brief period (hours or days) preceding it. The patient may be left with a mild headache. Incomplete or mild attacks are infrequent, and they may be as brief as 1 h, but are typically longer. The condition is among the most curious in neurology and may be mistaken for a psychiatric episode.

Hodges and Ward have made detailed psychologic observations in 5 patients during an episode. The psychologic deficit, except for its transience, was much the same as that in a permanent amnesia syndrome. Personality, cognition involving high-level functioning, semantic language, and visuospatial discrimination were all preserved. So-called immediate memory—i.e., registration (see earlier)—was likewise operating normally, but memory was essentially obliterated. The duration of retrograde amnesia was highly variable, but characteristically it shrank after the attack, leaving a permanent retrograde gap of about 1 h. However, subtle impairment of new learning persisted for up to a week after the acute attack insofar as this defect could be detected by special testing.

In a survey conducted in the Rochester, Minnesota, area, transient global amnesia (TGA) occurred at an annual rate of 5.2 cases per 100,000 population. The recurrence of such attacks is not uncommon, having been noted in 66 of 277 older adults who were observed for an average period of 80 months (Miller et al) and in 16 of 74 patients followed for 7 to 210 months (Hinge et al). Hinge and colleagues estimate the mean annual recurrence rate to be so low (4.7 percent) that most patients are likely to experience only one attack. One of our patients had more than 50 attacks, but among all the rest (more than 100 cases), 5 was the maximum. It seems children are not susceptible to the condition; however, a 13-year-old and 16-year-old with migraine were reported to have had similar attacks during participation in sports (Tosi and Righetti).

No consistent antecedent events have been identified, but certain ones—such as a highly emotional experience like hearing of the death of a family member, pain, exposure to cold water, sexual activity, and mild head trauma—have been reported in some cases (Haas and Ross; Fisher). The similarity to postconcussive amnesia is notable; this is always a concern if the patient was not under observation at the onset of the attack. We have also seen several patients in whom the attacks appeared after minor diagnostic procedures such as colonoscopy, but the residual effects of sedation are suspect in some of these. Several cases have been reported in high-altitude climbers and have created difficulty in distinguishing TGA from altitude sickness.

One can conceive of TGA as a syndrome that has several non idiopathic causes. The main concern is a focal temporal lobe seizure that can simulate the syndrome. Transient ischemic attack involving the same posterior regions is another. Whether migrainous episodes can produce a clinical syndrome is uncertain, as noted later,

but by far the largest number of cases are idiopathic after extensive evaluation.

The pathogenesis of idiopathic TGA has not been settled. It has been suggested that typical case represents an unusual form of temporal lobe epilepsy (transient epileptic amnesia [TEA]), but this seems an unlikely unifying hypothesis. A large number of patients have been studied with EEGs during an attack or shortly thereafter and have not shown seizure activity (Miller et al). Moreover, amnesic episodes caused by seizures are usually much briefer than those of TGA, and most or all temporal lobe seizures are associated with impairment of consciousness and an inability to interact fully with the social and physical environment. Using EEG and nasopharyngeal leads, Rowan and Protass found mesiotemporal spike discharges in 5 of 7 patients. Curiously, they attributed the discharges to ischemic lesions during drug-induced sleep. Palmini and coworkers cite exceptional cases of pure amnesic seizures in temporal lobe epilepsy, but even in their best examples, ictal and postictal function was not normal.

Transient global amnesia may be ischemic or perhaps migrainous in nature, though not atherosclerotic-thrombotic, but rarely (if ever) do the attacks progress to stroke. Regarding cerebrovascular disease and TGA, Hinge and associates and Hodges and Warlow, in a case-control study of 114 patients with TGA, found no evidence of an association with cerebrovascular disease; there was, however, a significantly increased history of migraine, as there was in the series of Miller and coworkers (14 percent) and of Caplan and colleagues. From indirect evidence of retrograde blood flow in the internal jugular arteries during the Valsalva maneuver (occasionally reported to precipitate an attack), Sander and colleagues and Chung and coworkers have suggested that venous congestion of the temporal lobes was operative. Other studies suggest that the draining veins in the neck lack valves in patients who have had TGA, which permits venous ischemia in the temporal lobes (Schreiber et al); rare cases associated with lateral sinus thrombosis also implicate derangements in venous blood flow in the genesis of TGA. None of these is definitive and they are mentioned here for completeness.

The most compelling cases for an ischemic basis of TGA, perhaps most relevant to migraine, come from Stillhard and colleagues, who demonstrated bitemporal hypoperfusion during an attack of TGA, and from Strupp and associates and Sedlaczek and colleagues, who demonstrated hippocampal and peri-hippocampal lesions (interpreted as cellular edema) with diffusion-weighted MRI, but only 2 days following an attack, not acutely. Like the clinical syndrome, the MRI findings are reversible (Fig. 21-2). The precipitation of identical attacks by vertebrobasilar and coronary angiography is also suggestive of an ischemic or migrainous causation.

A hypothesis generated by the authors of studies on delayed MRI lesions is of a mismatch between cerebral blood supply and demand in the limbic regions. This provides a potential explanation for the association of highly emotional events prior to an episode.

The benignity of transient global amnesia in most patients is noteworthy. Once the history and examination

Figure 21-2: MRI showing a tiny area of restricted diffusion in the left hippocampus, 36 hours after an episode of transient global amnesia.

have excluded vertebrobasilar ischemia and temporal lobe epilepsy, no treatment is required other than an explanation of the nature of the attack and reassurance, although we often hospitalize such patients briefly to be certain that the episode clears without further incident. The diagnosis of TGA should not be accepted if there has been ataxia, vertigo, diplopia, or other visual complaints, or if there are deficits in cognition that extend beyond the limited retrograde and complete anterograde amnesia.

APPROACH TO THE PATIENT WITH DEMENTIA AND THE AMNESIC STATE

The physician presented with a patient suffering from dementia must adopt an examination technique designed to expose the intellectual defect fully. Abnormalities of posture, movement, sensation, and reflexes cannot be relied on to disclose the disease process. Suspicion of a dementing disease is aroused when the patient presents multiple complaints that seem totally unrelated to one another and to any known syndrome; when symptoms of irritability, nervousness, and anxiety are vaguely described and do not fit exactly into one of the major psychiatric syndromes; and when the patient is incoherent in describing the illness and the reasons for consulting a physician.

Three categories of data are useful for the recognition and differential diagnosis of dementing brain disease:

1. A reliable history of the illness and its impact on daily life
2. Findings on mental examination
3. Ancillary examinations: CT, MRI, functional imaging, sometimes lumbar puncture, EEG, and appropriate laboratory procedures, as described in Chap. 2

The history should always be supplemented by information obtained from a person other than the patient, because, through lack of insight, the patient will have limited and variable grasp of his illness or its gravity; indeed, he may be unaware even of his chief complaint. Special inquiry should be made about the patient's general behavior, capacity for work, personality changes, language, mood, special preoccupations and concerns, delusional ideas, hallucinatory experiences, personal habits and care in hygiene, and such faculties as memory and judgment.

The examination of the mental status should include some of the following general categories with suggested examples for testing as modified for each patient's circumstances. In addition, the mode of answering and solving problems gives invaluable information about the mental operations of the subject and must be incorporated into any analysis of cognition. A perplexed or slowed individual may ultimately perform adequately but nonetheless have seriously flawed cortical or subcortical function. Each of the tests below is necessarily an abstraction but ones that separate particular functions of the brain. As already emphasized, the patient must have normal, or nearly so, attentiveness to carry out these tasks and a deficiency in any one of them may disrupt the performance of others.

1. *Insight* (patient's replies to questions about the chief symptoms): What is your difficulty? Are you ill? When did your illness begin?
 2. *Orientation* (knowledge of personal identity and present situation): What is your name, address, telephone number? What is your occupation? Are you married?
 - a. *Place*: What is the name of the place where you are now (building, city, state)? How did you get here? What floor is it on? Where is the bathroom?
 - b. *Time*: What is the date today (day of week and of month, year)? What time of the day is it? What meals have you had? When was the last holiday?
 3. *Memory*:
 - a. *Long-term*: Tell me the names of your children (or grandchildren) and their birth dates. When were you married? What was your mother's maiden name? What was the name of your first school-teacher? What jobs have you held? These must be corroborated by a spouse or other family member. We also find it useful to quiz the patient about cultural icons of the past that are appropriate to his age. Most patients should be able to name the recent presidents in reverse order.
 - b. *Recent past*: Tell me about your recent illness (compare with previous statements). What is my name (or the nurse's name)? When did you see me for the first time? What tests were done yesterday? What were the headlines of the newspaper today?
 - c. *Immediate recall (attention, short-term working memory)*: Repeat these numbers after me (give series of 3, 4, 5, 6, 7, 8 digits at a speed of 1 per second). Now when I give a series of numbers, repeat them in reverse order. Cross out all the a's on a printed page; count forward and backward; say the months of the year forward and backward; spell *world* forward and then backward. Verbal trail making (reciting alternating letters of the alphabet and their ordinal place, i.e., A-1, B-2, C-3, D-...)
 - d. *Memorization (learning)*: The patient is given three or four simple data (examiner's name, date, time of day, and a fruit, structure, or trait, such as honesty—we use "a red ball, Beacon Street, and an envelope") and is asked to repeat them after a minute; or is given a brief story containing several facts and is asked to recount the main facts as soon as the story is over. The capacity to reproduce them at intervals after committing them to memory is a test of *memory span*.
 - e. Another test of memory and verbal fluency we have found useful is the generation of a list of objects in a category; ask the patient to give the names of animals, vegetables, or makes of cars, as many as come to mind in 30 s or so; most individuals can list at least 12 items in each category.
 - f. *Visual facility*: Show the patient a picture of several objects; then ask him to name the objects.
4. *Capacity for calculation, construction, and abstraction*:
 - a. *Calculation*: Test ability to add, subtract, multiply, and divide. Subtraction of serial 3s and 7s from 100 is a good test of calculation as well as of concentration.
 - b. *Constructions*: Ask the patient to draw a clock and place the hands at 7:45, a map of the United States, a floor plan of her house; ask the patient to copy a cube and other figures.
 - c. *Abstract thinking*: See if the patient can describe the similarities and differences between classes of objects (orange and apple, horse and dog, desk and bookcase, newspaper and radio) or explain a proverb or fable ("People who live in glass houses shouldn't throw stones"; "A stitch in time saves nine"; "A rolling stone gathers no moss"; "Idle hands are the devil's workshop").
 5. *General behavior*: Attitudes, general bearing, evidence of hallucinosis, stream of coherent thought and attentiveness (ability to maintain a sequence of mental operations), mood, manner of dress, etc.
 6. *Special tests of localized cerebral functions*: Grasping, sucking, aphasia battery, praxis with both hands, and corticosenory function.

To enlist the full cooperation of the patient, the physician must prepare him for questions of this type. Otherwise, the patient's first reaction will be one of embarrassment or anger because of the implication that his mind is unsound. It could be pointed out to the patient that some individuals are rather forgetful or have difficulty in concentrating, or that it is necessary to ask specific questions in order to form some impression about his degree of nervousness when being examined. Reassurance that these are not tests of intelligence or of sanity is helpful. If the patient is agitated, suspicious, or belligerent, intellectual functions must be inferred from his remarks and from information supplied by the family.

This type of mental status survey can be accomplished in about 10 min. In our experience, a high level of performance on all tests eliminates the possibility of dementia in almost all cases. It may fail to identify a dementing disease in an uncooperative patient and in a highly intelligent individual in the earliest stages of disease.

The question of whether to resort to formal psychologic tests is certain to arise. Such tests yield quantitative data of comparative value but cannot of themselves be used for diagnostic purposes. The Mini-Mental Status Examination (MMSE) devised by Folstein and coworkers (Table 21-6), and the Montreal Cognitive Assessment (MOCA) are popularly used. A score of 24 on the widely used “mini-mental” is considered normal and scores below 21 generally indicate cognitive impairment. Patients with lower levels of education and older age have lower normative scores, but even individuals in their eighties with a high school education score 23 or above if not demented (see Crum et al for age and education adjusted normal score). A number of other tests that measure the degree of dementia (carrying the names of their originators: Roth, Pfeiffer, Blessed, Mattis) rely essentially on the points mentioned above and a brief assessment of the patient’s ability to accomplish the activities of daily living, which is lost in the later stages of disease.

Probably the Wechsler Adult Intelligence Scale (WAIS) is also accurate in detecting dementia. In this test, an index of deterioration is provided by the discrepancy between

the vocabulary, picture-completion, and object-assembly tests as a group (these correlate well with premorbid intelligence and are relatively insensitive to dementing brain disease) and other measures of general performance, namely arithmetic, block-design, digit-span, and digit-symbol tests. The Wechsler Memory Scale estimates the degree of memory failure and can be used to distinguish the amnesic state from a more general dementia (discrepancy of more than 25 points between the WAIS and the memory scale). Questions that measure spatial and temporal orientation and memory are the key items in most of these abbreviated scales of dementia. All of the aforementioned clinical and psychologic tests, and several others as well, measure the same aspects of behavior and intellectual function. The WAIS, MOCA, and the MMSE of Folstein and associates are the most widely used clinically in our experience and serve the clinician well.

MANAGEMENT OF THE DEMENTED PATIENT

Dementia is a clinical state of the most serious nature. The physician can see the patient serially over a period of weeks, during which the appropriate laboratory tests (blood, cerebrospinal fluid analysis, and CT, MRI and functional imaging as discussed in Chap. 39) can be carried out. The management of demented patients in the

TASK	INSTRUCTIONS	SCORING	
Date orientation	“Tell me the date?” Ask for omitted items.	One point each for year, season, date, day of week, and month	5
Place orientation	“Where are you?” Ask for omitted items.	One point each for state, county, town, building, and floor or room	5
Register three objects	Name three objects slowly and clearly. Ask the patient to repeat them.	One point for each item correctly repeated	3
Serial sevens	Ask the patient to count backwards from 100 by 7. Stop after 5 answers. (Or ask them to spell <i>world</i> backwards.)	One point for each correct answer (or letter)	5
Recall three objects	Ask the patient to recall the objects mentioned above.	One point for each item correctly remembered	3
Naming	Point to your watch and ask the patient “What is this?” Repeat with a pencil.	One point for each correct answer	2
Repeating a phrase	Ask the patient to say “no ifs, ands, or buts.”	One point if successful on first try	1
Verbal commands	Give the patient a plain piece of paper and say “Take this paper in your right hand, fold it in half, and put it on the floor.”	One point for each correct action	3
Written commands	Show the patient a piece of paper with CLOSE YOUR EYES printed on it.	One point if the patient’s eyes close	1
Writing	Ask the patient to write a sentence.	One point if sentence has a subject, a verb, and makes sense	1
Drawing	 Ask the patient to copy a pair of intersecting pentagons onto a piece of paper.	One point if the figure has 10 corners and 2 intersecting lines	1
Scoring	A score of 24 or above is considered normal.		30

hospital may be relatively simple if they are quiet and cooperative. If the disorder of mental function is severe, it is helpful if a nurse, attendant, or member of the family can stay with the patient at all times.

The primary responsibility of the physician is to diagnose the treatable forms of dementia and to institute appropriate therapy. If it is established that the patient has an untreatable dementing brain disease and the diagnosis is sufficiently certain, a responsible member of the family should be informed of the medical facts and prognosis and assisted in the initiation of social and support services. In the past, it was considered that patients themselves need be told only that they have a condition for which they are to be given rest and treatment. Most physicians (and patients) find this too patronizing; certainly, in the current social environment, patients ask directly if they have Alzheimer disease. To this query we usually respond that they may, but that more time is required to be certain. Some intelligent patients have insisted on knowing the details and implications of this statement, and we have felt obliged to give as much useful information as required by them.

Reassurance that the physician will be available to help the patient and family manage the situation is of utmost value. Crises should be preempted by regular contact with a general physician. If the dementia is slight and circumstances are suitable, patients should remain at home for the first years, continuing to engage in those accustomed activities of which they are capable. They should be spared responsibility and guarded against injury that might result from imprudent action, such as leaving a stove turned on or driving and getting lost—or worse. If they are still at work, plans for occupational retirement should be carried out. In more advanced stages of the disease, when mental and physical enfeeblement become pronounced, a skilled nursing facility or supervised home care should be arranged.

The value of centrally acting cholinergic agents and glutamate antagonists in the treatment of Alzheimer disease is modest but clear and should be weighed against the need for blood testing and side effects. These medications, however, offer psychologic benefit to the patient and family; Chap. 39 discusses the use of these medications.

Undesirable restlessness, nocturnal wandering, and belligerency may be reduced by administration of one of the antipsychotic or benzodiazepine drugs (see Chaps. 20, 43, and 48). Although randomized trials of these drugs have failed to show benefit in extreme circumstances, partly as a result of poor tolerance, there are few other options. Emotional lability and paranoid tendencies may be managed by the judicious use of quetiapine, olanzapine, risperidone, or haloperidol. Some patients are helped by short-acting sedatives such as lorazepam without any worsening of the mental condition, but all these drugs must be given with caution and some may be particularly problematic in patients with combined parkinsonism and dementia syndromes.

Questions asked by the patient's family must be answered patiently and sensitively by the physician. Common questions are "Should I correct or argue with the patient?" (No.) Orientation as to date, circumstances, and planned appointments is, however, helpful in preparing the patient for the day's activities. "Can the patient be left alone?" "Must I be there constantly?" (Depends on specific circumstances and the severity of dementia.) "Should the patient manage his own money?" (Generally not.) "Will a change of environment or a trip help?" (Generally not; often the disruption in daily routine worsens behavior and orientation.) "Can he drive?" (Best to advise against driving in most instances.) "What shall we do about the patient's fears at night and his hallucinations?" (Medication under supervision may help.) "When is a nursing home appropriate?" "How will the condition worsen? What should the family expect, and when?" (Uncertain, but usually a 5- to 10-year course.) Many families have found the information on the Alzheimer Association website, <http://www.Alz.org>, helpful, but physician guidance is required to make the material applicable to individual circumstances.

Visiting nurses, social agencies, live-in healthcare aides, day care settings, and respite care to relieve families from the constant burden of caring for the patient should all be used to advantage. Some of the inevitable practical problems accompanying the dissolution of personal life caused by dementia can be ameliorated by judicious use of powers of attorney or guardianship and similar legal vehicles.

Neurologic Disorders Caused By Lesions in Specific Parts of the Cerebrum

The long-standing controversy about cerebral functions, whether they are diffusely represented in the cerebrum with all parts roughly equivalent, or localized to certain lobes or regions, has been resolved to the satisfaction of most neurologists. Clinicians have demonstrated beyond doubt that particular functions are assignable to certain cortical regions. For example, the pre- and postrolandic zones control motor and sensory activities, respectively, the striate occipital zones control visual perception, the superior temporal gyri are auditory, and so on. Beyond these broad correlations, however, there is a notable lack of precision in the cortical localization of most of the behavioral and mental operations described in Chaps. 20 and 21. In particular, of the higher order functions, such as attention, vigilance, apperception, and analytic and synthetic thinking, none has a precise and predictable anatomy; or, more accurately, the neural systems on which they depend are widely distributed among several regions.

One may inquire into what precisely is meant by *cerebral localization*. Does it refer to the physiologic function of a circumscribed group of neurons in the cerebral cortex, indicated clinically by a loss of that function when the neurons in question are destroyed? This is the way in which neurologists have assigned functions to particular areas of the cerebral cortex. However, from what we know of the rich connectivity of all parts of the specialized cortical centers, one must assume that this is only partly the case. Most who ponder this subject believe that the organization of cerebral function is based on discrete networks of closely interconnected afferent and efferent neurons in several regions of the brain. These ensembles must be linked by both regional and more widespread systems of fibers. This is especially apparent in the discussion of the anatomy of complex cognitive properties such as intelligence, as described in Chap. 21. Thus, many basic functions are anchored in one cortical region and a lesion there causes loss of a particular ability. But it is apparent from physiologic studies such as functional imaging and electromagnetic stimulation that widely distributed networks are engaged, which nonetheless encompasses the region that can be ablated and eliminate the function in question.

These aspects of cerebral localization—brought out so clearly in the writings of Wernicke, Déjerine, and

Liepmann, have been elaborated by Luria (1966 and 1969) and the Russian school of physiologists and psychologists and extended by Geschwind (1965). In keeping with the model of interconnected networks, they viewed function not as the direct property of a particular, highly specialized region of the cerebrum but as the product of complex, diffusely distributed activity by which sensory stimuli are analyzed and integrated at various levels of the nervous system and then united, through a system of temporarily acquired connections, into a working mosaic adapted to accomplish a particular task. To some extent, this model has been corroborated by functional imaging studies, which show increased metabolic activity in several cortical regions during almost every form of human behavior, including willed motor acts, language tasks, and those coinciding with perceptive and apperceptive sensory experiences. Within such a functional system, the initial and final points (the task and the effect) remain unchanged, but the intermediate links (the means of performance of a given task) may be modified within wide limits and will never be exactly the same on two consecutive occasions. Thus, when a certain act is called for by a spoken command, the dominant temporal lobe must receive the message and transmit it to the premotor areas. Or it may be initiated by the intention of the individual, in which case the first measurable cerebral activity (a “readiness potential”) occurs anterior to the premotor cortex. The motor cortex is also always under the dynamic control of the proprioceptive, visual, and vestibular systems. Thus, a lesion that affects any one of several elements in the act may cause loss of a skilled ability, either the motor centers themselves or their connections with the other elements.

Another theoretical scheme of cerebral function identifies cortices of similar overall structure and divides the cerebral mantle into three longitudinally oriented zones, the triune brain articulated by Paul Maclean. A central vegetative neuronal system (alloccortex and hypothalamus) provides the mechanisms for all internal functions, the *milieu intérieur* of Bernard and Cannon. An outer zone, comprising the sensorimotor and association cortices and their projections, provides the mechanisms for perceiving the external world and interacting with it, and a region between them (limbic-paralimbic cortices) that provides the bridges that permit the adaptation of

Figure 22-1. Photograph of the lateral surface of the human brain. (Reproduced by permission from Carpenter MB, Sutin J: *Human Neuroanatomy*, 8th ed. Baltimore, Williams & Wilkins, 1982.)

the organism's needs to the external environment. This ostensibly metaphoric concept of central nervous system function, first proposed by Broca, was elaborated by Yakovlev and has been adopted more recently by Benson and by Mesulam (1998). Such a model retains to a large degree the cytoarchitectural similarities among areas that serve similar functions (i.e., the scheme of Brodmann discussed further on) and also respects the sequence of brain maturation (myelination) of connecting pathways proposed by Flechsig (see Fig. 28-3). In this way, localization may be viewed as the product of genetic patterns of structure, which mature during development, and their synaptic formations, which permit the development of complex circuits during lifelong learning and experience.

It is worthwhile to point out that these broadened concepts of cerebral function, which apply to all mental activities, contradicts both the historical notion that there is a functional equivalence of all cerebral regions and also the more recently developed one that assumes strict localization of any given activity.

From these remarks, it follows that subdivision of the cerebrum into frontal, temporal, parietal, and occipital lobes is somewhat of an abstraction in terms of landmarks and cerebral function. Some of these delineations were made long before our first glimmer of knowledge about the function of the cerebrum. Even when neuro-histologists began parceling the neocortex, they found that their areas did not fall neatly within zones bounded by sulci and fissures. Therefore, when the terms *frontal*, *parietal*, *temporal*, and *occipital* are used, it is largely to

provide the clinician with familiar and manageable anatomic landmarks for localization (Fig. 22-1).

The current method of study of cortical activity is by functional imaging techniques (positron emission tomography [PET] and functional magnetic resonance imaging [fMRI]). Invariably, an ensemble of areas, a "network" of the variety described earlier, is activated to perform even seemingly simple tasks such as recalling a name, visualizing or identifying an object, or carrying out a commanded task. The fact that multiple areas of the cortex are entrained may seem at odds with the classic view of lesional neurology, but as already stated, the discrepancy is one of epistemology in that normal function does not equate with abnormal function as exposed by a focal lesion. A lesion in the cerebrum merely exposes the site at which damage results in the greatest loss of that particular function but does not reveal the much wider area that is essential for the full normal operation of that function. Imaging studies similarly demonstrate that certain regions of the cortex are necessary to fully conduct particular behaviors, but they are not sufficient for their enactment.

GENERAL ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS OF CORTICAL FUNCTION

Pertinent to this subject are a number of morphologic and physiologic observations. Along strictly histologic lines, Brodmann distinguished 47 different areas of

Figure 22-2. Cytoarchitectural zones of the human cerebral cortex according to Brodmann. A. Lateral surface. B. Medial surface. C. Basal inferior surface. The functional zones of the cortex are illustrated in Fig. 22-3.

cerebral cortex (Fig. 22-2), and von Economo identified more than twice that number. Although this parceling was severely criticized by Bailey and von Bonin (and the data upon which Brodmann based his system were never published), it is still used by physiologists and clinicians, who find that the Brodmann areas do indeed approximate certain functional zones of the cerebral cortex (Fig. 22-3). Also, the cortex has been shown to differ in its various parts by virtue of connections with other areas of the cortex and with the thalamic nuclei and other lower centers. Hence, one must regard the cortex as a heterogeneous array of many anatomic systems, each with highly organized intercortical and diencephalic connections.

The sheer size of the cortex is remarkable. Unfolded, it has a surface extent of about 4,000 cm², about the size of a full sheet of newsprint (right and left pages). Contained in the cortex are many billions of neurons (estimated at 10 to 30 billion) and five times this number of supporting glial cells. The intercellular synaptic connections number in the trillions. Because nerve cells look alike and presumably function alike, the remarkable diversity in human intelligence, store of knowledge, and behavior must depend on the potential for almost infinite variations in neuronal interconnectivity.

Most of the human cerebral cortex is phylogenetically recent, hence the term *neocortex*. It was also referred to as *isocortex* by Vogt because of its uniform

Figure 22-3. A and B. Approximate distribution of functional zones on lateral (A) and medial (B) aspects of the cerebral cortex. *Abbreviations:* A1, primary auditory cortex; AA, auditory association cortex; AG, angular gyrus; CG, cingulate cortex; IPL, inferior parietal lobule; IT, inferior temporal gyrus; M1, primary motor area; MA, motor association cortex; MPO, medial parietooccipital area; MT, middle temporal gyrus; OF, orbitofrontal region; PC, prefrontal cortex; PH, parahippocampal region; PO, parolfactory area; PS, peristriate cortex; RS, retrosplenial area; S1, primary somatosensory area; SA, somatosensory association cortex; SG, supramarginal gyrus; SPL, superior parietal lobule; ST, superior temporal gyrus; TP, temporopolar cortex; V1, primary visual cortex; VA, visual association cortex. (Redrawn by permission from M-M Mesulam.)

embryogenesis and morphology. These latter features distinguish the neocortex from the older and less uniform *allocortex* (“other cortex”), which comprises mainly the hippocampus and olfactory cortex. Concerning the detailed histology of the neocortex, six layers (laminae) can be distinguished—from the pial surface to the underlying white matter they are as follows: the molecular (or plexiform), external granular, external pyramidal, internal granular, ganglionic (or internal pyramidal), and multiform (or fusiform) layers (illustrated in Fig. 22-4). Two cell types—relatively large pyramidal cells and smaller, more numerous rounded (granular) cells—predominate in the neocortex, and variations in its lamination are largely determined by variations in the size and density of these neuronal types.

Many variations in lamination have been described by cortical mapmakers, but two main types of neocortex are recognized: (1) the *homotypical cortex*, in which the six-layered arrangement is readily discerned, and (2) the *heterotypical cortex*, in which the layers are less distinct. The association cortex—the large areas (75 percent of the surface) that are not obviously committed to primary motor or sensory functions—is generally of this latter type. Homotypical areas are characterized by either granular or agranular nerve cells. The precentral cortex (Brodmann areas 4 and 6, mainly motor region) is dominated by pyramidal rather than granular cells, especially in layer V (hence the term *agranular*). Agranular cortex is distinguished by a high density of large pyramidal neurons. In contrast, the primary sensory cortices, post-central gyrus (areas 3, 1, 2), banks of the calcarine sulcus (area 17), and the transverse gyri of Heschl (areas 41 and 42), where layers II and IV are strongly developed for the receipt of afferent impulses, has been termed *granular cortex* because of the marked predominance of granular cells a preponderance of which are small neurons (Fig. 22-5).

Beyond these morphologic distinctions, the intrinsic organization of the neocortex follows a pattern elucidated by Lorente de Nó. He described vertical chains of neurons arranged in cylindrical modules or columns, each containing 100 to 300 neurons and heavily interconnected up and down between cortical layers and to a lesser extent, horizontally. Figures 22-4 and 22-5 illustrate the fundamental vertical (columnar) organization of these neuronal systems. Afferent fibers activated by various sensory stimuli terminate mainly in layers II and IV. Their impulses are then transmitted by internuncial neurons (interneurons) to adjacent superficial and deep layers and then to appropriate efferent neurons in layer V. Neurons of lamina III (association efferents) send axons to other parts of the association cortex in the same and opposite hemisphere. Neurons of layer V (projection efferents) send axons to subcortical structures and the spinal cord. Neurons of layer VI project mainly to the thalamus. In the macaque brain, each pyramidal neuron in layer V has about 60,000 synapses, and one afferent axon may synapse with dendrites of as many as 5,000 neurons; these figures convey some idea of the wealth and complexity of cortical connections. These columnar ensembles of neurons, on both the sensory and motor sides, function as the elementary working units of the cortex.

Whereas certain regions of the cerebrum are committed to special perceptual, motor, sensory, mnemonic, and linguistic activities, the underlying intricacy of the anatomy and psychophysical mechanisms in each region are just beginning to be envisioned. The lateral geniculate-occipital organization in relation to vision and recognition of form, stemming from the work of Hubel and Wiesel, may be taken as an example. In area 17, the polar region of the occipital lobe, there are discrete, highly specialized groups of neurons, each of which is activated in a small area of lamina 4 by spots of light or lines and transmitted

Figure 22-4. The basic cytoarchitecture of the cerebral cortex, adapted from Brodmann. The six basic cell layers are indicated on the left, and the fiber layers on the right (see text).

via particular cells in the lateral geniculate bodies; other groups of adjacent cortical neurons are essential for the perception of color. Lying between the main unimodal receptive areas for vision, audition, and somesthetic perception are zones of integration called *heteromodal* cortices. Here neurons respond to more than one sensory modality or neurons responsive to one sense are interspersed with neurons responsive to another.

The integration of cortical with subcortical structures is reflected in volitional or commanded movements. A simple movement of the hand, for example, requires activation of the premotor cortex (also called *accessory motor cortex*), which projects to the striatum and cerebellum and back to the motor cortex via a complex thalamic circuitry before the direct and indirect corticospinal pathways can activate certain combinations of spinal motor neurons, as described in Chaps. 3 and 4.

Interregional connections of the cerebrum are required for all natural sensorimotor functions; moreover, as indicated above, their destruction disinhibits or “releases” other areas. Denny-Brown referred to the latter as cortical tropisms. Thus, destruction of the premotor areas, leaving the precentral and parietal lobes intact, results in release of sensorimotor automatisms such as groping, grasping, and sucking. Parietal lesions result in complex avoidance movements to contact stimuli. Temporal lesions lead to a visually activated reaction to every observed object

and its oral exploration, and limbic sexual mechanisms are rendered hyperactive.

Another group of disorders known as *disconnection syndromes* depend not merely on involvement of certain cortical regions but more specifically on the interruption of inter- and intrahemispheric fiber tracts. Extensive white matter lesions may virtually isolate certain cortical zones and result in a functional state that is the equivalent of destruction of the overlying cortical region. Some of these disconnections are indicated schematically in Fig. 22-6; the usually involved fiber systems include the corpus callosum, anterior commissure, uncinate temporo-frontal fasciculus, occipito- and temporo-parietal tracts. An example is the isolation of the perisylvian language areas from the rest of the cortex, as occurs with anoxic-ischemic infarction of border zones between major cerebral arteries (see “Disconnection Syndromes” further on).

SYNDROMES CAUSED BY LESIONS OF THE FRONTAL LOBES

Anatomic and Physiologic Considerations

The frontal lobes lie anterior to the central or rolandic sulcus and superior to the sylvian fissure (see Fig. 22-1). They are larger in humans (30 percent of the cerebrum)

Figure 22-5. Four fundamental types of cerebral cortex and their distribution in the cerebrum. The primary visual cortex has a preponderance of small neurons; hence, it was historically called “granular.” The primary motor cortex, by contrast, has relatively fewer small neurons and was described as “agranular.” (Reproduced with permission from Kandel ER, Schwartz JH, Jessel TM: *Principles of Neural Science*, 4th ed. New York, McGraw-Hill, 2000.)

Figure 22-6. Connections involved in naming a seen object and in reading. The visual pattern is transferred from the visual cortex and association areas to the angular gyrus, which arouses the auditory pattern in the Wernicke area. The auditory pattern is transmitted to the Broca area through the arcuate fasciculus, where the articulatory form is aroused and transferred to the contiguous face area of the motor cortex. With destruction of the left visual cortex and splenium (or intervening white matter), the words perceived in the right visual cortex cannot cross over to the language areas and the patient cannot read.

than in any other primate (9 percent in the macaque). Several systems of neurons are located here, and they subserve different functions. Brodmann areas 4, 6, 8, and 44 relate specifically to motor activities. The *primary motor cortex*, i.e., area 4, is directly connected with somatosensory neurons of the anterior part of the postcentral gyrus as well as with other parietal areas, thalamic and red nuclei, and the reticular formation of the brainstem. The supplementary motor cortex, a portion of area 6, shares most of these connections. As pointed out in earlier chapters, all motor activity requires sensory guidance, and this comes from the somesthetic, visual, and auditory cortices and from the cerebellum via the ventral tier of thalamic nuclei.

Area 8 is concerned with turning the eyes and head contralaterally. Area 44 of the dominant hemisphere (Broca area) and the contiguous part of area 4 are “centers” of motor speech and related functions of the lips, tongue, larynx, and pharynx. Left-sided lesions cause a distinctive articulatory and language syndrome, and bilateral lesions in these areas cause paralysis of articulation, phonation, and deglutition. The medial-orbital gyri and anterior parts of the cingulate and insular gyri, which are the frontal components of the limbic system, take part in the control of respiration, blood pressure, peristalsis, and other autonomic functions. The most anterior parts of the frontal lobes (areas 9 to 12 and 45 to 47), sometimes referred to as the *prefrontal areas*, are particularly well

developed in human beings but have imprecisely determined functions. They are not, strictly speaking, parts of the motor cortex in the sense that electrical stimulation evokes no direct movement (the prefrontal cortex is said to be inexcitable). Yet these areas are involved in the initiation of planned action and executive control of all mental operations, including emotional expression.

The frontal agranular cortex (areas 4 and 6) and more specifically, pyramidal cells of layer V of the pre- and postcentral convolutions provide most of the cerebral efferent motor system that forms the pyramidal, or corticospinal, tract (see Figs. 3-2 and 3-3). Another massive projection from these regions is the frontopontocerebellar tract. In addition, there are several parallel fiber systems that pass from frontal cortex to the caudate and putamen, subthalamic and red nuclei, brainstem reticular formation, substantia nigra, and inferior olive, as well as to the ventrolateral, mediodorsal, and dorsolateral nuclei of the thalamus. Areas 8 and 6 are connected with the ocular and other brainstem motor nuclei and with identical areas of the other cerebral hemisphere through the corpus callosum. A tract, the fronto-occipital fasciculus, connects the frontal with the occipital lobe and the uncinate bundle connects the orbital part of the frontal lobe with the temporal lobe.

The granular frontal cortex has a rich system of connections both with lower levels of the brain (medial and ventral nuclei and pulvinar of the thalamus) and with

virtually all other parts of the cerebral cortex, including its limbic and paralimbic parts. As to its limbic connections, the frontal lobe is unique among cerebrocortical areas in that electrical stimulation of the orbitofrontal cortex and cingulate gyrus has manifest effects on respiratory, circulatory, and other vegetative functions. These parts of the frontal cortex also receive major afferent projections from other parts of the limbic system, presumably to mediate the emotional responses to sensory experiences; they, in turn, project to other parts of the limbic and paralimbic cortices (hippocampus, parahippocampus, anterior pole of the temporal lobe), amygdala, and midbrain reticular formation. Chapter 25 describes these frontal–limbic connections in greater detail.

Most of the popular notions relating to the function of the frontal lobes are oversimplified. In the frontal lobe, are presumed to reside the mechanisms that govern personality, character, motivation, and our unique capacities for abstract thinking, introspection, and planning. These qualities and traits do not lend themselves to easy definition and study and certainly not to discrete localization. Most are too subtle to isolate or even to measure accurately. Except for the more posterior frontal mechanisms subserving motility, motor speech, and certain behaviors relating to impulse (conation), neurologists recognize that the other features of frontal lobe disease are more abstruse.

Blood is supplied to the medial parts of the frontal lobes by the anterior cerebral artery and to the convexity and deep regions, by the superior (rolandic) division of the middle cerebral artery. The underlying deep white matter is supplied by a series of small penetrating arteries, called lenticulostriate vessels that originate directly from the initial portion (stem) of the middle cerebral artery, as detailed in Chap. 34.

Clinical Effects of Frontal Lobe Lesions

For descriptive purposes, the clinical effects of frontal lobe lesions can be grouped under the following categories: (1) motor abnormalities related to the prerolandic motor cortex; (2) speech and language disorders related to the dominant frontal lobe, which are described in the next chapter; (3) incontinence of bladder and bowel; (4) impairment of capacity for goal-directed sustained mental activity, and the ability to shift from one line of thought or action to another, i.e., aspects of attention manifest as impersistence and perseveration; (5) akinesia and lack of initiative and spontaneity (apathy and abulia); (6) changes in personality, particularly in mood and self-control (disinhibition of behavior); and (7) an abnormality of gait that has proved difficult to characterize (see also Chap. 7 on disorders of gait).

With regard to behavior and the frontal lobe, the anterior half of the brain is in a general sense committed to the planning, initiation, monitoring, and execution of all cerebral activity. This was aptly summarized by Luria (1966 and 1973) as “goal-directed behavior.” Of necessity in such a scheme, there must also be inhibitory mechanisms that control or modulate behavior. Thus, aside from the overt abnormalities of motor, speech, and

voluntary movement, lesions of the frontal lobes give rise to a loss of drive, impairment of consecutive planning, an inability to maintain serial relationships of events, and to shift easily from one mental activity to another. These are combined with sucking, grasping, and groping reflexes and other obligate behaviors. In the emotional sphere, frontal lobe lesions may cause anhedonia (lack of pleasure), apathy, loss of self-control, disinhibited social behavior, and euphoria, as described further on.

Motor Abnormalities

Voluntary movement involves the motor cortex in its entirety or at least large parts of it, and of the various effects of frontal lobe lesions, most is known about the motor abnormalities. Electrical stimulation of the motor cortex elicits contraction of corresponding muscle groups on the opposite side of the body; focal seizure activity has a similar effect. Stimulation of Brodmann area 4 produces movement of discrete muscle groups or, if sufficiently refined, of individual muscles. Repertoires of larger coordinated movements are evoked by stimulation of area 6, the premotor and supplementary motor cortices.

Lesions in the posterior part of the frontal lobe cause spastic paralysis of the contralateral face, arm, and leg. Motor impulses from the frontal lobe are conducted by the direct corticospinal tract and by tracts that descend from the motor, premotor, supplementary motor, and anterior parietal cortex to the spinal cord, either directly or via the red and reticular nuclei in the brainstem. Lesions of the more anterior and medial parts of the motor cortex result in less paralysis and more spasticity, as well as a release of sucking, groping, and grasping reflexes, the actual mechanisms for which probably reside in the parietal lobe and which, as conceptualized by Denny-Brown, are tropisms or automatisms that are normally inhibited by the frontal cortex. When the lesions of the motor parts of the frontal lobe are bilateral, there is a tetraparesis in which the weakness is not only more severe but also more extensive than in unilateral lesions, affecting both spinal and cranial muscles (pseudobulbar palsy).

Ablation of the right or left *supplementary motor areas* (the parts of area 6 that lie on the medial surfaces of the cerebral hemispheres) was found by Laplane and colleagues (1977b) to cause mutism, contralateral motor neglect, and impairment of bibrachial coordination. On the basis of blood flow studies, Roland and colleagues and Fuster suggest that an important function of the supplementary motor area is the ordering of motor tasks or the recall of memorized motor sequences, further evidence of the executive functions of the frontal lobes. Some insight into organization in supplementary motor cortex is given by seizures originating there; they give rise to curious postures such as a fencing position or flailing of the opposite arm.

Temporary paralysis of contralateral eye turning and sometimes of head turning follows a destructive lesion in area 8, on the dorsolateral aspect (convexity) of the cerebral cortex, often referred to as the frontal eye field (see Fig. 22-1). Seizure activity in this area causes a tonic deviation of the head and eyes to the opposite side.

Destruction of the Broca convolution (areas 44 and 45) and the adjacent insular and motor cortex of the dominant hemisphere result in a reduction or loss of motor speech, and of agraphia, and apraxia of the face, lips, and tongue, as described in Chap. 23.

The gait condition described by Bruns that is caused by a frontal lobe lesion was designated by him as an *ataxia of gait*; he made no reference to an ataxia of limb movements. This disorder is often also referred to now as an apraxia of gait, inappropriately in our opinion, because the term *apraxia* is best used to describe an inability to carry out a commanded or learned motor task, not an ingrained one (see Chap. 3). What is meant by these terms in application to gait has never been clearly specified, but broadly speaking, they signify a loss of the ability to use the lower limbs in the act of walking that cannot be explained by weakness, loss of sensation, or ataxia. The patient may retain these fundamental motor and sensory functions when examined in bed and can even make motions that simulate walking while seated or reclining. As detailed in Chap. 7, the resultant pattern is a slowed, slightly imbalanced, and short-stepped gait with the torso and legs not properly in phase when placed in motion, to which may be added the feature of "magnetic" gait, where one or both feet appear to be stuck to the ground as the body moves forward. Probably the basal ganglia and their connections to the frontal lobes are involved in these cases. The steps are shortened to a shuffle and balance is precarious; with further deterioration, the patient can no longer walk or even stand. *Cerebral paraplegia in flexion* is the most advanced stage; the affected individual lies curled up in bed, unable even to turn over (see Chap. 7 for further discussion).

Damage to the cortices anterior to areas 6 and 8, i.e., areas 9, 10, 45, and 46, the *prefrontal cortex*, and also the anterior cingulate gyri, has less easily defined effects on motor behavior. The prefrontal cortex is heteromodal and has strong reciprocal connections with the visual, auditory, and somatosensory cortices. Of these, the visuo-motor relationships are the most powerful. These frontal areas as well as the supplementary motor areas are involved in the planning and initiation of sequences of movement, as indicated in Chap. 4. In the monkey, for example, when a visual signal evokes movement, some of the prefrontal neurons become active immediately preceding the motor response; other prefrontal neurons are activated if the response is to be delayed. With prefrontal lesions on one side or the other, a series of motor abnormalities occur, for example, slight grasping and groping responses, a tendency to imitate the examiner's gestures and to compulsively manipulate objects that are in front of the patient (imitation and utilization behavior described by Lhermitte [1983]), reduced and delayed motor and mental activity (abulia), motor perseveration or impersistence (with left and right hemispheric lesions, respectively), and paratonic rigidity on passive manipulation of the limbs (oppositional resistance, or *gegenhalten*).

Incontinence is another manifestation of frontal lobe disease. Right- or left-sided lesions involving the posterior part of the superior frontal gyrus, the anterior cingulate

gyrus, and the intervening white matter result in a loss of control of micturition and defecation (Andrew and Nathan). There is no warning of fullness of the bladder or of the imminence of urination or bowel evacuation, and the patient is surprised at suddenly being wet or soiled. Less-complete forms of the syndrome are associated with frequency and urgency of urination during waking hours. The patient is embarrassed unless an element of indifference is added when the more anterior (nonmotor) parts of the frontal lobes are the sites of disease.

In the spheres of *speech and language*, a number of abnormalities other than Broca's aphasia appear in conjunction with disease of the frontal lobes: laconic speech, lack of spontaneity of speech, telegraphic speech (agrammatism), loss of fluency, perseveration of speech, a tendency to whisper instead of speaking aloud, and dysarthria. These are more prominent with left-sided lesions and are fully described in Chap. 23.

Cognitive and Intellectual Changes

In general, when one speaks of cognitive and behavioral aspects of frontal lobe function, reference is made to the more anterior (prefrontal) parts rather than the motor and linguistic parts. These most recently developed parts of the human brain, called the "organ of civilization" by Halstead and repeated by Luria, have the most elusive functions.

The effects of lesions of the frontal lobes were nicely divulged by Harlow's famous case of Phineas Gage, published in 1868; it has been the subject of numerous monographs ever since. His patient was a capable foreman of a railroad gang who became irreverent, dissipated, irresponsible, and vacillating (he also confabulated freely) following an injury in which an explosion drove a large iron-tamping bar into his frontal lobes. In Harlow's words, "he was no longer Gage." Another similarly dramatic example was Dandy's patient (the subject of a monograph by Brickner), who underwent a bilateral frontal lobotomy during the removal of a meningioma. Feuchtwanger, in a clinical study of 200 cases of frontal lobe injury, was impressed most with the lack of initiative, changes in mood (euphoria), and inattentiveness, without intellectual and memory deficits. Rylander, in a classic monograph, described similar changes in patients with unilateral and bilateral frontal lobectomies (see later). Kleist (1934), under the heading of *alogia*, stressed the importance of loss of capacity for abstract thought, as shown in tests of analogies, proverbs, definitions, etc. In chimpanzees, Jacobsen observed that the removal of the premotor parts of the frontal lobes led to social indifference, tameness, placidity, forgetfulness, and difficulty in problem solving, findings that led Egas Moniz, in 1936, to perform prefrontal lobotomies on psychotic patients (see Damasio). This operation and its successor, prefrontal leukotomy (undercutting of the prefrontal white matter) reached their height of popularity in the 1940s and (tragically) provided the opportunity to study the effects of a wide range of frontal lobe lesions in a large number of patients.

The findings in patients who underwent frontal leukotomy have been the subject of endless controversy.

Some workers claimed that there were few or no discernible effects of the operation, even with bilateral lesions. Others insisted that if the proper tests were used, a series of predictable and diagnostic changes in cognition and behavior could be demonstrated. The arguments pro and con and the inadequacies of many of the studies, both in methods of testing and in anatomic verification of the lesions (the extent and location of the lesions varied considerably, and this influenced the clinical effects), have been well summarized by Walsh. Admittedly, in patients who underwent bilateral frontal lobotomy, there was little if any impairment of memory function or of cognitive function as measured by intelligence tests, and certainly no loss of alertness and orientation. And some patients who had been disabled by schizophrenia, anxious depression, obsessive-compulsive neurosis, or a chronic pain syndrome did improve with respect to their psychiatric and pain symptoms. However, many were left with changes in personality, much to the distress of their families. They were indifferent to the feelings of others; gave no thought to the effects of their conduct; were tactless, distractible, and socially inept; and were given to euphoria and emotional outbursts. El-Hai has written a fascinating historical account of the procedure in the United States and a portrait of its main proponent at the time, Dr. Walter Freeman. Although no longer undertaken, the procedure must be viewed in the context of the understanding of, and limited options for, psychiatric disease at that time.

Luria (1973) had another interesting conception of the role of the frontal lobes in intellectual activity. He postulated that problem solving of whatever type (perceptual, constructive, arithmetical, psycholinguistic, or logical, definable also as goal-related behavior) proceeds in four steps: (1) the specification of a problem (in other words, a goal is perceived and the conditions associated with it are set); (2) formulation of a plan of action or strategy, requiring that certain linguistic activities be initiated in orderly sequence; (3) execution, including implementation and control of the plan; and (4) checking or comparing the results against the original plan to see if it was adequate.

Obviously, such complex psychologic activity must implicate many parts of the cerebrum and will suffer to some extent from a lesion in any of the parts that contribute to the functional system. Luria found that when the frontal lobes are injured, there was not only a general psychomotor slowing and easy distractibility but also an erroneous analysis of the above-listed conditions of the problem. "The plan of action that is selected quickly loses its regulating influence on behavior as a whole and is replaced by a perseveration of one particular link of the motor act or by the influence of some connection established during the patient's past experience." Furthermore, there was a failure to distinguish the essential sequences in the analysis and to compare the final solution with the original conception of the problem. Plausible as this scheme appears, like Goldstein's "loss of the abstract attitude" (the patient thinks concretely, i.e., he reacts directly to the stimulus situation), such psychophysiological analyses of the mental processes are

highly theoretical, and the factors to which they refer are not easily measured.

Finally, a lesion that includes the frontal eye field may engender a type of reduced attention to the contralateral visual environment. This probably is the result of a defect in visually guided attention and it is seen only irregularly in clinical practice. The degree of neglect seen with a nondominant parietal lobe lesion is not observed with frontal lobe lesions, and it is difficult to differentiate the frontal defect from the simple impediment of being unable to direct gaze in one direction.

In modern parlance, the frontal lobe, particularly its prefrontal components, is said to exert an executive function, referring here to the overall control and sequencing of other cognitive functions. This allows for a type of self-monitoring that guides the selection of strategies to solve problems, the inhibition of incorrect responses, the ability to deal with change in focus and novelty in tasks, and probably to be able to generalize from experience. Indeed, all ability to adapt to changes in circumstance and to learn from experience requires this executive function. Unlike some of the psychic properties mentioned above, these are subject to measurement by testing and they are observable during the clinical examination as deterioration in problem solving, by repetitiousness and stereotypes, and by ineptitude in managing simple social situations. Probably, the trouble all individuals experience in maintaining a stream of thought when interrupted, a type of loss of attention, tests this function.

Other Alterations of Behavior and Personality

A lack of initiative and spontaneity is the most common effect of frontal lobe disease, and it is much easier to observe than to quantitate. With relatively mild forms of this disorder, patients exhibit an idleness of thought, speech, and action, and they lapse into this state without complaint. They are tolerant of most conditions in which they are placed, although they may act unreasonably for brief periods if irritated, seemingly unable to think through the consequences of their actions. They let members of the family answer questions and "do the talking," interjecting a remark only rarely and unpredictably. Questions directed to such patients may evoke only brief, unqualified answers. Once started on a task, they may persist in it ("stimulus bound"); i.e., they tend to perseverate. Fuster, in his studies of the prefrontal cortex, emphasizes the failure over time to maintain events in serial order (impairment of temporal grading) and to integrate new events and information with previously learned data. Placidity is a notable feature of the behavior. Worry, anxiety, self-concern, hypochondriasis, complaints of chronic pain, and depression are all reduced by frontal lobe disease, as they were to some extent by frontal lobotomy.

Extensive and bilateral frontal lobe disease is accompanied by a quantitative reduction in all psychomotor activity. The number of movements, spoken words, and thoughts per unit of time diminish. Milder degrees of this state, associated with only a delay in responses, are called *abulia* as described earlier. The most severe degrees take the form of *akinetic mutism* wherein a nonparalyzed patient, alert and capable of movement and speech, lies

or sits motionless and silent for days or weeks on end. It has been attributed to bilateral lesions in the ventromedial frontal regions or frontal-diencephalic connections (but focal lesions in the upper midbrain do the same). Laplane found that the lack of motivation of the patient with bifrontal lesions and bipallidal lesions to be the same, although one would expect the latter to manifest more as a bradykinesia than as a bradyphrenia (slowness of thinking).

The opposite state, in a sense, is a behavioral disinhibition that in extreme form becomes a hyperactivity syndrome, or "organic drivenness," described by von Economo in children who had survived an attack of encephalitis lethargica. Disinhibition occurs largely with dorsolateral frontal lesions. In our patients, this syndrome has been produced most often by combined frontal and temporal lobe lesions, usually traumatic but also encephalitic, although exact clinicopathologic correlations could not be made. Such patients may also exhibit brief but intense involvement with some meaningless activity, such as sorting papers in an attic or hoarding objects or food. Possibly, compulsive behavior is related in some manner to this state and more particularly to lesions damaging the caudate-frontal connections. Combativeness and extreme insomnia or an otherwise disrupted sleep cycle are often part of the syndrome.

Pathological collecting behavior (hoarding) may be related to this type of drivenness and has been attributed to medial frontal lobe damage, including the cingulate gyri, by Anderson and colleagues based on a series of 13 patients. These patients, otherwise displaying mental clarity and despite negative personal and social consequences, collect massive amounts of useless items such as newspapers, junk mail, catalogs, food, clothing, and appliances, often encompassing several categories.

In addition to the disorders of initiative and spontaneity, frontal lobe lesions result in a number of other changes in personality and behavior. These, too, are easier to observe in the patient's natural environment than to measure by psychologic tests. It has been difficult to find a term for all these personality changes. Some patients, particularly those with inferofrontal lesions, feel compelled to make silly jokes that are inappropriate to the situation, *witzelsucht* or *moria*; they are socially uninhibited and lack awareness of their behavior. The patient is no longer the sensitive, compassionate, effective human being that he once was, having lost his usual ways of reacting with affection and consideration to family and friends. In more advanced instances, there is an almost complete disregard for social conventions and an interest only in immediate personal gratification. The patient at the same time seems to lose an appreciation of the motivations and thought processes of other sapient persons ("theory of mind"); this results in the inability to incorporate these factors into his responses. These changes, observed characteristically in lobotomized patients, came to be recognized as too great a price to pay for the loss of anxiety, pain, depression, and "tortured self-concern," hence the procedure became obsolete.

In general, the greatest cognitive-intellectual deficits relate to lesions in the dorsolateral parts of the

prefrontal lobes and that the greatest personality, mood, and behavioral changes stem from lesions of the medial-orbital parts, although the two disorders often merge with one another. Benson (and Kleist and others before him) related the syndrome of apathy and lack of initiative to lesions in the dorsolateral frontal cortex, and a facetious, unguarded, and socially inappropriate state (see below) to orbital and medial frontal lesions. This distinction has held up only broadly in our experience. Some studies of penetrating brain injuries have reported an inconsistent but interesting relationship between left dorsal frontal lesions and anger with hostility, and right side orbitofrontal lesions, with anxiety and depression. Again, in clinical work, few lesions have this degree of localizability, making conclusions about emotional states somewhat uncertain.

Although the frontal lobes are the subject of a vast literature and endless speculation (see reviews of Stuss and Benson and of Damasio), a unified concept of their function has not emerged, probably because they are so large and include several heterogeneous systems. There is no doubt that the mind is greatly altered by disease of the prefrontal parts of the frontal lobes, but often it is difficult to say exactly how it is changed. Perhaps at present it is best to regard the frontal lobes as the part of the brain that quickly and effectively orients and drives the individual, with all the percepts and concepts formed from past life experiences, toward action that is projected into the future.

Psychologic tests of frontal lobe function These are of particular value in establishing the presence of frontal lobe disease and are generally constructed to detect the ability to persist in a task and the opposite, to switch mental focus on demand. They include the Wisconsin card-sorting test, the Stroop color-naming test, sequencing of pictures, "trail making" (a two-part test in which the patient draws lines, first connecting randomly arrayed numbers on a paper in order and then connecting numbers and letters that correspond in order), the verbal equivalent of trail making, and the "go-no-go" test, both of which are used regularly in the mental status examination (see below), and the three-step hand posture test of Luria. The alphabet-number verbal trailmaking test requires the patient to give each letter of the alphabet followed by the corresponding number (A-1, B-2, C-3, etc.). In the Luria test and its variants, the patient is, for example, asked to imitate, then reproduce, a sequence of three hand gestures, typically making a closed fist, holding the open hand on its side, and then opening an outstretched palm. Patients with frontal lesions on either or both sides have difficulty performing the test in correct sequence, often perseverating, balking, or making unwanted gestures. Luria suggested testing this with the sequence of arm thrusting forward, clenching the fist, and forming a ring with the first two fingers—derivatives of this test are now used. He also pointed out (1969) that the natural kinetic "melody," or smoothness of transition from one hand position to the next is disrupted and there is a tendency to perseverate. This has been termed "kinetic limb apraxia" by some behavioral neurologists.

It should be kept in mind that similar impairments of performance may occur with all manner of confusional and inattentive states so that no conclusion can be made if the patient is less than fully attentive. More complex mental acts that may be easily tested and betray frontal lobe disease but are less specific, in that they are also disordered by lesions in other brain regions, include serial subtraction (“working memory”), interpretation of proverbs, tests of rapid motor response, and others.

Effects of frontal lobe disease may be summarized as follows:

- I. Effects of unilateral frontal disease, either left or right
 - A. Contralateral spastic hemiplegia
 - B. Contralateral gaze paresis
 - C. Apathy and loss of initiative or its opposite, slight elevation of mood, increased talkativeness, tendency to joke inappropriately (*witzelsucht*), lack of tact, difficulty in adaptation
 - D. If entirely prefrontal, no hemiplegia; but grasp and suck reflexes or instinctive grasping may be released
 - E. Anosmia with involvement of orbital parts
- II. Effects of right frontal disease
 - A. Left hemiplegia
 - B. Changes as in I.B, C, and D
- III. Effects of left frontal disease
 - A. Right hemiplegia
 - B. Broca’s aphasia with agraphia, with or without apraxia of the lips and tongue (see Chap. 23)
 - C. Sympathetic apraxia of left hand (see “Apraxia” in Chap. 3)
 - D. Changes as in I.B, C, and D
- IV. Effects of bifrontal disease
 - A. Bilateral hemiparesis
 - B. Spastic bulbar (pseudobulbar) palsy
 - C. If prefrontal, abulia or akinetic mutism, lack of ability to sustain attention and solve complex problems, rigidity of thinking, bland affect, social ineptitude, behavioral disinhibition, inability to anticipate, labile mood, and varying combinations of grasping, sucking, obligate imitative movements, utilization behavior
 - D. Decomposition of gait and sphincter incontinence

SYNDROMES CAUSED BY LESIONS OF THE TEMPORAL LOBES

Anatomic and Physiologic Considerations

The sylvian fissure separates the superior surface of each temporal lobe from the frontal lobe and anterior parts of the parietal lobe. There is no natural anatomic boundary between the temporal lobe and the occipital or the parietal lobe but the angular gyrus serves as a landmark for the latter. Figure 22-1 indicates the boundaries of the temporal lobes. The inferior branch of the middle cerebral artery supplies blood to the convexity of the temporal lobe, and the temporal branch of the posterior cerebral

artery supplies the medial and inferior aspects, including the hippocampus.

The temporal lobe includes the superior, middle, and inferior temporal, lateral occipitotemporal, fusiform, lingual, parahippocampal, and hippocampal convolutions and the transverse gyri of Heschl. The last of these constitutes the primary auditory receptive area and is located within the sylvian fissure. It has a tonotopic arrangement: fibers carrying high tones terminate in the medial portion of the gyrus and those carrying low tones, in the lateral and more rostral portions (Merzenich and Brugge). The planum temporale (area 22), an integral part of the auditory cortex, lies immediately posterior to the Heschl convolutions, on the superior surface of the temporal lobe. The left planum is larger in right-handed individuals. There are rich reciprocal connections between the medial geniculate bodies and the Heschl gyri. These gyri project to the unimodal association cortex of the superior temporal gyrus, which, in turn, projects to the paralimbic and limbic regions of the temporal lobe and to temporal and frontal heteromodal association cortices and the inferior parietal lobe. There is also a system of fibers that project back to the medial geniculate body and to lower auditory centers. The cortical receptive zone for labyrinthine impulses is less well demarcated than the one for hearing but is probably situated on the inferior bank of the sylvian fissure, just posterior to the auditory area. Least well delimited is the role of the medial parts of the temporal lobe in olfaction and gustatory perception, although seizure foci in the region of the uncus (uncinate seizure) often excite hallucinations of these senses.

The middle and inferior temporal gyri (areas 21 and 37) receive a massive contingent of fibers from the striate cortex (area 17) and the parastriate visual association areas (areas 18 and 19). These temporal visual areas make abundant connections with the medial limbic, rhinencephalic (olfactory), orbitofrontal, parietal, and occipital cortices, allowing for an intimate interconnection between the cortices subserving vision and hearing.

The superior part of the dominant temporal lobe is concerned with the acoustic or receptive aspects of language, as discussed in Chap. 23, which is devoted to this subject. The middle and inferior convolutions are sites of visual discriminations; they receive fiber systems from the striate and parastriate visual cortices and, in turn, project to the contralateral visual association cortex, the prefrontal heteromodal cortex, the superior temporal cortex, and the limbic and paralimbic cortex. Presumably, these systems subserve such functions as spatial orientation, estimation of depth and distance, stereoscopic vision, and hue perception. Similarly, the unimodal auditory cortex is closely connected with a series of auditory association areas in the superior temporal convolution, and the latter are connected with prefrontal and temporoparietal heteromodal areas and the limbic areas (see Mesulam, 1998). Most of these auditory connections have been worked out in the macaque but the limited number of well-studied lesions in patients suggests that they are also involved in complex verbal and nonverbal auditory discriminations in humans.

The most important functions of the hippocampus and other structures of the hippocampal formation (dentate gyrus, subiculum, entorhinal cortex, and parahippocampal gyrus) are learning and memory, already discussed in Chap. 21. There is an abundance of connections between the medial temporal lobe and the entire limbic system. For this reason, MacLean referred to these parts as the “visceral brain,” and Williams, as the “emotional brain.” Also included in this anatomic concept are the hippocampus, the amygdaloid nuclei, the fornices and limbic portions of the inferior and medial frontal regions, the cingulate cortices, and the septal and associated subcortical nuclei referred to as the limbic system (see Chap. 25).

Most of the temporal lobe cortex, including Heschl gyri, has nearly equally developed pyramidal and granular layers. In this respect, it resembles more the granular cortex of the frontal and prefrontal regions and inferior parts of the parietal lobes. Unlike the six-layered neocortex, the hippocampus and dentate gyrus are typical of the phylogenetically older three-layered allocortex.

A massive fiber system projects from the striate and parastriate zones of the occipital lobes to the inferior and medial parts of the temporal lobes. The temporal lobes are connected to one another through the anterior commissure and middle part of the corpus callosum; the inferior or uncinate fasciculus connects the anterior temporal and orbital frontal regions. The arcuate fasciculus connects the posterosuperior temporal lobe to the motor cortex and Broca area.

Physiologically, the temporal lobe is an integrator of “sensations, emotions, and behavior” in so far as it relates the organism’s sensory experiences to emotional meaning thought it’s proximity to the limbic system. Similar integrative mechanisms are operative in the parietal lobe, but only in the temporal lobe are they brought into close relationship to one’s instinctive and emotional life. Self-awareness also requires a coherent and sequential stream of thought. Where the inner “stream of thought” (William James’ term for constant thinking) is perceived is still an open question. Given the requirement that it be close to other integrated sensory experiences and that it incorporate the temporal lobe functions of both language and memory, a locus in the temporal lobes seems likely. Some hint of the role of the temporal lobe in our personal and emotional lives was suggested by Hughlings Jackson in the nineteenth century, derived from his insightful analysis of the psychic states accompanying temporal lobe seizures. Later, the observations of Penfield and his collaborators on the effects of stimulating the temporal lobes in the conscious patient undergoing surgical correction of epilepsy revealed something of its complex functions. The seminal writings on this subject include Williams’ chapter on temporal lobe syndromes in the *Handbook of Clinical Neurology* and the monographs by Penfield and Rasmussen (*The Cerebral Cortex of Man*) and by Alajouanine and colleagues (*Les Grandes Activités du Lobe Temporelle*).

Clinical Effects of Temporal Lobe Lesions

The symptoms that arise as a consequence of disease of the temporal lobes may be divided into disorders of:

(1) special senses (visual, auditory, olfactory, and gustatory), (2) language, (3) memory and time perception, (4) emotion, and behavior. Of central importance also are the roles of the superior part of the dominant (usually left) temporal lobe in language and handedness. Several of these functions and their derangements are of such scope and importance that they are accorded separate chapters. Language is discussed in Chap. 23, memory in Chap. 21, and the neurology of emotion and behavior in Chap. 25; these subjects are omitted from further discussion here.

Visual Disorders

In Chap. 13 (on vision), it was pointed out that lesions of the white matter of the central and posterior parts of the temporal lobe characteristically involve the lower arching fibers of the geniculocalcarine pathway (Meyer loop). This results in an upper homonymous quadrantanopia, usually not perfectly congruent. However, there is considerable variability in the arrangement of visual fibers as they pass around the temporal horn of the lateral ventricle, accounting for the smallness of the field defect in some patients after temporal lobectomy or stroke and extension into the inferior field in others. Quadrantanopia from a dominant (left-sided) lesion is often combined with aphasia.

Bilateral lesions of the temporal lobes render a monkey psychically blind. It can see and pick up objects but does not recognize them until they are explored orally. Natural emotional reactions such as fear are lost. This syndrome, named for Klüver and Bucy, has been identified only in partial form in humans. Using special tests, lesser degrees of visual imperception were uncovered in patients by Milner (1971) and by McFie and colleagues. This syndrome is further discussed in Chap. 25.

Visual hallucinations of complex form, including ones of the patients himself (autoscopy), appear during temporal lobe seizures. Penfield was able to induce what he called “interpretive illusions” (altered impressions of the present) and to reactivate past experiences completely and vividly in association with their original emotions. Temporal lobe abnormalities may also distort visual perception; seen objects may appear too large (macropsia) or small (micropsia), too close or far away, or unreal. Some visual hallucinations have an auditory component: an imaginary figure may speak and move and, at the same time, arouse intense emotion in the patient. The entire experience may seem unnatural and unreal to the patient.

Cortical Deafness

Bilateral lesions of the transverse gyri of Heschl, while rare, are known to cause a central deafness. Henschen, in his extensive review of 1,337 cases of aphasia that had been reported up to 1922, found 9 in which these parts were destroyed by restricted vascular lesions, with resulting deafness. There are now many more cases of this type in the medical literature; lesions in other parts of the temporal lobes have no effect on hearing. These observations are the basis for the localization of the primary auditory receptive area in the cortex of the transverse gyri (chiefly the first) on the posterosuperior

surface of the temporal lobe, deep within the sylvian fissure (areas 41 and 42). Subcortical lesions, which interrupt the fibers from both medial geniculate bodies to the transverse gyri, as in the two cases described by Tanaka and colleagues, have the same effect. With left-sided superotemporal lesions, there is usually an aphasia because of the proximity of the transverse gyri to the superotemporal association cortex. Hécaen has remarked that “cortically deaf” persons may seem to be unaware of their deafness, a state similar to that of blind persons who act as though they could see (the latter, called Anton syndrome is described further on).

For a long time, unilateral lesions of Heschl gyri were believed to have no effect on hearing; it has been found, however, that subtle deficits can be detected with careful testing. If very brief auditory stimuli are delivered, the threshold of sensation is elevated in the ear opposite the lesion. Also, while unilateral lesions do not diminish the perception of pure tones or clearly spoken words, the ear contralateral to a temporal lesion is less efficient if the conditions of hearing are rendered more difficult (binaural testing). For example, if words are slightly distorted (electronically filtered to alter consonants), they are heard less well in the ear contralateral to the lesion. In addition, the patient has more difficulty in equalizing the volume of sounds that are presented to both ears and in perceiving rapidly spoken numbers or different words presented to the two ears (dichotic listening). Few of these changes are evident by clinical examination.

Auditory Agnosia

Lesions of the secondary (unimodal association) zones of the auditory cortex—area 22 and part of area 21—have no effect on the perception of sounds and pure tones. However, the appreciation of complex combinations of sounds is severely impaired. This impairment, or auditory agnosia, takes several forms: inability to recognize sounds, different musical notes (amusia), or words and presumably each has a slightly different anatomic basis.

In *agnosia for sounds*, auditory sensations cannot be distinguished from one another. Such varied sounds as the tinkling of a bell, the rustling of paper, running water, and a siren all sound alike. The condition is usually associated with word deafness (“Pure Word Deafness” in Chap. 23 and below) or with amusia. Hécaen observed an agnosia for sounds alone in only two cases; one patient could identify only half of 26 familiar sounds, and the other could recognize no sound other than the ticking of a watch. Yet in both patients, the audiogram was normal, and neither had trouble understanding spoken words. In both, the lesion involved the right temporal lobe and the corpus callosum was intact.

Amusia proves to be more complicated, for the appreciation of music has several aspects: the recognition of a familiar melody and the ability to name it (musicality itself); the perception of pitch, timbre, and rhythm; and the ability to produce, read, and write music. There are many reports of musicians who became word-deaf with lesions of the dominant temporal lobe but retained their recognition of music and their skill in producing it. Others became agnostic for music but not for words,

and still others were agnostic for both words and music. According to Segarra and Quadfasel, impaired recognition of music results from lesions in the middle temporal gyrus and not from lesions at the pole of the temporal lobe, as had been postulated by Henschen. Many other studies implicate the superior temporal gyrus in these deficits. A loss of the ability to perceive and produce rhythm may or may not be associated. In any case, the temporal lobe opposite that responsible for language (i.e., the right) is implicated in almost all cases.

That the appreciation of music is impaired by lesions of the nondominant temporal lobe finds support in Milner’s studies of patients who had undergone temporal lobectomy. She found a lowering of the patient’s appreciation of the duration of notes, timbre, intensity of sounds, and memory of melodies following right temporal lobectomy; these abilities were preserved in patients with left temporal lobectomies, regardless of whether Heschl gyri were included. Shankweiler had made similar observations, but in addition found that patients had difficulty in denominating a note or naming a melody following left temporal lobectomy.

More recent observations permit somewhat different interpretations. Tramo and Bharucha examined the mechanisms mediating the recognition and discrimination of timbre (the distinctive tonal quality produced by a particular musical instrument) in patients whose right and left hemispheres had been separated by callosotomy. They found that timbre could be recognized by *each* hemisphere, somewhat better by the left than by the right. Also, it was observed that lesions of the right auditory cortex impaired the recognition of melody (the temporal sequence of pitches) and of harmony (the sounding of simultaneous pitches). However, if words were added to the melody, then either a left- or right-sided lesion impaired its recognition (Samson and Zatorre). From functional imaging studies, it appears that the left inferior frontal region is activated by tasks that involve the identification of familiar music (Platel et al), as if this were a semantic test, but passively listening to melodies activates the right superior temporal and occipital regions (Zatorre et al).

By way of summary, Stewart and colleagues systematically reviewed the subject and were able to separate disorders of musical listening into the following categories: appreciation of pitch (including interval, pattern, and tonal structure), timbre, temporal structure, emotional content, and memory for music. The authors present clinical cases, mostly strokes that illustrate each defect. Taken together, these data suggest that the nondominant hemisphere is important for the recognition of harmony and melody (in the absence of words), but that the naming of musical scores and all the semantic (writing and reading) aspects of music require the integrity of the dominant temporal and probably the frontal lobes as well.

Word Deafness (Auditory Verbal Agnosia)

In essence, word deafness is a failure of the left temporal lobe function in decoding the acoustic signals of speech and converting them into understandable words. This is

the essential element of Wernicke's aphasia and is discussed in Chap. 23. However, word deafness can occur by itself, without other features of Wernicke's aphasia. Other aspects of language such as reading, are not affected. The syndrome is sometimes seen as patients are improving from Wernicke's aphasia. Also, as mentioned earlier, verbal agnosia may be combined with agnosia for sounds and music, or the two may occur separately.

Auditory Illusions and Hallucinations

(See also Chap. 15)

Temporal lobe lesions that leave hearing intact may cause a hearing disorder in which sounds are perceived as being louder or less loud than normal. Sounds or words may seem strange or disagreeable, or they may seem to be repeated, a kind of sensory perseveration. If auditory hallucinations are also present, they may undergo similar alterations. Such paracusias may last indefinitely and, by changing timbre or tonality, alter musical appreciation as well.

With lesions of the temporal lobes, these may be elementary (murmurs, blowing, sound of running water or motors, whistles, clangs, sirens) or complex (musical themes, choruses, voices). Usually sounds and musical themes are heard more clearly than voices. Patients may recognize hallucinations for what they are, or they may be convinced that the voices are real and respond to them with intense emotion. Hearing may fade before or during the hallucination.

In temporal lobe epilepsy, the auditory hallucinations are known to occur alone or in combination with visual or gustatory hallucinations, visual distortions, dizziness, and aphasia. There may be hallucinations based on remembered experiences (experiential hallucinations, in the terminology of Penfield and Rasmussen).

The anatomy of lesions underlying auditory illusions and hallucinations, formerly the province of study by ablative lesions, is currently being studied using functional imaging techniques. In some instances, these sensory phenomena have been combined with auditory verbal (or nonverbal) agnosia; the superior and posterior parts of the dominant or both temporal lobes were then involved. Clinicoanatomic correlation is difficult in cases associated with tumors that distort the brain without completely destroying it and that also cause edema of the surrounding tissue. Moreover, it is often uncertain whether symptoms have been produced by destruction of tissue or by excitation, i.e., by way of seizure discharges. Elementary hallucinations have been reported with lesions of either temporal lobe, whereas the more complex auditory hallucinations and particularly polymodal ones (visual plus auditory) occur more often with left-sided lesions. It should also be noted that complex but unformed auditory hallucinations (e.g., the sound of an orchestra tuning up), as well as entire strains of music and singing, also occur, inexplicably, with lesions that appear to be restricted to the pons (*pontine auditory hallucinosis*, as noted in Chap. 15).

It is tempting to relate complex auditory hallucinations to disorders in the auditory association areas surrounding the Heschl gyri, but the available data

do not clearly justify such an assumption. In schizophrenic patients, the areas activated during a period of active auditory hallucinosis include not only Heschl gyri but also the hippocampus and other widely distributed structures mainly in the dominant hemisphere (see Chap. 53).

Vestibular Disturbances

In the superior and posterior part of the temporal lobe (posterior to the primary auditory cortex), there is an area that responds to vestibular stimulation by establishing one's sense of verticality in relation to the environment. If this area is destroyed on one side, the only clinical effect may be a transient illusion that the environment is tipped on its side or is upside down; more often, there is only subtle change in eye movements on optokinetic stimulation. Epileptic activation of this area induces vertigo or a sense of disequilibrium. As pointed out in Chap. 15, pure vertiginous epilepsy does occur but is a rarity, and if vertigo precedes a seizure, it is usually momentary and quickly submerged in other components of the seizure.

Autoscopy and out-of-body experiences Recently, there has been interest in the cortical vestibular area and states of autoscopy (seeing one's self from an external perspective) and the associated but not identical "out-of-body experience" that has been reported by patients who have near-death episodes. Stimulation of this cortical area for the treatment of intractable tinnitus has elicited autoscopy (DeRidder et al) and seizures originating in the same or adjacent areas have produced out of body sensations. These observations suggest that one's mental perspective of corporeal place may be mediated by the cortex at the temporal-parietal junction. This is not surprising as the representation of extrapersonal space is found in the parietal lobes as described further on (see Blanke et al).

Disturbances of Time Perception

In a temporal lobe seizure originating on either side, time may seem to stand still or to pass with great speed. On recovery from such a seizure, the patient, having lost all sense of time, may repeatedly look at the clock. Assal and Bindschaedler have reported an extraordinary abnormality of time sense in which the patient invariably placed the day and date 3 days ahead of the actual ones. There had been aphasia from a left hemispherical stroke years before, but the impairment of time sense occurred only after a left temporal stroke that also produced cortical deafness.

Certainly, the most common disruptions of the sense of time occur as part of confusional states of any type. The usual tendency is for the patient to report the current date as an earlier one, much less often as a later one. Characteristically, in this situation, the responses vary from one examination to the next. The patient with a Korsakoff amnesic state is unable to place events in their proper time relationships, presumably because of failure of retentive memory, a function assignable to the medial temporal lobes.

Disturbances of Smell and Taste

(See also Chap. 12)

The central anatomy and physiology of these two senses in humans have been elusive. Brodal concluded that the hippocampus was not involved; however, seizure foci in the medial part of the temporal lobe (in the region of the uncus) often evoke olfactory hallucinations. This type of “uncinate fit,” as originally pointed out by Jackson and Stewart, is often accompanied by a dreamy state, or, in the words of Penfield, an “intellectual aura.” The central areas identified physiologically with olfaction are the posterior orbitofrontal, subcallosal, anterior temporal, and insular cortices, i.e., the areas that mediate numerous visceral functions.

In comparison, hallucinations of taste are less common. Stimulation of the posterior insular area elicited a sensation of taste along with disturbances of alimentary function (Penfield and Faulk). There are cases in which a lesion in the medial temporal lobe caused both gustatory and olfactory hallucinations. Sometimes the patient cannot decide whether he experienced an abnormal odor, taste, or both. The anatomy and physiology of smell and taste are discussed further in Chap. 12. Alterations or loss of taste and smell with temporal lobe lesions has not been adequately studied, and these do not appear to be common in clinical practice.

Other (Nonauditory) Temporal Lobe Syndromes

There is a large inferolateral expanse of temporal lobe that has only vaguely assignable integrative functions. With lesions in these parts of the dominant temporal lobe, a defect in the retrieval of words (*amnesic dysnomia*) has been frequently observed. Stimulation of the posterior parts of the first and second temporal convolutions of fully conscious epileptic patients can arouse complex memories and visual and auditory images, some with strong emotional content (Penfield and Roberts).

The loss of certain visual integrative abilities, particularly face recognition (*prosopagnosia*), is usually assigned to lesions of the inferior occipital lobes, as discussed further on, but the area implicated borders on the adjacent inferior temporal lobe as well.

Careful psychologic studies disclose a difference between the effects of dominant and nondominant partial (anterior) temporal lobectomy (Milner, 1971). With the former, there is dysnomia and impairment in the learning of material presented through the auditory sense; with the latter, there is impairment in the learning of visually presented material. In addition, about 20 percent of patients who have undergone temporal lobectomy, left or right, show a syndrome similar to that which results from lesions of the prefrontal regions. Perhaps more significant is the observation that the remainder of the cases show little or no defect in personality or behavior.

Disorders of Memory, Emotion, and Behavior

Finally, attention must be drawn to the central role of the temporal lobe, notably its hippocampal and limbic parts, in memory and learning and in the emotional life of the individual. As indicated earlier, these functions and their

derangements have been accorded separate chapters. Memory is discussed in Chap. 21 and the neurology of emotion and behavior in Chap. 25.

To summarize, human temporal lobe syndromes include the following:

- I. Effects of unilateral disease of the dominant temporal lobe
 - A. Homonymous contralateral upper quadrantanopia
 - B. Wernicke’s aphasia (word deafness; auditory verbal agnosia)
 - C. Dysnomia or amnesic aphasia
 - D. Amusia (some types)
 - E. Visual agnosia
 - F. Occasionally, amnesic (Korsakoff) syndrome
- II. Effects of unilateral disease of the nondominant temporal lobe
 - A. Homonymous upper quadrantanopia
 - B. Inability to judge spatial relationships in some cases
 - C. Impairment in tests of visually presented nonverbal material
 - D. Agnosia for sounds and some qualities of music
- III. Effects of disease of either temporal lobe
 - A. Auditory, visual, olfactory, and gustatory hallucinations
 - B. “Dreamy” states with seizure (focal temporal lobe seizure)
 - C. Emotional and behavioral changes
 - D. Delirium-confusional states (usually nondominant)
 - E. Disturbances of time perception
- IV. Effects of bilateral disease
 - A. Korsakoff amnesic defect (hippocampal formations)
 - B. Apathy and placidity
 - C. Klüver-Bucy syndrome: compulsion to attend to all visual stimuli, hyperorality, hypersexuality, blunted emotional reactivity; the full syndrome is rarely seen in humans

SYNDROMES CAUSED BY LESIONS OF THE PARIETAL LOBES

Anatomic and Physiologic Considerations

This part of the cerebrum, lying behind the central sulcus and above the sylvian fissure, is the least well demarcated (see Fig. 22-1). Its posterior boundary, where it merges with the occipital lobe, is obscure, as is part of the inferior-posterior boundary, where it merges with the temporal lobe. On its medial side, the parietooccipital sulcus marks the posterior border, which is completed by extending the line of the sulcus downward to the preoccipital notch on the inferior border of the hemisphere. Within the parietal lobe, there are two important sulci: the postcentral sulcus, which forms the posterior boundary of the somesthetic cortex, and the interparietal sulcus, which runs anteroposteriorly from the middle of the posterior central sulcus and separates the mass of the parietal lobe into superior and inferior lobules

(see Fig. 22-1). The inferior parietal lobule is composed of the supramarginal gyrus (Brodmann area 40) and the angular gyrus (area 39). The superior parietal lobule is that remaining part of the lobe that is bounded below by interparietal sulcus, anteriorly by the postcentral sulcus, and extends onto the medial surface of the brain in Brodmann areas 5 and 7 (Fig. 22-2). The architecture of the postcentral convolution is typical of all primary receptive areas (homotypical granular cortex). The rest of the parietal lobe resembles the association cortex, both unimodal and heteromodal, of the frontal and temporal lobes.

The superior and inferior parietal lobules and adjacent parts of the temporal and occipital lobes are relatively much larger in humans than in any of the other primates and are relatively slow in attaining their fully functional state (beyond age 7 years). This area of heteromodal cortex has large fiber connections with the frontal, occipital, and temporal lobes of the same hemisphere and, through the middle part of the corpus callosum, with corresponding parts of the opposite hemisphere.

The *postcentral gyrus*, or *primary somatosensory cortex*, receives most of its afferent projections from the ventroposterior thalamic nucleus, which is the terminus of the ascending somatosensory pathways. The contralateral half of the body is represented somatotopically in this gyrus on the posterior bank of the Rolandic sulcus. It has been shown in the macaque that spindle afferents project to area 3a, cutaneous afferents to areas 3b and 1, and joint afferents to area 2 (Kaas). Stimulation of the postcentral gyrus elicits a numb, tingling sensation and sense of movement. Penfield (1941) remarked that rarely are these tactile illusions accompanied by pain, warmth, or cold. Stimulation of the motor cortex may produce similar sensations, as do discharging seizure foci from these regions. The primary sensory cortex projects to the superior parietal lobule (area 5), which is the somatosensory association cortex. Some parts of areas 1, 3, and 5 (except the hand and foot representations) probably connect, via the corpus callosum, with the opposite somatosensory cortex. There is some uncertainty as to whether area 7 (which lies posterior to area 5) is unimodal somatosensory or heteromodal visual and somatosensory; certainly, it receives a large contingent of fibers from the occipital lobe.

In humans, electrical stimulation of the cortex of the superior and inferior parietal lobules evokes no specific motor or sensory effects. Overlapping here, however, are the integrative zones for vision, hearing, and somatic sensation, the supramodal integration of which is essential to our awareness of space and person and certain aspects of language and calculation (apperception), as described below.

The parietal lobe is supplied by the middle cerebral artery, the inferior and superior divisions supplying the inferior and superior lobules, respectively, although the demarcation between the areas of supply of these two divisions is quite variable.

Despite Critchley's pessimistic prediction that establishing a formula of normal parietal function would prove to be a "vain and meaningless pursuit," our concepts of

the activities of this part of the brain have assumed some degree of order, in part from his own work. There is little reason to doubt that the anterior parietal cortex contains the mechanisms for tactile percepts. Discriminative tactile functions, listed below, are organized in the more posterior, secondary sensory areas. But the greater part of the parietal lobe functions as a center for integrating somatosensory with visual and auditory information in order to construct an awareness of one's own body (body schema) and its relation to extrapersonal space. Connections with the frontal and occipital lobes provide the necessary proprioceptive and visual information for movement of the body and manipulation of objects and for certain constructional activities (constructional apraxia). Impairment of these functions implicates the parietal lobes, more clearly the nondominant one (on the right).

The conceptual patterns on which complex voluntary motor acts are executed also depend on the integrity of the parietal lobes, particularly the dominant one. Defects in this region give rise to ideomotor apraxia, as discussed in Chap. 3 and further on. The understanding of spoken and written words is partly a function of the supramarginal and angular gyri of the dominant parietal lobe as elaborated in Chap. 23. The recognition and utilization of numbers, arithmetic principles, and calculation, which have important spatial attributes, are other functions integrated principally through these structures.

Clinical Effects of Parietal Lobe Lesions

Within the brain, perhaps no other territory surpasses the parietal lobes in the rich variety of clinical phenomena exposed under conditions of disease. Our current understanding of the effects of parietal lobe disease contrasts sharply with that of the late nineteenth century, when these lobes, in the textbooks of Oppenheim and Gowers, were considered to be "silent areas." However, some of the clinical manifestations of parietal lobe disease may be subtle, requiring special techniques for their elicitation.

Close to the core of the complex behavioral features that arise from lesions of the parietal lobes is the problem of *agnosia*. Allusion has already been made to agnosia in the discussion of lesions of the temporal lobes that affect language, and similar findings occur with lesions of the occipital lobe as discussed further on. In those contexts, agnosia refers to a *loss of recognition of an entity that cannot be attributed to a defect in the primary sensory modality*. The term *agnosia* extends to a loss of more complex integrated functions and mental symbolism as described below, a number of intriguing deficits arise. These syndromes expose properties of the parietal lobe that have implications regarding a map of the body schema and of external topographic space, of the ability to calculate, to differentiate left from right, to write words, and other problems discussed below. The fact that *apraxia*, an inability to carry out a commanded task despite the retention of motor and sensory function, may also arise from parietal lobe damage, and the relationship of the apraxias to language and to agnosias, exposes some of the most complicated issues in behavioral neurology. Some of the theoretical aspects

of agnosia, particularly those related to the disturbances of visual processing, are discussed later in the chapter.

Cortical Sensory Syndromes

The effects of a parietal lobe lesion on somatic sensation were first described by Verger and then more completely by Déjerine, in his monograph *L'agnosie corticale*, and by Head and Holmes. The latter, in their important paper of 1911, noted the close interrelationships between the thalamus and the sensory cortex. Although difficult to study, it is apparent that a large lesion of the primary sensory cortex, or beneath it, results in a circumscribed loss or reduction in sensation on the opposite side of the body. When primary sensory perception is altered, analysis of more complex and integrative sensory function is rendered less accurate.

However, as pointed out in the discussion of the organization of the sensory systems in Chap. 9, the parietal postcentral cortical defect is essentially one of *sensory discrimination*, i.e., impairment of the ability to integrate and localize stimuli that is reflected by an inability to distinguish objects by their size, shape, weight, and texture (astereognosis); to recognize figures written on the skin (agraphesthesia); to distinguish between single and double contacts (impairment of two-point discrimination); and to detect the direction of movement of a tactile stimulus. This type of sensory defect is sometimes referred to as "cortical," although it can be produced just as well by lesions of the subcortical connections. Clinicoanatomic studies indicate that parietocortical lesions that spare the postcentral gyrus produce only transient somatosensory changes or none at all (Corkin et al; Carmon and Benton). In other words, the primary perception of pain, touch, pressure, vibratory stimuli, and thermal stimuli is relatively intact in lesions of the parietal cortex that does not involve the postcentral gyrus.

The question of bilateral sensory deficits as a result of lesions in only one postcentral convolution was raised by the studies of Semmes and of Corkin and their associates. In tests of pressure sensitivity, two-point discrimination, point localization, position sense, and tactile object recognition, they found bilateral disturbances in nearly half of their patients with unilateral lesions, but the deficits were always more severe contralaterally and mainly in the hand and therefore the ipsilateral effect is rarely evident in clinical work. These disturbances of discriminative sensation and the subject of tactile agnosia are discussed more fully in Chap. 9.

Déjerine and Mouzon described the sensory syndrome in which touch, pressure, pain, thermal, vibratory, and position sense are lost on one side of the body or in a limb. This syndrome, typically the result of a thalamic lesion and not of a parietal one, may nonetheless occur with large, acute lesions (infarcts, hemorrhages) in the central and subcortical white matter of the parietal lobe. In this case, the symptoms partially recede in time, leaving more subtle defects in sensory discrimination. Smaller lesions, particularly ones that result from a glancing blow to the skull or a small infarct or hemorrhage, may cause a defect in cutaneous-kinesthetic perception in a discrete part of a limb, e.g., the ulnar or radial half

of the hand and forearm; these cerebral lesions may mimic a peripheral nerve or root lesion (Dodge and Meierowsky).

A *pseudothalamic pain syndrome* on the side deprived of sensation by a parietal lesion has been described (Biemond). In a series of 12 such patients described by Michel and colleagues, burning or constrictive pain, identical to the thalamic pain syndrome (described in Chap. 9), resulted from vascular lesions restricted to the cortex. The discomfort involved the entire half of the body or matched the region of cortical hypesthesia; in a few cases, the symptoms were paroxysmal.

Head and Holmes drew attention to a number of interesting points about patients with parietal sensory defects: the easy fatigability of their sensory perceptions; the inconsistency of responses to painful and tactile stimuli; the difficulty in distinguishing more than one contact at a time; the disregard of stimuli on the affected side when the healthy side is stimulated simultaneously (tactile inattention or extinction); the tendency of superficial pain sensations to outlast the stimulus and to be hyperpathic; and the occurrence of hallucinations of touch. Of these, the testing of sensory extinction by the presentation of two tactile stimuli simultaneously on both sides of the body has become a component of the routine neurologic examination for parietal lesions. In modern parlance, these are "cortical sensory" defects of extinction of double simultaneous stimulation—astereognosis and agraphesthesia.

With anterior parietal lobe lesions, there is sometimes an associated mild hemiparesis, as this portion of the parietal lobe contributes a considerable number of fibers to the corticospinal tract. Occasionally there is such a large degree of inability or disinclination to use the limb that it simulates a hemiplegia. More often, there is only a poverty of movement or a weak effort of the opposite side. The affected limbs, if involved with this apparent weakness, tend to remain hypotonic and the musculature may undergo slight atrophy of a degree possibly not explained entirely by inactivity alone. In some cases, as noted below, there is clumsiness in reaching for and grasping an object under visual guidance (optic ataxia), and exceptionally, at some phase in recovery from the hemisensory deficit, there is incoordination of movement and intention tremor of the contralateral arm and leg that closely simulates a cerebellar deficit (pseudocerebellar syndrome). While relatively rare, this type of ataxia is authenticated by our own case observations.

In instances of cortical sensory disturbance, the outstretched hand may display small random "searching" movements of the fingers that simulate playing a piano (pseudoathetosis); these are exaggerated when the eyes are closed. Fixed dystonic postures and asterixis have also been described after parietal lesions with sensory loss, but these are most often the result of thalamic damage.

Agnosia

A conceptual inability to recognize objects, persons, or sensory stimuli in the absence of a primary deficit in the sensory modality is termed *agnosia*, derived from the

Greek for lack of knowledge. It was included as a form of loss of insight as part of the confusional state in Chap. 20.

The idea that visual and tactile sensory information is synthesized into a body schema or image (perception of one's body and the relations of bodily parts to one another) was first formulated by Pick and elaborated by Brain. Long before their time, however, it was suggested that such information was the basis of our emerging awareness of ourselves, and philosophers had assumed that this comes about by the constant interplay between inherent percepts of ourselves and of the surrounding world.

The formation of the body schema is considered to be based on the constant influx and storage of sensations from our bodies as we move about; hence, motor activity is important in its development. A sense of extrapersonal space is central to this activity, and this also depends upon visual and labyrinthine stimulation. The mechanisms of these perceptions are best appreciated by studying their derangements in the course of neurologic disease of the parietal lobes.

Denny-Brown and Banker introduced the idea that the basic disturbance in all these defects is an inability to integrate a series of "spatial impressions"—tactile, kinesthetic, visual, vestibular, or auditory—a defect they referred to as *amorphosynthesis*. Examples of the loss of concept in their schema include finger agnosia, right-left confusion, acalculia, and all the apperceptive losses that attend damage of integrative sensory areas of the brain. The theoretical problem presented by agnosia is taken up in a later section.

Anosognosia and hemispacial neglect (Anton-Babinski syndrome) The observation that a patient with a dense hemiplegia, usually of the left side, may be indifferent to a paralysis, or is entirely unaware of it, was first made by Anton; later, Babinski named this disorder *anosognosia*. It expresses itself in several ways. For example, a lack of concern regarding paralysis was called *anosodiaphoria* by Babinski, an interesting term that is now little used. The term "denial" was introduced by Freud to explain the problem but is laden with psychic and psychoanalytical meaning and is less precise than "neglect."

With regard to parietal lobe disease, the term "anosognosia," using "anos," disease, is used to describe a group of disorders in which there is an unawareness of a deficit. While used most frequently to describe a lack of recognition, neglect, or indifference to a left-sided paralysis or even to ownership of the limb, the term *anosognosia* is appropriate to denote the inability to perceive a number of deficits based on cerebral disease including blindness, hemianopia, deafness, and memory loss. *Anosognosia* is usually associated with a number of additional abnormalities. Often there is a blunted emotionality. The patient is inattentive and apathetic, and shows varying degrees of general confusion. There may be an indifference to performance failure, a feeling that something is missing, visual and tactile illusions when sensing the paralyzed part, hallucinations of movement, and *allochiria* (one-sided stimuli are felt on the other side).

The patient may act as if nothing were the matter. If asked to raise the paralyzed arm, he may raise the intact

one or do nothing at all. If asked whether the paralyzed arm has been moved, the patient may say "yes." If the fact that the arm has not been moved is pointed out, the patient may admit that the arm is slightly weak. If told it is paralyzed, the patient may deny that this is so or offer an excuse: "My shoulder hurts." If asked why the paralysis went unnoticed, the response may be, "I'm not a doctor." Some patients report that they feel as though their left side had disappeared, and when shown the paralyzed arm, they deny it is theirs and assert that it belongs to someone else or even take hold of it and fling it aside. The mildest form of *anosognosia* is reflected by an imperfect and reduced appreciation of the degree of weakness. On the other extreme of the conceptual negation of paralysis are instances of self-mutilation of the paralyzed limb (*apotemnophilia*). It should be pointed out that the loss of body schema and the lack of appreciation of a left hemiplegia are separable, some patients displaying only one feature.

The lesion responsible for the various forms of one-sided *anosognosia* lies in the cortex and white matter of the superior parietal lobule. Rarely, a deep lesion of the ventrolateral thalamus and the juxtaposed white matter of the parietal lobe will produce a similar contralateral neglect. Unilateral *asomatognosia* is many times more frequent with right (nondominant) parietal lesions as with left-sided ones (seven times more often according to Hécaen). The apparent infrequency of right-sided agnosic symptoms with left parietal lesions is attributable in part, but not entirely, to their obscuration by an associated aphasia.

Another common group of parietal symptoms consists of neglect of one side of the body in dressing and grooming, recognition only on the intact side of bilaterally and simultaneously presented stimuli (*sensory extinction*) as mentioned above, deviation of head and eyes to the side of the lesion (transient), and torsion of the body in the same direction. The patient may fail to shave one side of the face, apply lipstick, or comb the hair only on one side.

Unilateral spatial neglect is brought out by having the patient bisect a line, draw a daisy or a clock, or name all the objects in the room. Homonymous hemianopia and varying degrees of hemiparesis may or may not be present and interfere with the interpretation of the lack of application on the left side of the drawing.

Clinical observations indicate that patients with right parietal lesions show variable but lesser elements of ipsilateral neglect in addition to the striking degree of contralateral neglect, suggesting that, *in respect to spatial attention, the right parietal lobe is truly dominant* (Weintraub and Mesulam). Damage of the superior parietal lobule, in addition to producing agnosias and apraxias, may interfere with voluntary movement of the opposite limbs, particularly the arm, as pointed out by Holmes. In reaching for a visually presented target in the contralateral visual field, and to a lesser extent in the ipsilateral field, the movement is misdirected and *dysmetric* (the distance to the target is misjudged).

Another subtle aspect of parietal lobe physiology revealed by human disease is the loss of exploratory and

orienting behavior with the contralateral arm and even a tendency to avoid tactile stimuli. Mori and Yamadori call this *rejection behavior*. Denny-Brown and Chambers attributed the released grasping and exploring that follow frontal lobe lesions to a disinhibition of inherent parietal lobe automatism but there is no way of confirming this. It is of interest that demented patients with prominent grasp reflexes tend not to grasp parts of their own bodies, but if there has been an additional parietal lesion, there is "self-grasping" of the forearm opposite the lesion (Ropper).

Conventional treatments for hemispatial neglect use prismatic glasses and training in visual exploration of the left side. Another approach demonstrates improvement by the application of vibratory stimulation to the right side of the neck, as reported by Karnath and colleagues, or of the ipsilateral labyrinth by caloric or electrical means (a similar treatment has been successful in some cases of dystonic torticollis, see Chap. 6). Based on the work of Ramachandran and colleagues, mirrors have been used to assist recovery of the side with agnosia. With a mirror in the right parasagittal plane, the patient observes the mirror image of their neglected hand and space and is induced to use that side more naturally. The larger problem is that these patients may not respond to rehabilitation if they lack an innate body schema.

Ideomotor and Ideational Apraxia

(See also Chap. 3)

As discussed extensively in Chap. 3, patients with parietal lesions of the *dominant* hemisphere who exhibit no defects in motor or sensory function, lose the ability to perform learned motor skills on command or by imitation. They can no longer use common implements and tools, either in relation to their bodies (e.g., brushing teeth, combing hair) or in relation to objects in the environment (e.g., a doorknob or hammer). The patient holds the implement awkwardly or seems at a loss to begin the act. It is as though the patient had forgotten the sequences of learned movements. The effects are bilateral. When defects of apraxia are intertwined with agnosic defects, the term *apractognosia* seems appropriate. A special type of visuospatial disorder, separable from neglect but also associated with lesions of the nondominant parietal lobe, is reflected in the patient's inability to reproduce geometric figures (*constructional apraxia*). A number of tests have been designed to elicit these disturbances, such as indicating the time by placement of the hands on a clock, drawing a map, copying a complex figure, reproducing stick-pattern constructions and block designs, making three-dimensional constructions, and constructing puzzles.

From the above descriptions, it is evident that the left and right parietal lobes function differently. The most obvious difference, of course, is that language and arithmetical functions are centered in the left hemisphere. It is hardly surprising, therefore, that verbally mediated spatial and praxic functions are more affected with left-sided than with right-sided lesions. This is ostensibly because language function, sited in the left hemisphere, is central to all cognitive functions. Hence cross-modal matching

tasks (auditory-visual, visual-auditory, visual-tactile, tactile-visual, auditory-tactile, etc.) are most clearly impaired with lesions of the dominant hemisphere. Such patients can read and understand spoken words but cannot grasp the meaning of a sentence if it contains elements of relationship (e.g., "the mother's daughter" versus "the daughter's mother," "the father's brother's son," "Jane's complexion is lighter than Marjorie's but darker than her sister's"). There are similar difficulties with calculation. The recognition and naming of parts of the body and the distinction of right from left and up from down are learned, verbally mediated spatial concepts that are disturbed by lesions in the dominant parietal lobe.

Gerstmann Syndrome

This syndrome, caused by a left (dominant) inferior parietal lesion, provides the most striking example of what might be viewed as a bilaterally manifest agnosia (the previously mentioned asomatognosia of Denny-Brown and Banker). The characteristic tetrad of features is (i) inability to designate or name the different fingers of the two hands (finger agnosia), (ii) confusion of the right and left sides of the body, (iii) inability to calculate (acalculia), and (iv) inability to write (dysgraphia). One or more of these manifestations may be associated with word blindness (alexia) and homonymous hemianopia or a lower quadrantanopia. The lesion is in the left *inferior parietal lobule* (below the interparietal sulcus), particularly involving the angular gyrus or subjacent white matter of the left hemisphere.

There has been a dispute as to whether the four main elements of the Gerstmann syndrome have a common basis or only an association. Benton states that they occur together in a parietal lesion no more often than do constructional apraxia, alexia, and loss of visual memory and that every combination of these symptoms and those of the Gerstmann syndrome occurs with equal frequency in parietal lobe disease. Others, including the authors, tend to disagree and have the experience that right-left confusion, digital agnosia, agraphia, and acalculia have special significance, possibly being linked through a unitary defect in spatial orientation of fingers, body sides, and numbers. The relationship between the finger agnosia and the inability to enumerate is especially intriguing and relates to other arithmetic difficulties, discussed below. Attempts to clarify a common or fundamental source for all the elements of the Gerstmann syndrome by functional imaging have been difficult to comprehend. In healthy subjects, Rusconi and colleagues were unable to find a shared cortical substrate that could give rise to the features of the Gerstmann syndrome.

Dyscalculia has attracted little critical attention, perhaps because it occurs most often as a by-product of aphasia and an inability of the patient to appreciate numerical language. Primary dyscalculia is usually associated with the other elements of the Gerstmann syndrome. Computational difficulty may also be part of the more complex visuospatial abnormality of the nondominant parietal lobe; there is then difficulty in the placing of numbers in specific spatial relationships while calculating. In such cases, there is no difficulty in

reading or writing the numbers or in describing the rules governing the calculation, but the computation cannot be accomplished correctly with pencil and paper. Hécaen has made a distinction between this type of *anarithmetia* and *dyscalculia*. In the latter, the process of calculation alone has been disturbed; in the former, there is an inability to manipulate numbers and to appreciate their ordinal relationships. Recognition and reproduction of numbers are intact in both. An analysis of how computation goes awry in each individual case is therefore required.

Visual Disorders With Parietal Lesions

A lesion deep to the inferior part of the parietal lobe, at its junction with the temporal lobe, involves the geniculocalcarine radiations and results in an incongruous homonymous hemianopia or an inferior quadrantanopia on the opposite side; but just as often, in practice, the defect is complete or almost complete and congruous. If the lesion is small and predominantly cortical, optokinetic nystagmus is usually retained; with deep lesions, it is abolished, with the target moving ipsilaterally (see Chap. 14).

Visual neglect is a typical feature of posterior parietal lesions on either side, more prominent with right-sided lesions. The problem that often arises is of distinguishing visual hemineglect (particularly of the left side) from a hemianopia. In its more severe forms the neglect is evident from casual observation of the patient's behavior or in drawings made by the patient that omit features on the left side; but here a more pervasive syndrome of *hemispacial neglect*, discussed earlier, may underlie the visual behavior. Occasionally, severe left-sided *visual neglect* results from a lesion in the right angular gyrus (see Mort et al). Visual neglect can also occur after focal lesions in the posterior medial temporal lobe (supplied by a branch of the posterior cerebral artery, in contrast to the middle cerebral artery supply of the angular gyrus of the inferior parietal lobule).

With posterior parietal lesions, as noted by Holmes and Horrax, there are deficits in localization of visual stimuli, inability to compare the sizes of objects, failure to avoid objects when walking, inability to count objects, disturbances in smooth-pursuit eye movements, and loss of stereoscopic vision. Cogan observed that the eyes may deviate away from the lesion upon forced lid closure, a "spasticity of conjugate gaze."

A common disorder of motor behavior of the eyelids is seen in many patients with large acute lesions of the right parietal lobe. Its mildest form is a disinclination to open the lids when the patient is spoken to. This gives the erroneous impression that the patient is drowsy or stuporous, but it will be found that a quick reply is given to whispered questions. In more severe cases, the lids are held shut and opening them is strongly resisted, to the point of making an examination of the pupils and fundi impossible.

Visual disorientation and disorders of extrapersonal space (topographic localization) Spatial orientation depends on the integration of visual, tactile, and kinesthetic perceptions, but there are instances in which the defect in visual perception predominates. Patients with this disorder are unable to orient themselves in an

abstract spatial setting (*topographagnosia*). Such patients cannot draw the floor plan of their house, a map of their town, or of the United States and cannot describe a familiar route, as from home to work, for example, or find their way in familiar surroundings. In brief, such patients have lost topographic memory. This disorder is almost invariably caused by lesions in the white matter deep to the inferior and superior parietal lobules and it is separable from anosognosia as summarized by Levine and colleagues.

A clever mental experiment posed to patients by Bisiach and Luzzatti has suggested that the loss of attention to one side of the environment extends to, or perhaps is derived from, the mental representation of space. Their patient with a right parietal lesion was asked to describe from memory the buildings lining the Piazza del Duomo, first as if seen from one corner of the piazza and then from the opposite corner. In each instance, the description omitted the left side of the piazza from the observer's perspective.

An important and not infrequent disorder of visual agnosia, a disorder of visually directed reaching with the hand, difficulty directing gaze, and simultanagnosia, is given the name *Balint syndrome*. It is, strictly speaking, a bilateral disorder of the parietal lobes but we discuss it below for convenience in order to append it to the clinically similar entity of cortical blindness.

Auditory Neglect

This defect in appreciation of the left side of the environment is less apparent than is visual neglect, but it is no less striking when it occurs. Many patients with acute right parietal lesions are initially unresponsive to voices or noises on the left side, but the syndrome is rarely persistent. Special tests demonstrate a displacement of the direction of the perceived origin of sounds toward the right. This defect is separable from visual agnosia (see De Renzi et al); curiously, it may be worsened by the introduction of visual cues. Subtle differences between the allocation of spatial attention to sound (auditory neglect) and a distortion in its localization may be found in different cases, but the main lesion usually lies in the right superior lobule.

In summary, the effects of disease of the parietal lobes are as follows:

- I. Effects of unilateral disease of the parietal lobe, right or left
 - A. Corticosensory syndrome and sensory extinction (or total hemianesthesia with large acute lesions of white matter)
 - B. Mild hemiparesis or poverty of movement (variable), poverty of movement, hemiataxia (seen only occasionally)
 - C. Homonymous hemianopia or inferior quadrantanopia (incongruent or congruent) or visual inattention
 - D. Abolition of optokinetic nystagmus with target moving toward side of the lesion
 - E. Neglect of the opposite side of external space (more prominent with lesions of the right parietal lobe; see later)

- II. Effects of unilateral disease of the dominant (left) parietal lobe (in right-handed and most left-handed patients); additional phenomena include
 - A. Disorders of language (especially alexia)
 - B. Gerstmann syndrome (dysgraphia, dyscalculia, finger agnosia, right-left confusion)
 - C. Tactile agnosia (bimanual astereognosis)
 - D. Bilateral ideomotor and ideational apraxia (see Chap. 3)
- III. Effects of unilateral disease of the nondominant (right) parietal lobe
 - A. Visuospatial disorders
 - B. Topographic memory loss
 - C. Anosognosia, dressing, and constructional apraxias (these disorders may occur with lesions of either hemisphere but are observed more frequently and are of greater severity with lesions of the nondominant one)
 - D. Confusion
 - E. Tendency to keep the eyes closed, resist lid opening, and blepharospasm
- IV. Effects of bilateral disease of the parietal lobes
 - A. Balint syndrome: visual-spatial imperception (simultagnosia), optic apraxia (difficulty directing gaze), and optic ataxia (difficulty reaching for objects)

With all these parietal syndromes, if the disease is sufficiently extensive, there may be a reduction in the capacity to think clearly as well as inattentiveness and slightly impaired memory.

It does seem reasonably certain that, in addition to the perception of somatosensory impulses that arrive in the postcentral gyrus, the parietal lobe participates in the integration of all sensory data, especially those that provide an awareness of one's body as well as a percept of one's surroundings and of the relation of one's body to extrapersonal space and of objects in the environment to each other. In this respect, the parietal lobe may be regarded as a special high-order sensory organ, the locus of transmodal intersensory, integration, particularly tactile and visual ones, which are the basis of our concepts of spatial relations. In this way, parietal lesions cause disorders of specific types of self-consciousness or self-awareness that are tied to sensory modalities. This is distinctly different from the distortions of perception caused by lesions of the temporal lobes.

Authoritative references on parietal function include Critchley's monograph on the parietal lobes and the chapter by Botez and Olivier in the *Handbook of Clinical Neurology*.

SYNDROMES CAUSED BY LESIONS OF THE OCCIPITAL LOBES

Anatomic and Physiologic Considerations

The occipital lobes are the termini of the geniculocalcarine pathways and are essential for visual perception and recognition. This part of the brain has a large

medial surface and smaller lateral and inferior surfaces (see Fig. 22-1). The parietooccipital fissure creates a noticeable medial boundary with the parietal lobe, but laterally the occipital lobe merges with the parietal and temporal lobes. The large calcarine fissure courses in an anteroposterior direction from the pole of the occipital lobe to the splenium of the corpus callosum; area 17, the primary visual receptive cortex, lies on its banks (see Figs. 22-1 and 22-2). Area 17 is a typical homotypical cortex but is unique in that its fourth receptive layer is divided into two granular cell laminae by a greatly thickened band of myelinated fibers, the external band of Baillarger. This stripe, also called the *line* or *band of Gennari*, is grossly visible and has given this area its name, *striate cortex*. The largest part of area 17 is the terminus of the retinal macular fibers that arrive via the lateral geniculate (see Fig. 13-2). The parastriate cortex (areas 18 and 19) lacks the line of Gennari and resembles the granular unimodal association cortex of the rest of similar areas in the cerebrum. Area 17 contains cells that are activated by the homolateral geniculocalcarine pathway (corresponding, of course, exclusively to the contralateral visual field); these cells are interconnected and project also to cells in areas 18 and 19. The latter are connected with one another and with the angular gyri, lateral and medial temporal gyri, frontal motor areas, limbic and paralimbic areas, and corresponding areas of the opposite hemisphere through the posterior third (splenium) of the corpus callosum.

The occipital lobes are supplied almost exclusively by the posterior cerebral arteries and their branches, either directly in most individuals or through an embryologically persistent branch of the internal carotid arteries ("fetal" posterior cerebral artery). A small area of the occipital pole receives blood supply from the inferior division of the middle cerebral artery. This assumes importance in the clinical finding of "macular sparing," discussed in Chap. 13.

The connections among these several areas in the occipital lobe are complex, and the notion that area 17 is activated by the lateral geniculate neurons and that this activity is then transferred and elaborated in areas 18 and 19 is surely not complete. Actually, 4 or 5 occipital receptive fields are activated by lateral geniculate neurons, and fibers from area 17 project to approximately 20 other visual areas, of which only 5 are well identified. These extrastriate visual areas lie in the lingula and posterior regions of the occipital lobes. As Hubel and Wiesel have shown, the response patterns of neurons in both occipital lobes to edges and moving visual stimuli, to on-and-off effects of light, and to colors reflects this complexity. Hence form, location, color, and movement each have separate localizable hierarchical arrangements of neurons in series. The monographs of Polyak and of Miller contain detailed information about the anatomy and physiology of this part of the brain.

Beyond the effects on vision of lesions in the occipital lobes, monkeys with bilateral lesions in the temporal visual zones lose the ability to identify objects; with posterior parietal lesions, there is loss of ability to locate objects.

Clinical Effects of Occipital Lobe Lesions

Visual Field Defects

The most familiar clinical abnormality resulting from a lesion of one occipital lobe, a contralateral *homonymous hemianopia*, has already been discussed in Chap. 13. Extensive destruction abolishes all vision in the corresponding opposite half of each visual field. With a neoplastic lesion that eventually involves the entire striate region, the field defect may extend from the periphery toward the center, and loss of color vision (hemichromatopsia) often precedes loss of black and white. Destruction of only part of the striate cortex on one side yields characteristic field defects that accurately indicate the loci of the lesion. A lesion confined to the pole of the occipital lobe results in a central hemianopic defect that splits the macula and leaves the peripheral fields intact. This observation indicates that half of each macula is unilaterally represented and that the maculae may be involved (split) in hemianopia. Bilateral lesions of the occipital poles, as in embolism of the posterior cerebral arteries, result in bilateral hemianopias and cortical blindness as detailed below. Unilateral quadrant defects and altitudinal field defects due to striate lesions indicate that the cortex on one side, above or below the calcarine fissure, is damaged. The cortex below the fissure is the terminus of fibers from the lower half of the retina; the resulting field defect is in the upper quadrant, and vice versa. Most bilateral altitudinal defects, either superior or inferior, are traceable to incomplete bilateral occipital lesions (cortex or terminal parts of geniculocalcarine pathways). Head and Holmes described several such delimited cases caused by gunshot wounds; embolic infarction is now the common cause.

As indicated in Chap. 13, the homonymous hemianopia that results from ablation of one occipital lobe is not absolute. In monkeys, visuospatial orientation and the capacity to reach for moving objects in the defective field are preserved (Denny-Brown and Chambers). In humans also, flashing light and moving objects can sometimes be seen in the blind field even without the patient's full awareness. Weiskrantz and colleagues have referred to these preserved functions as *blindisms* or *blindsight*. It is useful as a practical matter to note that the optokinetic responses are usually spared in hemianopic deficits of occipital origin.

Many of the complex behavioral defects involving visual function are caused by lesions at the junctions of the occipital and parietal or temporal lobes. They are discussed here with the occipital lobe syndromes for convenience but should be considered as transcending the largely arbitrary boundaries of these three lobes of the brain.

Cortical Blindness

With bilateral lesions of the occipital lobes (destruction of area 17 of both hemispheres), there is a loss of sight that can be conceptualized as bilateral hemianopia. The degree of blindness may be equivalent to that which follows severing of the optic nerves. The pupillary light

reflexes are preserved because they depend upon visual fibers that terminate in the midbrain, but reflex closure of the eyelids to threat or bright light may, or may not, be preserved (see Fig. 14-9). No changes are detectable in the retinas. The eyes are still able to move through a full range and, if there is macular sparing as there usually is with vascular lesions, optokinetic nystagmus can be elicited. Visual imagination and visual imagery in dreams are preserved. With rare exceptions, no cortical potentials can be evoked in the occipital lobes by light flashes or pattern changes (visual evoked response), and the alpha rhythm is lost in the electroencephalogram (EEG; see Chap. 2).

Less-complete bilateral lesions leave the patient with varying degrees of visual perception. There may also be visual hallucinations of either elementary or complex types. The mode of recovery from cortical blindness has been studied carefully by Gloning and colleagues, who describe a regular progression from cortical blindness through visual agnosia and partially impaired perceptual function to recovery. Even with recovery, the patient may complain of visual fatigue (asthenopia) and difficulties in fixation and fusion.

The usual cause of cortical blindness is occlusion of the posterior cerebral arteries (most often embolic) or the equivalent, occlusion of the distal basilar artery. The above-mentioned macular sparing may leave the patient with an island of barely serviceable central vision. The infarct may also involve the mediotemporal regions or thalami, which share the posterior cerebral artery supply, with a resulting Korsakoff amnesic defect and a variety of other neurologic deficits referable to the high midbrain and diencephalon (drowsiness, akinetic mutism as described in Chap. 17).

Visual Anosognosia (Anton Syndrome)

The main characteristic of this disorder is the denial of blindness by a patient who obviously cannot see. These patients act as though they could see, and in attempting to walk, collide with objects, even to the point of injury. They may offer excuses for the difficulties—"I lost my glasses," "The light is dim"—or may only evince indifference to loss of sight. The lesions in cases of negation of blindness extend beyond the striate cortex to involve the visual association areas.

Rarely, the opposite condition arises: a patient is able to see small objects but claims to be blind. This individual walks about avoiding obstacles, picks up crumbs or pills from the table, and catches a small ball thrown from a distance. This simulates the condition of hysterical blindness (see further on).

Visual Illusions (Metamorphopsias)

These may present as distortions of form, size, movement, or color. In a group of 83 patients with visual perceptual abnormalities, Hécaen found that 71 fell under one of four headings: deformation of the image, change in size, illusion of movement, or a combination of all three. Illusions of these types have been reported with lesions confined to the occipital lobes but are more frequently caused by shared occipitoparietal or

occipitotemporal lesions; consequently, they are also considered in earlier sections of this chapter as well as in Chaps. 13 and 16. The right hemisphere appears to be involved more often than the left. Illusions of movement occur more frequently with posterior temporal lesions or seizures, polyopia (one object appearing as two or more objects) more frequently with occipital lesions (it also occurs in hysteria), and palinopsia (perseveration of visual images, as in the frames of a celluloid film) with both posterior parietal and occipital lesions. Visual field defects are present in many of the cases. In all these conditions, the anatomic correlates are imprecise.

It is likely that an element of cortical vestibular disorder underlies the metamorphosis of parietooccipital lesions. The vestibular and proprioceptive systems are represented in the parietal lobes of each side and the lesions there are probably responsible for misperceptions of movement and spatial relations. The illusion of tilting of the environment or upside-down vision is known to occur with parietooccipital lesions, but occurs more often with abnormalities of the vestibular system.

Visual Hallucinations

These phenomena may be elementary or complex, and both types have sensory as well as cognitive aspects. Elementary (or unformed) hallucinations include flashes of light, colors, luminous points, stars, multiple lights (like candles), and geometric forms (circles, squares, and hexagons). They may be stationary or moving (zigzag, oscillations, vibrations, or pulsations). They are much the same as the effects that Penfield and Erickson obtained by stimulating the calcarine cortex in a conscious patient. Complex (formed) hallucinations include objects, persons, or animals and infrequently, more complete scenes that are indicative of lesions in the visual association areas or their connections with the temporal lobes. They may be of natural size, Lilliputian, or grossly enlarged. With hemianopia, they appear in the defective field or move from the intact field toward the hemianopic one. The patient may realize that the hallucinations are false experiences or may be convinced of their reality. Because the patient's response is usually in accord with the nature of the hallucination, he may react with fear to a threatening vision or casually if its content is benign.

The clinical setting for the occurrence of visual hallucinations varies. The simplest black-and-white moving scintillations are part of migraine. Others, some colored, occur as a seizure aura (see Chap. 16). Often, they are associated with a homonymous hemianopia, as already indicated. Frequently, they are part of a confusional state or delirium (see Chap. 20). Similar phenomena may occur as part of hypnagogic hallucinations in the narcolepsy-cataplexy syndrome. In the "peduncular hallucinosis" of Lhermitte (1932), the hallucinations are purely visual, appear natural in form and color, sometimes in pastels, move about as in an animated cartoon, and are considered by the patient to be unreal, abnormal phenomena (preserved insight). Ischemia in the

territories of the posterior cerebral arteries is the usual cause. Lhermitte used the term peduncle to represent the midbrain as the source of the hallucinations was ischemia in the high mesencephalon, creating images that may be akin to those experienced in dreaming. The hallucinations as mentioned are purely visual; if hallucinations are polymodal, the lesion is always in the occipitotemporal parts of the cerebrum.

A special syndrome of ophthalmopathic hallucinations occurs in persons with reduced vision, as discussed in Chap. 13. A similar phenomenon in elderly patients with partially impaired vision has been called the *Charles Bonnet syndrome*, following his description of visual hallucinations in a "sane" person. The topic of senile hallucinosis has been reviewed by Gold and Rabin, and 60 such patients with Bonnet syndrome were reported in detail by Teunisse and colleagues. The latter authors found that 11 percent of older persons with reduced vision experienced these phenomena at one time or another. Further comments are to be found in Chap. 13.

It is usually the case that the lesions responsible for visual hallucinations are situated in the occipital lobe or posterior part of the temporal lobe and that elementary hallucinations have their origin in the occipital cortex, and complex ones in the temporal cortex. However, the opposite may pertain; in some cases, formed hallucinations are related to lesions of the occipital lobe and unformed ones to lesions of the temporal lobe, according to Weinberger and Grant. Also, as emphasized by these authors, lesions that give rise to visual hallucinations, simple or elaborate, need not be confined to central nervous system structures but may be caused by lesions at every level of the neurooptic apparatus (retina, optic nerve, chiasm, etc.).

The Visual Agnosias (See also Lesions of the Parietal Lobe and Temporal Lobe)

Several syndromes involving visual dysfunction are due to lesions that span the occipital lobe and either the adjacent temporal or parietal lobes. They have been divided conceptually and anatomically into a dorsal and a ventral stream of information processing, the former running from the occipital to the parietal lobe and the latter from the occipital to the temporal lobe. Those of the temporal lobe include visual object agnosia, prosopagnosia, alexia, and color agnosia. In this way, the ventral stream may be considered to represent the "what" of visual processing to identify objects. The parietal-occipital, or dorsal stream syndromes are visual simultanagnosia, Balint syndrome and the earlier mentioned topographagnosia, that reflect disorders of "where" in visual behavior.

Visual object agnosia This rare condition, first described by Lissauer in 1890, consists of a failure to name and indicate the use of a seen object by spoken or written word or by gesture. The patient cannot even determine the generic class of the object presented. Visual acuity is intact, the mind is clear, and the patient is not aphasic—conditions requisite for the diagnosis of agnosia. If the object is palpated, it is recognized at once, and it can also be identified by smell or sound if it has

an odor or makes a noise. Moving the object or placing it in its customary surroundings facilitates recognition. In most reported instances of object agnosia, the patient retains normal visual acuity but cannot identify, match, or name objects presented in any part of the visual fields; if misnamed, the object is used in a fashion that reflects the incorrect perception. Amazingly, one encounters patients who have lost the capacity to recognize only one class of objects, e.g., animals or vegetables—suggesting that, in the human, stored information is grouped and classified in a way that is necessary for visual perception (we are unable to corroborate this from our own material). Lissauer conceived of visual object recognition as consisting of two distinct processes, the construction of a perceptual representation from vision (perception) and the mapping of this perceptual representation onto stored percepts or engrams of the object's functions and associations (apperception), and he proposed that impairment of either of these processes could give rise to a defect in visual object recognition.

As indicated in Chap. 13, visual object agnosia is usually associated with *visual verbal agnosia (alexia)* and homonymous hemianopia. *Prosopagnosia* (the inability to identify faces; see further on) is also present in most cases. The underlying lesions are usually bilateral, although McCarthy and Warrington have related a case with a restricted lesion of the left occipitotemporal region (by MRI). Two of our patients with visual object agnosia had an incomplete amnesic syndrome from a left-sided inferior occipital and mediotemporal infarction, reflecting a proximal occlusion of the posterior cerebral artery.

Prosopagnosia This term (from the Greek *prosopon*, "face," and *gnosis*, "knowledge") was introduced by Bodamer for a type of visual defect in which the patient cannot identify a familiar face by looking at either the person or a picture, even though he knows that a face is a face and can point out its features. Such patients also cannot learn to recognize new faces. They may also be unable to interpret the meaning of facial expressions or to judge the ages or distinguish the genders of faces. In identifying persons, the patient depends on other data, such as the presence and type of glasses or moustache, the type of gait, or sound of the voice. Similarly, species of animals and birds and specific models or types of cars cannot be distinguished from one another, but the patient can still recognize an animal, bird, or car as such. Other agnosias may be present in such cases (color agnosia, simultanagnosia) and there may be topographic disorientation, disturbances of body schema, and constructional or dressing apraxia. Visual field defects are nearly always present. Some neurologists have interpreted this condition as a simultanagnosia involving facial features. Another view is that the face, though satisfactorily perceived, cannot be matched to a memory store of faces. Levine has found a deficit in perception, characterized by insufficient feature analysis of all visual stimuli.

The small number of cases that have been studied anatomically and by CT scanning and MRI indicate that prosopagnosia is most often associated with bilateral lesions of the ventromedial occipitotemporal regions

(Damasio et al) including the inferior occipital or midfusiform gyri, but there are exceptions that are attributable to unilateral damage, almost always on the right side. The notion that there is a "face area" in the fusiform gyrus is expressed uncritically in the literature and seems to be an oversimplification.

A variant of this disorder is characterized by specific difficulty with facial matching or discrimination from partial cues, such as portions of the face or a profile. The distinction between this deficit and the usual type of prosopagnosia rests on the use of tests that do not require memory of a specific face. This difficulty with facial matching and discrimination is more likely to be seen with lesions of the right than of the left posterior hemisphere.

Closely allied and often associated with prosopagnosia is a subtle syndrome of loss of environmental familiarity, in which the patient is unable to recognize familiar places. The patient may be able to describe a familiar environment from memory and locate it on a map, but he experiences no sense of familiarity and gets lost when faced with the actual landscape. In essence, this is an *environmental agnosia*. This syndrome is associated with right-sided, medial temporooccipital lesions, although in some patients, as in those with prosopagnosia, the lesions are bilateral (Landis et al).

Environmental agnosia can be distinguished from the visual disorientation and disorder of spatial (topographic) localization discussed earlier. Patients with the latter disorder are unable to orient themselves in an abstract spatial setting (*topographagnosia*, or loss of topographic memory). They cannot draw the floor plan of their house or a map of their town or the United States and cannot describe a familiar route, as from their home to their place of work, or find their way in familiar surroundings.

Visual agnosia for words (alexia without agraphia) See Chap. 23 and further on in this chapter in the discussion of alexia without agraphia, under the "Disconnection Syndromes."

Color agnosia Here one must distinguish several different aspects of identification of colors, such as the correct perception of color (the loss of which is called *color blindness*) or the naming of a color. The common form of retinal color blindness is congenital and is readily tested by the use of Ishihara plates. Acquired color blindness caused by a cerebral lesion, with retention of form vision, is referred to as *central achromatopsia*. Here the disturbance is one of hue discrimination; the patient cannot sort a series of colored wools according to hue (Holmgren test) and may complain that colors have lost their brightness or that everything looks gray. Achromatopsia is frequently associated with visual field defects and with prosopagnosia. Most often, the field defects are bilateral and tend to affect the upper quadrants. However, full-field achromatopsia may exist with retention of visual acuity and form vision. There may also be a hemi- or quadrant-achromatopsia without other abnormalities, although special testing is required to reveal this defect. These features, together with the usually associated prosopagnosia, point to involvement of the inferomedial,

occipital, and temporal lobe(s) and the lower part of the striate cortex or optic radiation (Damasio et al, 1974a). The existence of a central achromatopsia is not surprising in view of the animal studies of Hubel, which identified sets of cells in areas 17 and 18 that are activated only by color stimuli.

A second group of patients with color agnosia have no difficulty with color perception (i.e., they can match seen colors), but they cannot reliably name them or point out colors in response to their names. They have a *color anomia*, of which there are at least two varieties. One is typically associated with pure word blindness, i.e., alexia without agraphia, and is best explained by a disconnection of the primary visual areas from the language areas (see further on). In the second variety, the patient fails not only in tasks that require the matching of a seen color with its spoken name but also in purely verbal tasks pertaining to color naming, such as naming the colors of common objects (e.g., grass, banana). This latter disorder is probably best regarded as a form of anomic aphasia, in which the aphasia is more or less restricted to the naming of colors (Meadows, 1974b). According to Damasio and associates, the lesion has involved the medial part of the left hemisphere at the junction of the occipital and temporal lobes, just below the splenium of the corpus callosum. All their patients also had a right homonymous hemianopia as a result of destruction of the left lateral geniculate body, optic radiation, or calcarine cortex.

Visual simultanagnosia This describes an inability to grasp the sense of the multiple components of a total visual scene despite retained ability to identify individual details. Wolpert pointed out that there was an inability to read all but the shortest words, spelled out letter by letter, and a failure to perceive simultaneously all the elements of a scene and to properly interpret the scene, which Wolpert called *simultanagnosia*. A cognitive defect of synthesis of the visual impressions was thought to be the basis of this condition. Some patients with this disorder have a right homonymous hemianopia; in others, the visual fields are full but there is one-sided extinction when tested with double simultaneous stimulation. This is an integral part of the Balint syndrome described below.

Through tachistoscopic testing, Kinsbourne and Warrington (1963) found that reducing the time of stimulus exposure permits single objects to be perceived, but not two objects. Rizzo and Robin proposed that the primary defect is in sustained attention to incoming visuospatial information. There is consistent localization. Nielsen has described it with a lesion of the inferolateral part of the dominant occipital lobe (area 18). In a patient who presented with an isolated "spelling dyslexia" and simultanagnosia, Kinsbourne and Warrington (1962) found the lesion to be localized within the inferior part of the left occipital lobe. In other instances, the lesions have been bilateral in the superior parts of the occipital association cortices.

Balint syndrome (See also Chap. 13.) In this not uncommon syndrome, the appreciation of a coherent and detailed visual world is disrupted and the patient

perceives only disconnected individual parts of the scene, as in the visual simultanagnosia described earlier. While it is due to lesions that span the occipital and parietal lobes, it is presented here for ease of exposition. Balint, a Hungarian neurologist, was the first to recognize this constellation. The defect is noted when the patient describes a complex scene in a disjointed way, single objects being pointed out, others missed entirely, the relationships and context of parts of the picture remaining unappreciated. The entire syndrome consists of (1) a disorder of visual attention mainly to the periphery of the visual field, in which the totality of a scene is not perceived despite preservation of vision for individual elements (visual simultanagnosia as discussed earlier); (2) difficulty in grasping or touching an object under visual guidance, as though hand and eye were not coordinated (called by Balint *optic ataxia*); and (3) an inability to project gaze voluntarily into the peripheral field and to scan it despite the fact that eye movements are full (termed psychic paralysis of fixation of gaze by Balint, incorrectly called *optic apraxia*).

An essential feature of the Balint syndrome appears to be a failure to properly direct oculomotor function in the exploration of space. This psychic paralysis of gaze is apparent when the patient is unable to turn his eyes to fixate an object in the right or left visual field or to consistently follow a moving object. The pattern in which the patient scans a picture is haphazard and fails to encompass entire areas. Normal individuals accomplish visual scanning in a fairly uniform manner beginning paracentrally and moving clockwise, then to the corners. Thus, the mechanism of simultanagnosia may be in part the result of this abnormality of eye movements as pointed out by Tyler.

Optic ataxia is detected when the patient reaches for an object, either spontaneously or in response to verbal command. To reach the object, the patient engages in a tactile search with the palm and fingers, presumably using somatosensory cues to compensate for a lack of visual information. The disorder may involve one or both hands and give the erroneous impression that the patient is blind. In contrast, movements that do not require visual guidance, such as those directed to the body or movements of the body itself, are performed naturally. The presence of visual inattention is tested by asking the patient to carry out tasks such as looking at a series of objects or connecting a series of dots by lines; often only one of a series of objects can be found, even though the visual fields seem to be full.

In almost all reported cases of the Balint syndrome, the lesions have been bilateral, mainly in the vascular border zones (areas 19 and 7) of the parietooccipital regions, although instances of optic ataxia alone have been described within a single visual field contralateral to a right or left parietooccipital lesion, and visual simultanagnosia, as noted earlier, has had variable localization. The neuropsychologic aspects of the syndrome and several interesting historical notes, including the attribution of original reporting to Inouye, can be found in the review by Rizzo and Vecera.

The effects of disease of the occipital lobes may be summarized as follows:

- I. Effects of unilateral disease, either right or left
 - A. Contralateral (congruent) homonymous hemianopia, which may be central (splitting the macula) or peripheral; also homonymous hemiachromatopsia
 - B. Elementary (unformed) hallucinations—usually because of irritative lesions
- II. Effects of left occipital disease
 - A. Right homonymous hemianopia
 - B. If deep white matter and splenium of corpus callosum is involved, alexia without agraphia
 - C. Visual object agnosia
- III. Effects of right occipital disease
 - A. Left homonymous hemianopia
 - B. With more extensive lesions, visual illusions (metamorphopsias) and hallucinations (more frequent with right-sided than left-sided lesions)
 - C. Loss of topographic memory and visual orientation
- IV. Bilateral occipital disease
 - A. Cortical blindness bilateral hemianopias,
 - B. Anton syndrome (visual anosognosia, denial of cortical blindness)
 - C. Loss of perception of color (achromatopsia)
 - D. Prosopagnosia (impaired face recognition, bilateral temporooccipital including fusiform gyrus)
 - E. Balint syndrome (bilateral dorsal parietooccipital) (see description in text)

DISTURBANCES OF CONNECTIONS BETWEEN THE CEREBRAL HEMISPHERES AND DISCONNECTION SYNDROMES

A line of disagreement, as old as neurology itself, pertains to the relationship between the two cerebral hemispheres. Fechner, in 1860, speculated that since the two hemispheres, joined by the corpus callosum, were virtual mirror images of one another and functioned in totality in conscious life, separating them would result in two minds. William McDougall rejected this idea and is said to have offered to have his own brain divided by Charles Sherrington should he have an incurable disease. He died of cancer, but the callosotomy was considered unnecessary, for already there were indications from the work of Sperry and colleagues that when separated, the two hemispheres had different functions.

The practice of surgical sectioning of the corpus callosum for the control of epilepsy greatly stimulated interest in the special functions of the right cerebral hemisphere when isolated from the left. It is in the sphere of visuospatial perception that right hemispherical dominance is most convincing. Lesions of the right posterior cerebral region result in an inability to utilize information about spatial relationships in making perceptual judgments and in responding to objects in a spatial framework. This is manifest in constructing

figures (constructional apraxia), in the spatial orientation of the patient in relation to the environment (topographic agnosia), in identifying faces (prosopagnosia), and in relating a scattering of visual stimuli to one another (simultanagnosia). Also, there are claims that the right hemisphere is more important than the left in visual imagery, attention, emotion (both in feeling and in the perception of emotion in others), and manual drawing (but not writing); in respect to these functions, however, the evidence is less firm. The idea that attention is a function of the right hemisphere derives from the neglect of left visual space and of somatic sensation in the anosognosic syndrome and also from the apathy that characterizes such patients. Certainly, the popular notion of the right hemisphere as “emotional” in contrast to the left one as “logical” has no basis in fact and represents a gross oversimplification of brain function and localization.

Similar issues arise, of course, in relation to handedness and language dominance in the left hemisphere as discussed in the following chapter. Here we comment only on how intriguing it is that praxis and linguistic skill are aligned on the same side of the brain, suggesting that an essential property of the dominant hemisphere is its ability to comprehend and manipulate symbolic representations of all types. At the same time, the colocalization of gnosis and visuospatial ability in the nondominant hemisphere has salience in that the two are so often interdependent in normal functioning.

Following the insightful clinical observations and anatomic studies of Wernicke, Déjerine, and Liepmann, the concept of disconnection of parts of one or both cerebral hemispheres as a cause of neurologic difficulty was introduced to neurologic thinking. In recent years, these ideas were resurrected and modernized by Geschwind (1965) and greatly extended by Sperry and by Gazzaniga. Geschwind called attention to several clinical syndromes resulting from interruption of the connections between the two cerebral hemispheres in the corpus callosum or between different parts of one hemisphere. Some of these are illustrated in Fig. 22-6.

When the entire corpus callosum is destroyed by tumor or surgical section, the language and perception areas of the left hemisphere are isolated from the right hemisphere. Patients with such lesions, if blindfolded, are unable to match an object held in one hand with that in the other. Objects placed in the right hand are named correctly, but not those in the left. Furthermore, if rapid presentation is used to avoid bilateral visual scanning, such patients cannot match an object seen in the right half of the visual field with one in the left half. They are also alexic in the left visual field, because the verbal symbols that are seen there and are projected to regions of the right hemisphere have no access to the language areas of the left hemisphere. If given a verbal command, such patients will execute it correctly with the right hand but not with the left; if asked to write from dictation with the left hand, they will produce only an illegible scrawl. Many remarkable conclusions regarding the nature of behavior and the special roles of each cerebral hemisphere have been drawn from clever observations

of patients with callosal section. Extensive discussion of these neuropsychologic abnormalities cannot be undertaken here; suffice it to say that these are not features seen in patients with the usual neurologic diseases, but they are nonetheless of interest to neurologists and are discussed in the writings of Gazzaniga.

In most lesions confined to the posterior portion of the corpus callosum (splenium), only the visual part of the disconnection syndrome occurs. Cases of occlusion of the left posterior cerebral artery provide the best examples. Because infarction of the left occipital lobe causes a right homonymous hemianopia, all visual information needed for activating the speech areas of the left hemisphere must thereafter come from the right occipital lobe. The patient with a lesion of the splenium of the corpus callosum or the adjacent white matter cannot read or name colors because the visual information cannot reach the left language areas. There is, however, no difficulty in copying words; presumably, the visual information for activating the left motor area crosses the corpus callosum more anteriorly. Spontaneous writing and writing to dictation are also intact because the language areas, including the angular gyrus, Wernicke and Broca areas, and the left motor cortex, are intact and interconnected, but after a delay, the patient is unable to read what he has previously written (unless it was memorized). This is the syndrome of *alexia without agraphia* mentioned earlier.

Surprisingly, a lesion that is limited to the anterior third of the corpus callosum (or a surgical section of this part, as in patients with intractable epilepsy) does not result in an apraxia of the left hand. A section of the entire corpus callosum does result in such an apraxia, i.e., a failure of only the left hand to obey spoken commands, the right one performing normally, indicating that the fiber systems that connect the left to the right motor areas cross in the corpus callosum posterior to the genu (but anterior to the splenium). Object naming and matching of colors without naming them are also done without error. However, when blinded, the patient cannot name a finger touched on the left hand or use it to touch a designated part of the body.

Of interest to the authors is the fact that one sometimes encounters patients with a lesion in all or some part of the corpus callosum without being able to demonstrate any aspect of the aforementioned disconnection syndromes. Notable is the observation that in some patients with a congenital agenesis of the corpus callosum (a developmental abnormality), none of the interhemispherical disconnection syndromes can be found. One must suppose that in such patients, information is transferred by another route—perhaps the anterior or posterior commissure—or that dual dominance for language and praxis was established during early development. (See a review of this subject by Lassonde and Jeeves.)

In addition to *alexia without agraphia*, the following intrahemispherical disconnections have received the most attention. They are mentioned here only briefly and are considered in more detail in the following chapter.

1. *Conduction* (also called “central”) *aphasia*. The patient has severely impaired repetition, but fluent and

paraphasic speech and writing and relatively intact comprehension of spoken and written language. The Wernicke area in the temporal lobe is putatively separated from the Broca area, presumably by a lesion in the arcuate fasciculus or external capsule or subcortical white matter. However, most often the lesion is in the supramarginal gyrus, as discussed in Chap. 23.

2. *Sympathetic apraxia in Broca's aphasia*. By destroying the origin of the fibers that connect the left and right motor association cortices, a lesion in the more anterior parts of the corpus callosum or the subcortical white matter underlying Broca area and contiguous frontal cortex causes an apraxia of commanded movements of the left hand (see Chap. 3 and earlier discussion).
3. *Pure word deafness*. Although the patient is able to hear and identify nonverbal sounds, there is loss of ability to discriminate speech sounds, i.e., to comprehend spoken language. The patient's speech may be paraphasic, presumably because of the inability to monitor his own speech. This defect has been attributed to a subcortical lesion of the left temporal lobe, spanning the Wernicke area and interrupting also those auditory fibers that cross in the corpus callosum from the opposite side. Thus, there is a failure to activate the left auditory language area (Wernicke area). Bilateral lesions of the auditory cortex have the same effect (see Chap. 23).
4. Furthermore, all of the syndromes that span the occipital and either parietal or temporal lobes are, in effect intrahemispherical disconnections in the stream of visual information as discussed earlier.

SPECIAL NEUROPSYCHOLOGIC TESTS

In the study of focal cerebral disease, there are two complementary approaches: the clinical-neurologic and the neuropsychologic. The first consists of the observation and recording of qualitative changes in behavior and performance and the identification of syndromes from which one may deduce the locus and nature of certain diseases. The second consists of recording a patient's performance on a variety of psychologic tests that have been standardized in a large population of age-matched normal individuals. These tests provide data that can be graded and treated statistically. An example is the *deterioration index*, deduced from the difference in performance on subtest items of the Wechsler Adult Intelligence Scale that hold up well in cerebral diseases (vocabulary, information, picture completion, and object assembly) and those that undergo impairment (digit span, similarities, digit symbol, and block design). A criticism of this index and others is the implicit assumption that cerebrocortical activity is a unitary function. However, it cannot be denied that certain psychometric scales reveal disease in certain parts of the cerebrum more than in others. These tests allow comparison of the patient's deficits from one point in the course of an illness to another. Walsh has listed the ones that he finds most valuable. In addition to the Wechsler

Adult Intelligence Scale, Wechsler Memory Scale, and an aphasia screening test, he recommends the following for quantifying particular psychological abilities and skills:

- I. *Frontal lobe disorders*
 - A. Milan Sorting Test, Halstead Category Test, and Wisconsin Card-Sorting Test as tests of ability to abstract and shift paradigms
 - B. The Porteus Maze Test, Reitan Trail-Making Test, and the recognition of figures in the Figure of Rey as tests of planning, regulating, and checking programs of action
 - C. Benton's Verbal Fluency Test for estimating verbal skill and verbal regulation of behavior
- II. *Temporal lobe disorders*
 - A. Figure of Rey, Benton Visual Retention Test, Illinois Nonverbal Sequential Memory Test, Recurring Nonsense Figures of Kimura, and Facial Recognition Test as modality-specific memory tests
 - B. Milner's Maze Learning Task and Lhermitte-Signoret amnesic syndrome tests for general retentive memory
 - C. Seashore Rhythm Test, Speech-Sound Perception Test from the Halstead-Reitan battery,

Environmental Sounds Test, and Austin Meaningless Sounds Test as measures of auditory perception

III. *Parietal lobe disorders*

- A. Figure of Rey, Wechsler Block Design and Object Assembly, Benton Figure Copying Test, Halstead-Reitan Tactual Performance Test, and Fairfield Block Substitution Test as tests of constructional praxis
- B. Several mathematical and logicogrammatical tests as tests of spatial synthesis
- C. Crossmodal association tests as tests of suprasensory integration
- D. Benson-Barton Stick Test, Cattell's Pool Reflection Test, and Money's Road Map Test, as tests of spatial perception and memory

IV. *Occipital lobe disorders*

- A. Color naming, color form association, and visual memory, as tests of visual perception; recognition of faces of prominent people, map drawing

It is the authors' opinion that the data obtained from the above tests should be used to supplement clinical observations. Taken alone, they cannot be depended upon for the localization of cerebral lesions.

Disorders of Speech and Language

Speech and language functions are of fundamental human significance, both in social interaction and in private intellectual life. When they are disturbed as a consequence of brain disease, the functional loss exceeds in many ways all others in gravity—even blindness, deafness, and paralysis. The neurologist is concerned with all derangements of speech and language, including those of reading and writing because they are almost invariably manifestations of disease of the brain.

Viewed broadly, language is the means of symbolic representation of objects, actions, and events and, therefore, the mirror of all higher mental activity. The internal manipulation of these symbols constitutes thinking and their retention is the substance of memory. In a narrower context, language is the means whereby patients communicate their complaints and problems to the physician and at the same time, the medium for all delicate interpersonal transactions. Consequently, any disease process that interferes with speech or the understanding of spoken words touches the very core of the physician–patient relationship. Finally, the study of language disorders and the development of language (taken up in Chap. 28) serve to illuminate the relationship between psychological functions and the anatomy and physiology of the brain.

GENERAL CONSIDERATIONS

It has been remarked that as human beings, we owe our commanding position in the animal world to two faculties: First, the ability to develop and employ verbal symbols as a background for our own ideation and as a means of transmitting thoughts, by spoken and written word, and second, the remarkable facility in the use of our hands. One curious and provocative fact is that both language and manual dexterity (as well as praxis) have evolved in relation to particular aggregates of neurons and pathways in one cerebral hemisphere (the dominant one). This is a departure from most other localized neurophysiologic activities, which are organized according to a contralateral or bilateral and symmetrical plan. The dominance of one hemisphere, usually the left, emerges in brain development together with speech and the preference for the right hand, especially its use for writing. It follows that a lack of development or loss of cerebral

dominance as a result of disease deranges both these traits, causing aphasia and apraxia.

There is abundant evidence that higher animals are able to communicate with one another by vocalization and gesture. However, the content of their communication is their feeling or reaction of the moment. This emotional language, as it is called, was studied by Charles Darwin, who noted that it undergoes increasing differentiation in the animal kingdom. Only in the chimpanzee do the first semblances of propositional language become recognizable. Indeed, there are distinct differences between the human and chimp versions of a gene called *FOXP2*, which has been linked to the ability to produce language, as noted in Chap. 28 (also see Balter). Another genetic influence on language has been found by Somerville and colleagues, who studied the locus implicated by a deletion in Williams syndrome and found that a duplication at this site caused a severe delay in the acquisition of expressive speech (see Chap. 38 for a discussion of the skills that are affected in Williams syndrome).

Instinctive patterns of emotional expression are, of course, also observed in human beings. They are the earliest modes of expression to appear (in infancy) and may have been the original forms of speech in primitive human beings. Moreover, the utterances we use to express joy, anger, and fear are retained even after destruction of all the language areas in the dominant cerebral hemisphere. The neural arrangement for this paralinguistic form of communication (intonation, exclamations, facial expressions, eye movements, body gestures), which subserves emotional expression, is bilateral and symmetrical and does not depend solely on the cerebrum. The experiments of Cannon and Bard demonstrated that emotional expression is possible in animals even after removal of both cerebral hemispheres provided that the diencephalon, particularly its hypothalamic part, remains intact. In the human infant, emotional expression is well developed at a time when much of the cerebrum is still immature.

Propositional, or symbolic language differs from emotional language in several ways. Instead of communicating feelings, it is the means of transferring ideas from one person to another, and it requires the substitution of a series of sounds or marks for objects, persons, and concepts. This is the essence of language.

It is not instinctive but learned and is therefore subject to all the modifying social and cultural influences of the environment. However, the learning process becomes possible only after the nervous system has attained a certain degree of maturation. Mature language function involves the comprehension, formulation, and transmission of ideas and feelings by the use of conventionalized verbal symbols, sounds, and gestures and their sequential ordering according to accepted rules of grammar. Facility in symbolic language, which is acquired over a period of 15 to 20 years, depends on maturation of the nervous system and on education. Many attempts have been made to crystallize the essential difference between human language and that of the higher primates that are able to communicate. Such distinctions, of course, bear on the definitions of language-dependent function, such as thinking, analysis, synthesis, and creativity. Beyond simply the complexity and range of symbolic representation and grammar available to humans in comparison to animals, Chomsky has proposed that the ability to frame recursive ideas (ones that refer to themselves by embedded phrases, such as: "John's sister's house") underlies creativity in human language and an infinite variety of sentences. This has been challenged but is an interesting concept.

Although speech and language are closely interwoven functions, they are not synonymous. Language refers to the production and comprehension of words whereas speech refers to the articulatory and phonetic aspects of verbal expression. A derangement of language function is always a reflection of an abnormality of the brain and, more specifically of the dominant cerebral hemisphere. A disorder of speech may have a similar origin, but not necessarily; it may be a result of abnormalities in different parts of the brain or to extracerebral mechanisms.

The profound importance of language may not be fully appreciated unless one reflects on the proportion of our time devoted to purely verbal pursuits. *External speech*, or *exophasia*, by which is meant the expression of thought by spoken or written words and the comprehension of the spoken or written words of others, is an almost continuous activity when human beings gather together. This contrasts with *inner speech*, or *endophasia*, i.e., the silent processes of thought and the formulation in our minds of unuttered words on which thought depends. The latter is almost incessant during our preoccupations, as we think always with words. Thought and language are thus inseparable. In learning to think, the child talks aloud to himself and only later learns to suppress the vocalization. Even adults may mutter subconsciously when pondering a difficult proposition. As Gardiner has remarked, any abstract thought can be held in mind only by the words or mathematic symbols denoting it. It is virtually impossible to comprehend what is meant by the word *religion*, for example, without the controlling and limiting consciousness of the word itself. "Words have thus become an integral part of the mechanism of our thinking and remain for ourselves and for others the guardians of our thoughts" (quoted from Brain). This is the reasoning that persuaded Head, Wilson, Goldstein, and others that any comprehensive theory of language

must include explanations in terms not only of cerebral anatomy and physiology but also of the psycholinguistic processes that are involved.

Disorders of speech and language may be broadly characterized under four headings;

1. Loss or impairment of the production or comprehension of spoken or written language because of an acquired lesion of the brain. This is the condition called *aphasia* or *dysphasia*.
2. Disturbances of speech and language with diseases that globally affect higher-order mental function, i.e., confusion, delirium, mental retardation, and dementia. Speech and language functions are seldom lost in these conditions but are deranged as part of a general impairment of perceptual and intellectual functions (Chap. 21). Common to this category are certain special disorders of speech, such as mutism as outlined by Geschwind in his article on the "non-aphasic disorders of speech" (1964) and extreme perseveration (*palilalia* and *echolalia*), in which the patient repeats, parrot-like, sounds, words, and phrases (see further on). The odd constructs of language and other disorders of verbal communication of schizophrenics and some autistic individuals, extending to the production of meaningless phrases, neologisms, or jargon, are probably best included in this category as well but they derive from a disorder of thought.
3. A defect in articulation with intact mental functions, and comprehension of spoken and written language and normal syntax (grammatical construction of sentences). This is a pure motor disorder of the muscles of articulation and may be a result of flaccid or spastic paralysis, rigidity, repetitive spasms (stuttering), or ataxia. The terms *dysarthria* and *anarthria* are applied to this category of speech disorder.
4. An alteration or loss of voice because of a disorder of the larynx or its innervation—*aphonia* or *dysphonia*. Articulation and language are unaffected.

Chapter 28 fully considers the important but separable category of developmental disorders of speech and language.

ANATOMY OF THE LANGUAGE FUNCTIONS

The conventional teaching, based on correlations between various disorders of language and damage to particular areas of the brain, postulates four main language areas, situated in most persons in the left cerebral hemisphere (Fig. 23-1). The entire language zone that encompasses these areas is *perisylvian*, i.e., it borders the sylvian fissure. Two language areas are receptive and two are executive, i.e., the latter are concerned with the production (output) of language. The main receptive area, subserving the perception of spoken and probably of internal language, occupies the posterosuperior temporal area (the posterior portion of area 22) and Heschl gyri (areas 41 and 42). The posterior part of area 22 in the planum temporale is referred to as *Wernicke area*. A second receptive

Figure 23-1. Diagram of the brain showing the classic language areas, numbered according to the scheme of Brodmann. The elaboration of speech and language probably depends on a much larger area of cerebrum, indicated roughly by all the shaded zones (see text). Note that areas 41 and 42, the primary auditory receptive areas, are shown on the lateral surface of the temporal lobe but extend to its superior surface, deep within the sylvian fissure.

area occupies the angular gyrus (area 39) in the inferior parietal lobule, anterior to the visual receptive areas. The supramarginal gyrus, which lies between these auditory and visual language “centers,” and the inferior temporal region, just anterior to the visual association cortex, are probably part of the language apparatus as well. Here are located the integrative centers for cross-modal visual and auditory language functions.

The main executive, or output, region, situated at the posterior end of the inferior frontal convolution (Brodmann areas 44 and 45), is referred to as *Broca area* and is concerned with motor aspects of speech. In some models of language, visually perceived words are given expression in writing through a fourth language area, the so-called Exner writing area in the posterior part of the second frontal convolution. However, this latter concept is controversial in view of the fact that widely separated parts of the language zone may cause a disproportionate disorder of writing. In any case, there are two parallel systems for understanding the spoken word and producing speech and for the understanding of the written word and producing writing. They develop separately but are the integral components of the semantic system.

These sensory and motor language areas are intricately connected with one another by a rich network of nerve fibers, one large bundle of which, the arcuate fasciculus, passes through the isthmus of the temporal lobe and around the posterior end of the sylvian fissure; other connections may traverse the external capsule of the lenticular nucleus (subcortical white matter of the insula). Many additional corticocortical connections lead into the perisylvian zones and project from them to other parts of the brain. Of special importance for the production of speech are the short association fibers that join the

Broca area with the lower rolandic cortex, which, in turn, innervates the muscles of the lips, tongue, pharynx, and larynx. The perisylvian language areas are also connected with the striatum and thalamus and with corresponding areas in the nondominant cerebral hemisphere through the corpus callosum and anterior commissure (see Fig. 22-6).

Having indicated the main regions involved with language, there remains considerable difference of opinion concerning the status of cortical language areas, and objection has been made to calling them “centers,” for they do not represent histologically or circumscribed structures of constant function. Moreover, a neuroanatomist would not be able to distinguish the cortical language areas microscopically from the cerebral cortex that surrounds them.

Knowledge of the anatomy of language has come almost exclusively from the postmortem study of humans with focal brain diseases. Two major theories have emerged from these studies. One has subdivided the language zone into separate afferent (auditory and visual) receptive parts, connected by identifiable tracts to the executive (efferent–expressive) centers. Depending on the exact location of the lesions, a number of special syndromes are elicited. The other broad theory, advanced originally by Marie (he later claims to have changed his mind) and supported by Head, Wilson, Brain, and Goldstein, favored the idea of a single language mechanism, roughly localized in the opercular, or perisylvian region of the dominant cerebral hemisphere. The aphasia in any particular case was presumed to be a result of the summation of damage to input or output modalities relative to this central language zone. Undeniably, there is recognizable afferent and efferent localization within the perisylvian language area, as discussed above, but there is also an undifferentiated central integrative mass action, in which the degree of deficit is to a considerable extent influenced by the size of the lesion. In addition, a strict division of aphasias into expressive and receptive, while still a strong practical concept, is not fully borne out by clinical observation. Nevertheless, there are several localizable language functions in the perisylvian cortex.

Carl Wernicke more than any other person must be credited with the anatomic–psychologic scheme upon which many contemporary ideas of aphasia rest. Earlier, Paul Broca (1865), and, even before him, Dax (1836), made the fundamental observations that a lesion of the insula and the overlying operculum deprived a person of speech and such lesions were always in the left hemisphere. Wernicke’s thesis was that there were two major anatomic loci for language: (1) an anterior locus, in the posterior part of the inferior frontal lobe (Broca’s area), in which were contained the “memory images” of speech movements, and (2) the insular region and adjoining parts of the posterior perisylvian cortex, in which were contained the images of sounds. (Meynert had already shown that aphasia could occur with lesions in the temporal lobe, the Broca area being intact.) Wernicke believed that the fibers between these regions ran in the insula and mediated the reflex arc between the heard

and spoken word. Later, Wernicke came to accept von Monakow's view that the connecting fibers ran around the posterior end of the sylvian fissure, in the arcuate fasciculus. Wernicke gave a comprehensive description of the receptive, or sensory, aphasia that now bears his name. The four main features he pointed out were (1) a disturbance of comprehension of spoken language and (2) of written language (alexia), (3) agraphia, and (4) fluent paraphasic speech. In Broca's aphasia, by contrast, comprehension was intact, but the patient was mute or employed only a few simple words. Wernicke also theorized that a lesion interrupting the connecting fibers between the two cortical speech areas would leave the patient's comprehension undisturbed but would prevent the intact sound images from exerting an influence on the choice of words. Wernicke proposed that this variety of aphasia be called *Leitungsaphasie*, or *conduction aphasia* (called *central aphasia* by Kurt Goldstein and *deep aphasia* by Martin and Saffran). Careful case analyses since the time of Broca and Wernicke have borne out these associations between a receptive (Wernicke) type of aphasia and lesions in the posterior perisylvian region and between a predominantly (Broca) motor aphasia and lesions in the posterior part of the inferior frontal lobe and the adjacent, insular, and opercular regions of the frontal cortex. We have certainly encountered cases that conform to the Wernicke model of conduction aphasia; the lesion in these cases may lie in the parietal operculum, involving the white matter deep to the supramarginal gyrus, where it presumably interrupts the arcuate fasciculus and posterior insular subcortex (the issue of conduction aphasia is discussed further on).

How these regions of the brain are organized into separable but interactive modules, resulting in the complex behavior of which we make daily use in interpersonal communication, is still being studied by linguists and cognitive neuropsychologists. They have dissected language into its most basic elements—phonemes (the smallest units of sound recognizable as language), morphemes (the smallest meaningful units of a word), graphemes, lexical and semantic elements (words and their meanings), and syntax (sentence structure). In general, as a restatement of the Wernicke-Broca scheme, *phonologic speech output difficulties are derived from left frontal lesions; semantic-comprehension difficulties are the result of left temporal lesions; and alexia and agraphia are associated with inferior parietal lesions*. These "modules" of language have been diagrammed by psycholinguists as a series of boxes and are connected to one another by arrows to indicate the flow of information and the manner in which they influence the spoken output of language. "Boxologies," as they are called, are consistent with current cognitive theory, which views language functions as the result of synchronized activity in vast neuronal networks made up of many cerebrocortical regions and their interconnecting pathways (Damasio and Damasio, 1989).

On the other hand, despite this level of theoretical sophistication, attempts to delineate the anatomy of speech and language disorders by means of conventional brain imaging techniques in aphasic patients have

been somewhat disappointing. In early studies using CT, LeCours and Lhermitte were unable to establish a consistent correspondence between the type of aphasia and the location of the demonstrable lesion. Similarly, Willmes and Poeck, in a retrospective study of 221 aphasic patients, failed to find an unequivocal association between the type of aphasia and the CT localization of the lesion. These poor correlations are in part related to the timing and the crudity of the CT scan. MRI scans performed soon after a stroke show somewhat more consistent correlations between the type of language disturbance and the location of lesions in the perisylvian cortex, but lesions in identical locations may produce functionally different language disorders. Functional magnetic resonance imaging (fMRI), while subjects are engaged in language production and comprehension, provides an additional perspective for understanding the language process, but so far only the broadest rules of localization can be confirmed. Studies of blood flow and topographic physiology during the acts of reading and speaking, while generally affirming nineteenth-century models of language, have shown widespread activation of Wernicke and Broca areas, as well as of the supplementary motor area and areas of the opposite hemisphere (see Price).

Although localization of the lesion that produces aphasia is in most instances roughly predictable from the clinical deficit, there are wide variations. The inconsistency has several explanations, one being that the net effect of any lesion depends not only on its locus and extent but also on the degree of cerebral dominance, i.e., on the degree to which the nondominant hemisphere assumes language function after damage to the dominant one. According to this view, a left-sided lesion has less effect on language function if cerebral dominance is poorly established than if dominance is strong. In all likelihood, the variability between patients in lesion location and the characteristics of aphasia has to do with subtle differences in the organization of the language cortices. Another explanation invokes the poorly understood concept that individuals differ in the ways in which they acquire language as children. This is believed to play a role in making available alternative means for accomplishing language tasks when the method initially learned has been impaired through brain disease. The extent to which improvement of aphasia represents "recovery" of function or generation of new modes of response has not been settled.

CEREBRAL DOMINANCE AND ITS RELATION TO LANGUAGE AND HANDEDNESS

The functional supremacy of one cerebral hemisphere is fundamental to language function. There are many ways of determining that the left side of the brain is dominant: (1) by the loss of speech that occurs with disease in parts of the left hemisphere and its preservation with lesions involving corresponding parts of the right hemisphere;

(2) by preference for and greater facility in the use of the right hand, foot, and eye; (3) by the arrest of speech with a focal seizure or with electrical or magnetic stimulation of the anterior (left) language area; (4) by the injection of sodium amytal or an equivalent drug into the left internal carotid artery (the Wada test—a procedure that produces mutism for a minute or two, followed by misnaming, including perseveration and substitution; misreading; and paraphasic speech); (5) by dichotic listening, in which different words or phonemes are presented simultaneously to the two ears (yielding a right ear–left hemisphere advantage); (6) by observing increases in cerebral blood flow during language processing; and (7) by lateralization of speech and language functions following commissurotomy.

Language hemisphere dominance is ostensibly related to hand dominance, but this is more of a supposition than a statement. Approximately 90 to 95 percent of the general population is right-handed; i.e., they innately choose the right hand for intricate, complex acts and are more skillful with it. The preference is more complete in some persons than in others. Most individuals are neither completely right-handed nor completely left-handed but strongly favor one hand for more complicated tasks. The reason for hand preference is not fully understood. There is strong evidence of a hereditary factor but the mode of inheritance is uncertain. Learning is also a factor; many left-handed children are shifted at an early age to right (shifted sinistrals) because it had been a perceived handicap to be left-handed in a right-handed world. Most right-handed persons, when obliged to use only one eye (looking through a keyhole, gun sight, telescope, etc.), sight with the right eye, and it has been stated that eye preference coincides with hand preference. Even if true, this still does not account for hemispheric dominance. It is, however, noteworthy that handedness develops simultaneously with language. The most that can be said at present is that localization of language and a preference for one eye, hand, and foot, as well as praxis, are all manifestations of some fundamental, partly inherited tendency for hemispheric specialization.

There are slight but definite anatomic differences between the dominant and the nondominant cerebral hemispheres. Yakovlev and Rakic, in a study of infant brains, observed that the corticospinal tract coming from the left cerebral hemisphere contains more fibers and decussates higher than the tract from the right hemisphere. More pertinent to language, the *planum temporale*, the region on the superior surface of the temporal lobe posterior to Heschl gyri and extending to the posterior end of the sylvian fissure, is slightly larger on the left in 65 percent of brains and larger on the right in only 11 percent (Geschwind and Levitsky). LeMay and Culebras noted in cerebral angiograms that the left sylvian fissure is longer and more horizontal than the right and that there is a greater mass of cerebral tissue in the area of the left temporoparietal junction. CT scanning has shown the right occipital horn to be smaller than the left, indicative perhaps of a greater right-sided development of visuospatial connections. Also, subtle cytoarchitectonic

asymmetries of the auditory cortex and posterior thalamus have been described; these and other biologic aspects of cerebral dominance have been reviewed by Geschwind and Galaburda particularly as they relate to developmental dyslexia (Chap. 28).

Left-handedness may result from disease of the left cerebral hemisphere in early life; this probably accounts for its higher incidence among the mentally retarded and brain injured. Presumably, the neural mechanisms for language then come to be represented during early development in the right cerebral hemisphere. Handedness and cerebral dominance may fail to develop in some individuals; this is particularly true in certain families. In these individuals, defects in reading as well as the faults of stuttering, mirror writing, and general clumsiness are frequent. In right-handed individuals, aphasia is almost invariably related to a left cerebral lesion; aphasia in such individuals as a result of purely right cerebral lesions ("crossed aphasia") is very rare, occurring in only 1 percent of cases (Joanette et al). Cerebral language dominance in ambidextrous and left-handed persons is not nearly so uniform. In a large series of left-handed patients with acquired aphasia, 60 percent had lesions confined to the left cerebral hemisphere (Goodglass and Quadfasel). Furthermore, in the relatively rare case of aphasia caused by a right cerebral lesion, the patient is nearly always left-handed and the language disorder is less severe and less enduring than in right-handed patients with comparable lesions in the left hemisphere (Gloning; Subirana). Taken together, these findings suggest a bilateral—albeit unequal—representation of language functions in non–right-handed patients. This has been affirmed by the Wada test; Milner and colleagues found evidence of bilateral speech representation in 32 (about 15 percent) of 212 consecutive left-handed patients.

The undoubted language capacities of the nondominant hemisphere have been documented by lesional neurology. In cases of congenital absence (or surgical section) of the corpus callosum, which permits the testing of each hemisphere, there has been virtually no demonstrable language function of the right hemisphere. However, Levine and Mohr found that the nondominant hemisphere retains a limited capacity to produce oral speech after extensive damage to the dominant hemisphere; their patient recovered the ability to sing, recite, curse, and utter one- or two-word phrases, all of which were completely abolished by a subsequent right hemisphere infarction. The fact that varying amounts of language function may remain after dominant hemispherectomy in adults with glioma also suggests a definite though limited capacity of the adult nondominant hemisphere for language production. Kinsbourne's observations of the effect of sodium amytal injections into the right-hemispheric arteries of patients who are aphasic from left-sided lesions make the same point.

Despite its minimal contribution to the purely linguistic or propositional aspects of language, the right hemisphere does have a role in the implicit communication of emotion through the subtleties of propositional language. These modulative aspects of language are

subsumed under the term *prosody*, by which is meant the melody of speech, its intonation, inflection, and pauses, all of which have emotional overtones. The prosodic components of speech and the gestures that accompany them enhance the meaning of the spoken word and endow speech with its richness and vitality. The related issue of an individual's accent, which carries such a strong regional identity and is acquired early in life, may also have an anatomic basis, but one that remains obscure (see later comments on the "Foreign Accent Syndrome").

Many diseases and focal cerebral lesions mute or reduce the prosody of speech, the most dramatic examples being the hypophonic monotone of Parkinson disease and the effortful utterances of Broca's aphasia. Largely through the work of Ross, it has become apparent that prosody is also greatly disordered in patients with strokes involving portions of the nondominant hemisphere that mirror the language areas of the left hemisphere. In these cases, there is impairment both of comprehension and of production of the emotional content of speech and its accompanying gestures. A prospective study of middle cerebral artery infarctions by Darby corroborated this view: *aprosodia*, as it has come to be called, was present only in those patients with lesions in the territory of the inferior division of the right middle cerebral artery. The deficit was most prominent soon after the stroke and was not found with lacunar lesions. In our patients, using bedside tests, we have had difficulty in appreciating *aprosodia* as a result solely of right perisylvian lesions, and in most cases, the damage has been more widespread.

There has been recent interest in a role for the cerebellum in language function, based partly on observations in the Williams syndrome, in which mental retardation is associated with a preservation of language skills that is sometimes striking in degree (Chap. 38). In this disease, the cerebellum is spared in the face of greatly diminished volume of the cerebral hemispheres (see Leiner et al). Some studies of cerebral blood flow also implicate the cerebellum in various language functions; based on our clinical experience, however, we would judge any language deficits from cerebellar disease to be subtle or nonexistent. Dysarthria, of course, is common with cerebellar disease.

APPROACH TO THE PATIENT WITH LANGUAGE DISORDERS

In the investigation of aphasia, it is first necessary to inquire into the patient's native language, handedness, and previous level of literacy and education. It has been surmised that following the onset of aphasia, individuals who had been fluent in more than one language (polyglots) improved more quickly in their native language than in a subsequently acquired one (a derivative of the Ribot law of retained distant memory). This rule seems to hold if the patient is not truly fluent in the more recently acquired language or has not used it for a long time.

More often, the language most used before the onset of the aphasia will recover first (Pitres law). Usually, if adequate testing is possible, more or less the same aphasic abnormalities are found in both the first and the more recently acquired language. Dementing illnesses such as Alzheimer disease, however, do cause increasing use of the first acquired language.

Many naturally left-handed children are trained to use the right hand for writing; therefore, in determining handedness, one must ask which hand is preferred for throwing a ball, threading a needle, sewing, or using a tennis racket or hammer, and which eye is used for sighting a target with a rifle or other instrument. It is important, before beginning the examination, to determine whether the patient is alert and can participate reliably in testing, as accurate assessment of language depends on these factors.

One should quickly ascertain whether the patient has other gross signs of a cerebral lesion such as hemiplegia, facial weakness, homonymous hemianopia, or cortical sensory loss. When a constellation of these major neurologic signs is present, the aphasic disorder is usually of the total (global) type. A right brachiofacial paralysis aligns with Broca's aphasia; in contrast, a restricted right hemianopia or quadrantopia is a common accompaniment of Wernicke's aphasia, and hemiparesis is absent. Dyspraxia of limbs and speech musculature in response to spoken commands or to visual mimicry is generally associated with Broca's aphasia, but sometimes with Wernicke's aphasia. Homonymous hemianopia without motor weakness tends often to be linked to pure word blindness, to alexia with or without agraphia, and to anomic aphasia.

The bedside analysis of aphasic disorders that we find most useful entails the systematic testing of six aspects of language function: *conversational speech, comprehension, repetition, reading, writing, and naming*. Simply engaging the patient in conversation permits assessment of the motor aspects of speech (praxis and prosody), fluency, and language formulation. If the disability consists mainly of sparse, laborious, nonfluent speech, it suggests, of course, Broca's aphasia, and this possibility can be pursued further by tests of repeating from dictation and by special tests of praxis of the oropharyngeal muscles. Fluent but empty paraphasic speech with impaired comprehension is indicative of Wernicke's aphasia. Impaired comprehension but perfectly normal formulated speech and intact ability to read suggest the rare syndrome of pure word deafness.

When conversation discloses virtually no abnormalities, other tests may still be revealing. The most important of these are reading, writing, repetition, and naming. Reading aloud single letters, words, and text may disclose the dissociative syndrome of pure word blindness. Except for this syndrome and isolated mutism (aphemia; see earlier), writing is disturbed in all forms of aphasia. Literal and verbal paraphasic errors may appear in milder cases of Wernicke's aphasia as the patient reads aloud from a text or from words in the examiner's handwriting. Similar errors appear even more frequently

when the patient is asked to explain the text, read aloud, or give an explanation in writing.

Testing the patient's ability to repeat spoken language is a simple and important maneuver in the evaluation of aphasic disorders. As with other tests of aphasia, it may be necessary to increase the complexity of the test from digits and simple words to complex words, phrases, and sentences to disclose the full disability. Defective repetition occurs in all the major forms of aphasia (Broca's, Wernicke's, and global) because of lesions in the perisylvian language areas. The patient may be unable to repeat what is said to him, despite relatively adequate comprehension—the hallmark of conduction aphasia. Contrariwise, normal repetition in an aphasic patient (transcortical aphasia) indicates that the perisylvian area is largely intact. In fact, the tendency to repeat may be excessive (echolalia). Preserved repetition is also characteristic of anomic aphasia and occurs occasionally with subcortical lesions. Disorders confined to naming, other language functions (reading, writing, spelling) being adequate, are diagnostic of amnesic, or anomic, aphasia and referable usually to lower temporal lobe lesions.

These deficits can be quantified by the use of any one of several examination procedures. Those of Goodglass and Kaplan (Boston Diagnostic Aphasia Examination [BDAE]) and of Kertesz (Western Aphasia Battery [WAB]) are the most widely used in the United States. The use of these procedures will enable one to predict the type and localization of the lesion in approximately two-thirds of the patients, which is not much better than detailed bedside examination. Using these tests, aphasia of the Broca, Wernicke, conduction, global, and anomic types accounted for 392 of 444 unselected cases studied by Benson.

CLINICAL VARIETIES OF APHASIA

In analyzing disorders of speech and language in the clinic or at the bedside, the first objective is to separate *dysarthria*, or slurred speech with preservation of language, from a genuine impairment in language function, *aphasia*. Here, we offer a practical approach to aphasia. Dysarthria is addressed in a later section. To recapitulate, the features of a language disorder that are used to advantage by the examiner in determining the type of aphasia are:

- natural sounding fluency, including normal cadence, the use of prepositions, and correct grammar;
- comprehension of language;
- the proper selection, use, and relationships between words;
- naming of displayed objects;
- the ability to repeat in comparison to spontaneous speech;
- reading; and
- writing

This type of systematic examination will enable one to decide whether a patient has a predominantly:

(i) *motor* or *Broca's aphasia*, sometimes called "expressive," "anterior," or "nonfluent" aphasia; (ii) *sensory* or *Wernicke's aphasia*, referred to also as "receptive," "posterior," or "fluent" aphasia; (iii) a *total* or *global aphasia*, with loss of all or nearly all speech and language functions; (iv) *transcortical aphasia*, meaning a motor or sensory aphasia with preserved repetition; or (v) one of the *disconnection language syndromes*, such as conduction aphasia, word deafness (auditory verbal agnosia), and word blindness (visual verbal agnosia or alexia). In addition, there is a condition of mutism, or a complete absence of verbal output, but this syndrome does not permit one to predict the exact locus of the lesion. *Anomia* (also called *nominal* or *amnesic* aphasia, meaning loss of naming ability) and the impaired ability to communicate by writing (*agraphia*) are found to some degree in practically all types of aphasia. As for agraphia, it rarely exists alone. Table 23-1 summarizes these main aphasic syndromes, which are described below. Even though these descriptions are based largely on deficits from vascular occlusion, they serve well in most circumstances of focal brain disease that cause language disturbances.

Broca's Aphasia

Broca's aphasia conforms to a primary deficit in language output and speech production with relative preservation of comprehension. There is a wide range of variation in the severity of the motor speech deficit, from the mildest poverty of speech and minimal dysarthria with entirely intact comprehension and ability to write (so-called Broca area aphasia; "mini-, or baby-Broca"), to a complete loss of all means of lingual, phonetic, written, and gestural communication. Because the muscles that can no longer be used in speaking may still function in other acts, they are not paralyzed. The term *apraxia* has been imprecisely applied to this deficit in oro-buccal-lingual use (it does not represent the loss of a previously learned ability) but there are accompanying apractic deficits of the orofacial apparatus as noted below.

In the most advanced form of the syndrome, patients lose all power of speaking. Not a word can be uttered in conversation, in attempting to read aloud, or in trying to repeat words that are heard. One might suspect that in this mutism the lingual and phonatory apparatus is paralyzed, until patients are observed to have no difficulty chewing, swallowing, clearing the throat, crying or shouting, and even vocalizing without words. Occasionally, the words *yes* and *no* can be uttered, usually in the correct context. Or patients may repeat a few stereotyped utterances over and over again, as if compelled to do so, a disorder referred to as *monophasia* (Critchley), *recurring utterance* (Hughlings Jackson), *verbal stereotypy*, or verbal automatism. If speech is possible at all, certain habitual expressions, such as "hi," "fine, thank you," or "good morning," seem to be the easiest to elicit, and the words of well-known songs may be sung hesitantly, or counting by consecutive numbers may remain facile. When angered or excited, an expletive may be uttered, thus emphasizing the fundamental distinction between propositional and emotional speech. The patient recognizes

Table 23-1

THE MAIN APHASIC SYNDROMES

TYPE OF APHASIA	SPEECH	COMPREHENSION	REPETITION	ASSOCIATED SIGNS	LOCALIZATION ^a
Broca's	Nonfluent, effortful, agrammatical, paucity of output but transmits ideas	Relatively preserved	Impaired	Right arm and face weakness	Frontal suprasylvian
Wernicke's	Fluent, voluble, well articulated but lacking meaning	Greatly impaired	None	Hemi- or quadrantanopia, no paresis	Temporal, infrasylvian including angular and supramarginal gyri
Conduction	Fluent	Relatively preserved	None	Usually none	Supramarginal gyrus or insula
Global	Scant, nonfluent	Very impaired	None	Hemiplegia usual	Large perisylvian or separate frontal and temporal
Transcortical motor	Nonfluent	Good	Largely preserved	Variable	Anterior or superior to Broca's area
Transcortical sensory	Fluent	Impaired as Wernicke's	Largely preserved	Variable	Surrounding Wernicke's area
Pure word deafness	Mildly paraphasic or normal	Impaired	Impaired	None or quadrantanopia	Bilateral (or left) middle of superior temporal gyrus
Pure word blindness (and alexia without agraphia)	Normal but unable to read aloud	Normal	Normal	Right hemianopia; unable to read own writing	Calcarine and white matter or callosum (or angular gyrus)
Pure word mutism (aphemia)	Mute, but able to write	Normal	None	None	Region of Broca's area
Anomic aphasia	Isolated word-finding difficulty	Normal various sites	Normal	Variable	Deep temporal lobe

^aLesion in dominant (left) hemisphere unless noted.

his verbal ineptitude and mistakes. Repeated failures in speech cause demonstrations of exasperation.

As a result of damage to the adjacent prerolandic motor area, the arm and lower part of the face are usually weak on the right side. The tongue may early on deviate away from the lesion, i.e., to the right, and be slow and awkward in rapid movements. For a time, despite the relative preservation of auditory comprehension and the ability to read, commands to purse, smack, or lick the lips, or to blow and whistle and make other purposeful orolingual and facial movements are poorly executed, which signifies that an apraxia has extended to certain acts involving the lips, tongue, and pharynx. In these circumstances, imitation of the examiner's actions is performed better than spontaneous execution of acts on command. Self-initiated actions and spontaneous emotional expressions of the face, by contrast, may be normal or better preserved. From imaging findings in patients with this type of speech, it is apparent that the coordination of orolingual movements that are responsible for articulation takes place in the left anterior insular cortex (see Dronkers) rather than primarily in the Broca area. Positron emission tomography (PET) shows activation of the insular region as well as of the lateral premotor cortex and the anterior pallidum during repetition of single words (Wise et al).

In the milder forms of Broca's aphasia and in the recovery phase of the severe form, patients are able to speak aloud to some degree, but the normal cadence and parsing of speech is choppy or lacking. Words are uttered slowly and laboriously, and enunciated poorly. Missing is the normal inflection, intonation, phrasing of words in a series, and pacing of word utterances. The overall impression is one of a *lack of fluency*, a term that has come to be almost synonymous with aphasias that derive from damage in and around the Broca area (nonfluent aphasia). This labored, uninflected speech stands in contrast to the fluent speech of Wernicke's aphasia described later, but there are exceptions in which nonfluency extends to Wernicke's aphasia.

Language is clearly affected in a restricted way in Broca's aphasia. Speech is sparse (10 to 15 words per minute as compared with the normal 100 to 115 words per minute) and consists mainly of nouns, transitive verbs, or important adjectives; phrase length is abbreviated and many of the small words (articles, prepositions, conjunctions) are omitted, giving the speech an abbreviated, telegraphic character (so-called agrammatism). The substantive content of the patient's language permits the crude communication of ideas, sometimes despite gross expressive difficulties. Repetition of the examiner's spoken language is as abnormal as the patient's own speech.

If a patient with nonfluent Broca's aphasia has no difficulty in repetition, the condition is termed *transcortical motor aphasia* (see further on). Furthermore, a true defect in language production is evidenced by impairment in the content of written words and sentences. Should the right hand be paralyzed, the patient cannot print with the left one, and if the right hand is spared, the patient fails as miserably in writing to dictation or replying to questions in written form. Letters are malformed and words misspelled. Although writing to dictation is impossible, letters and words can still be copied. The dysgraphia usually corresponds in degree to the severity of the spoken disturbance, but there are exceptions in which one is far more affected.

The comprehension of spoken and written language, though seemingly normal under casual conditions, is usually slightly defective in the full syndrome of Broca's aphasia and will break down under stringent testing, especially when novel or complicated material is introduced. The naming of objects and particularly parts of objects may be faulty in articulation, but the proper name can be chosen from a list. These are the most variable and controversial aspects of Broca's aphasia, as in some patients with a loss of motor speech and agraphia as a result of cerebral infarction, the understanding of spoken and written language may be normal. Mohr and colleagues (1978) have pointed out that in such patients an initial mutism is usually replaced by a rapidly improving dyspraxic and effortful articulation (a "mini-Broca's aphasia," in his terms), leading to complete recovery. The lesion in such cases is restricted to a zone in and immediately around the posterior part of the inferior frontal convolution (the latter being the Broca area per se). Mohr and colleagues (1978) have stressed the distinction between this relatively mild and restricted type of motor speech disorder and the more complex syndrome that is traditionally referred to as *Broca's aphasia*.

The lesion in the major form of Broca's aphasia subsumes a much larger area than the inferior frontal gyrus and includes the subjacent white matter and even the head of the caudate nucleus and putamen (Fig. 23-2), the anterior insula, and frontoparietal operculum. (The term *operculum* refers to the cortex that borders the sylvian fissure and covers or forms a lid over the insula, or island of Reil.) In other words, the lesion in the usual form of Broca's aphasia extends well beyond the so-called Broca area (Brodmann areas 44 and 45). Furthermore, persistence of Broca's aphasia is associated with the larger type of lesion illustrated in Fig. 23-2.

It is interesting historically that in one of Broca's original patients, whose expressive language had been limited to a few verbal stereotypes for 10 years before his death, inspection of the surface of the brain (the brain was never cut, although CT scans have since been made) disclosed an extensive lesion encompassing the left insula; the frontal, central, parietal operculum and included even part of the inferior parietal lobe posterior to the sylvian fissure. Wernicke area was spared, refuting a prediction made at the time by Marie. Inexplicably, Broca attributed the aphasic disorder to the lesion of the frontal operculum alone, and ignored the rest of the

Figure 23-2. Cerebral structures concerned with language output and articulation. Broca's area; pre- and postcentral gyri; striatum. Areas 43, 44, and 45 are Brodmann cytoarchitectonic areas. A lesion in any one of the components of this output network (B, C, or S) can produce a mild and transient Broca's aphasia. Large lesions, damaging all three components, produce severe, persistent Broca's aphasia with sparse, labored, agrammatic speech but well-preserved comprehension. (Illustration courtesy of Dr. Andrew Kertesz.)

lesion, which he considered to be a later spreading effect of the stroke. Perhaps he was influenced by the prevailing opinion of the time (1861) that articulation was a function of the inferior parts of the frontal lobes. The fact that Broca's name later became attached to a discrete part of the inferior frontal cortex helped to entrench the idea that Broca's aphasia is equated with a lesion in the Broca's area. However, as pointed out earlier, a lesion confined only to this area gives rise to a relatively modest and transient motor speech disorder (Mohr et al) or to no disorder of speech at all (Goldstein).

Motor speech disorders, both severe Broca's aphasia and the more restricted and transient types, are most often a result of vascular lesions. Embolic stroke in the territory of the upper (rolandic, superior) division of the middle cerebral artery is the most frequent type and results in an abrupt onset of aphasia. Small strokes may give way to rapid improvement (hours to days); contrariwise, infarctions that extend beyond the central Broca region at times produce a more severe clinical syndrome than might be anticipated from the size of the lesion. It is these latter strokes, especially if the underlying frontal white matter is damaged, that tend to cause lasting speech difficulty. Because of the territory that is supplied by the superior branch of the middle cerebral artery, strokes that cause Broca's aphasia are usually associated with right-sided

faciobrachial paresis (face, proximal arm, and hand) as described earlier, and sometimes with a left-sided manual-brachial apraxia (sympathetic apraxia as described in Chap. 3). Atherosclerotic thrombosis, primary or metastatic tumor, subcortical hypertensive, traumatic, or anticoagulant-induced hemorrhage, and seizure, should they involve the appropriate parts of the motor language cortex, may also declare themselves by a Broca's aphasia.

A closely related syndrome, *pure word mutism (aphemia)*, causes the patient to be wordless (mute) but leaves inner speech intact and writing undisturbed. Anatomically, this is believed to be in the nature of a disconnection of the motor cortex (Broca area) for speech from lower centers and is described with the dissociative speech syndromes discussed further on in this chapter.

Wernicke's Aphasia

This syndrome comprises two main elements: (1) impairment in the comprehension of speech—basically an inability to perceive word elements, both spoken and written, and (2) a relatively fluent but paraphasic speech (further defined below). The first of these grossly affects the internal stream of conversation and its attendant manipulation of symbolic language and causes a restricted form of confusion. The defect in language is manifest further by a variable inability to repeat spoken and written words. The location of the lesion in cases of Wernicke's aphasia is the left superior lateral temporal lobe near the primary auditory cortex. The involvement of visual association areas or their separation from the primary visual cortices is a common accompaniment that is reflected in an inability to read (alexia).

In contrast to Broca's aphasia, the patient with Wernicke's aphasia usually talks volubly, gestures freely, and appears strangely unaware of his deficit. Speech is produced mostly without effort; the phrases and sentences appear to be of normal length and are properly intoned and articulated. These attributes, in the context of aphasic disturbances, are referred to as "fluency" of speech (i.e., Wernicke's is a fluent aphasia). Despite the fluency and normal prosody, the patient's speech is remarkably devoid of meaning. The patient with Wernicke's aphasia produces many nonsubstantive words, and the words themselves are often malformed or inappropriate, a disorder referred to as *paraphasia*. A phoneme (the minimal unit of sound recognizable as language) or a syllable may be substituted within a word (e.g., "The grass is greel"); this is called *literal paraphasia*. The substitution of one word for another ("The grass is blue") is termed *verbal paraphasia* or *semantic substitution* and is even more characteristic of Wernicke's aphasia. Neologisms, i.e., syllables or words that are not part of the language, may also appear ("The grass is grumps"). In its extreme, the fluent, paraphasic speech of Wernicke's aphasia may be entirely incomprehensible (gibberish or *jargon aphasia*). Fluency, however, is not an invariable feature of Wernicke's aphasia. In some patients speech may be hesitant, in which case the block tends to occur in the part of the phrase that contains the central communicative (predicative) item, such as a key noun, verb,

or descriptive phrase. The patient with such a disorder conveys the impression of constantly searching for the correct word and of having difficulty in finding it. Wernicke's aphasia may also at times begin with complete mutism.

Although the motor apparatus required for the expression of language is intact, patients with severe Wernicke's aphasia have difficulty in functioning as social organisms because they are deprived of the main means of communication. They cannot understand fully what is said to them; a few simple commands may still be executed, but there is failure to carry out complex ones. They cannot read aloud or silently with comprehension, tell others what they want or think, or write spontaneously. Written letters are often combined into meaningless words, but there may be a scattering of correct words. In trying to designate an object that is seen or felt, they cannot find the name, even though they can sometimes repeat it from dictation; nor can they write from dictation the very words that they can copy. Copying performance is notably slow and laborious and conforms to the contours of the model, including the examiner's handwriting style. All these defects are present in varying degrees of severity and the mildest form consists of mild verbal and literal paraphasias and minimal difficulty with comprehension of grammatically complex material ("mini-Wernicke"). In general, the disturbances in reading, writing, naming, and repetition parallel the severity of impairment in comprehension. There are, however, exceptions in which either reading or the understanding of spoken language is disproportionately affected. Some aphasiologists thus speak of two Wernicke syndromes.

In terms of the idealized Broca-Wernicke schema, in Wernicke's aphasia the motor language areas are no longer under control of the auditory and visual areas. The disconnection of the motor speech areas from the auditory and visual ones accounts for the impairment of repetition and the inability to read aloud. Reading may remain fluent, but with the same paraphasic errors that mar conversational language. The occurrence of dyslexia (impaired visual perception of letters and words) with lesions of the Wernicke area is ostensibly explained by the fact that most individuals learn to read by transforming the printed word into the auditory form before it can gain access to the integrative centers in the posterior perisylvian region. Only in the congenitally deaf is there thought to be a direct pathway between the visual and central integrative language centers.

Wernicke's aphasia that is caused by stroke usually improves in time, sometimes to the point where the deficits can be detected only by asking the patient to repeat unfamiliar words, to name unusual objects or parts of objects, to spell difficult words, or to write complex self-generated sentences. A more favorable prognosis attends those forms in which some of the elements, e.g., reading, are only slightly impaired from the outset.

As discussed earlier, the term *Wernicke area* has been applied to the posterior part of area 22 in the most lateral part of the planum temporale. As a rule, in Wernicke's aphasia the lesion lies in the posterior perisylvian region (comprising posterosuperior temporal, supramarginal, angular, and posterior insular gyri) and is usually a

result of embolic occlusion of the inferior (lower) division of the left middle cerebral artery. A hemorrhage confined to the subcortex of the temporoparietal region or involvement of this area by tumor, abscess, herpes encephalitis, or extension of a small putaminal or thalamic hemorrhage may have similar effects but a better prognosis. Any lesion that involves structures deep to the posterior temporal cortex, including stroke, will cause an associated right homonymous quadrant or hemianopia. Usually, there is no weakness of limbs or face for which reason the fluently aphasic patient may be misdiagnosed as psychotic or confused, especially if there is jargon aphasia. According to Kertesz and Benson, persistence of Wernicke's aphasia is related to a lesion that involves both the left supramarginal and angular gyri and therefore, elements of Gerstmann syndrome may be evident.

The posterior perisylvian region, therefore, appears to encompass a variety of language functions, and seemingly minor changes in the size and locale of the lesion are associated with important variations in the elements of Wernicke's aphasia or lead to *conduction aphasia*, *pure word blindness*, or to *pure word deafness* (see below). The interesting theoretical problem is whether all the deficits observed are indicative of a unitary language function that resides in the posterior perisylvian region or, instead, of a series of separate sensorimotor activities whose anatomic pathways happen to be crowded together in a small region of the brain. In view of the multiple ways in which language is learned and deteriorates in disease, the latter hypothesis seems more likely.

Global Aphasia

This syndrome is caused by destruction of a large part of the language zone, embracing both Broca and Wernicke areas and much of the territory between them. The cause is usually an occlusion of the proximal middle cerebral artery, but it may be the result of hemorrhage, tumor, abscess or other lesions, and transiently as a postictal effect. Almost invariably, in cases of global aphasia, there is a degree of right hemiplegia, hemianesthesia, and homonymous hemianopia.

All aspects of speech and language are affected. At most, the patient can say only a few words, usually some cliché or habitual phrase, and can imitate single sounds, or only emit a syllable, such as "ah," or cry, shout, or moan. Many are initially mute. They may understand a few words and phrases, but, because of rapid fatigue and verbal and motor perseveration—they characteristically fail to carry out a series of simple commands or to name a series of objects. They cannot read or write or repeat what is said to them. The patient may participate in common gestures of greeting, show modesty and avoidance reactions, and engage in self-help activities. With the passage of time, some degree of comprehension of language may return, and the clinical picture that is then most likely to emerge is closest to that of a severe Broca's aphasia.

Improvement frequently occurs when the underlying cause is cerebral trauma, compression from edema, ictal or postictal paralysis, or a transient metabolic derangement such as hypoglycemia or hyponatremia,

which may also worsen the aphasia of an old lesion that had involved language areas.

TRANSCORTICAL AND CONDUCTION APHASIAS

These terms refer to disorders of language that result not from lesions of the cortical language areas themselves but from an apparent interruption of association pathways joining the primary receptive (sensory, auditory, and visual) areas to the language areas. Included also in this category are aphasias from lesions that separate the more strictly receptive parts of the language mechanism itself from the purely motor ones (conduction aphasia; see below) and to lesions that isolate the perisylvian language areas, separating them from the other parts of the cerebral cortex (*transcortical aphasias*).

The anatomic basis for most of these so-called disconnection syndromes is only partly defined. The theoretical concept is an interesting one and emphasizes the importance of afferent, intercortical, and efferent connections of the language mechanisms. However, the locale of the lesion that causes loss of a language function does not localize the language function itself, a warning enunciated long ago by Hughlings Jackson. Nevertheless, the language disorders described below occur with sufficient regularity and clinical uniformity to be almost as useful as the more common types of aphasia in localization and in revealing the complexity of language functions.

Conduction Aphasia

As indicated earlier, Wernicke theorized that certain clinical symptoms would follow a lesion that effectively separated the auditory and motor language areas without directly damaging either of them. Since then a number of well-studied cases have been described that conform to his proposed model of *Leitungsaphasie* (conduction aphasia), which is the name he gave it. The characteristic feature is severely impaired repetition of spoken language; the defect applies to both single words and nonwords. The second essential feature is reduced but still relatively preserved comprehension in comparison to Wernicke's aphasia. In other respects, the features of conduction aphasia resemble those of a mild Wernicke's aphasia. They share fluency and paraphasias in self-initiated speech, in repeating what is heard, and in reading aloud; writing is also similarly impaired. Dysarthria and dysprosody are usually lacking. Speech output is normal or somewhat reduced. As mentioned, comprehension is by no means perfect, but compared with one who has Wernicke's aphasia, the patient with conduction aphasia has relatively little difficulty in understanding words that are heard or seen and is aware of his deficit.

The lesion in the few autopsied cases has been located in the cortex and subcortical white matter in the upper bank of the left sylvian fissure, usually involving the supramarginal gyrus and occasionally the most posterior part of the superior temporal region. The reason for

classifying this aphasia as a disconnection syndrome according to Damasio and Geschwind is that the Wernicke and Broca areas are spared, and the critical structure involved is the connection between them—the arcuate fasciculus. This fiber tract streams out of the temporal lobe, proceeding somewhat posteriorly, around the posterior end of the sylvian fissure; there it joins the superior longitudinal fasciculus, deep in the anteroinferior parietal region, and proceeds forward, deep to the suprasylvian operculum, to the motor association cortex, including the Broca and Exner areas (see Fig. 22-1). However, in most of the reported cases, including those described by the Damasios, the left auditory complex, insula, and supramarginal gyrus were also involved. In any case, the usual cause of conduction aphasia is an embolic occlusion of the ascending parietal or posterior temporal branch of the middle cerebral artery, but other forms of vascular disease, particularly small subcortical hemorrhage, neoplasm, or trauma in this region produce the same syndrome.

Transcortical Aphasias (Preservation of Repetition)

The identifying feature of these language disturbances is a preservation of the ability to repeat. Destruction of the vascular border zones between anterior, middle, and posterior cerebral arteries, usually as a result of prolonged hypotension, carbon monoxide poisoning, or other forms of anoxic-ischemic injury, may effectively isolate the intact motor and sensory language areas, all or in part, from the rest of the cortex of the same hemisphere. In the case reported by Assal and colleagues, for example, multiple infarcts had isolated all of the language area.

In *transcortical sensory aphasia* the patient suffers a deficit of auditory and visual word comprehension, making writing and reading impossible, in every way conforming to Wernicke's aphasia. Speech remains fluent, with marked paraphasia, anomia, and empty circumlocutions. However, unlike the deficit in Wernicke's and conduction aphasias, the ability to repeat the spoken word is preserved. This facility in repetition may be of extreme degree, taking the form of echoing, parrot-like, word, phrases, and songs that are heard (echolalia). In a series of 15 such patients, CT and isotope scans have uniformly disclosed a lesion in the posterior parietooccipital region, according to Kertesz and colleagues. In general, this disorder has a good prognosis.

Presumably, in transcortical sensory aphasia, as in Wernicke's aphasia, information cannot be transferred to the Wernicke area for conversion into word meaning. Paraphasia is thought to result from the reduced control of the motor language areas by the auditory and visual areas, though the direct connection between them, presumably the arcuate fasciculus, is preserved. Preservation of this direct connection is said to account for the ability to repeat.

In *transcortical motor aphasia*, the patient is unable to initiate conversational speech, producing only a few grunts or syllables as in Broca-type aphasia. Comprehension is relatively preserved, but *repetition is strikingly intact*, distinguishing this syndrome from pure word mutism. Transcortical motor aphasia occurs in two clinical contexts:

(1) in a mild or partially recovered Broca's aphasia in which repetition remains superior to conversational speech (repeating and reading aloud are generally easier than self-generated speech) and (2) in states of abulia and akinetic mutism with frontal lobe damage. Several cases under our observation have resulted from infarctions in the watershed zone between the anterior and middle cerebral arteries after cardiac arrest or shock.

Pure Word Deafness

This uncommon disorder, a derivative of Wernicke's aphasia originally described by Lichtheim in 1885, is characterized by an impairment of auditory comprehension and repetition and an inability to write to dictation. Self-initiated utterances are usually correctly phrased, but sometimes paraphasic; spontaneous writing and the ability to comprehend written language are preserved, thus distinguishing this disorder from Wernicke's aphasia. Patients with pure word deafness may declare that they cannot hear, but shouting does not help, sometimes to their surprise. Audiometric testing and auditory evoked potentials disclose no hearing defect, and nonverbal sounds, such as a doorbell, can be heard without difficulty. The patient is forced to depend heavily on visual cues and frequently uses them well enough to understand most of what is said. However, tests that prevent the use of visual cues readily uncover the deficit. If able to describe the auditory experience, the patient says that words sound like a jumble of noises. As in the case of visual verbal agnosia (see below), the syndrome of pure auditory verbal agnosia is not pure, particularly at its onset, and paraphasic and other elements of Wernicke's aphasia may be detected (Buchman et al). At times, this syndrome is the result of resolution of a more typical Wernicke's aphasia, and it will be recognized that word deafness is an integral feature of all instances of Wernicke's aphasia. Conceptually, it has been thought of as an exclusive injury of the auditory processing system therefore allowing relative preservation of internal language.

In most recorded autopsy studies, the lesions have been bilateral, in the middle third of the superior temporal gyri, in a position to interrupt the connections between the primary auditory cortex in the transverse gyri of Heschl and the associated areas of the superoposterior cortex of the temporal lobe. In a few cases, unilateral lesions have been localized in this part of the dominant temporal lobe (see Chap. 22). Requirements of small size and superficiality of the lesion in the cortex and subcortical white matter are best fulfilled by an embolic occlusion of a small branch of the lower division of the middle cerebral artery.

Pure Word Blindness (Alexia Without Agraphia, Visual Verbal Agnosia)

The most striking feature of this syndrome is the retained capacity to write fluently, after which the patient cannot read what has been written (*alexia without agraphia*).

In fact, reading of any material is greatly impaired. When the patient with alexia also has difficulty in auditory comprehension and in repeating spoken words, the syndrome corresponds more closely to Wernicke's aphasia. In such cases, the individual loses the ability to understand written script, and, often, to name colors, i.e., to match a seen color to its spoken name, *visual verbal color anomia*. Such a person can no longer name or point on command to words, although he is sometimes able to read letters or numbers. However, understanding spoken language, repetition of what is heard, writing spontaneously and to dictation, and conversation are all intact. The ability to copy words is impaired but is better preserved than reading, and the patient may even be able to spell a word or to identify a word by having it spelled to him or by reading one letter at a time (letter-by-letter reading). In some cases, the patient manages to read single letters but not to join them together (*asyllabia*).

Autopsies of such cases have usually demonstrated a lesion that destroys the left visual cortex and underlying white matter, particularly the geniculocalcarine tract, as well as the callosal connections of the right visual cortex with the intact language areas of the dominant hemisphere (see "Disconnection Syndromes" in Chap. 22). In the case originally described by Déjerine in 1892, the disconnection occurred in the posterior part (splenium) of the corpus callosum, wherein lie the connections between the visual association areas of the two hemispheres (see Fig. 22-6). More often, the callosal pathways are interrupted in the forceps major or in the paraventricular region (Damasio and Damasio, 1983). In either event, the patient is blind in the right half of each visual field by virtue of the left occipital lesion, and visual information reaches only the right occipital lobe; however, this information cannot be transferred, via the callosal pathways to the language area of the left hemisphere.

A rare variant of this syndrome takes the form of *alexia without agraphia and without hemianopia*. A lesion deep in the white matter of the left occipital lobe, at its junction with the parietal lobe, interrupts the projections from the intact (right) visual cortex to the language areas, but spares the geniculocalcarine pathway (Greenblatt). This lesion, coupled with one in the splenium, prevents all visual information from reaching the language areas, including the angular gyrus, and Wernicke area.

In yet other cases, the lesion is confined to the angular gyrus or the subjacent white matter. In such cases also, a right homonymous hemianopia will be absent, but the *alexia may be combined with agraphia* and other elements of the Gerstmann syndrome, i.e., right-left confusion, acalculia, and finger agnosia (see "Gerstmann Syndrome," Chap. 22). This entire constellation of symptoms is sometimes referred to as the *syndrome of the angular gyrus*. Anomic aphasia may be added (see later).

Pure Word Mutism (Aphemia)

This syndrome was mentioned in the earlier discussion on Broca's aphasia. As a result of a vascular lesion or other type of localized injury of the dominant frontal lobe, the patient loses all capacity to speak while retaining

perfectly the ability to write, to understand spoken words, to read silently with comprehension, and to repeat spoken words. Right facial and brachial paresis may be associated. From the time speech becomes audible, language may be syntactically complete, showing neither loss of vocabulary nor agrammatism; or there may be varying degrees of dysarthria (hence "cortical dysarthria"), anomia, and paraphasic substitutions, especially for consonants. The most notable feature of this type of speech disorder is its transience; within a few weeks or months, language is restored to normal. Bastian, Broca, and more recently other authors called this syndrome *aphemia*, a term that was used originally by Broca in another context to describe the severe motor aphasia that now carries his name. Probably the syndrome is closely allied to the "mini-Broca's aphasia" described earlier under "Broca's Aphasia."

The anatomic basis of pure word mutism has not been determined precisely. In a few postmortem cases, reference is made to a lesion in Broca area. Damasio and Geschwind have stated that the lesion is anterior and superior to this area. A well-studied case has been reported by LeCours and Lhermitte. Their patient uttered only a few sounds for 4 weeks, after which he recovered rapidly and completely. From the onset of the stroke, the patient showed no disturbance of comprehension of language or of writing. Autopsy disclosed an infarct that was confined to the cortex and subjacent white matter of the lowermost part of the precentral gyrus; the Broca's area, one gyrus forward, was completely spared. Other cases have involved mainly the Broca's area.

Anomic (Amnesic, Nominal) Aphasia

Some degree of word-finding difficulty is part of almost every type of language disorder, including that which occurs with the confusional states and dementia. In fact, without an element of anomia, a diagnosis of aphasia is usually incorrect. Only when this feature is the most notable aspect of language difficulty is the term *anomic aphasia* employed. In this condition, a relatively uncommon form of aphasia in pure form, the patient loses only the ability to name people and objects. There are pauses in speech, groping for words, circumlocution, and substitution of another word or phrase that is intended to convey the meaning. Perseveration may be prominent. Or the patient may simply fail to name a shown object, in contrast to the usual aphasic patient, who produces a paraphasic error. Less frequently used words give more trouble. When shown a series of common objects, the patient may tell of their use, or demonstrate the same, instead of giving their names. The difficulty applies not only to objects seen but also to the names of things heard or felt (as per Geschwind). In addition to displaying normal fluency of spontaneous speech and preserved comprehension and repetition, the patients we have seen with anomic aphasia have been surprisingly adept in spelling.

Beauvois and coworkers have described a form of bilateral tactile aphasia caused by a left parietooccipital lesion in which objects seen and verbally described could be named, but not those felt with either hand. Recall of the

names of letters, digits, and other printed verbal material is almost invariably preserved, and immediate repetition of a spoken name is intact. That the deficit is principally one of naming is shown by the patient's correct use of the object and, usually, by an ability to point to the correct object on hearing or seeing the name and to choose the correct name from a list. The patient's understanding of what is heard or read is normal.

There is a tendency for patients with anomia to attribute their failure to forgetfulness or to give some other implausible excuse for the disability, suggesting that they are not completely aware of the nature of their difficulty, but some are aware of the defect. Of course, there are many more patients who fail not only to name objects but also to recognize the correct word when it is given to them. In such patients, the understanding of what is heard or read is not normal, i.e., the naming difficulty is but one symptom of another type of aphasic disorder.

Anomic aphasia has been associated with lesions in different parts of the language area, typically in the left temporal lobe. In these cases, the lesion has been deep to the posterior temporal lobe, particularly in the left thalamus, or in the middle temporal convolution, in a location to interrupt connections between sensory language areas and the hippocampal regions concerned with learning and memory. Mass lesions, such as a tumor, herpes encephalitis, or an abscess, are the most frequent causes; as these lesions enlarge, a contralateral upper quadrantic visual field defect or a Wernicke's aphasia is added. Occasionally, anomia appears with lesions caused by occlusion of the temporal branches of the posterior cerebral artery, and it is in these instances that we have seen the most pronounced cases of anomia, usually associated with a right hemianopia and alexia but normal writing ability. Anomia may be a prominent manifestation of transcortical motor aphasia (see later) and may be associated with the Gerstmann syndrome, in which case the lesions are found in the frontal lobe and angular gyrus, respectively.

An anomic type of aphasia is often an early sign of Alzheimer and Pick disease (minor degrees of it are common in old age) and is a principal feature of one type of degenerative lobar cerebral atrophy in the category of the primary progressive aphasia (see Chap. 39). Finally, anomic aphasia may be the only residual abnormality after partial recovery from Wernicke's, conduction, transcortical sensory, or (rarely) Broca's aphasia (Benson).

Foreign Accent Syndrome

This rare and somewhat amusing condition defies classification but is worthy of comment because it may be mistaken for hysteria or psychosis. An accent that is distinctly foreign but vague in actual region of origin replaces the patient's native speech pattern. The syndrome arises after a left-sided lesion, most often a stroke with a mild associated Broca's aphasia. Although the accent may be interpreted by the listener as compatible with German, Spanish, French, Asian, or another nationality, authoritative analysis indicates that the alterations are not specific to any genuine language and are simply attributed by the

listener to a known foreign accent. The syndrome is also encountered as a transient phenomenon during recovery from stroke. The relation to disorders of prosody, which is produced by lesions of the nondominant hemisphere, is unclear. LeCours and Lhermitte made an analysis of the disorder based on the obligate use of diphthongs in certain languages; these were not properly pronounced in the foreign accent syndrome and made French listeners detect an English accent. An extensive examination of one case and references to additional ones can be found in the article by Kurowski and colleagues.

AGRAPHIA

Writing is, of course, an integral part of language function, but a less essential and universal component, for a segment of the world's population speaks but does not read or write. It might be supposed that all the rules of language derived from the study of aphasia would be applicable to agraphia. In large part, this is true. One must be able to formulate ideas in words and phrases in order to have something to write as well as to say; hence, disorders of writing, like disorders of speaking, reflect all the basic defects of language. But there is an obvious difference between these two expressive modes. In speech, only one final motor pathway coordinating the movements of lips, tongue, larynx, and respiratory muscles is available, whereas if the right hand is paralyzed, one can still write with the left one, or with a foot, and even with the mouth by holding a pencil between the teeth (a contrivance used by individuals whose arms are paralyzed by cervical root avulsion from motorcycle accidents). An accurate general statement is that written language is disordered similarly to spoken language in the Broca's and Wernicke's aphasias and in most of their derivatives. When comprehension is impaired, writing to dictation is often impossible. Paraphasias appear in the writings of aphasics much the same as they do in speech.

The writing of a word can be accomplished either by the direct lexical method of recalling its spelling or by sounding out its phonemes and transforming them into learned graphemes (motor images), i.e., the phonologic method. Some authors state that in agraphia there is a specific difficulty in transforming phonologic information, acquired through the auditory sense, into orthographic forms; others see it as a block between the visual form of phonemes, and the cursive movements of the hand (Basso et al). In support of the latter idea is the fact that reading and writing usually develop together and are long preceded by the development of speech as a means of communication.

Pure agraphia as the initial and sole disturbance of language function is a rarity, but such cases have been described as summarized by Rosati and de Bastiani. Pathologically verified cases are virtually nonexistent, but imaging sometimes discloses a lesion of the posterior perisylvian area. This is in keeping with the observation that a lesion in or near the angular gyrus will occasionally cause a disproportionate disorder of writing as part

of the Gerstmann syndrome. As mentioned earlier in the chapter, the notion of specific center for writing in the posterior part of the second frontal convolution (the "Exner writing area") has been questioned (see Leischner). However, Croisile and associates do cite cases of dysgraphia in which a lesion (in the case they reported, a hematoma) was located in the centrum semiovale beneath the motor parts of the frontal cortex and direct electrical stimulation of the cortex rostral to the primary motor hand area disturbs handwriting without affecting other language or manual tasks according to Roux and colleagues, a veritable apraxia of writing.

Quite apart from these *aphasic agraphias*, in which spelling and grammatical errors abound, there are special forms of agraphia caused by abnormalities of spatial perception and praxis. Disturbances in the perception of spatial relationships underlie *constructional agraphia*. In this circumstance, letters and words are formed clearly enough but are wrongly arranged on the page. Words may be superimposed, reversed, written diagonally or in a haphazard arrangement, or from right to left; in the form associated with right parietal lesions, only the right half of the page is used. Usually one finds other constructional difficulties as well, such as inability to copy geometric figures or to make drawings of clocks, flowers, and maps, etc. This is a common feature of developmental dyslexia.

A third group of writing disorder may be called the *apraxic agraphias*. Here, language formulation is correct and the spatial arrangements of words are respected, but the hand has lost its skill in forming letters and words. Handwriting becomes a scrawl, losing all personal character. There may be an uncertainty as to how the pen should be held and applied to paper; apraxias (ideomotor and ideational) are present in the right hander. As a rule, other learned manual skills are simultaneously disordered. Speculations as to the basic fault here are discussed in Chap. 3, under "Apraxia and Other Nonparalytic Disorders of Motor Functions," and in Chap. 22, in relation to the functions of the frontal and parietal lobes.

In addition to the neurologic forms of agraphia, described above, psychologists have defined a group of *linguistic agraphias*, subdivided into phonologic, lexical, and semantic types. These linguistic models are based on loss of the ability to write (and to spell) particular classes of words. For example, the patient may be unable to spell pronounceable nonsense words, with preserved ability to spell real words (phonologic agraphia); or there may be preserved ability to write nonsense words but not irregular words, such as *island* (lexical agraphia); patients with semantic agraphia have difficulty incorporating the proper meaning into the written word, e.g., "the moon comes out at knight." For the most part, these linguistic agraphias have no well-established cerebral localization and only tenuous associations with the classic aphasias, for which reason this subject is of greater interest to linguists and psychologists than to neurologists.

The orthographic qualities of writing deteriorate in many motor disorders such as Parkinson disease, tremors, dystonias, and spasticity, but careful inspection shows that language content is normal.

Also worth brief comment is *mirror writing*, in which script runs in the opposite direction to normal with each letter also being reversed. Some normal individuals have an unusual facility to produce mirror writing, and it has been reported in developmentally delayed left-handed children. Those few instances in which mirror writing is acquired tend to be transient and incomplete with strokes in various parts of the left hemisphere, or rarely, the right hemisphere or bifrontal lesions (see the review by Schott).

SUBCORTICAL APHASIA (THALAMIC AND STRIATOCAPSULAR APHASIAS)

A lesion of the dominant thalamus, usually vascular and involving the posterior nuclei, may cause an aphasia, the clinical features of which are not entirely uniform. Typically, there is mutism initially and comprehension is impaired. During the early phases of recovery, spontaneous speech is reduced in amount and is dysfluent; less often, speech is fluent and paraphasic to the point of jargon. Reading and writing may or may not be affected. Characteristically, the patient's ability to repeat dictated words and phrases is preserved. This configuration has been termed "mixed transcortical aphasia," a syndrome originally described in bilateral border-zone infarctions or large left-frontal lesions. It may exist in isolation or in combination with the mixed transcortical aphasia. Complete recovery in a matter of weeks is the rule unless the underlying cause is a tumor. Anomia has also been described with ventrolateral thalamic lesions (Ojemann).

Aphasia has also been described frequently with dominant striatocapsular lesions, particularly if they extend laterally into the subcortical white matter of the temporal lobe and insula. The head of the caudate, anterior limb of the internal capsule, or the anterosuperior aspect of the putamen are the structures involved in different patients. The aphasia is characterized by nonfluent, dysarthric, paraphasic speech and varying degrees of difficulty with comprehension of language, naming, and repetition. The lesion is vascular as a rule, and a right hemiparesis is usually associated with it. In general, striatocapsular aphasia recovers more slowly and less completely than thalamic aphasia.

These two subcortical aphasias, thalamic and striatocapsular, resemble but are not identical to the Wernicke and Broca types of aphasia, respectively. For further discussion, the reader is directed to the articles of Naeser and of Alexander and their colleagues.

OTHER CEREBRAL DISORDERS OF LANGUAGE

The effects on speech and language of diffuse cerebral disorders, such as delirium tremens and Alzheimer disease, were mentioned in Chaps. 20 and 21. Pathologic changes in parts of the cerebrum other than the perisylvian regions may secondarily affect language function. The lesions that occur in the border zones between

major cerebral arteries and effectively isolate perisylvian areas from other parts of the cerebrum fall into this category (transcortical aphasias, see previous pages). Other examples are the lesions in the mediorbital or superior and lateral parts of the frontal lobes, which impair all motor activity to the point of abulia or akinetic mutism. The mute patient, in contrast to the aphasic one, emits no sounds. If the patient is less severely hypokinetic, his speech tends to be laconic, with long pauses and an inability to sustain a monologue. Extensive occipital lesions will, of course, impair reading, but they also reduce the utilization of all visual and lexical stimuli. Deep cerebral lesions, by causing fluctuating states of inattention and disorientation, induce fragmentation of words and phrases and sometimes protracted, uncontrollable talking (logorrhea). The nonaphasic language disorders of the confusional states, emphasized by Geschwind, have already been mentioned.

Also common in global or multifocal cerebral diseases are defects in prosody, both expressive and receptive. These appear in numerous states that affect global cerebral function, such as Alzheimer disease as well as with lesions of the nondominant (right) perisylvian region, as noted in Chap. 22.

Severe developmental delay often results in failure to acquire even spoken language, as pointed out in Chaps. 28 and 38. If there is any language skill, it consists only of the understanding of a few simple spoken commands. The subject of developmental dyslexia is discussed in "Developmental Dyslexia" in Chap. 28.

Treatment of Aphasia

The sudden onset of aphasia would be expected to cause great apprehension, but except for cases of pure or almost pure motor disorders of speech, most patients show remarkably little concern. It appears at times that the very lesion that deprives them of speech also causes at least a partial loss of insight into their own disability. This reaches almost a ludicrous extreme in some cases of Wernicke's aphasia, in which the patient becomes indignant when others cannot understand his jargon. Nonetheless, as improvement occurs, many patients do become discouraged. Reassurance and a program of speech rehabilitation are the best ways of helping the patient at this stage.

Whether contemporary methods of speech therapy accomplish more than can be accounted for by spontaneous recovery is still uncertain. Most aphasic disorders are caused by vascular disease and trauma, and they are nearly always accompanied by some degree of spontaneous improvement in the days, weeks, and months that follow the stroke or accident. A Veterans Administration Cooperative Study (Wertz et al) has suggested that intensive therapy by a speech pathologist does hasten improvement. Also, Howard and colleagues have shown increased efficacy of word retrieval in a group of chronic stable aphasics treated by two different techniques. More studies of this type, which control for the effects of time, of the patient's motivation and the interest of family and therapist, are needed. In an interesting personal experiment

by Wender, a classicist who had become aphasic, practice of Greek vocabulary and grammar led to recovery in that language, but there was little recovery of her facility with Latin, which was not similarly exercised.

The methods of language rehabilitation are specialized, and it is advisable to call in a person who has been trained in this field. However, inasmuch as a part of the benefit is also psychologic, an interested family member or schoolteacher can be of help if a speech therapist is not available in the community. Frustration, depression, and paranoia, which complicate some aphasias, may require psychiatric evaluation and treatment. The developmental language disorders of children pose special problems and are considered in Chap. 28.

In general, recovery from aphasia that is due to cerebral trauma is usually faster and more complete than that from aphasia because of stroke. The type of aphasia and particularly its initial severity (extent of the lesion) clearly influence recovery: global aphasia usually improves little, and the same is true of severe Broca's and Wernicke's aphasias (Kertesz and McCabe). Minimal or "mini" Broca's aphasia characterized by slightly effortful and halting speech, recovers quickly. The various dissociative speech syndromes and pure word mutism also tend to improve rapidly and often completely. In general, the outlook for recovery from any particular aphasia is more favorable in a left-handed person than in a right-handed one. Characteristically, in the course of recovery, a severe aphasia of one type may evolve into another type (global into severe Broca's; Wernicke's, transcortical, and conduction into anomic), which are patterns of recovery that may be attributed to the effects of therapy.

DISORDERS OF ARTICULATION AND PHONATION

The act of speaking involves a highly coordinated sequence of actions of the respiratory musculature, larynx, pharynx, palate, tongue, and lips. These structures are innervated by the vagal, hypoglossal, facial, and phrenic nerves, the nuclei of which are controlled by both motor cortices through the corticobulbar tracts. As with all movements, those involved in speaking are subject to extrapyramidal influences from the cerebellum and basal ganglia. The act of speaking requires that air be expired in regulated bursts and each expiration must be maintained long enough (by pressure mainly from the intercostal muscles) to permit the utterance of phrases and sentences. The current of expired air is then finely regulated by the activity of the various muscles engaged in speech.

Phonation, or the production of vocal sounds, is a function of the larynx, more particularly the vocal cords. The pitch of the speaking or singing voice depends upon the length and mass of the membranous parts of the vocal cords and can be varied by changing their tension; this is accomplished by means of the intrinsic laryngeal muscles, before any audible sound emerges. The controlled intratracheal pressure forces air past the glottis and separates the margins of the cords, setting up

a series of vibrations and recoils. Sounds thus formed are modulated as they pass through the nasopharynx and mouth, which act as resonators. *Articulation* consists of contractions of the pharynx, palate, tongue, and lips, which interrupt or alter the vocal sounds. Vowels are of laryngeal origin, as are some consonants, but the latter are formed for the most part during articulation; the consonants *m*, *b*, and *p* are labial, *l* and *t* are lingual, and *nk* and *ng* are guttural (throat and soft palate).

Defective articulation (dysarthria) and phonation (dysphonia) are recognized at once by listening to the patient speak during ordinary conversation or read aloud. Contrived test phrases such as “Methodist Episcopal” or attempts at rapid repetition of lingual, labial, and guttural consonants (e.g., *la-la-la-la*, *me-me-me-me*, or *k-k-k-k*) bring out the particular abnormality. Disorders of phonation call for a precise analysis of the voice and its apparatus.

Dysarthria and Anarthria

In pure dysarthria or its most severe representation, anarthria, there is no abnormality of the cortical language mechanisms. The patient is able to understand perfectly what is heard and has no difficulty in reading and writing, although he may be unable to utter intelligible words. This is the strict meaning of being inarticulate. Defects in articulation may be subdivided into several types: lower motor neuron (neuromuscular); spastic (pseudobulbar); rigid (extrapyramidal); cerebellar-ataxic; and hypo- and hyperkinetic dysarthrias, each of which is taken up below.

Lower Motor Neuron and Neuromuscular Dysarthria

This pattern of speech is caused by weakness or paralysis of the articulatory muscles, the result usually of disease of the motor nuclei of the medulla and lower pons or their intramedullary or peripheral extensions (*lower motor neuron paralysis*). In advanced forms of this disorder, the shriveled tongue lies inert and fasciculating on the floor of the mouth, and the lips are lax and tremulous. Saliva constantly collects in the mouth because of dysphagia, and drooling is troublesome. Dysphonia, an alteration of the voice to a rasping monotone because of vocal cord paralysis, is often an additional feature. As this condition evolves, speech becomes slurred and progressively less distinct. There is special difficulty in the enunciation of vibratives, such as *r*, and as the paralysis becomes more complete, lingual and labial consonants are finally not pronounced at all. In the past, bilateral paralysis of the palate, causing nasality of speech, often occurred with diphtheria and poliomyelitis, but now it occurs most often with progressive bulbar palsy, a form of motor neuron disease (see “Progressive Bulbar Palsy,” Chap. 39), and with certain other neuromuscular disorders, particularly myasthenia gravis. Bilateral paralysis of the lips, as occurs in the facial diplegia of the Guillain-Barré syndrome or of Lyme disease, interferes with enunciation of labial consonants; *p* and *b* are slurred and sound more like *f* and *v*. Degrees of both of these abnormalities are also observed in myasthenia gravis, but there are usually

additional features of palatal weakness and softening of guttural consonants and nasal air escape.

Spastic (Pseudobulbar) Dysarthria

Diseases that involve the corticobulbar tracts bilaterally, usually a result of vascular, demyelinating, or motor neuron disease (amyotrophic lateral sclerosis), result in the syndrome of spastic bulbar (pseudobulbar) palsy. The patient may have had a clinically inapparent vascular lesion at some time in the past, affecting the corticobulbar fibers on one side; however, because the bulbar muscles on each side are innervated by both motor cortices, there may be little or no impairment in speech or swallowing until another stroke occurs involving the other corticobulbar tract at any level. Upon the second stroke, the patient immediately becomes dysphagic, dysphonic, and anarthric or dysarthric, often with paresis of the tongue and facial muscles. This condition, unlike bulbar paralysis from lower motor neuron involvement, entails no atrophy or fasciculations of the paralyzed muscles; instead, the jaw jerk and other facial reflexes usually become exaggerated, the palatal reflexes are retained or increased, and emotional control is impaired (spasmodic, crying, and laughing—the pseudobulbar affective state described in Chap. 25). Amyotrophic lateral sclerosis is a condition in which the signs of spastic and atrophic bulbar palsy are combined.

When the dominant frontal operculum is damaged, speech may be dysarthric, usually without pseudobulbar impairment in emotional control. In the beginning, with vascular lesions, the patient may be mute; but with recovery or in mild degrees of the same condition, speech is notably slow, thick, and indistinct, much like that of partial bulbar paralysis. The terms *cortical dysarthria* and *cortical anarthria*, among many others, have been applied to this disorder, which is more closely related to forms of Broca’s aphasia than to the dysarthrias being considered in this section. Also, in many cases of partially recovered Broca’s aphasia and in the “mini-Broca” syndrome, the patient is left with a dysarthria that may be difficult to distinguish from a pure articulatory defect. Careful testing of other language functions, especially writing reveals the aphasic aspect of the defect.

A severe dysarthria that is difficult to classify, but resembles that of cerebellar disease, may occur with a left hemiplegia, usually the result of capsular or right opercular infarction. It tends to improve over several weeks but initially may be so severe as to make speech incomprehensible (Ropper).

Rigid (Extrapyramidal) Dysarthria

In Parkinson and other extrapyramidal diseases associated with rigidity of muscles, one observes a rather different disturbance of articulation, characterized by rapid mumbling and cluttered utterance and slurring of words and syllables. The voice is low-pitched and monotonous, lacking both inflection and volume (hypophonia), and trailing off in volume at the ends of sentences. Words are spoken hastily and run together in a pattern that is almost the opposite of the slowed pattern of spastic dysarthria. In advanced cases, speech is whispered and almost

unintelligible. It may happen that the patient finds it impossible to talk while walking but can speak better if standing still, sitting, or lying down. In the extrapyramidal disorder of progressive supranuclear palsy, the dysarthria and dysphonia tend instead to be spastic in nature.

With chorea and myoclonus, speech may also be affected in a highly characteristic way. Talking is loud, harsh, improperly stressed or accented, and poorly coordinated with breathing (*hyperkinetic dysarthria*). Unlike the defect of pseudobulbar palsy or Parkinson disease, chorea and myoclonus cause abrupt interruptions of the words by superimposition of involuntary inspirations and movements of bulbar muscles. The abnormality has been described as “hiccup speech,” in that the breaks are unexpected, as in singultation. Accompanying grimacing and other movement abnormalities must sometimes be depended upon for diagnosis. The Tourette syndrome of multiple motor and vocal tics is characterized both by startling vocalizations (barking noises, squeals, shrieks, grunting, sniffing, snorting) and by speech disturbances, notably stuttering and the involuntary utterance of obscenities (coprolalia).

Elements of both corticobulbar (spastic) and extrapyramidal speech disturbances are combined in Wilson disease, acquired hepatocerebral degeneration, in Hallervorden-Spatz disease (PKAN, the new and preferable designation based on the kinase that is affected in the disease), and in the form of cerebral palsy called *double athetosis*. The speech is loud, slow, and labored; it is poorly coordinated with breathing and accompanied by facial contortions and athetotic excesses of tone in other muscles. In diffuse cerebral diseases such as syphilitic general paresis, slurred, tremulous speech is one of the cardinal signs.

Ataxic Dysarthria (See Chap. 5)

This condition is a component of acute and chronic cerebellar lesions. It may be observed in multiple sclerosis and various degenerative disorders involving the cerebellum, or as a sequela of anoxic encephalopathy or heat stroke. The principal features are slowness of speech, slurring, monotony, and unnatural separation of the syllables of words. The coordination of speech and respiration is erratic. There may not be enough breath to utter certain words or syllables, and others are expressed with greater force than intended (explosive speech). *Scanning dysarthria*, speaking metronomically as if scanning poetry for meter, is another distinctive cerebellar pattern and is most often a result of mesencephalic lesions involving the brachium conjunctivum. However, in some cases of cerebellar disease, especially if there is an element of spastic weakness of the tongue from corticobulbar involvement, there may be only a slurring dysarthria, and it is not possible to predict the anatomy of the lesions from analysis of speech alone. Myoclonic jerks involving the speech musculature may be superimposed on cerebellar ataxia in a number of diseases such as Creutzfeldt-Jakob prion infection and Lance-Adams postanoxic encephalopathy.

Acquired Stuttering

This abnormality, characterized by interruptions of the normal rhythm of speech by involuntary repetition and

prolongation or arrest of uttered letters or syllables, is a common developmental disorder, discussed in Chap. 28. But as pointed out by Rosenbek and colleagues and by Helm and colleagues, it may appear in patients who are recovering from aphasic disorders and who had never stuttered in childhood. This form of acquired stuttering in adults has some different features from the developmental type in that the repetitions, prolongations, and blocks are not restricted to the initial syllables of words, stuttering occurs at equal frequency for grammatical as for substantive words, there is little adaptation with continued speaking, and is generally unaccompanied by grimacing or associated movements, as happens in some developmental types. These features are discussed in the review by Lundgren and colleagues. Stuttering differs from palilalia, in which there is repetition of a word or phrase with increasing rapidity, and from echolalia, in which there is an obligate repetition of words or phrases.

In many instances, acquired stuttering is transitory; if it is permanent, according to Helm and associates, bilateral cerebral lesions are present. Nevertheless, we have observed some cases in which only a left-sided, predominantly motor aphasia provided the background for acquired stuttering, and others in which stuttering was an early sign of cerebral glioma originating in the left parietal region. Benson also cites patients in whom stuttering accompanied fluent aphasia. The causative lesion in acquired stuttering may be subcortical and even, as in an exceptional case described by Ciabarra and colleagues, located in the pons. The treatment of Parkinson disease with L-dopa and, occasionally, an acquired cerebral lesion may reactivate developmental stuttering. The latter may explain the emergence of stuttering with oddly situated lesions, such as the aforementioned pontine infarct.

Aphonia and Dysphonia

A few points should be made concerning the fourth group of speech disorders, i.e., those that are a result of disturbances of phonation. In adolescence, there may be a persistence of the unstable “change of voice” normally seen in boys during puberty. As though by habit, the patient speaks part of the time in falsetto, and the condition may persist into adult life. Its basis is unknown. Probably the larynx is not masculinized, i.e., there is a failure in the spurt of growth (length) of the vocal cords that ordinarily occurs in pubertal boys. Voice training has been helpful.

Paresis of respiratory movements, as in myasthenia gravis, Guillain-Barré syndrome, and severe pulmonary disease, may affect the voice because insufficient air is provided for phonation. Also, disturbances in the rhythm of respiration may interfere with the fluency of speech. This is particularly noticeable in extrapyramidal diseases, where one may observe that the patient tries to talk during part of inspiration as noted earlier. Another common feature of the latter diseases is the reduction in volume of the voice (hypophonia) because of limited excursion of the breathing muscles—the patient is unable to shout or to speak above a whisper. Whispering speech is also a feature of advanced Parkinson disease, stupor, and occasionally

concussive brain injury and frontal lobe lesions, but strong stimulation may make the voice audible.

With paresis of both vocal cords, the patient can speak only in whispers. Because the vocal cords normally separate during inspiration, their failure to do so when paralyzed may result in an inspiratory stridor. If one vocal cord is paralyzed as a result of involvement of the tenth cranial nerve by tumor, for example, the voice becomes hoarse, low-pitched, rasping, and somewhat nasal in quality. The pronunciation of certain consonants such as *b*, *p*, *n*, and *k* is followed by an escape of air into the nasal passages. The abnormality is sometimes less pronounced in recumbency and increased when the head is thrown forward. Prolonged tracheal intubation that causes pressure necrosis of the posterior cricoarytenoid cartilage and the underlying posterior branch of the laryngeal nerve is an increasingly common iatrogenic cause.

Various tremor disorders, but especially severe essential tremor, affect the voice by creating an oscillatory effect on the vocal cords (see Chap. 6 for a full discussion). An unusual form of this disease causes a vibrato voice tremor almost in isolation, but most cases occur in the context of severe generalized essential tremor. As noted below, the pitch of voice may increase and simulate spasmodic dysphonia. Only the most severe cases of Parkinson tremor impart a warbling to the voice but this appears to be from vibration of the body and chest.

Spasmodic ("Spastic") Dysphonia

This is a relatively common condition about which little is known. *Spasmodic dysphonia* is a better term than the still-appearing spastic dysphonia, as the adjective *spastic* suggests corticospinal involvement, whereas the disorder is probably of extrapyramidal origin. The authors, like most neurologists, have seen many patients, middle-aged or elderly men and women, otherwise healthy, who lose the ability to speak quietly and fluently. Any attempt to speak results in simultaneous contraction of the speech musculature, so that the patient's voice is strained and speaking requires an effort. The patient sounds as though

he were trying to speak while being strangled. Shouting is easier than quiet speech, and whispering is unaltered. Other actions utilizing approximately the same muscles (swallowing and singing) are usually unimpeded.

Spasmodic dysphonia is usually relatively nonprogressive and occurs as an isolated phenomenon, but we have observed exceptions in which it occurs in various combinations with blepharospasm, spasmodic torticollis, writer's cramp, or some other type of segmental dystonia. The nature of spasmodic dysphonia is unclear. As a neurologic disorder, it may be akin to writer's cramp, i.e., a restricted dystonia (see Chap. 6). As mentioned just above, we have at times had difficulty differentiating a severe essential tremor of voice from spasmodic dysphonia. They may even coexist (fortunately, the treatments are similar). An anatomic basis for the condition has not been demonstrated, but careful neuropathologic studies have not been made.

Glottic spasm, as in tetanus, tetany, and certain hereditary metabolic diseases, results in crowing, stridulous phonation.

Treatment Speech therapists, observing such a patient strain to achieve vocalization, often assume that relief can be obtained by making the patient relax, and psychotherapists believed at first that a search of the patient's personal life around the time when the dysphonia began would enable the patient to understand the problem and regain a normal mode of speaking. But both these methods have failed without exception. Drugs useful in the treatment of Parkinson disease and other extrapyramidal diseases are practically never effective. Sectioning of one recurrent laryngeal nerve can be beneficial, but recurrence is to be expected. The most effective treatment, comparable to treatment of other segmental dystonias, consists of the injection of 5 to 20 U of botulinum toxin, under laryngoscopic guidance, into each thyroarytenoid or cricothyroid muscle. Relief lasts for several months. Hoarseness and raspiness of the voice is also a result of structural changes in the vocal cords, the result of cigarette smoking, acute or chronic laryngitis, polyps, and laryngeal edema after extubation.

Disorders of Energy, Mood, and Autonomic and Endocrine Functions

CHAPTER 24 **Fatigue, Asthenia, Anxiety, and Depression**

CHAPTER 25 **The Limbic Lobes and the Neurology of Emotion**

CHAPTER 26 **Disorders of the Autonomic Nervous System, Respiration, and Swallowing**

CHAPTER 27 **The Hypothalamus and Neuroendocrine Disorders**

Fatigue, Asthenia, Anxiety, and Depression

In this chapter, we consider the clinically related phenomena of lassitude, fatigue, nervousness, irritability, anxiety, and depression. These complaints form the core of a group of “symptom-based” disorders that are a large part of medical practice. Although more abstruse than paralysis, sensory loss, seizures, or aphasia, they are no less important, if for no other reason than their frequency. In an audit of one neurologic practice, anxiety and depressive reactions were the main diagnosis in 20 percent of patients, second only to the symptom of headache (Digon et al). Similarly, in two primary care clinics in Boston and Houston, fatigue was the prominent complaint in 21 and 24 percent of patients, respectively. Some of these symptoms represent only slight aberrations of function or a heightening or exaggeration of normal reactions to environmental stress or to medical and neurologic diseases; others are integral features of the diseases themselves; and still others represent disturbances of neuropsychiatric function that are components of the diseases described in Chaps. 51 through 53 on psychiatry.

FATIGUE AND ASTHENIA

Of the symptoms considered in this chapter, lassitude and fatigue are the most frequent, and the most vague. *Fatigue* refers to the universally familiar state of weariness or exhaustion resulting from physical or mental exertion. *Lassitude* has much the same meaning, although it connotes more of an inability or disinclination to be active, physically or mentally. More than half of all patients entering a general hospital register a complaint of fatigability or admit to it when questioned. During World War I, fatigue was such a prominent symptom in combat personnel as to be given a separate place in medical nosology, namely *combat fatigue*, a term that came to be applied to practically all acute psychiatric disorders occurring on the battlefield. In subsequent wars, it has become a key element of the posttraumatic stress disorders related to exposure to highly stressful circumstances. The common clinical antecedents and accompaniments of fatigue, its significance, and its physiologic and psychologic bases will be better understood if we first consider the effects of fatigue on the normal individual.

Effects of Fatigue on the Normal Person

Fatigue has three basic meanings: (1) biochemical and physiologic changes in muscles and a reduced capacity to generate force manifest as weakness, or asthenia; (2) a disorder in behavior, taking the form of a reduced output of work (*work decrement*) or a lack of endurance; and (3) a subjective feeling of tiredness and discomfort.

The *decreased productivity and capacity for work*, which is a direct consequence of fatigue, has been investigated by industrial psychologists. Their findings clearly demonstrate the importance of motivational factors on work output, whether the effort is of physical or mental type. Quite striking are individual constitutional differences in energy, which vary greatly, just as do differences in temperament. What should be emphasized is that *in the majority of persons complaining of fatigue, one does not find true muscle weakness*. This may be difficult to prove, for many such individuals are disinclined to exert full effort in tests of peak power of muscle contraction or in endurance of muscular activity.

The Clinical Significance of Fatigue

Patients experiencing lassitude and fatigue have a more or less characteristic way of expressing their symptoms. They say that they are “wiped, or burned out,” “tired all the time,” “weary,” “exhausted,” or “pooped out,” or that they have “no pep,” “no ambition,” or “no interest.” They manifest their condition by showing an indifference to the tasks at hand, by emphasizing how hard they are working, and how stressed they are by circumstances; they are inclined to sit around or lie down or to occupy themselves with trivial tasks. On closer analysis, one observes and hears that many such patients have difficulty in initiating activity and also in sustaining it; i.e., their endurance is diminished. This condition, of course, is the familiar aftermath of sleeplessness or prolonged mental or physical effort, and, under such circumstances, it is accepted as a normal physiologic reaction. When, however, similar symptoms appear without relation to such antecedents, they should be suspected of being the manifestations of disease.

The physician’s task is initially to determine whether the patient is merely suffering from the common physical and mental effects of overwork. Overworked, overwrought

people are observable everywhere in our society. In addition to fatigue, such persons frequently show irritability, restlessness, sleeplessness, and anxiety, sometimes to the point of panic attacks and a variety of somatic symptoms, particularly abdominal, thoracic, and cranial discomforts. Formerly, society accepted this state in responsible individuals and prescribed the obvious cure, a vacation. Even Charcot made time for regular "cures" during the year, in which he retired to a spa without family, colleagues, or the drain of work. Nowadays, the need to contain this type of stress, to which some individuals are more prone than others, has spawned an industry of meditation, yoga, and similar activities. Individuals with hobbies, nonwork interests, and athletic pursuits seem to be less subject to this problem. A common error in diagnosis, however, is to ascribe fatigue to overwork when actually it is a manifestation of anxiety or depression, as described below.

Fatigue as a Symptom of Psychiatric Illness

The majority of patients who seek medical help for unexplained chronic fatigue and lassitude are found to have some type of psychiatric illness. Formerly this state was called "neurasthenia," a term introduced by Beard, but because lassitude and fatigue rarely exist as isolated phenomena, the current practice is to label such cases according to the total clinical picture. The usual associated symptoms are anxiety, irritability, depression, insomnia, headaches, dizziness, difficulty in concentrating, reduced sexual drive, and loss (or sometimes increase) of appetite. In one series, 85 percent of persons admitted to a general hospital and seen in consultation by a psychiatrist for the chief complaint of chronic fatigue were diagnosed, finally, as having anxious depression or an anxiety state. In a subsequent study, Wessely and Powell found similarly that 72 percent of patients who presented to a neurologic center with unexplained chronic fatigue proved to have a psychiatric disorder, most often a depressive illness.

Several features are common to the psychiatric group with fatigue. Tests of peak muscle power on command, with the patient exerting full effort, reveal no weakness. The sense of fatigue may be worse in the morning. There is an inclination to lie down and rest, but sleep does not follow. The fatigue is worsened by mild exertion and relates more to some activities than to others. Inquiry may disclose that the symptom was first experienced in temporal relation to a grief reaction, a surgical procedure, physical trauma such as an automobile accident, or a medical illness such as myocardial infarction. The feeling of fatigue interferes with both mental and physical activities; the patient is easily worried, is "full of complaints," and finds it difficult to concentrate in attempting to solve a problem or to read a book, or in carrying on a complicated conversation. Also, sleep is disturbed, with a tendency to early morning waking, so that such persons are at their worst in the morning, both in spirit and in energy output. Their tendency is to improve as the day wears on, and they may even feel fairly normal by evening. It may be difficult to decide whether the fatigue is a primary manifestation of the disease or secondary to a lack of interest.

Among chronically fatigued individuals without medical disease, not all deviate enough from normal to justify the diagnosis of anxiety or depression. Many persons, because of circumstances beyond their control, have little motivation and much idle time. They are bored with the monotony of their routine. Such circumstances are conducive to fatigue, just as the opposite, a strong emotion or a new enterprise that excites optimism and enthusiasm, will dispel fatigue. Some persons are born with low impulse and energy and become more so at times of stress; they have a lifelong inability to exercise vigorously, to compete successfully, to work hard without exhaustion, to withstand illness or recover quickly from it, or to assume a dominant role in a social group—a "constitutional asthenia" (Kahn's term). Most of these traits are evident from childhood. These difficulties are not currently framed in these terms because they sound judgmental, but disorders of this type have been known since antiquity and only vary in name and social context in each era.

Fatigue in Neurologic Diseases

Not unexpectedly, fatigue and intolerance of exercise (i.e., fatigue with mild exertion) are prominent manifestations of myopathic disease. Even in myasthenia gravis, the muscles exhibiting fatigue are usually weak, however, in the resting state. In addition to myasthenia gravis, the classes of myopathy in which weakness, inability to sustain effort, and excessive fatigue are notable features include the muscular dystrophies, congenital myopathies, other disorders of neuromuscular transmission (Lambert-Eaton syndrome), toxic myopathies (e.g., from cholesterol-lowering drugs), some of the glycogen storage myopathies, and mitochondrial myopathies. One type of glycogen storage disease, McArdle phosphorylase deficiency, is exceptional in that fatigue and weakness are accompanied by pain and sometimes by cramps and contracture. The first contractions after rest are of near-normal strength, but after 20 to 30 contractions, there occurs a deep ache and an increasing firmness and shortening of the contracting muscles. Another such process, acid maltase deficiency, is at times associated with disproportionate weakness and fatigue of respiratory muscles, which leads to dyspnea and retention of carbon dioxide. The characteristics of these diseases are presented in the chapters on muscle disease. Further comments on muscular fatigue can be found in Chap. 48.

Fatigue of varying degree is also a regular feature of all diseases that are marked by denervation of muscle and loss of muscle fibers. Fatigue in these cases is a result of the excessive work imposed on the remaining intact muscle (overwork fatigue). This is most characteristic of amyotrophic lateral sclerosis and the postpolio syndrome, but it also occurs in patients who are recovering from Guillain-Barré syndrome and in those with chronic polyneuropathy.

Not surprisingly, many neurologic diseases that are characterized by incessant muscular activity or by difficulty engaging the muscles (Parkinson disease, cerebral palsy, Huntington disease, hemiballismus) also induce fatigue. Muscles partially paralyzed by a stroke feel tired

and may cause an overall fatigue state. The distinguished neuroanatomist A. Brodal gave an interesting account of his own stroke and its effects on muscle power. Fatigue is often a major complaint of patients with multiple sclerosis; its cause is unknown, although the effect of cytokines circulating in the cerebrospinal fluid has been postulated. The depression that follows stroke or myocardial infarction frequently presents with the complaint of fatigue rather than other signs of mood disorder. Inordinate fatigue is a common complaint among patients with post-concussive syndrome (see Chap. 35). Severe fatigue that causes the patient consistently to go to bed right after dinner and makes all mental activity effortful should suggest an associated depression. These central fatigue states and their possible mechanisms, almost all speculative, have been discussed by Chaudhuri and Behan.

Many states of disordered autonomic function in which static or orthostatic hypotension are features, are associated with a fatigue state. Whether there is in addition a type of central autonomic (hypothalamic) fatigue, aside from the endocrine changes discussed below, is uncertain, but such an entity seems plausible and has been included in models of the illness currently called chronic fatigue syndrome.

Fatigue in Medical Diseases

A wide variety of *medications* and other therapeutic agents, particularly when first administered, sometimes induce fatigue. The main offenders in this respect are antihypertensive drugs, especially beta-adrenergic blocking agents, antiepileptics, antispasticity drugs, anxiolytics, chemotherapy and radiation therapy and, paradoxically, many antidepressant and antipsychotic drugs. Introduction of these medications in gradually escalating doses may obviate the problem, but just as often, an alternative medicine must be chosen. The administration of beta-interferon for the treatment of multiple sclerosis (and alpha-interferon for other diseases) induces fatigue of varying degree. Surgeons and nurses can testify to fatigue that comes with exposure to anesthetics in inadequately ventilated operating rooms. Similarly, fatigue and headache may result from exposure to carbon monoxide or natural gas in homes with furnaces in disrepair or from leaking gas pipes, but this is also a frequent delusion in anxious, depressed, or demented patients.

The *sleep apnea* syndrome is an important and often overlooked cause of fatigue and daytime drowsiness. In overweight men who snore loudly and need to nap frequently, testing for sleep apnea is indicated (this subject was taken up in Chap. 19). Correcting the obstructive apnea that underlies this condition leads to a dramatic reduction in fatigue. The same holds for patients who have neuromuscular diseases that affect the diaphragm and other respiratory muscles.

Acute or chronic infection is an important cause of fatigue. Everyone has at some time or other sensed the abrupt onset of exhaustion, a tired ache in the muscles, or an inexplicable listlessness, only to discover later that he was "coming down with the flu." Chronic infections such as hepatitis, tuberculosis, brucellosis, infectious mononucleosis, HIV, and bacterial endocarditis may not

be evident immediately but should be suspected when fatigue is a new symptom and disproportionate to other symptoms such as mood change, nervousness, and anxiety. Whether a chronic form of Lyme disease is responsible for chronic fatigue, as often imputed, is uncertain at best. Often, fatigue begins with an obvious infection (such as influenza, hepatitis, or infectious mononucleosis), but persists for several weeks after the overt manifestations of infection have subsided; it may then be difficult to decide whether the fatigue represents the lingering effects of the infection or is due to psychologic-asthenic symptoms during convalescence. This difficult problem is discussed below. Patients with systemic lupus, Sjögren syndrome, or polymyalgia rheumatica may complain of severe fatigue; in the last of these, fatigue may be the initial and a profound symptom.

Metabolic and endocrine diseases of various types may cause inordinate degrees of lassitude and fatigue. Sometimes there is, in addition, a true muscular weakness. In Addison, Sheehan, and Simmonds diseases, fatigue may dominate the clinical picture. Aldosterone deficiency is another established cause of chronic fatigue. In persons with hypothyroidism with or without frank myxedema, lassitude and fatigue are frequent complaints, as are muscle aches and joint pains. Fatigue may also be present in patients with hyperthyroidism, but it is usually less troublesome than nervousness. Uncontrolled diabetes mellitus is accompanied by excessive fatigability, as are hyperparathyroidism, hypogonadism, and Cushing disease. Fatigue as a feature of vitamin B₁₂ deficiency, as stated in many textbooks, has not been evident in the cases with mild deficiency that we have observed.

Reduced cardiac output and diminished pulmonary reserve are important causes of breathlessness and fatigue, which are brought out by mild exertion. Anemia, when severe, is another cause, probably predicated on a similar inadequacy of oxygen supply to tissues. Mild grades of anemia are usually asymptomatic, and tiredness is still far too often ascribed to it. An occult malignant tumor, e.g., pancreatic, hepatic, or gastric carcinoma, may announce itself by inordinate fatigue. In patients with metastatic carcinoma, and especially lymphoma, leukemia, or multiple myeloma, fatigue is a usual and prominent symptom. Uremia is accompanied by fatigue; the associated anemia may play a role. Any type of *nutritional deficiency* may, when severe, cause lassitude; in its early stages, this may be the chief complaint. Weight loss and a history of alcoholism and dietary inadequacy provide the clues to the nature of the illness.

Pregnancy causes fatigue, which may be profound in the later months. To some extent the underlying causes, including the work of carrying excess weight and an anemia, are obvious; but if excessive weight gain and hypertension are associated, preeclampsia should be suspected.

Postviral and Chronic Fatigue Syndromes

A particularly difficult problem arises in the patient who complains of severe fatigue for many months or even years after a bout of infectious mononucleosis or some other viral illness. This has been appropriately called the

postviral fatigue syndrome. The majority of patients are women between 20 and 40 years of age, but there are undoubtedly young men with the same illness. A few such patients had been found to have unusually high titers of antibody to Epstein-Barr virus (EBV), which suggested a causal relationship and gave rise to terms such as the *chronic infectious mononucleosis* or *chronic EBV syndrome* (Straus et al). However, subsequent studies made it clear that a majority of patients with complaints of chronic fatigue have neither a clear-cut history of infectious mononucleosis nor serologic evidence of this or another infection (Straus; Holmes et al). In some of these patients, the fatigue state has allegedly been associated with obscure immunologic abnormalities similar to those attributed (spuriously) to silicone breast implants or minor trauma. The currently fashionable designation for these abstruse states of persistent fatigue is the *chronic fatigue syndrome*.

Some perspective is provided by the recognition that a malady of this precise nature, under many different names, has long pervaded postindustrial western society, as described by Shorter in an informative history of the chronic fatigue syndrome. The attribution of fatigue to viral or Lyme infection and to ill-defined immune dysfunction are only the latest in a long line of putative explanations. At various times, even in our recent memory, colitis and other forms of bowel dysfunction, spinal irritation, hypoglycemia, brucellosis, and chronic candidiasis, "multiple chemical sensitivity," retroviral infection, or environmental allergies, among others, have been proposed without basis as causes. Unfortunately, these spurious associations have only served to marginalize the disease and patients who suffer from it.

The current criteria for the diagnosis of chronic fatigue syndrome are the presence of persistent and disabling fatigue for at least 6 months, coupled with an arbitrary number (6 or 8) of persistent or recurrent somatic and neuropsychologic symptoms including low-grade fever, cervical or axillary lymphadenopathy, myalgias, migrating arthralgias, sore throat, forgetfulness, headaches, difficulties in concentration and thinking, irritability, and sleep disturbances (Holmes et al). A number of such patients in our experience have complained of paresthesias in the feet or hands. On close questioning, many of these sensations prove to be odd, particularly numbness in the bones or muscles or fluctuating patches of numbness or paresthesia on the chest, face, or nose. Unusual descriptions may be given if the patient is allowed adequate time to describe the symptoms. A few have reported blurred or "close to" double vision; in neither case are there physical findings to corroborate the sensory experiences.

There is a common association with the similarly obscure entity of *fibromyalgia*, consisting of neck, shoulder, and paraspinal pain and point tenderness, as described in Chaps. 11 and 48. Despite these complaints, the patient may look surprisingly well and the neurologic examination is normal. The term for this same entity, *myalgic encephalomyelitis*, is preferred in Great Britain and captures the association between the two syndromes.

Complaints of muscle weakness are also frequent among such patients, but Lloyd and coworkers, who

studied their neuromuscular performance and compared them with control subjects, found no difference in maximal isometric strength or endurance in repetitive submaximal exercise and no change in intramuscular acidosis, serum creatine kinase (CK) levels, or depletion of energy substrates. These individuals share with depressed patients a subnormal response to cortical magnetic motor stimulation after exercise (Samii et al), which can be said to match their symptoms of reduced endurance but otherwise is difficult to interpret. In a small number of affected persons, a chronic but usually mild hypotension, elicited with tilt-table testing and reversed by mineralocorticoids, has been proposed as a cause of chronic fatigue (Rowe et al). Electromyography and nerve conduction studies are typically normal, as is the spinal fluid, but the electroencephalogram (EEG) may be mildly and nonspecifically slowed. Batteries of psychologic tests have disclosed variable impairments of cognitive function, misinterpreted by advocates of the "organic" nature of the syndrome as proof of some type of encephalopathy.

In a large group of patients who were studied 6 months after viral infections, Cope and colleagues found that none of the features of the original illness was predictive of the development of chronic fatigue; however, a previous history of fatigue or psychiatric problems, and an indefinite diagnosis were often associated with persistent disability. In one study of more than 1,000 patients who were observed for 6 months following an infective illness, the chronic fatigue syndrome was no more frequent than in the general population (Wessely et al). One thing is clear to the authors: that applying the label of *chronic fatigue syndrome* in susceptible individuals tends to perpetuate this state.

Having oriented the above discussion to imply that many cases of chronic fatigue have a psychologic, or asthenic basis, it should be emphasized that previously healthy individuals, for years after a severe febrile viral infection may have persistent fatigue; the best-characterized situation follows mononucleosis, but other febrile illnesses have been implicated as well. These cases, in our experience, have arisen suddenly, mostly in adolescents and young men, and less often women, who experience overwhelming fatigue during a well-documented and prolonged viral infection. They continue to take interest in activities in which they are able to participate, do not show anxiety or major depressive symptoms, and have the best prognosis, although complete recovery may take up to 3 to 5 years. Often these patients are able to define the date on which the illness began. The term *postviral fatigue state* is most appropriate for this group. Impressive in some of our cases have been severe headaches and orthostatic hypotension, with wide swings in blood pressure resulting in syncope as well as intermittent hypertension. Alcohol intolerance may develop. It would seem that the more ambiguous and less-severe cases of chronic fatigue, particularly those with fibromyalgia, may have a different basis, but this cannot be stated with certainty.

At the present time, the status of the chronic fatigue syndrome is undetermined. The possibility of an obscure metabolic or immunologic derangement secondary to a viral infection cannot be dismissed, as discussed by

Swartz, but the majority of cases lack such a history. Certainly, high levels of cytokines, such as occur after many types of illness and with cancer, and some of the numerous endocrine aberrations are capable of causing fatigue and lethargy. From a neurologic perspective, the hypothalamus is the structure most implicated by the loss of endurance and the presence of associated symptoms such as orthostatic intolerance, tachycardia and some of the endocrine changes enumerated later in the chapter. Treatment is discussed further on.

Differential Diagnosis of Fatigue

If one looks critically at patients who seek medical help because of incapacitating exhaustion, lassitude, and fatigability, it is evident that the most commonly overlooked diagnoses are anxiety and depression as described in Chap. 52. The correct conclusion can usually be reached by keeping these illnesses in mind as one elicits the history from patient and family. Difficulty arises when symptoms of the psychiatric illness are so inconspicuous as not to be appreciated; one comes then to suspect the diagnosis only by having eliminated the common medical causes. Repeated observation may bear out the existence of an anxiety state or gloomy mood. Reassurance in combination with a therapeutic trial of antidepressant drugs may suppress symptoms of which the patient was barely aware, thus clarifying the diagnosis. The best that can be done is to assist the patient in adjusting to the adverse circumstances that have brought him under medical surveillance.

In intractable cases, tuberculosis, brucellosis, Lyme disease, hepatitis, bacterial endocarditis, mycoplasmal pneumonia, HIV, EBV, cytomegalovirus (CMV), coxsackie B, and other viral infections, and malaria, hookworm, giardiasis, and other parasitic infections need to be considered in the differential diagnosis, and an inquiry made for their characteristic symptoms, signs, and when appropriate, laboratory findings; however, such infections are infrequently found. There should also be a search for anemia, renal failure, chronic inflammatory disease such as temporal arteritis and polymyalgia rheumatica (sedimentation rate); an endocrine survey (thyroid, calcium, and cortisol levels) and an evaluation for an occult tumor are also in order in obscure cases. It must be remembered that chronic intoxication with alcohol, barbiturates, or other sedative drugs, some of which are given to suppress nervousness or insomnia, may contribute to fatigability. The rapid and recent onset of fatigue should always suggest the presence of an infection, a disturbance in fluid balance, gastrointestinal bleeding, or rapidly developing circulatory failure of either peripheral or cardiac origin. The features that suggest sleep apnea have been mentioned above and are discussed further in Chap. 19.

Finally, it bears repeating that lassitude and fatigue must be distinguished from genuine muscular weakness. The demonstration of reduced power, reflex changes, fasciculations, and atrophy sets the case analysis along different lines, bringing up for particular consideration diseases of the peripheral nervous system or of the musculature. Rare, difficult-to-diagnose diseases that cause

inexplicable muscle weakness and exercise intolerance are otherwise inevident hyperthyroidism, hyperparathyroidism, ossifying hemangiomas with hypophosphatemia, some of the periodic paralyses, hyperinsulinism, disorders of carbohydrate and lipid metabolism, and the mitochondrial myopathies, all of which are discussed in later chapters of the book on disease of muscle.

Treatment of Fatigue

It has been our impression that most patients with ongoing complaints of very low energy without a clearly preceding febrile infection from the outset and without one of the medical illnesses associated with fatigue, have elements of depression. They are probably best treated with gradually increasing exercise levels and perhaps with antidepressant medication, although this regimen has not always been successful. There are reports of success in treating these patients with mineralocorticoids (predicated on the above-mentioned orthostatic intolerance), estradiol patches, hypnosis, and a variety of other medical and nonmedical treatments. Cognitive and behavioral therapies have been summarized in the *Effective Health Care* report by Bagnall and colleagues from the National Health Service Centre for Reviews and Dissemination and in the extensive review by Chambers and colleagues, neither of which came to a firm conclusion about the effects of treatment, but acknowledged that cognitive behavioral therapy and graded exercise therapy may be of value. A few patients with chronic fatigue exhibit the psychologic disorder related to litigation ("compensation neurosis"). Noteworthy is the frequency with which a similar syndrome has become the basis of court action against employers or claims against the government, as in the "building-related illness" (formerly "sick-building syndrome"). As alluded to earlier, attribution of fatigue to Lyme disease and obscure infections or allergies should be made cautiously if there is no firm evidence.

NERVOUSNESS, ANXIETY, STRESS, AND IRRITABILITY

The world is full of nervous, tense, apprehensive, and worried people. The stresses of contemporary society are often blamed for their plight. The poet W.H. Auden referred to his era as "the age of anxiety," and little has changed since then. Medical historians have identified comparable periods of pervasive anxiety dating back to the time of Marcus Aurelius and Constantine, when societies were undergoing rapid and profound changes, and individuals were assailed by an overwhelming sense of insecurity, personal insignificance, and fear of the future (Rosen).

Like lassitude and fatigue, nervousness, irritability, and anxiety are among the most frequent symptoms encountered in office and hospital practice. A British survey found that more than 40 percent of the population, at one time or another, experienced symptoms of severe anxiety, and approximately 5 percent suffered from lifelong anxiety states (Lader). The vast amount of anti-anxiety

medication and alcohol that is consumed in our society would tend to corroborate these figures. Of course, any person facing a challenging or threatening task for which he may feel unprepared and inadequate experiences some degree of nervousness and anxiety. Anxiety is then not abnormal, and the alertness and attentiveness that accompany it may actually improve performance up to a point. Barratt and White found that mildly anxious medical students performed better on examinations than those lacking in anxiety. As anxiety increases, so does the standard of performance, but only to a point, after which increasing anxiety causes a rapid decline in performance (Yerkes-Dodson law).

If worry or depression stands in clear relation to serious economic reverses or loss of a loved one, the symptom is also usually accepted as normal, but no less worthy of emotional support. Only when it is excessively intense or prolonged or when accompanying visceral derangements are prominent do anxiety and depression become matters of medical concern. Admittedly, the line that separates normal emotional reactions and pathologic ones is not sharp. Chapter 52 deals with these matters more fully.

Here we are concerned with *nervousness, irritability, stress, anxiety, and depression as symptoms*, together with current views of their origins and biologic significance.

Anxiety Reactions and Panic Attacks

There is no unanimity among psychiatrists as to whether symptoms of nervousness, irritability, anxiety, and fear comprise a single emotional reaction, varying only in its severity or duration, or a group of discrete reactions, each with distinctive clinical features. In some writings, anxiety is classified as a form of subacute or chronic fear but there is reason to question this assumption. Anxious patients, when frightened under experimental conditions, state that the fear reaction differs in being more overwhelming. The exceedingly frightened person is "frozen," unable to act or to think clearly, and his responses are automatic and sometimes irrational. The fear reaction is characterized by overactivity of both the sympathetic and parasympathetic nervous systems, and the parasympathetic effects (bradycardia, sphincteric relaxation) may predominate, unlike anxiety, in which sympathetic effects are the more prominent ones. Long ago, Cicero distinguished between an acute and transient attack of fear provoked by a specific stimulus (*angor*) and a protracted state of fearfulness (*anxietas*). This distinction was elaborated by Freud, who regarded fear as an appropriate response to a sudden, unexpected external threat and anxiety as a neurotic maladjustment.

Less readily distinguishable from anxiety is the complaint of *nervousness*. By this vague term, the layperson usually refers to a state of restlessness, inner tension, uneasiness, apprehension, irritability, or hyperexcitability. Unfortunately, the term may have a wide range of other connotations, such as a distressing hallucination or paranoid idea, a frankly hysterical outburst, or even tics or tremulousness. Obviously, a careful inquiry as to what the patient means in complaining of nervousness is always a necessary first step in the analysis.

Most often nervousness represents no more than a transient psychic and behavioral state in which the person is maximally challenged or threatened by difficult personal problems. Some persons claim to have been nervous throughout life or to be nervous periodically for no apparent reason. In these instances, the symptoms blend imperceptibly with those of anxiety disorder or depression, described below.

We use the term *anxiety* to denote an emotional state characterized by subjective feelings of nervousness, irritability, uneasy anticipation, and apprehension, often but by no means always with a definite topical content and the physiologic accompaniments of strong emotion, i.e., one or more of the symptoms of breathlessness, tightness in the chest, choking sensation, palpitation, increased muscular tension, dizziness, trembling, sweating, and flushing. The vasomotor and visceral accompaniments are mediated through the autonomic nervous system, particularly its sympathetic part, and involve also the thyroid and adrenal glands.

Panic Attacks

The symptoms of anxiety may be manifest either in acute episodes, each lasting several minutes or up to an hour, or as a protracted state that may last for weeks, months, or years. In the *panic attack*, the patient is suddenly overwhelmed by feelings of apprehension, or a fear that he may lose consciousness and die, have a heart attack or stroke, lose his reason or self-control, become insane, or commit some horrible crime. These experiences are accompanied by a series of physiologic reactions, mainly sympathoadrenal hyperactivity, resembling the "fight-or-flight" reaction. Breathlessness, a feeling of suffocation, dizziness, sweating, trembling, palpitation, and precordial or gastric distress are typical but not invariable physical accompaniments. As a persistent and less-severe state, the patient experiences fluctuating degrees of nervousness, palpitation or excessive cardiac impulse, shortness of breath, light-headedness, faintness, easy fatigue, and intolerance of physical exertion.

Attacks tend to occur during periods of relative calm and in nonthreatening circumstances. Usually, the apprehension and physical symptoms escalate over a period of minutes to an hour and then abate over 20 to 30 min, leaving the patient tired, weak, and perplexed. The dramatic symptoms of the panic attack have usually abated by the time the patient reaches a doctor's office or an emergency department, but the blood pressure may still be elevated, and there may be tachycardia. Otherwise, the patient looks remarkably collected. Often, discrete anxiety attacks and persistent states of anxiety merge with one another. The fear of further attacks leads many patients, particularly women, to become agoraphobic and homebound, fearing public places, especially if alone.

Because panic is a common disorder, affecting 2 to 4 percent of the population at some time in their lives as cited by Roy-Byrne and colleagues, and the symptoms mimic acute neurologic disease, the neurologist is often called upon to distinguish panic attacks from temporal lobe seizures or from vertiginous disorders. Except for

the occasional inability of the patient to think or articulate clearly during a panic attack, the manifestations of epilepsy are quite different. Practically never is consciousness lost during a panic attack. If dizziness predominates in the attacks, there may be concern about vertebrobasilar ischemia or labyrinthine dysfunction (see Chap. 15). Vertigo from any cause is accompanied by many of the autonomic symptoms displayed during a panic attack, but careful questioning in the latter will elicit the characteristic apprehension, breathlessness, and palpitations, and the absence of ataxia or other neurologic signs.

Recurrent panic attacks and chronic anxiety have a familial aspect, with one-fifth of first-degree relatives affected and a high degree of concordance in monozygotic twins. The panic symptoms tend to be periodic, beginning in the patient's twenties; a later onset is more usually coupled with depression, treatment of which is discussed in Chap. 52. Most often, panic in younger persons is a component of a generalized anxiety disorder, but it may stand alone as the only mental symptom or be an opening feature of schizophrenia.

Persistent Anxiety and Anxious Depression

Episodic or sustained anxiety without a disorder of mood (i.e., without depression) is classified as *generalized anxiety disorder*, or formerly, *anxiety neurosis*. The term *neurocirculatory asthenia* (among many others) had been applied to the chronic form when accompanied by prominent fatigue and exercise intolerance, in which case it blends into the fatigue states discussed earlier. The symptoms of anxiety may, however, be part of several other psychiatric disorders; it may be combined with other somatic symptoms in hysteria and is the most prominent feature of *phobic disorder*. Symptoms of persistent anxiety with insomnia, lassitude, and fatigue should always raise the suspicion of a *depressive* illness, especially when they begin in middle adult life or beyond. Also, unexplained anxiety or panic attacks may sometimes herald the onset of a schizophrenic illness. As with fatigue, the symptoms of both anxiety and depression are prominent features of the postconcussion syndrome, and of *posttraumatic stress syndrome* (see Chap. 35). These disorders highlight the difficulty in separating generalized anxiety disorder as a unique psychiatric entity. When visceral symptoms predominate or the psychic counterparts of fear and apprehension are absent, the presence of thyrotoxicosis, Cushing disease, pheochromocytoma, hypoglycemia, and menopausal symptoms should be considered.

Posttraumatic Stress Disorder (PTSD)

This state has been alluded to previously in several contexts, but in the past decades it has come to have specific connotation and to stand as a separate disorder. An extremely stressful, or traumatic event that causes fear and helplessness, triggers a persistent psychological state in which the patient reexperiences the event, avoids reminders of it, and is in a constant state of hyperarousal. Current diagnostic criteria require that this condition persist for over a month, prior to that time the condition is termed "acute stress disorder." Even proponents of posttraumatic stress disorder (PTSD) as a separate

medical condition acknowledge that there is considerable overlap with anxious depression, the critical difference being the existence of a triggering traumatic event. They make the point that the original event may not be initially articulated by the patient but symptoms such as palpitations, dyspnea, dysphoria, and unexplained pains and other physical symptoms may be prominent, just as in depression.

The biologic distinctions that have been made between anxious depression and PTSD include lower-than-normal cortisol levels, an attenuated increase of these levels in the immediate aftermath of the event, and an exaggerated suppression in response to dexamethasone. However, elevated circulating levels of norepinephrine and increased sensitivity of α_2 -adrenergic receptors that are found in the posttraumatic syndrome are shared with all other anxiety states (Southwick et al). Many of these studies have been poorly controlled.

It is apparent that there is a wide range of human vulnerability to prolonged difficulties after traumatic events. In all probability, this parallels to some extent an endogenous susceptibility to PTSD. Examples of this are the elicitation of symptoms by events not even witnessed personally, such as national disasters that are shared by large populations but produce symptoms in only a very few individuals, and the wide variation of responses to witnessing death and destruction during wartime.

The authors' view is in agreement with the consensus that PTSD represents a special type of induced anxiety state with fairly stereotyped psychologic aspects, often with an accompanying depression and somatic symptoms. Separating it by highlighting the triggering event serves a useful nosologic purpose and draws attention to the need for treatment in individuals such as those returning from battle or after rape or violent attack.

Selective serotonin reuptake inhibitors have been suggested for initial treatment but the other classes of antidepressant drugs are also effective. Limiting anxiolytics such as benzodiazepines is recommended, but there are few data on which to make these judgments. A sympathetic psychiatrist is helpful in reassuring affected individuals and giving them perspectives to cope with the trauma. The review by Yehuda is very informative on this subject and many of the comments above are taken from her summary. An emerging notion is that sedatives or narcotics administered immediately after the inciting event may reduce the incidence and severity of PTSD, for example in battlefield conditions.

Stress and Stress Syndromes

The psychologic phenomenon of *stress* is closely allied to nervousness, fatigue, and anxiety and all of them are pervasive features of modern life. In general terms, stress has been defined as a feeling of self-doubt about being able to cope with some situation over a period of time. The term *stress syndrome* refers to perturbations of behavior and accompanying physiologic changes that are ascribable to environmental challenges of such intensity and duration as to overwhelm the individual's adaptive capacity. The biologic effects of this phenomenon can be

recognized in many species; chickens laying fewer eggs when moved to a new coop and cows giving less milk when put in a new barn, or monkeys going berserk when repeatedly frustrated by threats that they cannot control. Human beings forced to work under confined conditions and constant danger and cultural groups removed from their home and traditional way of life lose their coping skills and suffer anxiety and stress reactions.

Hans Selye, influenced by Pavlov's concepts of stress, produced lesions in the visceral organs by exposing animals to life-threatening stressors combined with corticosteroids. Cardiac contraction-band necrosis and the shallow hemorrhagic gastrointestinal tract lesion (Cushing ulcer) are two examples of such catecholamine-mediated organ damage that is precipitated by acutely stressful circumstances. The dramatic syndrome of ballooning of the left ventricular apex, or takotsubo-like cardiomyopathy (so-named for the shape of the Japanese octopus trapping pot), is a manifestation of catecholamine excess caused by acute stress.

There is also equivocal epidemiologic evidence that chronic stress in certain individuals, captured in the type A personality, raises the risk of cardiac disease, but the mechanism here, if it indeed exists, is likely to be through a physiologic intermediary such as systemic hypertension or perhaps inflammation that leads to atherosclerosis. Presumably, they have an increased output of "stress hormones" (cortisol and adrenaline).

Such psychologic disorders, bearing a direct relationship to environmental stressors, are among the most common occupational health problems. Stress syndromes are distinguished from anxiety disorders, in which the psychologic disturbance arises from within the individual and has no definite relationship to environmental stimuli. Whether certain individuals are by nature hyperresponsive to such stimuli is not known. The only therapeutic approach is to attempt to alter the patient's perception of stress—for example, with psychotherapy and meditation exercises—and to remove him, if possible, from recognizable environmental stressors. (See "Editorial" in references.)

Irritable Mood and Aggressive Behavior

The phenomenon of irritability, or an irritable mood, must be familiar to almost everyone, exposed as we are to all of the noise, niggling inconveniences, and annoyances of daily life. It is, nevertheless, a difficult symptom to interpret in the context of psychopathology. Freud used the term *Reizbarkeit* in a restricted sense to denote an undue sensitivity to noise—and considered it a manifestation of anxiety, but obviously, this symptom has a much broader connotation and significance. For one thing, some people are by nature irritable throughout life. Also, irritability is an almost expected reaction in overworked, overwrought individuals, who become irritable by force of circumstances. An irritable mood or feeling may be present without observed manifestations (inward irritability), or there may be an overt loss of control of temper, with irascible verbal and behavioral outbursts, provoked by trivial but frustrating events.

Irritability in the foregoing circumstances can hardly be considered a departure from normal. However, when it becomes a recurrent event in a person of normally placid temperament, it assumes significance, for it may then signify an ongoing anxiety state or depression. Irritability is also a common symptom of obsessive-compulsive disorders. Here the irritability tends to be directed inward, indicating perhaps a sense of frustration with personal disability (Snaith and Taylor). Depressed patients are frequently irritable; as a corollary, this symptom should always be sought in patients suspected of being depressed. The days preceding menses and the mother's common postnatal mood disorder are characterized by high levels of outwardly directed irritability. Short-temperedness and irritability are also common features of the manic state. The most extreme degrees of irritability, exemplified by repeated quarrelsome and assaultive behavior (irritable aggression), are rarely observed in anxiety disorders and endogenous depression but are usually the mark of sociopathy and conventional brain disease (in the past, general paresis). Such irritable aggression is also observed in some patients with Alzheimer disease and other types of dementia, particularly of the frontotemporal type, and following traumatic contusions or encephalitis of the temporal and frontal lobes.

Cause, Mechanism, and Biologic Significance of Nervousness and Anxiety

These have been the subjects of much biologic and psychologic speculation, and completely satisfactory explanations are not available. As noted above, some individuals go through life in a chronic state of low-grade anxiety, the impetus for which may or may not be apparent. Spontaneous episodes of anxiety demand another explanation. Some psychologists regard anxiety as anticipatory behavior, i.e., a state of uneasiness about something that may happen in the future. William McDougall spoke of it as "an emotional state arising when a continuing strong desire seems likely to miss its goal." The primary emotion, somewhat muted perhaps, may be one of fear, and its arousal under conditions that are not overtly threatening may be explained as a conditioned response to some recondite component of a formerly threatening stimulus. The James-Lange theory of emotion, which is dated but should not be dismissed, suggests that the dominant feature of the experience of anxiety is simply the physical experience of the associated autonomic discharge.

Infusions of lactic acid can make the symptoms of anxiety worse and, in susceptible individuals, may elicit a panic attack. The patient seems not to tolerate the work or exercise needed to build up stamina. The urinary excretion of epinephrine was found to be elevated in some patients with panic disorder; in others, there is an increased urinary excretion of norepinephrine and its metabolites. During periods of intense anxiety, aldosterone excretion is increased to 2 or 3 times normal.

There is evidence that corticosteroids and corticotropin-releasing hormone (CRH) have a role in the genesis of anxiety. A systemic release of corticosteroid accompanies all states of stress, and the administration of corticosteroids

may give rise to anxiety and panic in some patients and to depression in others, suggesting a linkage between steroid stimulation of the limbic system activities that generate these states. In animal models, stress elicited by predators or electric shock as well as by withdrawal of alcohol and other drugs precipitates activity in CRH pathways (amygdala to hypothalamus, raphe nuclei, nucleus ceruleus, and other regions of the brainstem); blocking such activity by drugs or by destruction of the amygdala eliminates anxiety and fear-like behavior. Admittedly, the concepts of fear, stress, and anxiety are used interchangeably in these models, but repeated stimuli that produce fear and stress may eventually induce a state akin to anxiety, and the amygdala appears to be involved in the perpetuation of this anxiety state. The meaning of these effects, i.e., whether they are primary or secondary, is not certain, but it is evident that prolonged and diffuse anxiety is associated with certain biochemical abnormalities of the blood and probably of the brain.

In addition to the role of the amygdala, animal studies have related acute anxiety to a disturbance of function of the locus ceruleus and the septal and hippocampal areas, the principal norepinephrine-containing nuclei. The locus ceruleus is involved in rapid eye movement (REM) sleep and drugs such as the tricyclic antidepressants and monoamine oxidase inhibitors, which suppress REM sleep, also decrease anxiety. Certain of the serotonin receptors in the brain, different from those implicated in depression, have been related to anxiety. Other parts of the brain must also be involved; bifrontal orbital leukotomy diminishes anxiety, possibly by interrupting the medial forebrain connections with the limbic parts of the brain. Positron emission tomography (PET) studies in subjects who anticipate an electric shock show enhanced activity in the temporal lobes and insula, implicating these regions in the experience of acute anxiety (see also "Physiology of the Limbic System" in Chap. 25). Other credible studies have demonstrated a role for the anterior cingulate gyrus in eliciting many of the autonomic features (particularly increased heart rate) of excessive arousal and anxiety.

Several other alterations in neurotransmitter function have been implicated in the anxious state. The finding that a small proportion of the inherited personality trait of anxiety can be accounted for by one polymorphism of the serotonin transporter gene is provocative (Lesch et al) but requires confirmation.

DEPRESSIVE REACTIONS

There are few persons who do not at some time experience periods of severe discouragement and despair. As with nervousness, irritability, and anxiety, depression of mood that is appropriate to a given situation in life (e.g., grief reaction) is seldom the basis of medical concern. Persons in these situations tend to seek help only when their grief or unhappiness is persistent and beyond control. However, there are numerous instances in which the symptoms

of depression assert themselves for reasons that are not apparent. Often the symptoms are interpreted as a medical illness, bringing the patient first to the internist or neurologist. Sometimes another disease is found (such as cancer, chronic hepatitis, or other infection or postinfectious asthenia) in which chronic fatigue is confused with depression; more often the opposite pertains, i.e., an endogenous depression is the essential problem even when there has been evidence earlier of a viral or bacterial infection.

From the patient and the family it is learned that the patient has been "feeling unwell," "low in spirits," "blue," "down," "unhappy," or "morbid." There has been a change in his emotional reactions of which the patient may not be fully aware. Activities that were formerly found pleasurable are no longer so. Often, however, change in mood is less conspicuous than reduction in psychic and physical energy, and it is in this type of patient that diagnosis is most difficult. A complaint of fatigue is almost invariable; not uncommonly, it is worse in the morning after a night of restless sleep. The patient complains of a "loss of energy," "weakness," "tiredness," "having no energy," that his job has become more difficult. His outlook is pessimistic. The patient is irritable and preoccupied with uncontrollable worry over trivialities. With excessive worry, the ability to think with accustomed efficiency is reduced; the patient complains that his mind is not functioning properly, and he is forgetful and unable to concentrate. If the patient is naturally of suspicious nature, paranoid tendencies may assert themselves.

Particularly troublesome may be the patient's tendency to *hypochondriasis*. Indeed, most cases formerly diagnosed as hypochondriasis are now regarded as depression with superimposed anxiety. Pain from whatever cause, a stiff joint, a toothache, fleeting chest or abdominal pains, muscle cramps, or other disturbances such as constipation, frequency of urination, insomnia, pruritus, burning tongue, or weight loss may lead to obsessive complaints. The patient passes from doctor to doctor, seeking relief from symptoms that would not trouble the normal person, and no amount of reassurance relieves his state of mind. The anxiety and depressed mood of these persons may be obscured by their preoccupation with visceral functions.

When the patient is examined, his facial expression is often plaintive, troubled, pained, or anguished. The patient's attitude and manner betray a prevailing mood of depression, hopelessness, and despondency. In other words, the affect, which is the outward expression of feeling, is consistent with the depressed mood. During the interview, the patient may be tearful and may cry openly. In some, there is a kind of immobility of the face that mimics parkinsonism, though others are restless and agitated (pacing, wringing their hands, etc.). Occasionally the patient will smile, but the smile impresses one as more a social gesture than a genuine expression of feeling.

The stream of speech is slow. Sighing is frequent. There may be long pauses between questions and answers. The latter are brief and may be monosyllabic. There is a paucity of ideas. The impediment extends to all topics of conversation and affects movement of the

limbs as well. The most extreme forms of decreased motor activity, rarely seen in the office or clinic, border on muteness and stupor (“anergic depression”). Conversation is replete with pessimistic thoughts, fears, and expressions of unworthiness, inadequacy, inferiority, hopelessness, and sometimes guilt. In severe depressions, bizarre ideas and bodily delusions may be expressed (“blood drying up,” “bowels are blocked with cement,” “I am half dead”).

Several theories have emerged concerning the cause of the pathologic depressive state, but none can be confirmed with confidence except for a heritable aspect. These views are elaborated on in Chap. 52.

It is the authors’ belief that depressive states are among the most commonly overlooked diagnoses in

clinical medicine. Part of the trouble is with the word itself, which implies being unhappy about something. Endogenous depression should be suspected in all states of chronic ill health, hypochondriasis, disability that exceeds the manifest signs of a medical disease, neurasthenia and ongoing fatigue, and chronic pain syndromes. Inasmuch as recovery is the rule, suicide is a tragedy for which the medical profession must sometimes share responsibility. In extreme circumstances, however, the patient is impelled to suicide and efforts on the part of the physician cannot be considered as a failure.

Depressive illnesses and theories of their causation and management are considered extensively in Chap. 52.

The Limbic Lobes and the Neurology of Emotion

The medical literature is replete with references to illnesses based on emotional disorders. Careful examination of clinical material discloses that diverse phenomena are being so classified: anxiety states, cycles of depression and mania, reactions to distressing life situations, psychosomatic diseases, and illnesses of obscure nature. Obviously, great license is being taken with the term *emotional*. Such ambiguity renders neurologic analysis difficult. Nevertheless, in certain clinical states patients appear to be excessively apathetic or elated under conditions that are not normally conducive to such displays of emotion. It is to these disturbances that the following remarks pertain. Emotion may be defined as any feeling state—for example, fear, anger, excitement, love, or hate—associated with certain types of bodily changes (mainly visceral and under control of the autonomic nervous system) and leading usually to an impulse to action or to a certain type of behavior. If the emotion is intense, there may ensue a disturbance of intellectual functions, that is, a disorganization of rational thought and a tendency toward a more automatic behavior of unmodulated, stereotyped character.

In its most easily recognized human form, emotion is initiated by a stimulus, real or imagined, the perception of which involves recognition, memory, and specific associations. The emotional state that is engendered is mirrored in a psychic experience, i.e., a *feeling*, which is purely subjective and known to others only through the patient's verbal expressions or by judging his behavioral reactions. This behavioral aspect, which is in part autonomous (hormonal-visceral) and in part somatic, shows itself in the patient's facial expression, bodily attitude, vocalizations, or directed voluntary activity, an observable display for which we use the term *affect*. In other words, the components of emotion appear to consist of (1) the perception of a stimulus, which may be internal (an idea) or external, (2) the feeling, (3) the autonomic-visceral changes, (4) the outward display (*affect*), and (5) the impulse to a certain type of activity. In many cases of neurologic disease, it is not possible to separate these components from one another, and to emphasize one of them does no more than indicate the particular bias of the examiner. Obviously, neural networks of both affective response and cognition are involved.

Anatomic Considerations

The occurrence of abnormal emotional reactions in the course of disease is associated with lesions that preferentially involve certain parts of the nervous system. These structures are grouped under the term *limbic* and are among the most complex and least understood parts of the nervous system. The Latin word *limbus* means "border" or "margin." Credit for introducing the term *limbic* to neurology is usually given to Broca, who used it to describe the ring of gray matter formed primarily by the cingulate and parahippocampal gyri that encircles the corpus callosum and underlying upper brainstem. Actually, Thomas Willis had pictured this region of the brain and referred to it as the *limbus* in 1664. Broca preferred his term, *le grand lobe limbique*, to *rhinencephalon*, which was the term then in vogue and referred more specifically to structures having an olfactory function. Neuroanatomists have extended the boundaries of the *limbic lobe* to include not only the cingulate and parahippocampal gyri but also the underlying hippocampal formation, the subcallosal gyrus, and the paraolfactory area. The terms *visceral brain* and *limbic system*, introduced by MacLean, have an even wider designation and more completely describe the structures involved in emotion and its expression; in addition to all parts of the limbic lobe, they include a number of associated subcortical nuclei such as those of the amygdaloid complex, septal region, preoptic area, hypothalamus, anterior thalamus, habenula, and central midbrain tegmentum, including the raphe nuclei and interpeduncular nucleus. The major structures that constitute the limbic system and their relationships are illustrated in Figs. 25-1 and 25-2.

The cytoarchitectonic arrangements of the limbic cortex clearly distinguish it from the surrounding neocortex. The latter, as stated in Chap. 22, differentiates into a characteristic six-layer structure (isocortex). In contrast, the inner part of the limbic cortex, the hippocampus, is composed of irregularly arranged aggregates of nerve cells that tend to be in a trilaminar configuration (archi- or allocortex). The cortex of the cingulate gyrus, which forms the outer ring of the limbic lobe, is transitional between neocortex and allocortex—hence, it is called mesocortex. The entorhinal cortex adjacent to the anterior hippocampus has a similar

Figure 25-1. Sagittal diagram of the limbic system. *A.* Surface topography of the limbic system and associated prefrontal cortex. *B.* Connections of the limbic structures and their relation to the thalamus, hypothalamus, and midbrain tegmentum. The cortical parts of the limbic system, or limbic lobe, are interconnected by a septohypothalamic–mesencephalic bundle ending in the hippocampus, and the fornix, which runs from the hippocampus back to the mammillary bodies, and by tracts from the mammillary bodies to the thalamus and from the thalamus to the cingulate gyrus. The Papez circuit is the internal component of this system. See also Fig. 25-2 and the text. (Reproduced with permission from Kandel ER, Schwartz JH, Jessell TM: *Principles of Neural Science*, 4th ed. New York, McGraw-Hill, 2000.)

transitional architecture. Information from a wide array of cortical neurons is funneled into the dentate gyrus and then to the CA (cornu ammonis) pyramidal cells of the hippocampus. Output from the hippocampus is mainly from the pyramidal cells of the CA1 segment and subiculum, whose axons form the fibria and fornix. The amygdaloid complex, a subcortical nuclear component of the limbic system, also has a unique composition, consisting of several separable nuclei, each with connections to other limbic structures.

The connections between the orbitofrontal neocortex and limbic lobes, between the individual components of the limbic lobes, and between the limbic lobes and the hypothalamus and midbrain reflect their many functional relationships in regard to emotion. At the core of this system lies the medial forebrain bundle, a complex set of ascending and descending fibers that connect the orbitomesiofrontal cortex, septal nuclei, amygdala, and hippocampus rostrally, and certain nuclei in the

midbrain and pons caudally. This system, of which the hypothalamus is the central part, was designated by Nauta as the *septohypothalamo–mesencephalic continuum*.

There are many other interrelationships among various parts of the limbic system, only a few of which can be indicated here. The best known of these is *Papez circuit*. It leads from the hippocampus, via the fornix, to the mammillary body and septal and preoptic regions (see Fig. 25-1). The mammillothalamic tract (bundle of Vicq d’Azyr) connects the mammillary nuclei with the anterior nuclei of the thalamus, which, in turn project to the cingulate gyrus and then, via the cingulum back to the hippocampus. The cingulum runs concentric to the curvature of the corpus callosum; it connects various parts of the limbic lobe to one another and projects to the striatum and to certain brainstem nuclei as well. Also, the cingulum receives fibers from the inferior parietal lobule and temporal lobe, which are multimodal association centers for the integration of visual, auditory, and

Figure 25-2. Schematic block diagram of the limbic connections. The internal connections (*bold lines*) represent the circuit described by Papez. The external connections (*thin lines*) are more recently described pathways. This figure also shows the connections to the amygdala and prefrontal and association cortices. tactile perceptions. It is connected to the opposite cingulum through the anterior corpus callosum.

Physiology of the Limbic System

The functional properties of the limbic structures first became known during the third and fourth decades of the twentieth century. From ablation and stimulation studies, Cannon, Bard, and others established the fact that the hypothalamus contains the suprasegmental integrations of the autonomic nervous system, both the sympathetic and parasympathetic parts. Soon after, anatomists found efferent pathways from the hypothalamus to the neural structures subserving parasympathetic and sympathetic reflexes. One such segmental reflex, involving the sympathetic innervation of the adrenal gland, served as the basis of Cannon's emergency theory of sympathoadrenal action, which for many years dominated thinking about the neurophysiology of acute emotion.

Following Cannon, Bard incorrectly localized the central regulatory apparatus for respiration, wakefulness, and sexual activity in the hypothalamus. Only later, the hypothalamus was found to contain neurosecretory cells, which control the secretion of the pituitary hormones; also within it are special sensory receptors for the regulation of hunger, thirst, body temperature, and levels of circulating electrolytes. Gradually the idea emerged of a hypothalamic-pituitary-autonomic system that is essential to both the basic homeostatic and emergency ("fight-or-flight") reactions of the organism. The functional anatomy of these autonomic and neuroendocrine systems is discussed in Chaps. 26 and 27.

The impression of the leading psychologists of the nineteenth century that autonomic reactions were the

essential motor component of instinctual feeling has been partially corroborated. It was proposed that emotional experience was merely the self-awareness of these visceral activities (the James-Lange theory of emotion alluded to in Chap. 24). The limitations of this theory became evident when it was demonstrated by Cannon that the capacity to manifest emotional changes remained after all visceral afferent fibers had been interrupted. Nonetheless, it remains true that perception of visceral activities can greatly alter the emotional state. An example is the perception of a rapid heartbeat, leading to heightened anxiety, which results in further acceleration in the heart rate.

Although the natural stimuli for emotion involve the same neocortical perceptive-cognitive mechanisms, as do nonemotional sensory experiences, there are important differences, which relate to the prominent visceral effects and particular behavioral reactions evoked by emotion. Clearly, specific parts of the nervous system must be utilized. Bard, in 1928, first produced "sham rage" in cats by removing the cerebral hemispheres and leaving the hypothalamus and brainstem intact. This is a state in which the animal reacts to all stimuli with expressions of intense anger and signs of autonomic overactivity. In subsequent studies, Bard and Mountcastle found that only if the ablations included the amygdala on both sides would sham rage be produced; removal of all the neocortex, but sparing of the limbic structures resulted in placidity. Interestingly, in the macaque, a normally aggressive and recalcitrant animal, removal of the amygdaloid nuclei bilaterally greatly reduced the reactions of fear and anger (see further on). The role of the hypothalamus and amygdala in the production of both directed and undirected anger and displays of rage has turned out to be far more complex. In any case, Papez, on the basis of these and his own anatomic observations, postulated that the limbic parts of the brain elaborate the functions of central emotion and participate as well in emotional expression. The intermediate position of the limbic structures enables them to transmit neocortical effects from their outer side to the hypothalamus and midbrain on their inner side.

The role of the *cingulate gyrus* in the behavior of animals and humans has been the subject of much discussion. Stimulation is said to produce autonomic effects similar to the vegetative correlates of emotion (increase in heart rate and blood pressure, dilatation of pupils, piloerection, respiratory arrest, breathholding). More complex responses, such as fear, anxiety, or pleasure, have been reported during neurosurgical stimulative and ablative procedures, although these results are inconsistent. Bilateral cingulectomies performed in the past on psychotic and anxious patients result in an overall diminution of emotional reactions (Ballantine et al; Brown). Some investigators believe that the cingulate gyri are also involved in memory processing (functioning presumably in connection with the mediodorsal thalamic nuclei and mediotemporal lobes) and in exploratory behavior and visually focused attention. In humans, this system appears to be more efficient in the nondominant hemisphere. According to Bear, and as conceptualized by Baleyrier and Mauguier, the cingulate gyri serve dual functions in cognition and in emotional reactions.

Another aspect of limbic function has come to light with information about the neurotransmitters that interconnect the structures within the system. The concentration of norepinephrine is highest in the hypothalamus and next highest in the medial parts of the limbic system; at least 70 percent of this monoamine is concentrated in terminals of axons that arise in the medulla and in the locus ceruleus of the rostral pons. Axons of other ascending fibers, especially those originating in the reticular formation of the midbrain and terminating in the amygdala and septal nuclei as well as in lateral parts of the limbic lobe are rich in serotonin.

The axons of neurons in the ventral tegmental parts of the midbrain, which ascend in the medial forebrain bundle and the nigrostriatal pathway, contain a high content of dopamine. Perhaps this explains the observation that a severe depressive reaction may be produced by electrical stimulation of the substantia nigra with an aberrantly placed electrode for the treatment of Parkinson disease (see Chap. 39). The many structures listed above and their connections certainly constitute a unified functional system. The term *limbic system* is a simplification, particularly as the various parts differ widely in respect to their connections with the neocortex and central nuclei, their transmitters, and their effects when damaged. But it can be said that lesions in this system most consistently and specifically alter emotionality; thus it remains a useful concept.

EMOTIONAL DISTURBANCES DUE TO DISEASES INVOLVING LIMBIC STRUCTURES

Many of the foregoing ideas about the role of the limbic system have come from experimentation in laboratory animals. Only in relatively recent years have neurologists, primed with the knowledge of these studies, begun to relate emotional disturbances in patients with disease of limbic structures. These clinical observations, summarized in the following pages, form an interesting chapter in neurology. Table 25-1 lists the most readily recognized disturbances of emotion. The list is tentative, as our understanding of many of these states, particularly their pathologic basis, is incomplete. Only a small number of these derangements can be used as indicators of lesions and diseases in particular parts of the human brain. Taken in context, however, these disturbances are useful diagnostically. As knowledge of emotional disorders increases, an understanding of the functioning of limbic structures will undoubtedly bring together large segments of psychiatry and neurology.

Emotional Disturbances in Hallucinatory and Pain States

These are portrayed by the patient with a florid delirium. Threatened by imaginary figures and voices that seem real and inescapable, the patient trembles, struggles to escape, and displays the full picture of terror. The patient's

Table 25-1

affect, emotional reaction, and visceral and somatic motor responses are altogether appropriate to the content of hallucinations. We have seen a patient slash his wrists and another try to drown himself in response to hallucinatory voices that admonished them for their worthlessness and the shame they had brought on their families. But the abnormality in these circumstances is one of disordered perception and thinking, and we have no reason to believe that there is a fundamental derangement of the mechanisms for emotional expression.

There also occurs a state, difficult to classify, of overwhelming emotionality in patients who are in severe, acute pain. The patient's attention can be captured only briefly, but within moments, there is a return to an extreme state of angst, groaning, and anger. We have encountered this with spinal subdural hemorrhage, subarachnoid hemorrhage, explosive migraine, trauma with multiple fractures, and intense pelvic, renal, or abdominal pain, all understandable as responses to extralimbic stimuli.

Disinhibition of Emotional Expression

Emotional Lability

It is a commonplace clinical experience that cerebral diseases of many types, seemingly without respect to location, weaken the mechanism of control of emotional expression. A patient whose cerebrum has been damaged, for example, by a series of vascular lesions, may suffer the humiliation of crying in public upon meeting an old friend or hearing the national anthem, or of displaying uncontrollable laughter in response to a mildly amusing remark or an attempt to tell a funny story. There may also be easy vacillation from one state to another, an *emotional lability* that has for more than a century been accepted as a sign of "organic brain disease." In this type of emotional disturbance, the response, while excessive, does not quite reach the degree of forced emotionality of the special form of lability described as pseudobulbar (see below); furthermore, it is appropriate to the stimulus and the affect is congruent with the visceral and motor components of the expression. The anatomic substrate is obscure. Perhaps lesions of the frontal lobes more than of other parts of the brain are conducive to this state, but the

authors are unaware of a critical clinicoanatomic study that substantiates this impression. Emotional lability is a frequent accompaniment of diffuse cerebral diseases, such as Alzheimer disease, but these diseases involve the limbic cortex as well. Also under this heading might be included the tearfulness and facile mood that so often accompany chronic diseases of the nervous system, and the shallow facetiousness (*witzelsucht*) and behavioral disinhibition of the patient with frontal lobe disease.

Pseudobulbar (Spasmodic) Laughing and Crying

This form of disordered emotional expression, characterized by outbursts of involuntary, uncontrollable, and stereotyped laughing or crying, has been recognized since the late nineteenth century. Numerous references to these conditions (the *Zwangslachen* and *Zwangswainen* noted by German neurologists and the *rire et pleurer spasmodiques* described by the French) can be found in the writings of Oppenheim, von Monakow, and Wilson (see Wilson for historical references). The term *emotional incontinence* applied by psychiatrists may be accurate but is a bit pejorative. Forced laughing or crying always has a pathologic basis in the brain, either diffuse or focal; hence, this stands as a syndrome of multiple causes. It may occur with degenerative and vascular diseases of the brain (Table 25-2) and no doubt is the direct result of them, but often the diffuse nature of the underlying disease precludes useful topographic analysis and clinicoanatomic correlation.

The best examples of pathologic laughing and crying are provided by multiple lacunar vascular disease and by amyotrophic lateral sclerosis, multiple sclerosis, and progressive supranuclear palsy, in each case the lesions being distributed bilaterally and generally involving the motor tracts, specifically, the corticobulbar motor system as discussed further on. They may also be part of the residue of the more widespread lesions of hypoxic-ischemic encephalopathy, Binswanger ischemic encephalopathy, cerebral trauma, infiltrative gliomas of the frontal lobe or pons, and infectious and noninfectious encephalitides. Typical in our experience is a sudden hemiplegia from a stroke that is engrafted upon a preexistent (and often clinically silent) lesion in the opposite hemisphere; this sets the stage for the pathologic displays of emotionality.

In this state, there is sometimes a striking incongruity between the loss of voluntary movements of muscles innervated by the motor nuclei of the lower pons and medulla (inability to forcefully close the eyes, elevate and retract the corners of the mouth, open and close the mouth, chew, swallow, phonate, articulate, and move the tongue) and the preservation of movement of the same muscles in yawning, coughing, throat clearing, and spasmodic laughing or crying (i.e., in reflexive pontomedullary activities). This is the motor syndrome of *pseudobulbar palsy* for which reason the term *pseudobulbar affective state* has been applied to the emotional disorder.

On the slightest provocation and sometimes for no apparent reason, the patient is thrown into a stereotyped spasm of laughter that may last for moments or up to many minutes, to the point of exhaustion. Or, far more often, the opposite happens—the mere mention of the patient's family or the sight of the doctor provokes an uncontrollable spasm of crying or, more accurately stated, a caricature of crying. The severity of the emotional display and the ease with which it is provoked does not correspond with the severity of the pseudobulbar paralysis or with an exaggeration of the facial and masseter ("jaw jerk") tendon reflexes. In some patients with forced crying and laughing, there is little or no detectable weakness of facial and bulbar muscles; in others, forced laughing and crying are lacking despite a severe upper motor neuron weakness of these muscles. In certain diseases, such as progressive supranuclear palsy and central pontine myelinolysis, of which pseudobulbar palsy is a frequent manifestation, forced laughing and crying are less dramatic or absent. Consequently, the pathologic emotional state cannot be equated with pseudobulbar palsy even though the two usually occur together.

Is this state, whether one of involuntary laughing or of crying, activated by an appropriate stimulus? In other words, does the emotional response accurately reflect the patient's affect or feeling? There are no simple answers to these questions. One problem is to determine what constitutes an appropriate stimulus for the patient in question. Virtually always, the emotional response is set off by some stimulus or thought; but usually, it is trifling, or at least it appears so to the physician. Merely addressing the patient or making some casual remark in his presence may suffice. Oppenheim and others stated that these patients need not feel sad when crying or mirthful when laughing, and at least in some cases, this is in agreement with our experience. Other patients, however, do report a general congruence of affect and emotional experience (mood), but the amplitude of the response is nonetheless excessive.

Noteworthy are the stereotyped nature of the initial motor facial response, and the relatively undifferentiated nature of the emotional reaction. Laughter or crying may merge, one with the other. Poock (1985) puts great emphasis on the latter point, but it does not seem surprising when one considers the closeness of these two forms of emotional expression, a phenomenon that is particularly evident in young children. More impressive to us is the fact that in some patients with pseudobulbar palsy, laughing and crying, or caricatures thereof, are the

Table 25-2

CAUSES OF PSEDOBULBAR AFFECTIVE DISPLAY

Bilateral strokes (lacunes in the cerebral hemispheres or pons) most often after several strokes in succession
Binswanger diffuse leukoencephalopathy (Chap. 34)
Amyotrophic lateral sclerosis with pseudobulbar palsy
Progressive supranuclear palsy
Multiple sclerosis with bilateral corticobulbar demyelinating lesions
Bilateral traumatic lesions of the hemispheres
Gliomatosis cerebri
Hypoxic-ischemic encephalopathy
Pontine myelinolysis
Wilson disease

only available forms of emotional expression; intermediate phenomena, such as smiling and frowning, are lost. In other patients with pseudobulbar palsy, there are lesser degrees of forced laughing and crying, perhaps bridging the gap between this phenomenon, and the type of emotional lability discussed earlier.

Wilson, in his discussion of the anatomic basis and mechanism of forced laughing and crying, pointed out that both involve the same facial, vocal, and respiratory musculature and have similar visceral accompaniments (dilatation of facial vessels, secretion of tears, etc). Two major supranuclear pathways control the pontomedullary mechanisms of facial and other movements required in laughing and crying. One is the familiar corticobulbar pathway that runs from the motor cortex through the posterior limb of the internal capsule and controls volitional movements; the other is a more anterior pathway that descends just rostral to the genu of the internal capsule, and contains facilitatory and inhibitory fibers. Unilateral involvement of the anterior pathway leaves the opposite side of the face under volitional control but paretic during laughing, smiling, and crying (emotional facial paralysis); the opposite is observed with a unilateral lesion of the posterior pathway. Wilson's argument, based to some extent on clinicopathologic evidence, was that in pseudobulbar palsy, it was the descending motor pathways, which naturally inhibit the expression of the emotions, that were interrupted although he was uncertain of the exact level. Almost 40 years later, Poeck (1985), after reviewing all the published pathologic anatomy in 30 verified cases, was able to do no more than conclude that supranuclear motor pathways are always involved, with loss of a control mechanism somewhere in the brainstem between thalamus and medulla. However, this clinical state is observed in amyotrophic lateral sclerosis, where the corticobulbar tracts may be involved at a cortical and subcortical level. As mentioned earlier, the lesions are bilateral in practically all instances (Poeck, 1985). There have been reports of spasmodic laughter following unilateral striatocapsular infarction (Ceccaldi et al) and occasional cases after unilateral pontine infarction or arteriovenous malformation, but these were not verified pathologically.

Of interest is the beneficial effect on distressing pseudobulbar displays of drugs such as imipramine and fluoxetine (Schiffer et al). A study has also shown benefit from dextromethorphan combined with quinidine in the pseudobulbar state of amyotrophic lateral sclerosis (Brooks et al). In a few personally observed cases, both the emotional lability and pathologic laughter and crying were partially suppressed by these drugs; but in most others, there was no effect.

A rare but probably related syndrome is *le fou rire prodromique* (prodromal laughing madness) of Féré, in which uncontrollable laughter begins abruptly and is followed after several hours by hemiplegia. We have seen two such cases in which basilar artery occlusion evolved after a brief bout of such forced laughter. Martin cites examples where patients laughed themselves to death. Again, the pathologic anatomy is unsettled. Protracted laughing and (less often) crying may occur rarely as a

manifestation of epileptic seizures, usually of focal temporal lobe type. Ictal laughter is usually without affect (mirthless laughter); Daly and Mulder referred to these as "gelastic" seizures. The concurrence of gelastic seizures and precocious puberty is characteristic of an underlying hamartoma (or other lesion) of the hypothalamus (see Chaps. 16 and 27).

Aggressiveness, Anger, Rage, and Violence

Aggressiveness is an integral part of social behavior. The emergence of this trait early in life enables the individual to secure a position in the family and later in an ever-widening social circle. Individual differences are noteworthy. Timidity, for example, is a persistent trait recognized in infancy (Kagan). Males tend to be more aggressive than females. The degree to which excessively aggressive behavior is tolerated varies in different cultures. In most civilized societies, tantrums, rage reactions, and outbursts of violence and destructiveness are not condoned and one of the principal objectives of child rearing and education is the suppression and sublimation of such behavior. The rate at which this developmental process proceeds varies from one individual to another. In some males and the cognitively impaired, it is not complete until 25 to 30 years of age; the deviant behavior results in *sociopathy* (see Chap. 28). Undoubtedly, from our own casual and others' more systematic observations, aggressiveness is an inherited tendency.

That seemingly groundless outbreaks of unbridled and disorganized rage may rarely represent the initial or main manifestation of disease is not fully appreciated. A patient with these symptoms may, with little provocation, change from a reasonable state to one of the wildest rage, with a blindly furious impulse to violence and destruction. In such states, the patient appears out of contact with reality and is impervious to all argument or pleading. There are examples also of a dissociation of affect and behavior in which the patient may spit, cry out, attack, or bite without seeming to be angry. This is especially true of the developmentally delayed.

All the human and animal data point to an origin of aggressiveness, anger, and rage in the temporal lobes and particularly in the amygdala. In humans, stimulation of the medial amygdaloid nuclei, through depth electrodes, evokes a display of anger, whereas stimulation of the lateral nuclei does not; destruction of the amygdaloid complex bilaterally reportedly reduces aggressiveness (Kiloh; Narabayashi et al). Lesions in the mediadorsal thalamic nuclei, which receive projections from the amygdaloid nuclei, render humans more placid and docile. In an unintended experiment in a patient with Parkinson disease, Bejjani and colleagues found that aggressive behavior could be induced by stimulation of the posteromedial hypothalamus. As with the comparable elicitation of depression from an aberrant electrode in the substantia nigra that was reported by the same group, it is not clear whether the effect was because of changes induced in adjacent neuronal pathways or if the physiologic response was the result of excitatory or inhibitory neuronal activity in the hypothalamus.

Sex hormones influence the activity of these temporal lobe circuits; testosterone promotes aggressiveness and estradiol suppresses it, suggesting an explanation for sex differences in the disposition to anger. Surprisingly, propranolol and lithium have benefited such patients more than haloperidol, other neuroleptics, or sedatives.

Animal studies have corroborated observations in humans. As mentioned in the introductory section, bilateral removal of the amygdaloid nuclei in the macaque greatly reduces the expressions of both fear and anger. Electrical stimulation in or near the amygdala of the unanesthetized cat yields a variety of motor and vegetative responses. One of these has been referred to as the *fear* or *flight* response, in which the animal appears frightened, and runs away and hides; another is the *anger* or *defense* reaction, characterized by growling, hissing, and piloerection. However, structures other than the amygdaloid nuclei are also involved in these reactions. Lesions in the ventromedial nuclei of the hypothalamus (which receive abundant input from the amygdaloid nuclei) have been shown to cause aggressive behavior, and bilateral ablation of Brodmann area 24 (rostral cingulate gyrus) has produced the opposite state—tameness and reduced aggressiveness—at least in some species.

Rage reactions of the intensity described above may be encountered in the following medical settings: (1) rarely as part of a temporal lobe seizure; (2) as an episodic reaction without recognizable seizures or other neurologic abnormality, as in certain sociopaths; (3) in the course of a recognizable acute neurologic disease; and (4) with the clouding of consciousness that accompanies a metabolic or toxic encephalopathy; (5) as a reaction to designed psychogenic drugs (dragonfly, K4, and others).

Rage in Temporal Lobe Seizures

(See also “Focal Seizures” in Chap. 16)

According to Gastaut and colleagues, a directed attack of uncontrollable rage may occur either as part of a seizure or as an interictal phenomenon. Some patients describe a gradual heightening of excitability for 2 to 3 days, either before or after a seizure, before bursting into a rage. Certainly, such attacks have been observed, but they are rare. A lesser degree of aggressive behavior as part of a temporal lobe seizure is not uncommon; it is usually part of the ictal or postictal behavioral automatism and tends to be brief in duration and poorly directed. Usually, the lesion is in the temporal lobe of the dominant hemisphere. Similarly, a feeling of rage or severe anger occurs but is relatively infrequent as an ictal emotion, much less common than feelings of fear, sadness, or pleasure (Williams reported only 17 cases of anger among 165 patients with ictal emotion). Geschwind emphasized the frequency of a profound deepening of all of the patient’s emotional experiences in temporal lobe epilepsy.

Rage Attacks Without Seizure Activity

In some instances of this type, the patient had from early life been hot-headed, intolerant of frustration, and

impulsive, exhibiting behavior that would be classified as sociopathic (Chap. 51). There are others, however, who, at certain periods of life, usually adolescence or early adulthood, begin to have episodes of wild, aggressive behavior. Alcohol or some other drug may trigger episodes. One suspects epilepsy, but there is no history of a recognizable seizure and no interruption of consciousness, which are so typical of focal temporal lobe epilepsy. We have been consulted from time to time on patients who report a proclivity to anger, cursing, and momentary unreasonableness in behavior that is acquired in adulthood. Most such individuals are remorseful afterwards and otherwise function at a high cognitive level. Each of these patients described a first-order relative with the same traits. In a very few such cases, in which aggression has resulted in serious injury to others (or homicide), depth electrodes placed in the amygdaloid nuclear complex have recorded what could be construed as seizure discharges. Attacks of excitement and various autonomic accompaniments have been aroused by stimulation of the same region, and the abnormal behavior has in some instances been relieved by ablation of the abnormally discharging structures. Mark and Ervin have documented a number of examples of this “dyscontrol syndrome,” but we are doubtful that they are truly epileptic.

Violent Behavior in Acute or Chronic Neurologic Disease

One encounters patients in whom intense excitement, rage, and aggressiveness begin abruptly in association with an acute neurologic disease or in a phase of partial recovery. In most cases, the medial and anterior temporal lobes have been damaged. Serious head injury with protracted coma may be followed by personality changes consisting of aggressive outbursts, suspiciousness, poor judgment, indifference to the feelings of family, and variable degrees of cognitive impairment. Hemorrhagic leukoencephalitis, lobar hemorrhage, infarction, traumatic contusion, and herpes simplex encephalitis affecting the medial and orbital portions of the frontal lobes and anterior portions of the temporal lobes may have the same effect (Fig. 25-3). Fisher noted the occurrence of intense rage reactions as an aftermath of a dominant temporal lobe lesion that had caused a Wernicke type of aphasia. Cases of this type have also been reported with ruptured aneurysm of the circle of Willis and extension of a pituitary adenoma; references to these reports can be found in the articles of Poeck (1969) and of Pillieri.

Also of interest are the effects of slow-growing tumors of the temporal lobe. Malamud described outbursts of rage in association with temporal lobe gliomas. Other of his patients harboring such tumors had no rage reactions but exhibited a clinical picture superficially resembling schizophrenia. It is noteworthy that 8 of the 9 patients with temporal lobe glioma described by Malamud also had seizures. The anteromedial part of the left temporal lobe has been the site of the tumor in the majority of cases. Falconer and Serafetinides have described patients with rage reactions in whom there was a hamartoma or sclerotic focus in this region.

Figure 25-3. A. Localization of lesions that, in humans, can lead to aggressive behavior and placidity. B. Localization of lesions that, in humans, can lead to placidity, release of oral behavior, and hypersexuality. (From Poeck [1969].)

A special form of violent outburst during REM sleep is detailed in Chap. 19, on Sleep. This, REM sleep behavior disorder, is associated with certain degenerative brain diseases.

Aggressive Behavior in Acute Toxic–Metabolic Encephalopathies and Drug Intoxications

Here the patient is not in a clear-headed state and rage or aggression is superimposed on an encephalopathy of toxic or metabolic origin. The most dramatic examples in our experience have been during hypoglycemic reactions. When the patient is left alone, the aggressive behavior is undirected and disorganized, but anyone in the immediate neighborhood may be struck by the agitated individual. Attempts at physical restraint provoke an even more violent reaction.

A similar state may occur with phencyclidine and cocaine intoxication, and with other hallucinogens, accompanied by agitation and, usually, by hallucinosis. Perhaps the most berserk episodes we have encountered have been after ingestion of large amounts of designed street drugs such as the hallucinogen dragonfly and with cannabis derivatives such as K4 (Spice). These furious behaviors may last for hours or days and are resistant to large doses of haloperidol and benzodiazepines. We have found alpha-2 agonists such as dexmedetomidine to be effective. Outbursts of rage and violence with alcohol intoxication are somewhat different in nature: some instances represent a rare paradoxical or idiosyncratic reaction to alcohol (see Chap. 42); more typically alcohol appears to disinhibit an underlying sociopathic behavior pattern.

Placidity and Apathy

Animals normally indulge in and display highly energized, exploratory activity of their environment. Some of this activity is motivated by the drive for sexual satisfaction and procurement of food; in humans, it may be a matter of curiosity. These activities are governed by “expectancy circuits,” involving nuclear groups in mesolimbic and mesocortical dopaminergic circuits connected with the diencephalon and mesencephalon via the medial forebrain bundles; lesions that interrupt these connections are said to abolish the expectancy reactions. Positron emission tomography (PET) studies correlate functional difficulty in the initiation of movements with impaired activation of the anterior cingulum, putamen, prefrontal cortex, and supplementary motor area (Playford et al).

A quantitative reduction in all activity is probably the most frequent of all psychobehavioral alterations in patients with cerebral disease, particularly in those with involvement of the anterior parts of the frontal lobes. There are fewer thoughts, fewer words uttered, and fewer movements per unit of time. That this is not a purely motor phenomenon is disclosed in conversation with the patient, who seems to perceive and think more slowly, to make fewer associations with a given idea, to initiate speech less frequently, and to exhibit less inquisitiveness and interest. This reduction in psychomotor activity is recognized as a striking personality change by the family.

Depending on how this state is viewed, it may be interpreted as a heightened threshold to stimulation, inattentiveness or inability to maintain an attentive attitude, impaired thinking, apathy, or lack of impulse (*abulia*). In a sense, all are correct, for each represents a different aspect of the reduced mental activity. Clinicoanatomic correlates are inexact, but bilateral lesions deep in the septal region (basal frontal, as sometimes occur with bleeding from an anterior communicating aneurysm) have resulted in the most striking lack of impulse, spontaneity, and conation (drive) (see Fig. 25-3). Impairment of learning and memory functions may be added. Typically, the patient is fully attentive, wide awake, and looks around. Upon recovery, memory is retained for all that happened. In this respect, *abulia* differs from stupor and hypersomnolence.

Patients who exhibit *abulia* are difficult to test because they respond slowly or not at all to every type of test. Yet on rare occasions, when intensely stimulated, they may speak and act normally. It is as though some energizing mechanism (possibly striatocortical), different from the reticular activating system of the upper brainstem, were impaired. Often, patients with severe *abulia* perform better with automatic or overlearned behaviors, such as talking on the telephone.

Quite apart from this abulic syndrome, which has already been discussed in relation to coma and to extensive lesions of the frontal lobes (Chaps. 17 and 22), there are lesser degrees in which a lively, sometimes volatile person has been rendered placid (hypobulic) by a disease of the nervous system.

Most often, the frontal lobe damage is bilateral, but sometimes on the left only, as discussed in Chap. 22.

Diseases as diverse as hydrocephalus, glioma, strokes, trauma, and encephalitis may be causative. Formerly, changes of this type were observed following bilateral prefrontal leukotomy. Barris and Schuman, and many others have documented states of extreme placidity with lesions of the anterior cingulate gyri. Unlike the case in depression, the mood is neutral; the patient is apathetic rather than depressed.

The subdued emotional behavior described earlier differs from that observed in the *Klüver-Bucy syndrome*, which results from total bilateral temporal lobectomy in adult rhesus monkeys (see also Chap. 22). While these animals were made rather placid and lacked the ability to recognize objects visually (they could not distinguish edible from inedible objects), they had a striking tendency to examine everything orally, were unusually alert and responsive to visual stimuli (they touched or mouthed every object within their visual fields), became hypersexual, and increased their food intake. This constellation of behavioral changes has been sought in human beings, for example, after removal of the temporal lobes but the complete picture has occurred only infrequently (Marlowe et al; Terzian and Dalle). Pillieri, and Poeck (1969) have collected cases that have come closest to reproducing the syndrome (see Fig. 25-3). Many human examples have occurred in conjunction with diffuse diseases (Alzheimer and Pick cerebral atrophies, meningoencephalitis because of toxoplasmosis, herpes simplex, and AIDS) and hence are of limited value for anatomic analysis. With bitemporal surgical ablations, placidity and enhanced oral behavior were the most frequent consequences; altered sexual behavior and visual agnosia were less frequent. In all patients who showed placidity and an amnesic state, the hippocampi and medial parts of the temporal lobe had been destroyed, but not the amygdaloid nuclei.

Reduced emotionality in humans, albeit one that is very restricted in scope, is associated with acute lesions in the right, or nondominant, parietal lobe. Not only is the patient indifferent to the paralysis but, as Bear points out, he is unconcerned about his other diseases as well as personal and family problems, is less able to interpret the emotional facial expressions of others, and is inattentive in general. There may be a lack of emotional inflection to speech (aprosodia) and an inability to interpret the emotional state of other individuals, as discussed in Chap. 23. Dimond and coworkers interpret this to mean that the right hemisphere is more involved in affective-emotional experience than the left, which is committed to language. Observations derived from the study of split-brain patients and from selective anesthetization of the cerebral hemispheres by intracarotid injection of amobarbital (Wada test) lend some support to this probably oversimplified view. Rarely, lesions of the left (dominant) hemisphere appear to induce the opposite effect, a frenzied excitement lasting for days or weeks.

Altered Sexuality

The normal pattern of sexual behavior in both males and females may be altered by cerebral disease quite apart from impairment due to obvious physical disability or

to diseases that destroy or isolate the segmental reflex mechanisms (see Chap. 26).

Hypersexuality in men or women is a rare but well-documented complication of neurologic disease. It has long been believed that lesions of the orbital frontal lobes may remove moral-ethical restraints and lead to indiscriminate sexual behavior, and that superior frontal lesions may be associated with a general loss of initiative that reduces all, including sexual, impulsivity. In rare cases, extreme hypersexuality marks the onset of encephalitis or develops gradually with tumors of the temporal region. Possibly the limbic parts of the brain are disinhibited, the ones from which MacLean and Ploog could evoke penile erection and orgasm by electrical stimulation (medial dorsal thalamus, medial forebrain bundle, and septal preoptic region).

In humans, Heath has observed that stimulation of the ventroseptal area (through depth electrodes) evokes feelings of pleasure and lust. Also, Gorman and Cummings have described two patients who became sexually disinhibited after a shunt catheter had perforated the dorsal septal region. This is in keeping with the experience of Heath and Fitzjarrell, who found that infusion of acetylcholine into the septal region (as an experimental treatment for Parkinson disease) produced euphoria and orgasm, and with Heath's recordings from the septum of patients during sexual intercourse, showing greatly increased activity with spikes and slow waves. Perhaps these are examples of a true overdrive of libido, as contrasted with simple disinhibition of sexual behavior. However, we know of no case in which a stable lesion that caused abnormal sexual behavior has been studied carefully by sections of the critical parts of the brain.

In clinical practice, the most common cause of disinhibited sexual behavior, next to the aftermaths of head injury and cerebral hemorrhage, is the use of dopaminergic drugs in Parkinson disease. An intriguing effect of the administration of L-dopa in a few patients has been excessive or perverse sexual behavior, as in the cases described by Quinn and colleagues. Usually there are other manifestations of manic behavior. Primary mania may do the same.

Hyposexuality, meaning loss of libido, is most often the result of a depressive illness. However, certain medications, notably antihypertensive, antiepileptic, serotonergic antidepressant, and neuroleptic drugs may be responsible in individual patients. A variety of cerebral diseases may also have this effect, in parallel with a loss of interest and drive in a number of spheres.

Lesions that involve the tuberoinfundibular region of the hypothalamus are known to cause specific disturbances in sexual function. If such lesions are acquired early in life, pubertal changes are prevented from occurring; or, hamartomas of the hypothalamus, as in von Recklinghausen neurofibromatosis and tuberous sclerosis, may cause sexual precocity. Autonomic neuropathies and lesions involving the sacral parts of the parasympathetic system, the most common being prostatectomy, may abolish normal sexual performance but do not alter libido or orgasm.

Blumer and Walker have reviewed the literature on the association of epilepsy and abnormal sexual behavior. They

note that sexual arousal, as an ictal phenomenon, is apt to occur in relation to temporal lobe seizures, particularly when the discharging focus is in the mediotemporal region. However, these authors also emphasize the high incidence of global hyposexuality in patients with temporal lobe epilepsy. Temporal lobectomy in such patients has sometimes been followed by a period of hypersexuality.

Acute Fear, Anxiety, Elation, and Euphoria

The phenomenon of acute fear and anxiety occurring as a prelude to or part of a seizure is familiar to every neurologist. Williams's study, already mentioned, is of particular interest; from a series of about 2,000 epileptics, he was able to cull 100 patients in whom an emotional experience was part of the seizure. Of the latter, 61 experienced feelings of fear and anxiety, and 21 experienced depression. Daly has made similar observations. These clinical data call to mind the effects that had been noted by Penfield and Jasper when they stimulated the upper, anterior, and inferior parts of the temporal lobe and cingulate gyrus during surgical procedures; frequently, the patient described feelings of strangeness, uneasiness, and fear. In most instances, consciousness was variably impaired at the same time, and some patients had hallucinatory experiences as well.

In these cortical stimulations, neuronal circuits subserving fear are coextensive with those of anger; both are thought to lie in the medial part of the temporal lobe and amygdala, as discussed earlier. Both in animals and in humans, electrical stimulation in this region can arouse each emotion, but the circuitry subserving fear appears to be located lateral to that of anger and rage. Destruction of the central part of the amygdaloid nuclear complex abolishes fear reactions. These nuclei are connected to the lateral hypothalamus and midbrain tegmentum, regions from which Monroe and Heath, as well as Nashold and associates, have been able to evoke feelings of fear and anxiety by electrical stimulation.

Depression is less frequent as an ictal emotion, although it occurs often enough as an interictal phenomenon (Benson et al). Of interest is the observation that lesions of the dominant hemisphere are more likely than nondominant ones to be attended by an immediate pervasive depression of mood, disproportionate to the degree of severity of physical disability (Robinson et al). We are inclined to the view that the onset of depression after a stroke is a reaction to disability, i.e., a reactive depression, akin to that which follows myocardial infarction (Chap. 52).

Odd mixtures of depression and anxiety are often associated with temporal lobe tumors and less often with tumors of the hypothalamus and third ventricle (see review by Alpers), and they sometimes occur at the onset of a degenerative disease, such as multiple system atrophy.

Elation and *euphoria* are less well documented as limbic phenomena, nor has this elevation in mood in some patients with multiple sclerosis ever been adequately explained. Feelings of pleasure and satisfaction as well as "stirring sensations" are unusual, but well-described emotional experiences in patients with temporal lobe seizures, and this type of affective response, like that of fear, has been elicited by stimulating several different parts of the

temporal lobe (Penfield and Jasper). In states of hypomania and mania, every experience may be colored by feelings of delight and pleasure, and a sense of power, and the patient may remember these experiences after he has recovered.

Differential Diagnosis of Perturbations in Emotion and Affect

Aside from clinical observation, there are no reliable means of evaluating or quantifying the emotional disorders described earlier. Although neurologic medicine has done little more than describe and classify some of the clinical states dominated by emotional derangements, knowledge of this type is nonetheless of both theoretical and practical importance. In theory, it prepares one for the next step, of passing from a superficial to a deeper order of inquiry, where questions of pathogenesis and etiology can be broached. Practically, it provides certain clues that are useful in differential diagnosis. A number of particular neurologic possibilities must always be considered when one is confronted with one of the following clinical states.

Uninhibited Laughter and Crying and Emotional Lability

As indicated earlier, one may confidently assume that the syndrome of forced or spasmodic laughing and crying signifies cerebral disease, and, more specifically, bilateral disease of the corticobulbar tracts (see Table 25-2). Usually the motor and reflex changes of spastic bulbar (pseudobulbar) palsy (described in the discussion of "Spastic [Pseudobulbar] Dysarthria" in Chap. 23) are associated usually, but not always, with heightened facial and mandibular reflexes ("jaw jerk"), and often corticospinal tract signs in the limbs as well. Extreme emotional lability also indicates bilateral cerebral disease, although only the signs of unilateral disease may be apparent clinically. The most common pathologic bases for these clinical states are lacunar infarction or other cerebrovascular lesions, diffuse hypoxic-hypotensive encephalopathy, amyotrophic lateral sclerosis, and multiple sclerosis, as already indicated; but in a number of less-common processes, such as progressive supranuclear palsy and Wilson disease, it may be quite a prominent feature. Abrupt onset, of course, points to vascular disease.

Placidity and Apathy

These may be the earliest and most important signs of cerebral disease. Clinically, placidity and apathy must be distinguished from the akinesia or bradykinesia of Parkinson disease and the reduced mental activity of depressive illness. Here, Alzheimer disease, normal-pressure hydrocephalus, and frontal-corporum callosum tumors are the most common pathologic states underlying apathy and placidity, but these disturbances may complicate a variety of other frontal and temporal lesions, such as those occurring with demyelinating disease or as an aftermath of ruptured anterior communicating aneurysm.

Outbursts of Rage and Violence

Most often such an outburst is but another episode in a lifelong sequence of sociopathic behaviors (see Chap. 51).

More significance attaches to its abrupt appearance as a sudden departure from an individual's normal personality. If an outburst of rage accompanies a seizure, the rage should be viewed as the consequence of the disruptive effect of seizure activity on temporal lobe function; however, as indicated earlier, an outburst of uncontrolled rage and violence is only rarely a manifestation of temporal lobe epilepsy. Lesser degrees of poorly directed combative behavior as part of ictal or postictal automatism are more common. Rarely, rage and aggressivity are expressive of an acute neurologic disease that involves the mediotemporal and orbitofrontal regions, such as a glioma. We have several times observed such states in the course of a dementing disease and in a stable individual as a transient expression of an obscure encephalopathy.

Rage reactions with continuous violent activity must be distinguished from *mania*, in which there is flight of ideation to the point of incoherence, euphoric or irritable mood, and incessant psychomotor activity; from *organic drivemess*, in which continuous motor activity, accompanied by no clear ideation occurs, usually in a child, as an aftermath of encephalitis; and from extreme instances of *akathisia*, where incessant restless movements and pacing may occur in conjunction with extrapyramidal symptoms.

Extreme Fright and Agitation

Here the central problem must be clarified by determining whether the patient is delirious (clouding of consciousness, psychomotor overactivity, and hallucinations), deluded (schizophrenia), manic (overactive, flight of ideas), or experiencing an isolated panic attack (palliation, trembling, feeling of suffocation). Rarely does panic prove to be an expression of temporal lobe epilepsy. In an adult without a characterologic trait of anxiety, an acute panic attack may signify the onset of a depressive illness or schizophrenia.

Bizarre Ideation Developing Over Weeks or Months

Although these symptoms are usually caused by a psychosis (schizophrenia or bipolar disease), one should consider a tumor, immune or paraneoplastic encephalitis, or other lesion of the temporal lobe, particularly when accompanied by temporal lobe seizures, aphasic symptoms, rotatory vertigo (rare), and quadrantic visual field defects. Such states have also been described in hypothalamic disease, suggested by somnolence, diabetes insipidus, visual field defects, and in hydrocephalus (see Chap. 27).

Disorders of the Autonomic Nervous System, Respiration, and Swallowing

The human internal environment is regulated in large measure by the integrated activity of the autonomic nervous system and endocrine glands. Their visceral and homeostatic functions, essential to life and survival, are involuntary. Why the forces of evolution favored this separation from volition is an interesting question. Claude Bernard expressed this idea in sardonic terms when he wrote, "nature thought it prudent to remove these important phenomena from the caprice of an ignorant will."

Although only few neurologic diseases exert their effects primarily or exclusively on the autonomic-neuroendocrine axis, there are numerous medical diseases that implicate this system in some way: hypertension, asthma, and certain dramatic disorders of cardiac conduction, to name some of the important ones. However, many general neurologic diseases involve the autonomic nervous system to a varying extent, giving rise to symptoms such as syncope, sphincteric dysfunction, pupillary abnormalities, erectile dysfunction, diaphoresis, cardiac dysrhythmias, and disorders of thermoregulation. Finally, in addition to their central role in visceral innervation, autonomic parts of the neuraxis and parts of the endocrine system are engaged in all emotional experience and its display, as discussed in Chap. 25.

Breathing is unusual among nervous system functions. Although continuous throughout life, it is not altogether automatic, being partly under volitional control. Current views of the central and peripheral control of breathing, and the ways in which it is altered by certain diseases are of considerable interest to neurologists, if for no other reason than respiratory failure is common in neurologic conditions such as coma, cervical spinal cord injury, and a large number of acute and chronic neuromuscular diseases. Many of these same comments pertain to the function of swallowing, which is largely automatic and continues at regular intervals even in sleep but is also initiated voluntarily. Furthermore, swallowing fails in ways similar to breathing as a consequence of neurologic diseases.

The autonomic, endocrine, and respiratory systems, although closely related, give rise to disparate clinical syndromes. This chapter deals more strictly with the autonomic nervous system and the neural mechanisms of respiration and swallowing, and the next chapter, with the hypothalamus and neuroendocrine disorders.

The following discussion of anatomy and physiology serves as an introduction to both chapters.

Anatomic Considerations

The most remarkable feature of the autonomic nervous system is that a major part of it is located outside the brain and spinal cord, in proximity to the visceral structures that it innervates. This position alone seems to symbolize its relative independence from the cerebrospinal system. In distinction to the somatic neuromuscular system, where a single motor neuron bridges the gap between the central nervous system (CNS) and the effector organ, in the autonomic nervous system there are always two efferent neurons serving this function, one (preganglionic) arising from its nucleus in the brainstem or spinal cord and the other (postganglionic) arising from specialized nerve cells in peripheral ganglia. Figure 26-1 illustrates this fundamental anatomic feature.

The autonomic nervous system, from an anatomic point of view, is divided into two parts: the craniosacral, or parasympathetic, and the thoracolumbar, or sympathetic (Figs. 26-2 and 26-3). The systems differ architecturally in that the ganglion in the sympathetic nervous system is located in a contiguous and interconnected, longitudinal chain (sympathetic chain) paravertebrally, whereas the parasympathetic ganglia are distributed in proximity to the structures they innervate. Moreover, the main neurotransmitter of the postganglionic connection to the end organ is norepinephrine in the case of the sympathetic nerves and acetylcholine for parasympathetic innervation. There are exceptions with regard to the sympathetic innervation of sweat glands (sudomotor), which are cholinergic. The neurotransmitter between the pre- and postneurons throughout the autonomic nervous system, sympathetic and parasympathetic, is acetylcholine as reiterated further on. These synapses between pre- and postganglionic cholinergic nerves are not blocked by atropine (nicotinic) whereas the postganglionic impulses are blocked by atropine (muscarinic).

Functionally, the two parts are complementary in maintaining a balance in the tonic activities of many visceral structures and organs. This rigid separation into sympathetic and parasympathetic parts, although useful for purposes of exposition, is physiologically not absolute.

Figure 26-1. Sympathetic outflow from the spinal cord and the course and distribution of sympathetic fibers. The preganglionic fibers are in heavy lines; postganglionic fibers are in thin lines. (From Pick.)

From a neurologist's perspective, the two components are often affected together. Nonetheless, the notion of a balanced sympathetic and parasympathetic autonomic system has stood the test of time and remains a valid concept.

The Parasympathetic Nervous System

(See Fig. 26-2)

There are two divisions of the parasympathetic nervous system: cranial and sacral. The *cranial division* originates in the visceral nuclei of the midbrain, pons, and medulla. These nuclei include the Edinger-Westphal pupillary nucleus, superior and inferior salivatory nuclei, dorsal motor nucleus of the vagus, and adjacent reticular nuclei.

Axons (preganglionic fibers) of the visceral cranial nuclei course through the oculomotor, facial, glossopharyngeal, and vagus cranial nerves. The preganglionic fibers from the Edinger-Westphal nucleus traverse the oculomotor nerve and synapse in the ciliary ganglion in the orbit; axons of the ciliary ganglion cells innervate the ciliary muscle and pupillary sphincter (see Fig. 14-9).

The preganglionic fibers of the superior salivatory nucleus enter the facial nerve and, at a point near the geniculate ganglion, form the greater superficial petrosal nerve, through which they reach the sphenopalatine ganglion; postganglionic fibers from the cells of this ganglion innervate the lacrimal gland (see also Figs. 26-2 and 47-3). Other fibers originating in the salivatory nuclei are carried in the facial nerve and traverse the tympanic

cavity as the chorda tympani to eventually join the submandibular ganglion. Cells of this ganglion innervate the submandibular and sublingual glands. Axons of the inferior salivatory nerve cells enter the glossopharyngeal nerve and reach the otic ganglion through the tympanic plexus and lesser superficial petrosal nerve; cells of the otic ganglion send fibers to the parotid gland.

Preganglionic fibers, derived from the dorsal motor nucleus of the vagus and adjacent visceral nuclei in the lateral reticular formation (mainly the nucleus ambiguus), enter the vagus nerve and terminate in ganglia situated in the walls of many thoracic and abdominal viscera. The ganglionic cells give rise to short postganglionic fibers that activate smooth muscle and glands of the pharynx, esophagus, and gastrointestinal tract (the vagal innervation of the colon is somewhat uncertain but considered to extend up to the descending colon) and of the heart, pancreas, liver, gallbladder, kidney, and ureter.

The *sacral part of the parasympathetic system* originates in the lateral horn cells of the second, third, and fourth sacral segments. Axons of these sacral neurons, constituting the preganglionic fibers, traverse the sacral spinal nerve roots of the cauda equina and synapse in ganglia that lie within the walls of the distal colon, bladder, and other pelvic organs. Thus, the sacral autonomic neurons, like the cranial ones, have long preganglionic and short postganglionic fibers, a feature that permits a circumscribed influence upon the target organ.

Figure 26-2. The parasympathetic (craniosacral) division of the autonomic nervous system. Preganglionic fibers extend from nuclei of the brainstem and sacral segments of the spinal cord to peripheral ganglia. Short postganglionic fibers extend from the ganglia to the effector organs. The lateral-posterior hypothalamus is part of the supranuclear mechanism for the regulation of parasympathetic activities. The frontal and limbic parts of the supranuclear regulatory apparatus are not indicated in the diagram (see text). (Reproduced by permission from Noback CL, Demarest R: *The Human Nervous System*, 3rd ed. New York, McGraw-Hill, 1981.)

Figure 26-3. The sympathetic (thoracolumbar) division of the autonomic nervous system. Preganglionic fibers extend from the intermediolateral nucleus of the spinal cord to the peripheral autonomic ganglia, and postganglionic fibers extend from the peripheral ganglia to the effector organs, according to the scheme in Fig. 26-1. (Reproduced by permission from Noback CL, Demarest R: *The Human Nervous System*, 3rd ed. New York, McGraw-Hill, 1981.)

In organs containing smooth muscle that is innervated by parasympathetic fibers and therefore not under voluntary control, there is a parallel innervation of adjacent voluntary striated muscle by anterior horn cells. For example, the neurons that activate the external sphincter of the bladder (voluntary muscle) differ from those that supply the smooth muscle of the internal sphincter as discussed further on. In 1900, Onufrowicz (calling himself Onuf) described a discrete group of relatively small cells in the anterior horns of sacral segments 2 to 4. These neurons were originally thought to be autonomic in function, mainly because of their histologic features. There is now evidence that they are somatomotor, innervating the skeletal muscle of the external urethral and anal sphincters (Holstege and Tan). Neurons in sacral cord segments located in a region analogous to the intermediolateral cell column of the sympathetic nervous system (see later), innervate the detrusor and internal sphincter of the bladder wall. In passing, it is worth noting that in motor system disease, in which bladder and bowel functions are usually preserved until late in the disease, the neurons in the Onuf nucleus, in contrast to other somatomotor neurons in the sacral cord, tend not to be involved in the degenerative process (Mannen et al).

There are elaborate connections between supranuclear centers, mainly in the hypothalamus, to the pupillary sphincters, lacrimal and salivary glands that course the brainstem. With regard to the supranuclear innervation of parasympathetic nuclei in the sacral segments, little is known. There appear to be connections to these neurons from the hypothalamus, locus ceruleus, and pontine micturition centers but their course in the human spinal cord has not been identified with certainty.

The Sympathetic Nervous System

(See Fig. 26-3)

The *preganglionic neurons of the sympathetic division originate* in the intermediolateral cell column of the spinal gray matter, from the eighth cervical to the second lumbar segments. Low and Dyck (1977) have estimated that each segment of the cord contains approximately 5,000 lateral horn cells and that there is an attrition of 5 to 7 percent per decade in late adult life. The axons of the nerve fibers originating in the intermediolateral column are of small caliber and are myelinated; when grouped, they form the *white communicating rami* as shown in Fig. 26-1. These preganglionic fibers synapse with the cell bodies of the postganglionic neurons, which are collected into two large ganglionated chains or cords, one on each side of the vertebral column (paravertebral ganglia), and several single prevertebral ganglia. These constitute the sympathetic ganglia.

Axons of the sympathetic ganglion cells are also of small caliber but are unmyelinated. Most of the postganglionic fibers pass via *gray communicating rami* to their adjacent spinal nerves of T5 to L2; they supply blood vessels, sweat glands, and hair follicles, and also form plexuses that supply the heart, bronchi, kidneys, intestines, pancreas, bladder, and sex organs. The postganglionic fibers of the prevertebral ganglia (located in

the retroperitoneal posterior abdomen rather than paravertebrally, along the sides of the spinal column) form the hypogastric, splanchnic, and mesenteric plexuses, which innervate the glands, smooth muscle, and blood vessels of the abdominal and pelvic viscera (see Fig. 26-3).

The sympathetic innervation of the adrenal medulla is unique in that its secretory cells receive preganglionic fibers directly, via the splanchnic nerves. This is an exception to the rule that organs innervated by the autonomic nervous system receive only postganglionic fibers. This special arrangement can be explained by the fact that cells of the adrenal medulla are the morphologic homologues of the postganglionic sympathetic neurons and secrete epinephrine and norepinephrine (the postganglionic transmitters) directly into the bloodstream. In this way, the sympathetic nervous system and the adrenal medulla act in unison to produce diffuse effects, as one would expect from their role in emergency reactions.

There are 3 cervical (superior, middle, and inferior, or stellate), 11 thoracic, and 4 to 6 lumbar sympathetic ganglia. The head receives its sympathetic innervation from the eighth cervical and first two thoracic cord segments, the fibers of which pass through the inferior to the middle and superior cervical ganglia. Postganglionic fibers from cells of the superior cervical ganglion follow the internal and external carotid arteries and innervate the blood vessels and smooth muscle, as well as the sweat, lacrimal, and salivary glands of the head. Included among these postganglionic fibers, issuing mainly from T1, are the pupillo dilator fibers and those innervating the Müller muscle of the upper eyelid (it connects the upper tarsus to the undersurface of the levator); there is a separate small inferior tarsus muscle that is also sympathetically innervated. The arm receives its postganglionic innervation from the inferior cervical ganglion and uppermost thoracic ganglia (the two are fused to form the stellate ganglion). The cardiac plexus and other thoracic sympathetic nerves are derived from the stellate ganglion and the abdominal visceral plexuses, from the fifth to the ninth or tenth thoracic ganglia. The lowermost thoracic ganglia have no abdominal visceral connections; their axons course rostrally and caudally in the sympathetic chain. The upper lumbar ganglia supply the descending colon, pelvic organs, and legs.

The terminals of autonomic nerves and their junctions with smooth muscle and glands have been more difficult to visualize and study than the motor end plates of striated muscle. As the postganglionic axons enter an organ, usually via the vasculature, they ramify into many smaller branches and disperse, without a Schwann cell covering, to innervate the smooth muscle fibers, the glands, and, in largest number, the small arteries, arterioles, and precapillary sphincters (see Burnstock). Some of these terminals penetrate the smooth muscle of the arterioles; others remain in the adventitia. At the ends of the postganglionic fibers and in part along their course there are swellings that lie in close proximity to the sarcolemma or gland cell membrane; often the muscle fiber is grooved to accommodate these swellings. The axonal swellings contain synaptic vesicles, some clear

and others with a dense granular core. The clear vesicles contain acetylcholine and those with a dense core contain catecholamines, particularly norepinephrine (Falck). This is well illustrated in the iris, where nerves to the dilator muscle (sympathetic) contain dense-core vesicles and those to the constrictor (parasympathetic) contain clear vesicles. A single nerve fiber innervates multiple smooth muscle and gland cells.

Visceral Afferents Somewhat arbitrarily, anatomists have declared the autonomic nervous system to be purely efferent motor and secretory in function. However, most autonomic nerves are mixed, also containing afferent fibers that convey sensory impulses from the viscera and blood vessels. The cell bodies of these sensory neurons lie in the posterior root sensory ganglia; some central axons of these ganglionic cells synapse with lateral horn cells of the spinal cord and subserve visceral reflexes; others synapse in the dorsal horn and convey or modulate impulses for conscious sensation. Secondary afferents carry sensory impulses to certain brainstem nuclei, particularly the nucleus tractus solitarius, as described later, and the thalamus via the lateral spinothalamic and polysynaptic pathways.

The Central Regulation of Visceral Function

Integration of autonomic function takes place at two levels, the brainstem and the cerebrum. In the brainstem, the main visceral afferent nucleus is the nucleus tractus solitarius (NTS). Cardiovascular, respiratory, and gastrointestinal afferents, carried in cranial nerves X and IX via the nodose and petrosal ganglia, terminate on specific subnuclei of the NTS. The caudal subnuclei are the primary receiving site for viscerosensory fibers; other less-well-defined areas receive baroreceptor and chemoreceptor information. The caudal NTS integrates these signals and projects to a number of critical areas in the hypothalamus, amygdala, and insular cortex, involved primarily in cardiovascular control, as well as to the pontine and medullary nuclei controlling respiratory rhythms. The NTS therefore serves a critical integratory function for both circulation and respiration, as described further on.

Perhaps the major advance in our understanding of the autonomic nervous system occurred with the elaboration of the autonomic regulating functions of the hypothalamus. Small, insignificant-appearing nuclei in the walls of the third ventricle and in buried parts of the limbic cortex have rich bidirectional connections with autonomic centers in various parts of the nervous system. As indicated in Chap. 25, the hypothalamus serves as the integrating mechanism of the autonomic nervous system and limbic system. The regulatory activity of the hypothalamus is accomplished in two ways, through direct pathways that descend to particular groups of cells in the brainstem and spinal cord, and through the pituitary and thence to other endocrine glands. The supranuclear regulatory apparatus of the hypothalamus includes three main cerebral structures: the frontal lobe cortex, the insular cortex, and the amygdaloid and adjacent nuclei.

The ventromedial prefrontal and cingulate cortices function as the highest levels of autonomic integration.

Stimulation of one frontal lobe may evoke changes in temperature and sweating in the contralateral arm and leg; massive lesions here, which usually cause a hemiplegia, may modify the autonomic functions in the direction of either inhibition or facilitation. Lesions involving the posterior part of the superior frontal and anterior part of the cingulate gyri (usually bilateral, occasionally unilateral) result in loss of voluntary control of the bladder and bowel. Most likely a large contingent of these fibers terminates in the hypothalamus, which, in turn, sends fibers to the brainstem and spinal cord. The descending spinal pathways from the hypothalamus are believed to lie ventromedial to the corticospinal fibers.

The insular cortex receives projections from the NTS, the parabrachial nucleus of the pons, and the lateral hypothalamic nuclei. Direct stimulation of the insula produces cardiac arrhythmias and a number of other alterations in visceral function. The cingulate and hippocampal gyri and their associated subcortical structures (substantia innominata and the amygdaloid, septal, piriform, habenular, and midbrain tegmental nuclei) have been identified as important cerebral autonomic regulatory centers. Together they have been called the *visceral brain* (see Chap. 25). Of particular importance in autonomic regulation is the amygdala, the central nucleus of which is a major site of origin of projections to the hypothalamus and brainstem. The anatomy and the effects of stimulation and ablation of the amygdala have been discussed in Chap. 25, in relation to the neurology of emotion.

In addition to the aforementioned central relationships, it should be noted that important interactions between the autonomic nervous system and the endocrine glands occur at a peripheral level. The best-known example is in the adrenal medulla. A similar relationship pertains to the pineal gland, in which norepinephrine (NE) released from postganglionic fibers that end on pineal cells stimulates several enzymes involved in the biosynthesis of melatonin. Similarly, the juxtaglomerular apparatus of the kidney and the islets of Langerhans of the pancreas may function as neuroendocrine transducers insofar as they convert a neural stimulus (in these cases adrenergic) to an endocrine secretion (renin, glucagon, and insulin, respectively). The numerous autonomic-endocrine interactions are elaborated in the next chapter.

Finally, there is the essential role that the hypothalamus plays in the initiation and regulation of autonomic activity, both sympathetic and parasympathetic. Sympathetic responses are most readily obtained by stimulation of the posterior and lateral regions of the hypothalamus, and parasympathetic responses from the anterior regions. The descending sympathetic fibers are largely or totally uncrossed. According to Carmel, fibers from the caudal hypothalamus at first run in the prerubral field, dorsal and slightly rostral to the red nucleus, and then ventral to the ventrolateral thalamic nuclei; then they descend in the lateral tegmentum of the midbrain, pons, and medulla to synapse in the intermediolateral cell column of the spinal cord. In the medulla, the descending sympathetic pathway is located in the posterolateral retroolivary area, where it is frequently

involved in lateral medullary infarctions. In the cervical cord, the fibers run in the posterior angle of the anterior horn (Nathan and Smith). According to the latter authors, some of the fibers supplying sudomotor neurons run outside this area but also remain ipsilateral. Jansen and colleagues, by the use of viral vectors in rodents, were able to label certain neurons of the hypothalamus and the ventral medulla that stimulated sympathetic activity in both the stellate ganglion and the adrenal gland. They hypothesized that this dual control underlies the fight-or-flight response, as described in Chap. 25. By contrast, the pathways of descending parasympathetic fibers are not well defined.

Afferent projections from the spinal cord to the hypothalamus have been demonstrated in animals and provide a potential route by which sensation from somatic and possibly visceral structures may influence autonomic responses.

Physiologic and Pharmacologic Considerations

The function of the autonomic nervous system in its regulation of the visceral organs is to a high degree independent of voluntary control and awareness. Furthermore, when the autonomic nerves are interrupted, these organs continue to function (the organism survives), but they are no longer as effective in maintaining homeostasis and adapting to the demands of changing internal conditions and external stresses.

Viscera have a double-nerve supply, sympathetic and parasympathetic and in general these two parts of the autonomic nervous system exert opposite effects. For example, the effects of the sympathetic nervous system on the heart are excitatory and those of the parasympathetic inhibitory. However, some structures—sweat glands, cutaneous blood vessels, and hair follicles—receive only sympathetic postganglionic fibers, and the adrenal gland, as indicated earlier, has only a preganglionic sympathetic innervation. Also, some parasympathetic neurons have been identified in sympathetic ganglia.

Neurohumoral Transmission

All autonomic functions are mediated through the release of chemical transmitters. The modern concept of neurohumoral transmission had its beginnings in the early decades of the twentieth century. In 1921, Loewi discovered that stimulation of the vagus nerve released a chemical substance (*Vagusstoff*) that slowed the heart. Later this substance was shown by Dale to be acetylcholine (ACh). Also, in 1920, Cannon reported that stimulation of the sympathetic trunk released an epinephrine-like substance, which increased the heart rate and blood pressure. He named this substance “sympathin,” subsequently shown to be noradrenaline, or NE. Dale found that ACh had pharmacologic effects similar to those obtained by stimulation of parasympathetic nerves; he designated these effects as “parasympathomimetic.” These observations placed neurochemical transmission on solid ground and laid the basis for the distinction between cholinergic and adrenergic transmission in the autonomic nervous system.

The most important of the autonomic neurotransmitters are ACh and NE. ACh is synthesized at the terminals of axons and stored in presynaptic vesicles until it is released by the arrival of nerve impulses. ACh is released at the terminals of all preganglionic fibers (in both the sympathetic and parasympathetic ganglia), as well as at the terminals of all postganglionic parasympathetic and a few special postganglionic sympathetic fibers, mainly those subserving sweat glands. Of course, ACh is also the chemical transmitter of nerve impulses to the skeletal muscle fibers. Parasympathetic postganglionic function is mediated by two distinct types of ACh receptors: *nicotinic* and *muscarinic*, so named by Dale because the choline-induced responses were similar either to those of nicotine or to those of the alkaloid, muscarine. The postganglionic parasympathetic receptors are located within the innervated organ and are muscarinic; i.e., they are antagonized by atropine drugs. As already mentioned the receptors in ganglia, like those of skeletal muscle, are nicotinic; they are not blocked by atropine but are counteracted by other agents (e.g., tubocurarine).

It is likely that more than ACh is involved in nerve transmission at a ganglionic level. Many peptides—substance P, enkephalins, somatostatin, vasoactive intestinal peptide, adenosine triphosphate (ATP), and nitric oxide—have been identified in the autonomic ganglia, localizing in some cases to the same cell as ACh. (This negates “Dale’s principle,” or “law,” which stipulates that one neuron elaborates only one neurotransmitter.) Particular neuronal firing rates appear to cause the preferential release of one or another of these substances. Most of the neuropeptides exert their postsynaptic effects through the G-protein transduction system, which uses adenylyl cyclase or phospholipase C as an intermediary. The neuropeptides act as modulators of neural transmission, although their exact function in many cases remains to be determined.

With two exceptions, postganglionic sympathetic fibers release only NE at their terminals. The sweat glands and some blood vessels in muscle are innervated by postganglionic sympathetic fibers, but their terminals, as mentioned, release ACh. The NE that is discharged into the synaptic space activates specific *adrenergic receptors* on the postsynaptic membrane of target cells.

Adrenergic receptors are of two types, classified originally by Ahlquist as *alpha* and *beta*. In general, the alpha receptors mediate vasoconstriction, relaxation of the gut, and dilatation of the pupil; beta receptors mediate vasodilatation, especially in muscles, relaxation of the bronchi, and an increased rate and contractility of the heart. Each of these receptors is subdivided further into two types. Alpha₁ receptors are postsynaptic; alpha₂ receptors are situated on the presynaptic membrane and, when stimulated, *diminish the release of the transmitter*. Beta₁ receptors are, for all practical purposes, limited to the heart; their activation increases the heart rate and contractility. Beta₂ receptors, when stimulated, relax the smooth muscle of the bronchi and of most other sites, including the blood vessels of skeletal muscle. A comprehensive account of neurohumoral transmission and receptor function can be found in the monograph by Cooper and colleagues.

Discussed in the following pages are the ways in which the two divisions of the autonomic nervous system, acting in conjunction with the endocrine glands, maintain the homeostasis of the organism. As stated earlier, the integration of these two systems is achieved primarily in the hypothalamus. In addition, the endocrine glands are influenced by circulating catecholamines, and some of them are innervated by adrenergic fibers. Chapter 27 discusses further these autonomic–endocrine relations.

Regulation of Blood Pressure

As was indicated briefly in Chap. 18, blood pressure depends on the adequacy of intravascular blood volume, on systemic vascular resistance, and on the cardiac output. Both the autonomic and endocrine systems influence the muscular, cutaneous, and mesenteric (splanchnic) vascular beds, heart rate, and stroke volume of the heart. Together, these actions serve to maintain normal blood pressure and allow reflex maintenance of blood pressure with changes in body position. Two types of baroreceptors function as the afferent component of this reflex arc by sensing pressure gradients across the walls of large blood vessels. Those in the carotid sinus and aortic arch are sensitive to reductions in pulse pressure (the difference between systolic and diastolic blood pressure), while those in the right heart chambers and pulmonary vessels respond more to alterations in blood volume. The carotid sinus baroreceptors are rapidly responsive and capable of detecting beat-to-beat changes, in contrast to the aortic arch nerves, which have a longer response time and discriminate only the larger and more prolonged alterations in pressure.

The nerves arising from these receptors are small-caliber, thinly myelinated fibers that course in cranial nerves IX and X and terminate in the nucleus of the tractus solitarius (NTS). In response to increased stimulation of these receptors, vagal efferent activity is reduced, resulting in reflex cardioacceleration. This is accomplished through polysynaptic connections between the NTS and the dorsal motor nucleus of the vagus; it is from this structure that vagal neurons project to the sinoatrial node, atrioventricular node, and the muscle of the left ventricle. Thus, vagal activity results in reduction in heart rate and in the contractile force of the myocardium (negative inotropy). Increased systemic vascular resistance is mediated concurrently through parallel connections between the NTS and the medullary pressor areas that project to the intermediolateral cells of the midthoracic cord. The main sympathetic outflow from these thoracic segments is via the greater splanchnic nerve to the celiac ganglion, the postganglionic nerves of which project to the capacitance vessels of the gut. The splanchnic capacitance veins act as a reservoir for as much as 20 percent of the total blood volume, and interruption of the splanchnic nerves results in severe postural hypotension. After a high-carbohydrate meal there is a marked hyperemia of the gut and compensatory peripheral vasoconstriction in the muscles and skin. It has also been noted that the mesenteric vascular bed is responsive to the orthostatic redistribution of blood volume but not to mental stress.

The opposite response to the one described earlier, namely bradycardia and hypotension, results when vagal tone is enhanced and sympathetic tone reduced. This response can be triggered by baroreceptors, or it may arise from cerebral stimuli such as fear or sight of blood in susceptible individuals as well as from extreme pain, particularly arising in the viscera.

Two slower-acting humoral mechanisms regulate blood volume and complement the control of systemic vascular resistance. Pressure-sensitive renal juxtaglomerular cells release renin, which stimulates production of angiotensin and influences aldosterone production, both of which affect an increase of blood volume. Of lesser influence in the control of blood pressure is antidiuretic hormone, discussed in the next chapter; but the effects of this peptide become more important when autonomic failure forces a dependence on secondary mechanisms for the maintenance of blood pressure. In addition to its presence in autonomic ganglia, nitric oxide has been found to have an important local role in maintaining vascular tone, mainly by way of attenuating the response to sympathetic stimulation. The extent to which this latter function is under neural control is not clear.

Regulation of Bladder Function

The familiar functions of the bladder and lower urinary tract—the storage and intermittent evacuation of urine—are served by three structural components: the bladder itself, the main component of which is the large detrusor (transitional type) muscle; a functional internal sphincter composed of similar muscle; and the striated external sphincter or urogenital diaphragm. The sphincters assure continence; in the male, the internal sphincter also prevents the reflux of semen from the urethra during ejaculation. For micturition to occur, the sphincters must relax, allowing the detrusor to expel urine from the bladder into the urethra. This is accomplished by a complex mechanism involving mainly the parasympathetic nervous system (the sacral peripheral nerves derived from the second, third, and fourth sacral segments of the spinal cord and their somatic sensorimotor fibers) and, to a lesser extent, sympathetic fibers derived from the thorax. The vaguely localizable brainstem “micturition centers,” with their spinal and suprasegmental connections, may contribute (Fig. 26-4).

The detrusor muscle receives motor innervation from nerve cells in the intermediolateral columns of gray matter, mainly from the third and also from the second and fourth sacral segments of the spinal cord (the “detrusor center”). These neurons give rise to preganglionic fibers that synapse in parasympathetic ganglia within the bladder wall. Short postganglionic fibers end on muscarinic acetylcholine receptors of the muscle fibers. There are also beta-adrenergic receptors in the dome of the bladder, which are activated by sympathetic fibers that arise in the intermediolateral nerve cells of T10, T11, and T12 segments. These preganglionic fibers pass via inferior splanchnic nerves to the inferior mesenteric ganglia (see Fig. 26-1); pre- and postganglionic sympathetic axons are conveyed by the hypogastric nerve to the pelvic plexus

Figure 26-4. Innervation of the urinary bladder and its sphincters.

and the bladder dome. The internal sphincter and base of the bladder (trigone), consisting of smooth muscle, are also innervated to some extent by the sympathetic fibers of the hypogastric nerves; their receptors are mainly of alpha-adrenergic type, which makes it possible to therapeutically manipulate the function of the sphincter with adrenergically active drugs as well as the more commonly used cholinergic ones (see further on).

The external urethral and anal sphincters are composed of striated muscle fibers. Their innervation, via the pudendal nerves, is derived from a densely packed group of somatomotor neurons (nucleus of Onuf) in the anterolateral horns of sacral segments 2, 3, and 4. Cells in the ventrolateral part of Onuf's nucleus innervate the external urethral sphincter, and cells of the mediodorsal part innervate the anal sphincter. The muscle fibers of the sphincters respond to the nicotinic effects of ACh.

The pudendal nerves also contain afferent fibers coursing from the urethra and the external sphincter to the sacral segments of the spinal cord. These fibers convey impulses for reflex activities and, through connections with higher centers, for sensation. Some of these fibers probably course through the hypogastric plexus, as indicated by the fact that patients with complete transverse lesions of the cord as high as T12 may report vague sensations of urethral discomfort. The bladder is sensitive to pain and pressure; these senses are transmitted to higher centers along the sensory pathways described in Chaps. 8 and 9.

Unlike skeletal striated muscle, the detrusor, because of its postganglionic system, is capable of some contractions, although imperfect, after complete destruction of the sacral segments of the spinal cord. Isolation of the sacral cord centers (transverse lesions of the cord above the sacral levels) and their peripheral nerves permits contractions of the detrusor muscle, but they still do not empty the bladder completely; patients with such lesions usually develop dyssynergia of the detrusor and external sphincter muscles (see later), indicating that coordination of these muscles must occur at supraspinal levels (Blaivas). With acute transverse lesions of the upper cord, the function of sacral segments is abolished for several weeks in the same way as the motor neurons of skeletal muscles (the state of spinal shock).

The storage of urine and the efficient emptying of the bladder are possible only when the spinal segments, together with their afferent and efferent nerve fibers, are connected with the so-called micturition centers in the pontomesencephalic tegmentum. In experimental animals, this center (or centers) lies within or adjacent to the locus ceruleus. A medial region triggers micturition, while a lateral area seems more important for continence. These neurons receive afferent impulses from the sacral cord segments; their efferent fibers course downward via the reticulospinal tracts in the lateral funiculi of the spinal cord and activate cells in the nucleus of Onuf, as well as in the intermediolateral cell groups of the sacral segments (Holstege and Tan). In cats, the pontomesencephalic

centers receive descending fibers from anteromedial parts of the frontal cortex, thalamus, hypothalamus, and cerebellum, but the brainstem centers and their descending pathways have not been precisely defined in humans. Other fibers from the motor cortex descend with the corticospinal fibers to the anterior horn cells of the sacral cord and innervate the external sphincter. According to Ruch, the descending pathways from the midbrain tegmentum are inhibitory and those from the pontine tegmentum and posterior hypothalamus are facilitatory. The pathway that descends with the corticospinal tract from the motor cortex is inhibitory. Thus the net effect of lesions in the brain and spinal cord on the micturition reflex, at least in animals, may be either inhibitory or facilitatory (DeGroat).

Almost all of this information has been inferred from animal experiments; there is little human pathologic material to corroborate the role of brainstem nuclei and cortex in bladder control. What information is available is reviewed extensively by Fowler, whose article is recommended. Also of interest here is the study by Blok and colleagues, who performed positron emission tomography (PET) studies in volunteer subjects during micturition. Increased blood flow was detected in the right pontine tegmentum, periaqueductal region, hypothalamus, and right inferior frontal cortex. When the bladder was full but subjects were prevented from voiding, increased activity was seen in the right ventral pontine tegmentum. The meaning of these lateralized findings is unclear, but the study supports the presumption that pontine centers are involved in the act of voiding.

The act of micturition is both reflex and voluntary. When the normal person desires to void, there is first a voluntary relaxation of the perineum, followed sequentially by an increased tension of the abdominal wall, a slow contraction of the detrusor, and an associated opening of the internal sphincter; finally, there is a relaxation of the external sphincter (Denny-Brown and Robertson). It is useful to think of the detrusor contraction as a spinal stretch reflex, subject to facilitation and inhibition from higher centers. Voluntary closure of the external sphincter and contraction of the perineal muscles cause the detrusor contraction to subside. The abdominal muscles have little role in initiating micturition except when the detrusor muscle is not functioning normally. The voluntary restraint of micturition is a cerebral affair and is mediated by fibers that arise in the frontal lobes (paracentral motor region), descend in the spinal cord just anterior and medial to the corticospinal tracts, and terminate on the cells of the anterior horns and intermediolateral cell columns of the sacral segments, as described earlier. The coordination of detrusor and external sphincter function depends mainly on the descending pathway from the posited centers in the dorsolateral pontine tegmentum.

Regulation of Bowel Function

The colon and anal sphincters are obedient to the same principles that govern bladder function. Unique to the bowel, however, is an intrinsic enteric nervous system that originates in the myenteric (or Auerbach) plexus

and the submucosal plexus (of Meissner), located in the gut wall. The first stimulates smooth muscle and the latter also regulates mucosal secretion and blood flow. This embedded system controls peristalsis largely independent of other autonomic influences but is highly responsive to local chemical and mechanical stimuli. As outlined in the thorough review by Benarroch that should be consulted by interested readers, acetylcholine is the dominant neurotransmitter in the enteric nerves but nitric oxide and numerous peptide transmitters are found in profusion.

Emergency and Alarm Reactions

Inasmuch as the autonomic nervous system and the adrenal glands were accepted for many years as the neural and humoral basis of all instinctive and emotional behavior. In states of chronic anxiety and acute panic reactions, depressive psychosis, mania, and schizophrenia, all of which are characterized by an altered emotionality, no consistent autonomic or endocrine dysfunction has been demonstrated except perhaps for diminished responses of growth hormone in panic disorders. The lack of cortisol suppressibility by injection of adrenocorticotrophic hormone (ACTH) had for some time also been considered to be a consistent aspect of depressive illnesses but that too, has not been entirely specific. This has been disappointing, as the emergency theory of sympathoadrenal action provided by Cannon was such a promising concept of the neurophysiology of acute emotion, and Selye had extended this theory so plausibly to explain all the reactions to stress in animals and humans.

According to these theories, strong emotion, such as anger or fear, excites the sympathetic nervous system and the adrenal cortex (via corticotropin-releasing factor [CRF] and ACTH), which are under direct neural and endocrine control. These sympathoadrenal reactions are brief and sustain the animal in "flight or fight" as discussed in Chap. 25. Animals deprived of adrenal cortex or human beings with Addison disease cannot tolerate stress because they are incapable of mobilizing both the adrenal medulla and adrenal cortex. Prolonged stress and production of ACTH activates all the adrenal hormones (glucocorticoids, mineralocorticoids, and adrenocorticoids) and has been studied extensively in relation to immune reactions and other systemic functions but with no consistent findings that are yet clinically applicable.

Tests for Abnormalities of the Autonomic Nervous System

With few exceptions, such as testing pupillary reactions and examination of the skin for abnormalities of color and sweating, the neurologist tends to be casual in evaluating the function of the autonomic nervous system. Nonetheless, several simple but informative tests can be used to confirm one's clinical impressions and to elicit abnormalities of autonomic function that may aid in diagnosis. For the detection of certain disease, it is almost imperative that blood pressure be evaluated to detect a drop with change in body position from lying or sitting, to standing. A combination of tests is usually

necessary, because certain ones are particularly sensitive to abnormalities of sympathetic function and others to parasympathetic or baroreceptor afferent function. These are described later and are summarized in Table 26-1. A scheme for the examination of pupillary abnormalities was presented in Fig. 14-11.

Testing of Blood Pressure and Heart Rate

These are among the simplest and most important tests of autonomic function and most laboratories have automated techniques to quantitate them. McLeod and Tuck state that in changing from the recumbent to the standing position, a fall of more than 30 mm Hg systolic and 15 mm Hg diastolic is abnormal; others give figures of 20 and 10 mm Hg. They caution that the arm on which the cuff is placed must be held horizontally when standing, so that the decline in arm pressure will not be obscured by the

added hydrostatic pressure. As emphasized in Chap. 18 on syncope, the determination of blood pressure in orthostatic testing is ideally done by having the patient remain supine for as long as it is practical before testing, and shifting from a supine to standing position, without the interposition of sitting. Moreover, blood pressure is most informative if measured immediately after standing and again at approximately 1 and 3 min. The expected response is a momentary and slight increase in pressure that is usually not detected with a manual blood pressure cuff, followed by a slight drop within seconds of standing, and then a slow recovery during the first minute. Persistent hypotension at 1 min indicates sympathetic adrenergic failure and the later measurement affirms this if blood pressure fails to recover or continues to decline (Fig. 26-5A).

The main cause of an orthostatic drop in blood pressure is, of course, hypovolemia. In the context of recurrent

Table 26-1

CLINICAL TESTS OF AUTONOMIC FUNCTION

TEST	NORMAL RESPONSE	MAIN PART OF REFLEX ARC TESTED
Noninvasive Bedside Tests		
Blood-pressure response to standing or vertical tilt	Fall in BP \leq 30/15 mm Hg	Afferent and sympathetic efferent limbs
Heart rate response to standing	Increase 11–90 beats/min; 30:15 ratio \geq 1.04	Vagal afferent and efferent limbs
Isometric exercise	Increase in diastolic BP, 15 mm Hg	Sympathetic efferent limb
Heart rate variation with respiration	Maximum–minimum heart rate \geq 15 beats/min; E:I ratio 1.2 ^a	Vagal afferent and efferent limbs
Valsalva ratio (see text)	\geq 1.4 ^a	Afferent and efferent limbs
Sweat tests	Sweating over all body and limbs	Sympathetic efferent limb
Axon reflex	Local piloerection, sweating	Postganglionic sympathetic efferent fibers
Plasma noradrenaline level	Rises on tilting from horizontal to vertical	Sympathetic efferent limb
Plasma vasopressin level	Rise with induced hypotension	Afferent limb
Invasive Tests		
Valsalva maneuver (BP response with indwelling arterial catheter or continuous noninvasive BP measurement)	Phase I: Rise in BP Phase II: Gradual reduction of BP to plateau; tachycardia Phase III: Fall in BP Phase IV: Overshoot of BP, bradycardia ^a	Afferent and sympathetic efferent limbs
Baroreflex sensitivity	(1) Slowing of heart rate with induced rise of BP ^a (2) Steady-state responses to induced rise and fall of BP	(1) Parasympathetic afferent and efferent limbs (2) Afferent and efferent limbs
Infusion of pressor drugs	(1) Rise in BP (2) Slowing of heart rate	(1) Adrenergic receptors (2) Afferent and efferent parasympathetic limbs
Other Tests of Vasomotor Control		
Radiant heating of trunk	Increased hand blood flow	Sympathetic efferent limb
Immersion of hand in hot water	Increased blood flow of opposite hand	Sympathetic efferent limb
Cold pressor test	Reduced blood flow, rise in BP	Sympathetic efferent limb
Emotional stress	Increased BP	Sympathetic efferent limb
Tests of Pupillary Innervation		
4% cocaine	Pupil dilates	Sympathetic innervation
0.1% adrenaline	No response	Postganglionic sympathetic innervation
1% hydroxyamphetamine hydrobromide	Pupil dilates	Postganglionic sympathetic innervation
2.5% methacholine 0.125% pilocarpine	No response	Parasympathetic innervation
0.5% apraclonidine	Pupil dilates and ptosis resolves in Horner syndrome	Parasympathetic innervation

^aAge-dependent response.

Figure 26-5. A. Blood pressure and heart rate changes elicited by standing and head-up tilt in a healthy individual. B. Blood pressure and heart rate changes elicited by Valsalva in a healthy individual. (With permission from Bannister R: *Autonomic Failure: A Textbook of Clinical Disorders of the Autonomic Nervous System*, 2nd ed. Oxford, Oxford University Press, 1988.)

fainting, however, an excessive drop reflects inadequate sympathetic vasoconstrictor activity. The use of a tilt table, as described in "Tilt-Table Testing" in Chap. 18 and further on, is an additional means of inducing orthostatic changes and also elicits reflex fainting in patients prone to syncope from an oversensitive cardiac reflex, i.e., one that produces vasodilatation (neurocardiogenic syncope). In response to the induced drop in blood pressure, the heart rate (under vagal control) normally increases. *The failure of the heart rate to rise in response to the drop in blood pressure with standing is the simplest bedside indicator of vagal nerve dysfunction.* Neurally mediated syncope may show one of three initial patterns with testing on a tilt table: a paroxysmal vasodepressor response alone, a

combined bradycardic and hypotensive response, and solely bradycardia. The tilt table allows differentiation among these or, more often, clarifies the order in which the events occur.

In addition, the heart rate, after rising initially in response to upright standing posture (not with the tilt table), slows after about 15 beats to reach a stable rate by the thirtieth beat. The ratio of R-R intervals in the electrocardiogram (ECG), corresponding to the thirtieth and fifteenth beats (the 30:15 ratio), is an even more sensitive measure of the integrity of vagal inhibition of the sinus node. A ratio in adults under age 60 of less than 1.07 is usually abnormal, indicating a loss of vagal tone and the normal ratio is progressively higher for younger ages, for example, it is usually above 1.12 at age 30 and 1.1 at age 40.

Another simple procedure for quantitating purely vagal function consists of measuring the *variation in heart rate during deep breathing* (respiratory sinus arrhythmia). The ECG is recorded while the patient breathes at a regular rate of 6 breaths per minute. Normally, the heart rate varies by as many as 15 beats per minute or even more between expiration and inspiration; differences of less than 7 beats per minute for ages 60 to 69 and 9 for ages 50 to 59 may be abnormal.

A yet more accurate test of vagal function is the measurement of the ratio of the longest R-R interval during forceful slow expiration (standardized as constant blowing at a pressure of 40 mm Hg for 10 s) to the shortest R-R interval during inspiration, which allows the derivation of an expiration–inspiration (E:I) ratio. This is the best validated of all the heart-rate measurements, particularly as computerized methods can be used to display the spectrum of beat-to-beat ECG intervals during breathing. The results of these tests must always be compared with those obtained in normal individuals of the same age. Up to age 40 years, E:I ratios of less than 1.2 (signifying a variation of 20 percent) are abnormal. The ratio decreases with age, and markedly so beyond age 60 years (at which time it approaches 1.04 or less), as it does also in the presence of even mild diabetic neuropathy. Thus the test results must be interpreted cautiously in the elderly or in diabetic individuals. Similar ratios have been developed for heart-rate change during the Valsalva maneuver; the *Valsalva ratio*.

Computerized methods of *power spectral analysis* may be used to express the variance in heart rate as a function of the beat-to-beat interval. Several power peaks are appreciated: one related to the respiratory sinus arrhythmia and others that reflect baroreceptor and cardiac sympathetic activity. All of these tests of heart-rate variation are usually combined with measurement of heart rate and blood pressure during the Valsalva maneuver, as described below, and with the tilt-table test, as described in Chap. 18.

In the *Valsalva maneuver*, the subject exhales into a manometer or against a closed glottis for 10 to 15 s, creating a markedly positive intrathoracic pressure. The sharp reduction in venous return to the heart causes a drop in cardiac output and in blood pressure; the response on baroreceptors is to cause a reflex tachycardia and, to a lesser extent, peripheral vasoconstriction. With release of

intrathoracic pressure, the venous return, stroke volume, and blood pressure rise to higher-than-normal levels; reflex parasympathetic influence then predominates and a bradycardia results (Fig. 26-5B). Failure of the heart rate to increase during the positive intrathoracic pressure phase of the Valsalva maneuver points to sympathetic dysfunction, and failure of the rate to slow during the period of blood pressure overshoot points to a parasympathetic disturbance. In patients with autonomic failure, the fall in blood pressure is not aborted during the last few seconds of increased intrathoracic pressure, and there is no overshoot of blood pressure when the breath is released. The Valsalva ratio, referring to the maximum heart rate generated by the maneuver to the lowest heart rate within 30 s of that peak, is another often-used measure in comprehensive autonomic testing.

Tests of Vasomotor Reactions

These generally test sympathetic cholinergic function. Measurement of the skin temperature is a rough but useful index of vasomotor function. Vasomotor paralysis results in vasodilatation of skin vessels and a rise in skin temperature; vasoconstriction lowers the temperature. With a skin thermometer, one may compare affected and normal areas under standard conditions. The normal skin temperature is 31°C (87.8°F) to 33°C (91.4°F) when the room temperature is 26°C (78.8°F) to 27°C (80.6°F). Vasoconstrictor tone may also be tested by measuring the reduction in skin temperature at a distant site before and after immersing one or both hands in cold water (see the discussion of the cold pressor test later).

The integrity of the sympathetic reflex arc, which includes baroreceptors in the aorta and carotid sinus, their afferent pathways, the vasomotor centers, and the sympathetic and parasympathetic outflow can be tested in a general way by combining the cold pressor test, grip test, mental arithmetic test, and Valsalva maneuver, as described below.

Vasoconstriction induces an elevation of the blood pressure. This is the basis of the *cold pressor test*. In normal persons, immersing one hand in ice water for 1 to 5 min raises the systolic pressure by 15 to 20 mm Hg and the diastolic pressure by 10 to 15 mm Hg. Similarly, the *sustained isometric contraction* of a group of muscles (e.g., those of the forearm in handgrip) for 5 min normally increases the heart rate and the systolic and diastolic pressures by at least 15 mm Hg. The response in both of these tests is reduced or absent with lesions of the sympathetic reflex arc, particularly of the efferent limb, but neither of these tests has been well quantitated or validated. The stress involved in doing *mental arithmetic* in noisy and distracting surroundings will also stimulate a mild but measurable increase in pulse rate and blood pressure. Obviously this response does not depend on the afferent limb of the sympathetic reflex arc and must be mediated by cortical-hypothalamic mechanisms.

If the response to the Valsalva maneuver is abnormal and the response to the cold pressor test is normal, the lesion is probably in the baroreceptors or their afferent nerves; such a defect has been found in diabetic and

tabetic patients and is common in many neuropathies. A failure of the heart rate and blood pressure to rise during mental arithmetic coupled with an abnormal Valsalva maneuver suggests a defect in the central or peripheral efferent sympathetic pathways.

Tests of Sudomotor Function

The integrity of sympathetic efferent pathways can be assessed further by tests of sudomotor activity. There are several of these, all used mainly in specialized autonomic testing laboratories; furthermore, most of them cannot differentiate central from peripheral causes of anhidrosis. The most rudimentary tests involve weighing sweat after it is absorbed by small squares of filter paper. Also, powdered charcoal dusted on the skin will cling to moist areas and not to dry ones.

In the *sympathetic or galvanic skin-resistance test*, a set of electrodes placed on the skin measures the resistance to the passage of a weak current through the skin; in all likelihood, the change in electrical potential is the result of an ionic current within the sweat glands, not simply an increase in sweating that lowers skin resistance. This method can be used to outline an area of reduced sweating because of a peripheral nerve lesion, as the response depends on sympathetic activation of sweat glands (Gutrecht). However, the galvanic skin response is subject to habituation with repeated stimuli and will show no response if there is a sensory neuropathy. The starch iodine test or use of a color indicator such as quinizarin (gray when dry, purple when wet) and the more recently introduced plastic or silicone method are other acceptable procedures to delineate peripheral nerve or spinal cord lesions based on the loss of sympathetic innervation. Together they are termed “thermoregulatory sweat testing” and are semiquantitative and mainly topographic in nature. They reflect postganglionic sudomotor function.

A more quantitative and reproducible examination of postganglionic sudomotor function, termed QSART (quantitative sudomotor axon reflex test), has been developed and studied extensively by Low. It is essentially a test of distal sympathetic axonal integrity utilizing the local axon reflex. A 10 percent solution of acetylcholine is iontophoresed onto the skin using 2 mA for 5 min. Sweat output is recorded in the adjacent skin by sophisticated circular cells that detect the sweat water. The forearm, proximal leg, distal leg, and foot have been chosen as standardized recording sites. By this test, Low has been able to define patterns of absent or delayed sweating that signify postganglionic sympathetic failure in small-fiber neuropathies and excessive sweating or reduced latency in response, as is seen in reflex sympathetic dystrophy. This is the preferred method of studying sweating and the function of distal sympathetic fibers, but its technical complexity makes it available only in specially equipped laboratories.

Lacrimal Function

Tearing can be estimated roughly by inserting one end of a 5-mm-wide and 25-mm-long strip of thin filter paper into the lower conjunctival sac while the other end hangs

over the edge of the lower lid (the Schirmer test). The tears wet the strip of filter paper, producing a moisture front. After 5 min, the moistened area extends for a length of approximately 15 mm in normal persons. An extent of less than 10 mm is suggestive of hypolacrimalia. This test is used mainly to detect the dry eyes (keratoconjunctivitis sicca) of the Sjögren syndrome, but it may also be helpful in fully studying various autonomic neuropathies.

Tests of Bladder, Gastrointestinal, and Penile Erectile Function

Bladder function is best assessed by the cystometrogram, which measures intravesicular pressure as a function of the volume of saline solution permitted to flow by gravity into the bladder. The rise of pressure as 500 mL of fluid is allowed to flow gradually into the bladder, the emptying contractions of the detrusor, and the volume at which the patient reports a sensation of bladder fullness can be recorded by a manometer. (A detailed account of cystometric techniques can be found in the monograph of Krane and Siroky.) A simple way of determining bladder atony (prostatic obstruction and overdistention having been excluded) is to measure the residual urine (by catheterization of the bladder) immediately after voluntary voiding or to estimate its volume by ultrasound imaging.

Disorders of gastrointestinal motility are readily demonstrated radiologically. In dysautonomic states, a barium swallow may disclose a number of abnormalities, including atonic dilatation of the esophagus, gastric atony and distention, delayed gastric emptying time, and a characteristic small bowel pattern consisting of an increase in frequency and amplitude of peristaltic waves and rapid intestinal transit. A barium enema may demonstrate colonic distention and a decrease in propulsive activity. Sophisticated manometric techniques are now available for the measurement of gastrointestinal motility (see Low et al).

Nocturnal penile tumescence is recorded in some sleep laboratories and may be used as an ancillary test of sacral autonomic (parasympathetic) innervation.

Pharmacologic Tests of Autonomic Function

After examining the pupils in ambient light, bright light, and low light to determine if one has lost sympathetic or parasympathetic innervation, pharmacologic tests can be used to refine diagnosis. Part of the rationale behind these special tests is the "Cannon law," or the phenomenon of denervation hypersensitivity, in which an effector organ, 2 to 3 wk after denervation, becomes hypersensitive to its particular neurotransmitter substance and related drugs. In clinical testing, an agent is instilled into both conjunctival sacs and the nonmiotic pupil is used as a control to compare the one suspect of being involved by Horner syndrome.

Relatively recently, the weak direct sympathetic agonist apraclonidine has been used most widely to demonstrate that miosis is due to sympathetic denervation of the pupil. It reverses miosis that is due to a central or a peripheral lesion and is easier to obtain than older agents. A positive test, reversal of miosis, depends on the

denervation hypersensitivity that develops after several days or more of the presence of the Horner syndrome. If there is a negative result, no enlargement of the pupil, the miosis is probably physiologic. The drug has the additional advantage of often reversing the ptosis of Horner syndrome (see Chap. 14 and Fig. 14-10 for discussion). The drug may cause respiratory suppression in children and is avoided.

Once the presence of a genuine Horner syndrome has been established, it is possible to differentiate pre- or postganglionic (superior cervical ganglion) sympathetic denervation of the pupil by instilling 1 percent hydroxyamphetamine; its effect depends on the presence of existing norepinephrine in the end terminals of the nerves that innervate the iris. Failure to dilate indicates a postganglionic lesion.

Another test, now used mostly in children, in whom apraclonidine represents a risk, is the topical application into the conjunctival sac of a 4 to 10 percent cocaine solution that potentiates the effects of NE by preventing its reuptake. A normal response to cocaine consists of pupillary dilatation. In sympathetic denervation caused by lesions of the post- or preganglionic fibers, no change in pupillary size occurs because no transmitter substance is available and the cocaine has no substrate to potentiate. The reason for lack of response in chronic preganglionic lesions is presumed to be a depletion of NE in the postganglionic fibers. In cases of central sympathetic lesions, slight mydriasis may occur.

Cutaneous Flare Response

The intracutaneous injection of 0.05 mL of 1:1,000 histamine normally causes a 1-cm wheal after 5 to 10 min. This is surrounded by a narrow red areola, which in turn, is surrounded by an erythematous flare that extends 1 to 3 cm beyond the border of the wheal. A similar "triple response" follows the release of histamine into the skin as the result of a scratch. It can be elicited in sensitive individuals by scratching the skin (dermatographia).

The wheal and the deeply colored red areola are caused by the direct action of histamine on blood vessels in response to local injury, while the flare depends on the integrity of the axon reflex. This axon reflex is mediated by antidromic stimulation of small sensory C fibers that results in the release by the same fibers of various vasoactive substances such as bradykinin and substance P. Destruction of the dorsal root ganglion, but not the dorsal root, eliminates the flare. The flare component is influenced centrally through a yet unknown mechanism. In familial dysautonomia, the flare response to histamine and to scratch is absent. It may also be absent in peripheral neuropathies that involve sympathetic nerves (e.g., diabetes, alcoholic-nutritional disease, Guillain-Barré disease, amyloidosis, porphyria). The quantitative sudomotor response to topical acetylcholine, described earlier, is preferred for its sensitivity and accuracy but requires special equipment.

The dermatographic wheal and flare response may be lost below the level of a recent cord injury but returns over days or longer, comparable to recovery from spinal shock.

Pressor Infusion and Other Direct Cardiovascular Tests

While these are not parts of the routine laboratory evaluation of autonomic nervous system disease, they nonetheless present interesting physiologic information. The infusion of NE causes a rise in blood pressure, which is usually more pronounced for a given infusion rate in dysautonomic states than it is with normal subjects. In many instances, e.g., the Guillain-Barré syndrome, the excessive rise in blood pressure is thought to be more a result of inadequate muting of the hypertension by baroreceptors than it is a reflection of true denervation hypersensitivity, i.e., it reflects dysfunction of the afferent limb of the reflex arc. In patients with familial dysautonomia, the infusion of NE produces erythematous blotching of the skin, like that which may occur under emotional stress, probably representing an exaggerated response to endogenous NE.

The infusion of angiotensin II into patients with idiopathic orthostatic hypotension also causes an exaggerated blood pressure response. A similar response to methacholine and NE has been interpreted as a denervation hypersensitivity to neurotransmitter or related substances. A different mechanism must be invoked for the blood pressure response induced by angiotensin; perhaps it is caused by a defective baroreceptor function.

The integrity of autonomic innervation of the heart can be evaluated by the intramuscular injection of atropine, ephedrine, or neostigmine while the heart rate is monitored. Normally, the intramuscular injection of 0.8 mg of atropine causes tachycardia as a result of a parasympathetic block and a withdrawal of vagal tone. No such change occurs in cases of parasympathetic (vagal) denervation of the heart, the most common such conditions being diabetes and the Guillain-Barré syndrome and the most dramatic being the brain death state, in which there is no longer any tonic vagal activity to be ablated by atropine.

Laboratory methods are available for the measurement of NE and dopamine β -hydroxylase in the serum. Normally, when a person changes from a recumbent to a standing position, the serum NE level rises two- or threefold. In patients with central and peripheral autonomic failure, there is little or no elevation on standing or with exercise. The dopamine β -hydroxylase enzyme is deficient in patients with a rare form of sympathetic dysautonomia.

In summary, the noninvasive tests listed in Table 26-1 and described earlier are quite adequate for the clinical testing of autonomic function. Low has emphasized that the most informative tests are those that are quantitative and have been standardized and validated in patients with both mild and severe autonomic disturbances. At the bedside, the most convenient ones are measurement of orthostatic heart rate and blood pressure changes, blood pressure response to the Valsalva maneuver, estimation of heart-rate changes with deep breathing, pupillary responses to light and dark, and a rough estimate of sweating of the palms and soles and with lesions of the spinal cord, on the trunk. The results of these tests and the clinical situation will determine whether further testing is needed.

CLINICAL DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM

Acute Autonomic Paralysis (Dysautonomic Polyneuropathy; Pure Pandysautonomia)

Since this condition was first reported by Young and colleagues in 1975, many more cases in both adults and children have been placed on record. Over a period of a week or a few weeks with or without a preceding systemic or respiratory infection, the patient develops some combination of anhidrosis, orthostatic hypotension, paralysis of pupillary reflexes, loss of lacrimation and salivation, erectile dysfunction, impaired bladder and bowel function (urinary retention, postprandial bloating, and ileus or constipation), and loss of certain pilomotor and vasomotor responses in the skin (flushing and heat intolerance). Fatigue, sometimes severe, is a prominent complaint in most patients, and abdominal pain and vomiting in others. A few develop sleep apnea or the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), leading to hyponatremia. The cerebrospinal fluid (CSF) protein is normal or slightly increased.

Clinical and laboratory findings indicate that both the sympathetic and parasympathetic parts of the autonomic nervous system are affected, mainly at the postganglionic level. Somatosensory and motor nerve fibers appear to be spared or are affected to only a slight extent, although many patients complain of paresthesias, and tendon reflexes are frequently lost. In one of the patients described by Low and colleagues, there was physiologic and morphologic (sural biopsy) evidence of loss of small myelinated and unmyelinated somatic fibers and foci of epineurial mononuclear cells; in other cases, sural nerve fiber counts have been normal; and in an autopsied case, in which there had also been sensory loss, there was lymphocytic infiltration in sensory and autonomic nerves (Fagius et al). The original patient described by Young and colleagues and most of the other patients reported with pure dysautonomia are said to have recovered completely or almost so within several months, but many of our patients have been left with disordered gastrointestinal and sexual functions. In addition to an idiopathic form of autonomic paralysis, some cases are postinfectious, and there is a similar but rare paraneoplastic form (see Chap. 31 under "Paraneoplastic Sensory Neuronopathy"). Antibodies against ganglionic acetylcholine receptors have been found in half of idiopathic cases and one-quarter of paraneoplastic ones (Vernino et al).

Some children with this disease and a few adults have had a syndrome of predominantly cholinergic dysautonomia with pain and dysesthesias (Kirby et al); there is little or no postural hypotension and the course has been more chronic than that in cases of complete dysautonomia described earlier.

In view of the identical autonomic disturbances in the Guillain-Barré syndrome and the high incidence of minor degrees of weakness, reflex loss, CSF protein elevation, and especially paresthesias, it is likely that pure pandysautonomia is also an immune-mediated

polyneuropathy affecting the autonomic fibers within peripheral nerves, in most ways comparable to the Guillain-Barré syndrome. The aforementioned autopsy findings reported by Fagius and coworkers support such a relationship. In animals, autonomic paralysis has been produced by injection of extracts of sympathetic ganglia and Freund's adjuvant (Appenzeller et al), similar to the experimental immune neuritis that is considered as an animal model of the Guillain-Barré syndrome.

An acquired form of orthostatic intolerance, referred to as *sympathotonic orthostatic hypotension* (Polinsky et al), may represent another variant or partial form of autonomic paralysis. In this syndrome, unlike the common forms of orthostatic hypotension (see later), the fall in blood pressure is accompanied by tachycardia. Hoeldtke and colleagues, who described 4 such patients, found that the vasomotor reflexes and NE production were normal; these investigators were inclined to attribute the disorder to a process affecting lower thoracic and lumbar sympathetic neurons. Its relationship to the entity of *postural orthostatic tachycardia syndrome* (POTS) discussed in Chap. 18 and to the orthostatic intolerance associated with the chronic fatigue syndrome is uncertain. Individual cases of POTS have been associated with mutations or epigenetic alterations in the norepinephrine transporter gene (Shannon and colleagues). Some instances of orthostatic intolerance appear as part of the asthenia-anxiety disorders in which the autonomic changes may represent sympathetic overactivity in susceptible individuals.

There are several reports of improvement of pandysautonomia after intravenous gamma globulin infusion, but these are difficult to judge as many patients improve spontaneously over the same time frame, usually many months. In addition, plasma exchange has been used with apparent benefit in a patient with antibodies against the ganglionic acetylcholine receptor (Schroeder et al).

Lambert-Eaton Myasthenic Syndrome One of the characteristic features of the fully developed Lambert-Eaton myasthenic syndrome, which is discussed in Chap. 53, is *dysautonomia*, characterized by dryness of the mouth, erectile dysfunction, difficulty in starting the urinary stream, and constipation. Presumably, circulating antibodies against the voltage-gated calcium channel interfere with the release of ACh at both muscarinic and nicotinic sites.

Idiopathic Orthostatic Hypotension; Pure Autonomic Failure (See also Chap. 18)

This clinical state is now known to be caused by at least two conditions. One is a degenerative disease of middle and late adult life, first described by Bradbury and Eggleston in 1925 and designated by them as *idiopathic orthostatic hypotension* and by subsequent authors, "primary autonomic failure." In this disorder, the lesions involve mainly the postganglionic sympathetic neurons (Petito and Black); the parasympathetic system is relatively spared and the CNS is uninvolved. In the second more common disorder that is now classified as a *multiple system atrophy*, described initially by Shy and Drager, the preganglionic lateral horn neurons of the thoracic spinal segments degenerate; these changes are responsible for the orthostatic hypotension.

Later, signs of basal ganglionic or cerebellar disease or both are added as discussed later and in Chaps. 18 and 39 but a few cases remain as a pure autonomic failure. In both types of orthostatic hypotension, anhidrosis, erectile dysfunction and atonicity of the bladder may be conjoined, but orthostatic fainting is the main problem.

The clinical differentiation of these two types of orthostatic hypotension depends largely on the appearance, with time, of associated CNS signs as described later. The distinction between the sympathetic postganglionic and the central preganglionic types of disease is also based on pharmacologic and neurophysiologic evidence, but it must be emphasized that the results of these tests do not always conform to clinical expectations from the examination. Nonetheless, Cohen and associates, who studied the postganglionic sudomotor and vasomotor functions of 62 patients with IOH, found that the signs of postganglionic denervation were uncommon in patients classified as having the central type.

In the postganglionic type of autonomic failure, plasma levels of NE are subnormal while the patient is recumbent because of failure of the damaged nerve terminals to synthesize or release catecholamines. When the patient stands, the NE levels do not rise, as they do in a normal person. Also, in this type, there is denervation hypersensitivity to infused NE. In the central preganglionic (Shy-Drager) type, the resting NE levels in the plasma are normal but again, on standing, there is no rise, and the response to exogenously administered NE is normal. In both types, the plasma levels of dopamine β -hydroxylase, the enzyme that converts dopamine to NE, are subnormal (Ziegler et al). The use of these neurochemical tests in clinical practice is difficult and the data in the literature are inconsistent. Low's monograph should be consulted for procedural details.

Pathologic studies have disclosed the central type of autonomic failure to be somewhat heterogeneous. Oppenheimer, who collected all the reported central cases with complete autopsies, found that they fell into two groups: (1) that which was designated by Adams as *striatonigral degeneration* or, later, *Shy-Drager syndrome*, where autonomic failure was associated with a parkinsonian syndrome and often with the presence of cytoplasmic inclusions in sympathetic neurons, and (2) another with involvement of the striatum, cerebellum, pons, and medulla but without inclusions, formerly designated *olivopontocerebellar degeneration* (there are now reported to be glial and neuronal cytoplasmic inclusions in all these cases). Both conditions are now referred to as *multiple system atrophy*, the term introduced by Oppenheimer, the first type, MSA-P to denote the parkinsonism and the second type, MSA-C reflecting cerebellar degeneration as discussed in Chap. 39. If the process remains purely an autonomic failure, MSA-A is used.

In all forms of multiple system atrophy, the autonomic failure is attributable to degeneration of lateral horn cells of the thoracic cord. There is also a degeneration of nerve cells in the vagal nuclei as well as nuclei of the tractus solitarius, locus ceruleus, and sacral autonomic nuclei, accounting for laryngeal abductor weakness (laryngeal paralysis and stridor are features in some

cases), incontinence, and erectile dysfunction. NE and dopamine are depleted in the hypothalamus (Spokes et al). The sympathetic ganglia have usually been normal. In Parkinson disease, where fainting is sometimes a problem, Lewy bodies are found in degenerating sympathetic ganglion cells but the medications used for treatment also exaggerate hypotension.

Treatment of orthostatic hypotension consists of having the patient sleep with the head of the bed elevated, administering the peripherally acting alpha agonist, midodrine starting at 2.5 mg q4h, slowly raising the dose to 5 mg q4h, taking the last dose before about 7 P.M. to void supine hypertension while asleep, and if that is not successful, the mineralocorticoid fludrocortisone acetate (Florinef) 0.1 mg twice daily. The latter should be used cautiously in patients with severe supine hypertension; its effect may take up to 2 wk to be manifest so rapid elevation of the dose is not advised. Fainting can sometimes be avoided by the countermeasures of having the patient tightly cross his legs upon standing and using elastic stockings that compress the veins of the legs and lower abdomen.

Peripheral Neuropathy With Secondary Orthostatic Hypotension

Impairment of autonomic function, of which orthostatic hypotension is the most serious feature, occurs as part of many acute and chronic peripheral neuropathies (e.g., diabetic, alcoholic–nutritional, amyloid, Guillain-Barré, heavy metal, toxic, and porphyric). Disease of the peripheral nervous system may affect the circulation in two ways: the nerves from baroreceptors may be affected, interrupting normal afferent homeostatic reflexes, or postganglionic efferent sympathetic fibers may be involved in their course in the spinal nerves. The severity of the autonomic failure need not parallel the degree of motor weakness. An additional feature of the acute dysautonomias is a tendency to develop hyponatremia, presumably as a result of dysfunction of afferent fibers from venous, right atrial, and aortic arch volume receptors; this elicits a release of antidiuretic hormone arginine vasopressin (AVP). These same stretch baroreceptors are implicated in the intermittent hypertension that sometimes complicates these acute neuropathies.

Of particular importance is the autonomic disorder that accompanies diabetic neuropathy. It presents as erectile dysfunction, constipation, or diarrhea (especially at night), hypotonia of the bladder, gastroparesis, and orthostatic hypotension, in some combination. Invariably, there are signs of a sensory polyneuropathy, consisting of a distal loss of vibratory and thermal-pain sensation and reduced or lost ankle reflexes; but again, the severity of affection of the two systems of nerve fibers may not be parallel. The pupils are often small and the amplitude of constriction to light is reduced (similar to Argyll Robertson pupils); this has been attributed to damage of cells in the ciliary ganglia. A curious syndrome or “insulin neuritis” has been described, in which, autonomic failure and painful sensory neuropathy arise at the time of rapid glycemic control (see Gibbons and Freeman).

Gastroparesis can be disabling, painful, and difficult to treat, for example in diabetic autonomic neuropathy. Camilleri has reviewed the subject and outlined the defect in gastric emptying that interrelates with glucose metabolism and an unexplained association with psychiatric symptoms. Management is by altering nutritional intake and with metoclopramide for mild cases and additional domperidone, prochlorperazine, and erythromycin in severe ones.

Another polyneuropathy with unusually prominent dysautonomia is that caused by amyloidosis. Extensive loss of pain and thermal sensation is usually present; other forms of sensation may also be reduced to a lesser degree. Motor function is much less altered. Sympathetic function is more affected than parasympathetic. Iridoplegia (pupillary paralysis) and disturbances of other smooth muscle and glandular functions are variable. Diabetic and amyloid polyneuropathy are further described in Chap. 46.

Both the primary and secondary types of orthostatic hypotension are also discussed in connection with syncope in Chap. 18.

Familial Autonomic Neuropathy in Infants and Children (Riley-Day Syndrome) and Other Inherited Dysautonomias (See also Chap. 46)

Riley-Day syndrome is a disease of children, inherited as an autosomal recessive trait. The main symptoms are postural hypotension and lability of blood pressure, faulty regulation of temperature, diminished hearing, hyperhidrosis, blotchiness of the skin, insensitivity to pain, emotional lability, and cyclic vomiting. The tendon reflexes are hypoactive, and mild slowing of motor nerve conduction velocities is common. There is denervation sensitivity of the pupils and other structures. The main pathologic feature is a deficiency of neurons in the superior cervical ganglia and in the lateral horns of the spinal cord. Also, according to Aguayo and to Dyck and their colleagues, the number of unmyelinated nerve fibers in the sural nerve is greatly decreased. It is likely that this disease represents a failure of embryologic migration or formation of the first- and second-order sympathetic neurons. It is now known that this defect is the result of a mutation in the gene (*IKBKAP*) that codes for a protein (*IKAP*) that is currently considered to be associated with transcription regulation (Anderson et al). This results in a decrease in the amount of functional protein in autonomic neurons.

Autonomic symptoms are also a prominent feature of the small-fiber neuropathy of Fabry disease (alpha-galactosidase deficiency) as a result of the accumulation of ceramide in hypothalamic and intermediolateral column neurons (see “Fabry Disease” in Chap. 46).

Another inherited form of peripheral dysautonomia is characterized by severe pain in the feet on exercise and an autosomal dominant pattern of inheritance (Robinson et al). Bending, crouching, and kneeling increase stabbing pains in the feet. There is no sweat response to intradermal injection of 1 percent ACh and no autonomic fibers were found in punch biopsies of the skin. Systemic amyloidosis

is the other type of peripheral neuropathy that has prominent features of autonomic failure.

Autonomic Failure in the Elderly

(See also Chap. 29)

Orthostatic hypotension is prevalent in the elderly, so much so that norms of blood pressure and heart rate changes have been difficult to establish. Caird and coworkers reported that among individuals who were older than 65 years of age and living at home, 24 percent had a fall of systolic blood pressure on standing of 20 mm Hg; 9 percent had a fall of 30 mm Hg; and 5 percent had a fall of 40 mm Hg. An increased frequency of thermoregulatory impairment also has been documented. The elderly are also more liable to develop hypothermia and, when exposed to high ambient temperature, to hyperthermia. Loss of sweating of the lower parts of the body and increased sweating of the head and arms probably reflect a neuropathy or neuronopathy. The number of sensory ganglion cells decreases with age (Castro). Erectile dysfunction and incontinence also increase with age, but these, of course, may be the result of a number of processes besides autonomic failure and many of the medications used to treat ailments that come with aging, such as hypertension, prostatic hypertrophy, depression, and impotence, have autonomic effects and can cause orthostatic hypotension.

It is of interest that an idiopathic type of small fiber neuropathy that occurs predominantly in elderly women ("burning hands and feet" syndrome) has no associated autonomic features (see Chap. 46).

Horner (Oculosympathetic) and Stellate Ganglion Syndromes (See also Chap. 14)

Interruption of postganglionic sympathetic fibers at any point along the internal carotid arteries or a lesion of the superior cervical ganglion results in miosis, drooping of the eyelid, and abolition of sweating over one side of the face; this constellation is the Horner, or more properly, Bernard-Horner syndrome (see also "Horner Syndrome" in Chap. 14). The same syndrome in less-obvious form may be caused by interruption of the preganglionic fibers at any point between their origin in the intermediolateral cell column of the C8-T2 spinal segments and the superior cervical ganglion or by interruption of the descending, uncrossed hypothalamospinal pathway in the tegmentum of the brainstem or cervical cord. The common causes are neoplastic or inflammatory involvement of the cervical lymph nodes or proximal part of the brachial plexus, surgical and other types of trauma to cervical structures (e.g., jugular venous catheters), carotid artery dissection, syringomyelic or traumatic lesions of the first and second thoracic spinal segments, and infarcts or other lesions of the lateral part of the medulla (Wallenberg syndrome). There is also an idiopathic variety that is in some cases hereditary. If a Horner syndrome develops early in life, the iris on the affected side fails to become pigmented and remains blue or mottled gray-brown (heterochromia iridis; see Fig 14-10).

A lesion of the stellate ganglion, e.g., compression by a tumor arising from the superior sulcus of the lung (Pancoast tumor), produces the interesting combination of a Horner syndrome and paralysis of sympathetic reflexes in the limb (the hand and arm are dry and warm). With preganglionic lesions, facial flushing may develop on the side of the sympathetic disorder; this is brought on in some instances by exercise (harlequin effect). The combination of segmental anhidrosis and an Adie pupil is sometimes referred to as the *Ross syndrome*; it may be abrupt in onset and idiopathic, or it may follow a viral infection.

Keane has provided data as to the relative frequency of the lesions causing oculosympathetic (Horner) paralysis. In 100 successive cases, 63 were of central type caused by brainstem strokes, 21 were preganglionic from trauma or tumors of the neck, 13 were postganglionic from miscellaneous causes, and in 3 cases the localization could not be determined (see Chap. 14 for further discussion).

The pupillary disturbances associated with oculomotor nerve lesions, the Adie pupil, and other parasympathetic and pharmacologic testing for sympathetic abnormalities of pupillary function are considered fully in Chap. 14 and in Table 14-6 with the accompanying text. Apraclonidine, 0.5 percent, has become the favored drug for diagnostic testing as noted earlier.

Sympathetic and Parasympathetic Paralysis in Tetraplegia and Paraplegia

Lesions of the C4 or C5 segments of the spinal cord, if complete, will interrupt suprasegmental control of both the sympathetic and sacral parasympathetic nervous systems. Much the same effect is observed with lesions of the upper thoracic cord (above T6). Lower thoracic lesions leave much of the descending sympathetic outflow intact, only the descending sacral parasympathetic control being interrupted. Traumatic necrosis of the spinal cord is the usual cause of these states, but they also may be a result of infarction, certain forms of myelitis, radiations damage, and tumors.

As discussed in greater detail in Chap. 44, the initial effect of an acute cervical cord transection is abolition of all sensorimotor reflex, and autonomic functions of the isolated spinal cord. The autonomic changes include hypotension, loss of sweating and piloerection, paralytic ileus and gastric atony, and paralysis of the bladder. The flare component of the axon reflex may be lost. Plasma epinephrine and NE are reduced. This state, known as *spinal shock*, usually lasts for several weeks as described in Chap. 44. The basic mechanisms are not known, but changes in neurotransmitters (catecholamines, enkephalins, endorphins, substance P, and 5-hydroxytryptamine) and their inhibitory activities are considered to play a role. Naloxone mitigates some of the aspects of spinal shock; this may be, at least in part, the result of release of preformed endogenous opioids from the distal axons that are separated from their cells of origin in the periaqueductal gray region. Once these endogenous substances are exhausted, the phenomenon of spinal shock ends (see Chap. 44).

After spinal shock dissipates, reflex sympathetic and parasympathetic functions return because the afferent and efferent autonomic connections within the isolated segments of the spinal cord are intact, although no longer under the control of higher centers. With *cervical cord lesions*, there is a loss of the sympathetically mediated cardiovascular changes in response to stimuli reaching the medulla. However, cutaneous stimuli (pinprick or cold) in segments of the body below the transection will raise the blood pressure. However, a fall in blood pressure is not compensated by sympathetic vasoconstriction. Hence tetraplegics are almost obligatorily prone to orthostatic hypotension. Pinching the skin below the lesion causes gooseflesh in adjacent segments. Heating the body results in flushing and sweating over the face and neck, but not in the trunk and legs, because of the loss of connections from the hypothalamus. Bladder and bowel, including their sphincters, which are at first flaccid, become automatic as spinal reflex control returns. There may be reflex penile erection or priapism and even rarely ejaculation. With lesions in the upper thoracic cord, similar but lesser degrees of labile blood pressure are seen; in several of our patients with destructive myelitis, a viral infection of fever brought out episodes of a drop in blood pressure to approximately 80/60 mm Hg and a subsequent rapid rise to 190/110 mm Hg.

After a time, the tetraplegic patient may develop a *mass reflex* in which flexor spasms of the legs and involuntary emptying of the bladder are associated with a marked rise in blood pressure, bradycardia, and sweating and pilomotor reactions in parts below the cervical segments (*autonomic dysreflexia*). These reactions may also be evoked by pinprick, passive movement, contactual stimuli of the limbs and abdomen, and pressure on the bladder. An exaggerated vasopressor reaction also occurs in response to injected NE. In such attacks, the patient experiences paresthesias of the neck, shoulders, and arms; tightness in the chest and dyspnea; pupillary dilatation; pallor followed by flushing of the face; sensation of fullness in the head and ears; and a throbbing headache. Plasma NE and dopamine rise slowly during the autonomic discharge. When such an attack is severe and prolonged, electrocardiographic changes may appear, sometimes with evidence of myocardial injury that has been attributed to direct catecholamine toxicity or, alternatively, to myocardial ischemia caused by increased afterload or to coronary vasospasm. Seizures and visual defects have also been observed, related to cerebral dysautoregulation. Clonidine, up to 0.2 mg tid, has been useful in preventing the hypertensive crises.

Acute Autonomic Crises ("Sympathetic Storm")

Several toxic and pharmacologic agents such as cocaine and phenylpropanolamine are capable of producing abrupt overactivity of the sympathetic and parasympathetic nervous systems—severe hypertension and mydriasis coupled with signs of CNS excitation—sometimes including seizures. Tricyclic antidepressants in excessive doses are also known to produce autonomic effects, but

in this case cholinergic blockade leads to dryness of the mouth, flushing, absent sweating, and mydriasis. The main concern with tricyclic antidepressant overdose is the development of a ventricular arrhythmia, also on an autonomic basis, presaged by prolongation of the QT interval on the ECG. Poisoning with organophosphate insecticides (e.g., Parathion), which have anticholinesterase effects, causes a combination of *parasympathetic overactivity* and motor paralysis (see discussion of poisonings in Chap. 43). A severe autonomic disturbance involving both postganglionic sympathetic and parasympathetic function is produced by ingestion of the rodenticide *N*-3-pyridylmethyl-*N'*-*p*-nitrophenylurea (PNU, Vacor). The exaggerated sympathetic state that accompanies tetanus—manifest by diaphoresis, mydriasis, and labile or sustained hypertension—has been attributed to circulating catecholamines.

Among the most dramatic syndromes of unopposed sympathetic-adrenal medullary hyperactivity occur in cases of severe head injury and with hypertensive cerebral hemorrhage. Three separate mechanisms of the hypersympathetic state are observed at different times after the injury or cerebral hemorrhage: an outpouring of adrenal catecholamines at the time of the ictus with acute hypertension and tachycardia; a brainstem-mediated vasopressor reaction (Cushing response, described later); and a later chronic phenomenon, consisting of episodes of extreme hypertension, profuse diaphoresis, and pupillary dilatation, usually arising during episodes of several minutes' duration of rigid extensor posturing (the "diencephalic autonomic seizures" of Penfield, described later and in Chap. 35 in relation to head injury). Most patients who exhibit such paroxysms are decorticate from traumatic lesions of the deep cerebral white matter or from acute hydrocephalus (the likely explanation of Penfield's cases); in any case, they are clearly not epileptic. These attacks may be the result of the removal of inhibitory influences on the hypothalamus, creating, in effect, a hypersensitive decorticated autonomic nervous system.

Regarding the acute sympathetic reaction, experimental evidence suggests that nuclei in the caudal medullary reticular formation (reticularis gigantocellularis and parvocellularis) can precipitate severe hypertensive reactions. These nuclear centers are tonically inhibited by the NTS, which receives afferent input from arterial baroreceptors and chemoreceptors. Bilateral lesions of the NTS therefore produce extreme elevations in blood pressure, and this abrupt rise plays a role in the genesis of "neurogenic" pulmonary edema. These sympathetically mediated effects are eliminated by sectioning of the cervical spinal cord and by alpha-adrenergic blockade.

The *Cushing response*, reflex, triad, or "reaction," as Cushing described it, occurs as a result of an abrupt increase in intracranial pressure. It consists of hypertension, bradycardia, and slow, irregular breathing elicited by the stimulation of mechanically sensitive regions in the paramedian caudal medulla (Hoff and Reis). Similar pressure-sensitive areas in the upper cervical spinal cord are also implicated in the Cushing response when intraspinal pressure is raised abruptly; a ventral medullary

vasodepressor area that acts in the opposite manner has been found in animals. The proximate cause of the Cushing response is probably from mechanical distortion of the lower brainstem, either from a mass in the posterior fossa or, more often, from a large mass in one of the hemispheres or a subarachnoid hemorrhage that elevates the pressure within the fourth ventricle. Often, only the hypertensive component of the reaction occurs, with the systolic blood pressure reaching levels of 200 mm Hg, spuriously suggesting the presence of a pheochromocytoma or renal artery stenosis. The most severe instances of this type of centrally provoked hypertensive syndrome have occurred in children with cerebellar tumors who presented with headache and extreme systolic hypertension. Difficulty may arise in differentiating this response from hypertensive encephalopathy, especially from cases that derive from renovascular hypertension, which may likewise be accompanied by headache and papilledema. In differentiating these two, it is useful to note that primary hypertensive encephalopathy is associated with a tachycardia or normal heart rate and that systolic blood pressure levels above 210 mm Hg are attained only rarely in the Cushing response.

During episodes of intense sympathetic discharge of any type, there are *alterations in the ECG*, mainly in the ST segments and T waves; in extreme cases, evidence of myocardial damage can be observed. Both direct sympathetic innervation of the heart and the surge in circulating NE and cortisol are the cause of these findings. A similar hyperadrenergic mechanism has been proposed to explain sudden death from fright, asthma, status epilepticus, and cocaine overdose. Investigations by Schobel and colleagues had suggested that sustained sympathetic overactivity is responsible for the hypertension of *preeclampsia*, which may be considered in some ways as a dysautonomic state but this may be an oversimplification. Further information on these topics is contained in Chap. 35 and in the reviews by Samuels and Ropper.

A role has also been inferred for the ventrolateral medullary pressor centers in the maintenance of *essential hypertension*. Geiger and colleagues removed a looped branch of the posteroinferior cerebellar artery that had been apposed to the ventral surface of the medulla in 8 patients who had intractable essential hypertension; they found that 7 improved. Vascular decompression of cranial nerves has proved to be a credible therapeutic measure for hemifacial spasm and some cases of vertigo and trigeminal neuralgia, as discussed in Chap. 4, but the notion of vascular compression of the ventral medulla as a mechanism for typical essential hypertension requires confirmation before being accepted.

The Effects of Thoracolumbar Sympathectomy

Surgical resection of the thoracolumbar sympathetic trunk, widely used in the 1940s in the treatment of hypertension but now of historical interest, provided the clinician with the clearest examples of extensive injury to the peripheral sympathetic nervous system, though a similar defect had long been suspected in one type of primary orthostatic hypotension (see earlier). In general, bilateral thoracolumbar sympathectomy results in surprisingly

few disturbances. Aside from loss of sweating over the denervated areas of the body, the most pronounced abnormality is an impairment of vasomotor reflexes. In the upright posture, faintness and syncope are frequent because of pooling of blood in the splanchnic bed and lower extremities. Although the blood pressure may fall steadily to shock levels, there is little or no pallor, nausea, vomiting, or sweating—the usual accompaniments of syncope. Bladder, bowel, and sexual function are preserved, though semen is sometimes ejaculated into the posterior urethra and bladder (retrograde ejaculation).

Raynaud Syndrome

This disorder, characterized by episodic, painful blanching of the fingers and presumably caused by digital artery spasm, was first described by Raynaud in 1862. The appearance is of a triphasic sequence of color change of pallor, cyanosis, and subsequent rubor of the affected fingers or toes, but about one-third of such patients have no cyanosis. The episodes are brought on by cold or emotional stress and are usually followed by redness on rewarming. Numbness, paresthesia, and burning often accompany the color changes. It is a disease of early onset, the mean age in idiopathic cases being 14 years; it occurs in a number of clinical settings.

Although most cases are idiopathic, in about half there is an associated connective tissue disease, scleroderma being the main one (Porter et al). In these patients, mostly women with the onset of digital symptoms after age 30 years, the Raynaud phenomenon may antedate the emergence of scleroderma or another rheumatologic autoimmune disorder by many years; such disease usually develops within 2 years. In a small group, predominantly men, the syndrome is induced by local trauma, such as prolonged sculling on a cold day, and particularly by vibratory injury incurred by the sustained use of a pneumatic drill or hammer (a syndrome well known in quarry workers). Obstructive arterial disease—as might occur with the thoracic outlet syndrome, vasospasm because of drugs (ergot, cytotoxic agents, cocaine), previous cold injury (frostbite), and circulating cryoglobulins—is a less-common cause. Still, in 64 of 219 patients studied by Porter and coworkers, the Raynaud syndrome was classified as idiopathic, and most of our cases have been of this type. Formerly, the idiopathic form was called *Raynaud disease*; the type with associated disease is known as *Raynaud phenomenon*. The presence of distorted and proliferative capillaries in the nail bed, visible with an ophthalmoscope, has been used as a bedside aid to reveal cases of connective tissue disease.

Other processes seen by neurologists, foremost among them carpal tunnel syndrome, also cause cold sensitivity in the fingers. Attacks of digital pain and color change from vasculitis, atherosclerotic vascular occlusion, and other causes of occlusive vascular disease only superficially resemble the Raynaud phenomenon; a search for cryoprecipitable proteins (cryoglobulins) is another cause and a search for these proteins in the blood is appropriate.

Irrespective of the associated disease, one of two mechanisms seems to be operative in the pathogenesis—either

an arterial constriction or a decrease in the intraluminal pressure. The former, in purest form, is observed in young women on exposure to cold and aggravated by emotional stress; a decrease in intraluminal pressure is associated with arterial obstruction. Treatment is directed to the associated conditions and prevention of precipitating factors. Cervicothoracic sympathectomy has not proved to be an effective measure.

Treatment Avoidance of cold exposure is an obvious strategy, as almost all affected patients have discovered by the time they see the physician. Drugs that cause vasoconstriction are interdicted (ergots, sympathomimetics, clonidine, and serotonin receptor agonists). Calcium channel blockers are most effective, nifedipine being the most widely used, in doses of 30 to 60 mg per day. Other treatments are summarized in the review by Wigley.

Erythromelalgia, first described by S. Weir Mitchell, is a condition in which the feet and lower extremities become red and painful on exposure to warm temperatures for prolonged periods (see the section on this disease in Chap. 11, where the clinical and genetic aspects of this illness are described).

Disorders of Sweating

Hyperhidrosis results from overactivity of sudomotor nerve fibers under a variety of conditions. It may occur as an initial excitatory phase of certain peripheral neuropathies (e.g., because of arsenic or thallium) and be followed by anhidrosis; it is one aspect of the reflex sympathetic dystrophy pain syndromes (see Chap. 5). This is also observed as a localized effect in painful mononeuropathies (causalgia) and diffusely in a number of painful polyneuropathies (“burning foot” syndrome). A type of nonthermoregulatory hyperhidrosis may occur in spinal paraplegics, as mentioned earlier. Loss of sweating in one part of the body may require a compensatory increase in normal parts—for example, the excessive facial and upper truncal sweating that occurs in patients with transection of the high thoracic cord.

Localized hyperhidrosis may be a troublesome complaint in some patients. One variety, presumably of congenital origin, affects the palms. The social embarrassment of a “succulent hand” or a “dripping paw” is often intolerable. It is taken to be a sign of nervousness, although many persons with this condition disclaim all other anxiety symptoms. Cold, clammy hands are common in individuals with anxiety; indeed, this has been a useful sign in distinguishing an anxiety state from hyperthyroidism, in which the hands are also moist but warm. Extirpation of T2 and T3 sympathetic ganglia relieves the more severe cases of palmar sweating; a Horner syndrome does not develop if the T1 ganglion is left intact. In other cases, the hyperhidrosis affects mainly the feet or the axillae. Treatment with local injections of botulinum toxin has been useful and is now favored over ablative procedures.

Anhidrosis in restricted skin areas is a frequent and useful finding in peripheral nerve disease. It is caused by the interruption of the postganglionic sympathetic fibers, and its boundaries can be mapped by means of

the sweat tests described earlier in the chapter. The loss of sweating corresponds to the area of sensory loss. In contrast, sweating is not affected in restricted spinal root disease because there is much intersegmental mixing of the preganglionic axons once they enter the sympathetic chain and there are no preganglionic autonomic fibers in the roots below L2.

A postinfectious anhidrosis syndrome has been described, sometimes accompanied by mild orthostatic hypotension. This process is probably a limited form of the “pure pandysautonomia” described earlier. Corticosteroids are said to be beneficial but the process is so infrequent that there are no dependable data.

Other rare but interesting disorders of sweating are *Ross syndrome*, of Adie pupil (see Chap. 14), areflexia and segmental anhidrosis with compensatory hyperhidrosis in other regions of the body, and idiopathic *pure sudomotor failure*, characterized by urticaria, generalized anhidrosis and elevated IgE; in this syndrome there is no sweating to thermoregulatory needs but preserved sweating with emotional stimuli.

Disturbances of Bladder Function

With regard to the neurologic diseases that cause bladder dysfunction, multiple sclerosis, usually with urinary urgency, is by far the most common. In Fowler’s clinic, other spinal cord disorders accounted for 12 percent of cases, degenerative diseases (Parkinson disease and multiple system atrophy) for 14 percent, and frontal lobe lesions for 9 percent. These data and the physiologic principles elaborated earlier enable one to understand the effects of the following lesions on bladder function:

Complete Destruction of the Cord Below T12 This occurs with lesions of the conus, as from trauma, myelodysplasias, tumor, venous angioma, and necrotizing myelitis. The bladder is paralyzed for voluntary and reflex activity and there is no awareness of the state of fullness; voluntary initiation of micturition is impossible; the tonus of the detrusor muscle is abolished and the bladder distends as urine accumulates until there is overflow incontinence; voiding is possible only by the Credé maneuver, i.e., lower abdominal compression and abdominal straining. Usually the anal sphincter and colon are similarly affected, and there is “saddle” anesthesia and abolition of the bulbocavernosus and anal reflexes as well as the tendon reflexes in the legs. The cystometrogram shows low pressure and no emptying contractions.

Disease of the Sacral Motor Neurons in the Spinal Gray Matter, the Anterior Sacral Roots, or Peripheral Nerves Innervating the Bladder The typical causes of this configuration are lumbosacral meningomyelocoele and the tethered cord syndrome, in effect, a lower motor neuron paralysis of the bladder. The disturbance of bladder function is the same as above, except that sacral and bladder sensation are intact. Other causes of cauda equina disease are compression by epidural tumor or disc, neoplastic meningitis, and radiculitis from herpes or cytomegalovirus (Elsberg syndrome). It is noteworthy that a hysterical patient can suppress motor function and suffer a similar distention of the bladder (see later).

Interruption of Sensory Afferent Fibers From the Bladder Diabetes and tabes dorsalis are typical causes, leaving the motor nerve fibers unaffected. This is a primary sensory bladder paralysis. The disturbance in function is the same as in the two processes earlier. Although a flaccid (atonic) paralysis of the bladder may be purely motor or sensory, as described earlier, in most clinical situations there is *interruption of both afferent and efferent innervation*, as in cauda equina compression or severe polyneuropathy. Neuropathies affecting mainly the small fibers are the ones usually implicated (diabetes, amyloid, etc.), but urinary retention also occurs in certain acute neuropathies such as Guillain-Barré syndrome.

Upper Spinal Cord Lesions, Above T12 Such lesions result in a *reflex neurogenic (spastic) bladder*. In addition to multiple sclerosis and traumatic and compressive myelopathies, which are the most common causes, myelitis, neuromyelitis optica, spondylosis, dural arteriovenous fistula, syringomyelia, and tropical spastic paraparesis may cause a bladder disturbance of this type. If the cord lesion is of sudden onset, the detrusor muscle suffers the effects of spinal shock. At this stage, urine accumulates and distends the bladder to the point of overflow. This overflow incontinence is the result of vesicular pressure exceeding the opening pressure of the sphincter in an areflexic bladder. As the effects of spinal shock subside, the detrusor usually becomes reflexively overactive, and because the patient is unable to inhibit the detrusor and control the external sphincter, urgency, precipitant micturition, and incontinence result. Incomplete lesions result in varying degrees of urgency in voiding. With slowly evolving processes involving the upper cord, such as multiple sclerosis, the bladder spasticity and urgency worsen with time and incontinence becomes more frequent. In addition, initiation of voluntary micturition is impaired and bladder capacity is reduced. Bladder sensation depends on the extent of involvement of sensory tracts. Bulbocavernosus and anal reflexes are preserved. The cystometrogram shows uninhibited contractions of the detrusor muscle in response to small volumes of fluid. Most puzzling to the authors have been cases of cervical cord injury in which reflex activity of the sacral mechanism does not return; the bladder remains hypotonic.

Stretch Injury of the Bladder Wall This occurs with anatomic obstruction at the bladder neck and occasionally with psychogenic retention of urine. Repeated overdistention of the bladder wall often results in varying degrees of decompensation of the detrusor muscle and permanent atonia or hypotonia, although the evidence for this mechanism is uncertain. The bladder wall becomes fibrotic and bladder capacity is greatly increased. Emptying contractions are inadequate, and there is a large residual volume even after the Credé maneuver (manual abdominal compression) and strong contraction of the abdominal muscles. As with motor and sensory paralyses, the patient is subject to cystitis, ureteral reflux, hydronephrosis and pyelonephritis, and calculus formation.

Nonpsychogenic Urinary Retention in Women Fowler has described a disorder of bladder function

in women, in which there is impaired relaxation of the periurethral striated muscle, as recorded by EMG. The complex repetitive discharges that are characteristic of the disorder are similar to, but distinctive from those seen in myotonia and cannot be voluntarily simulated. Fowler has theorized that the disorder is an efferent denervation of the detrusor muscle, which is coincident with the clinical observation that bladder distention in these patients is usually painless. This disorder has been seen in association with polycystic ovarian syndrome. Most young women with painless dilation of the bladder are diagnosed as having a psychogenic cause. The existence of a *bona fide* organic disorder may reduce stigma and facilitate treatment in some such patients. Some patients have been successfully treated with a sacral nerve stimulator.

Frontal Lobe Incontinence There is a supranuclear type of hyperactivity of the detrusor that results in precipitant voiding. If the lesions are extensive enough in the frontal lobes, the patient, because of an abulic or confused mental state, may additionally be unconcerned by the subsequent incontinence. The bladder itself and the associated sphincter functions are normal as would be seen in a precontinent child. These types of frontal lobe incontinence are considered in the description of abnormalities consequent to frontal lobe damage in Chap. 22.

Brainstem Lesions Influencing Bladder Function As discussed earlier, a role for pontine centers in human micturition has been inferred from animal experiments. The existence of a well-delineated pontine nucleus for micturition is controversial (Barrington nucleus). MRI studies by Sakakibara and colleagues have documented isolated pontine lesions as a cause of several different types of micturition difficulties.

Therapy of Disordered Micturition

Several drugs have been used in the management of flaccid and spastic disturbances of bladder function. In the case of a flaccid paralysis, bethanechol (Urecholine) produces contraction of the detrusor by direct stimulation of its muscarinic cholinergic receptors. In spastic paralysis, the detrusor can be relaxed by propantheline (Pro-Banthine, 15 to 30 mg tid), which acts as a muscarinic antagonist, and by oxybutynin (Ditropan, 5 mg bid or tid), which acts directly on the smooth muscle and also has a muscarinic antagonist action. Atropine, which is mainly a muscarinic antagonist, only partially inhibits detrusor contraction.

More recently, alpha₁-sympathomimetic-blocking drugs such as terazosin, doxazosin, and tamsulosin have been used to relax the urinary sphincter and facilitate voiding. Their widest use has been in men with prostatic hypertrophy, but they may be beneficial in patients with dyssynergia of the sphincter (failure of the sphincter to open when the detrusor contracts) from neurologic disease. Several other drugs may be useful in the treatment of neurogenic bladder but can be used rationally only on the basis of sophisticated urodynamic investigations (Krane and Siroky).

Often the patient must resort to intermittent self-catheterization, which can be safely carried out with

scrupulous attention to sterile technique (washing hands, disposable catheter, etc.). Some forms of chronic antibiotic therapy and acidification of urine with vitamin C (1,000 g/d) are practical aids, but their use has gone through cycles of popularity based on various studies with differing results. In selected paraplegic patients, the implantation of a sacral anterior root stimulator may prove to be helpful in emptying the bladder and achieving continence (Brindley et al).

Disturbances of Bowel Function

Ileus from spinal shock, reflex neurogenic colon, and sensory and motor paralysis are all recognized clinical entities. The colon, stomach, and small intestine may be hypotonic and distended and the anal sphincters lax, either from deafferentation, deafferentation, or both. The anal and, in the male, the bulbocavernosus reflex may be abolished. Defecation may be urgent and precipitant with higher spinal and cerebral lesions. Because the same spinal segments and nearly the same spinal tracts subserve bladder and bowel function, meningomyeloceles and other cauda equina and spinal cord diseases often cause so-called double incontinence. Fecal incontinence is less frequent than urinary incontinence, however, because the bowel is less-often filled and its content is usually solid.

Bowel dysmotility, mainly by way of ileus may be a prominent feature of immune neuropathies such as Guillain-Barré syndrome (see Chap. 46), pure pandysautonomia, and severe diabetic autonomic neuropathy discussed earlier. In a few cases of the latter, antibodies against the alpha subunit of the ganglionic acetylcholine receptor has been found by Vernino and colleagues. Systemic diseases may affect the colonic sphincters; examples are myotonic dystrophy and scleroderma, which may weaken the internal sphincter, and polymyositis and myasthenia gravis, which may impair the function of the external sphincter and allow bowel gas to escape (Schuster). The inability to control flatulence may be an early sign of skeletal muscle sphincteric weakness in myasthenia. Also, sphincteric damage may complicate hemorrhoidectomy.

In recent years there has been considerable interest in weakness of the muscles of the pelvic floor as a cause of double incontinence, especially in the female. Also, it has been suggested that paradoxical contraction of the puborectus and external anal sphincter may be a cause of severe constipation (anismus). Extreme degrees of descent of the pelvic floor are believed to injure the pudendal nerves, as reflected in prolonged terminal latencies in nerve conduction studies.

Many cases of ileus, even to the extent of megacolon, have a pharmacologic basis, being a result of the use of drugs that paralyze the parasympathetic system or narcotics that have a direct effect on the motility of gastrointestinal smooth muscle.

The serotonin receptor agonist cisapride had been used in partially restoring gastrointestinal motility in some cases of neurogenic ileus as, for example, the early stages of the Guillain-Barré syndrome and in pediatric bowel diseases. Because of ventricular arrhythmias and

a few cases of sudden cardiac death, its administration is currently allowed only by experienced pediatric gastroenterologists.

Congenital Megacolon (Hirschsprung Disease)

This is a rare disease affecting mainly male infants and children. It is caused by a congenital absence of ganglion cells in the myenteric plexus. The internal anal sphincter and rectosigmoid are involved most often and are the parts affected in restricted forms of Hirschsprung disease (75 percent of cases), but the aganglionosis is sometimes more extensive. The aganglionic segment of the bowel is constricted and cannot relax, thus preventing propagation of peristaltic waves, which, in turn, produces retention of feces and massive distention of the colon above the aganglionic segment. Enterocolitis is the most serious complication and is associated with a high mortality. Some cases of megaloureter are attributed to a similar defect.

Hirschsprung disease in most cases has been traced to a mutation of the RET oncogene and perhaps to polymorphisms in other genes; the variability in clinical severity corresponds to polymorphisms in the responsible gene. Other genes, such as the one that codes for the endothelin receptor, are implicated in a small group with the disease. There are several other familial diseases that may manifest as an enteric neuropathy including an unusual mitochondrial disorder discussed in Chap. 37, Allgrove syndrome, and an entity termed familial visceral myopathy.

Disturbances of Sexual Function

Sexual function in the male, which is not infrequently affected in neurologic disease, may be divided into several parts: (1) sexual impulse, drive, or desire, referred to as *libido*, discussed in Chap. 25; (2) penile erection, enabling the act of sexual intercourse (potency); and (3) ejaculation of semen by the prostate through the urethra.

The arousal of libido in men and women may result from a variety of stimuli, some purely psychic. Neocortical influences referable to sex involve the limbic system and are transmitted to the hypothalamus and spinal centers. The suprasegmental pathways traverse the lateral funiculi of the spinal cord near the corticospinal tracts to reach sympathetic and parasympathetic segmental centers. Penile erection is effected through sacral parasympathetic motor neurons (S3 and S4), the nervi erigentes, and pudendal nerves. There is some evidence also that a sympathetic outflow from thoracolumbar segments (originating in T12-L1) via the inferior mesenteric and hypogastric plexuses can mediate psychogenic erections in patients with complete sacral cord destruction. Activation from these segmental centers opens vascular channels between arteriolar branches of the pudendal arteries and the vascular spaces of the corpora cavernosa and corpus spongiosum (erectile tissues), resulting in tumescence. Detumescence occurs when venous channels open widely. Ejaculation involves rhythmic contractions of the prostate, compressor (sphincter) urethrae, and bulbocavernosus and ischiocavernosus muscles, which

Figure 26-6. The pathways involved in human penile erection. See text for details. (Reproduced by permission from Weiss.)

are under the control of both the sympathetic and parasympathetic centers. Afferent segmental influences arise in the glans penis and reach parasympathetic centers at S3 and S4 (reflexogenic erections). Figure 26-6 shows the organization of this neural system and the locations of lesions that can abolish normal erectile function. Similar neural arrangements exist in females.

The different aspects of sexual function may be affected separately. Loss of libido may depend on both psychic and somatic factors. It may be complete, as in old age or in medical and endocrine diseases, or it may occur only in certain circumstances or in relation to certain situations. In the latter case, which is a result of psychological factors, reflex penile erection during rapid eye movement (REM) sleep, and even emission of semen, may occur.

Sexual desire can be altered in the opposite direction, i.e., it may be excessive. This, too, is usually psychologic or psychiatric in origin, as in manic states, but sometimes it occurs with neurologic disease, such as encephalitis and tumors that affect the diencephalon, septal region, and temporal lobes; with the dementias; and as a result of certain medications such as L-dopa, as discussed in Chap. 25. In the instances of neurologic diseases with hypersexuality, there are usually other signs of disinhibited behavior as well.

On the other hand, sexual drive may be present but penile erection impossible to attain or sustain. The most common cause of erectile dysfunction is a depressive state. Prostatectomy is another, the result of damage to the parasympathetic nerves embedded in the capsule of the gland. It occurs also in patients who suffer disease of the sacral cord segments and their afferent and efferent connections (e.g., cord tumor, myelitis, tabes, and diabetic and many other polyneuropathies), in which case nocturnal erections are absent. The parasympathetic nerves cannot then be activated to cause tumescence of the corpora cavernosa and corpus spongiosum. The phosphodiesterase inhibitors such as sildenafil (*Viagra*) have proved to be useful in the treatment of erectile dysfunction in some patients with sexual dysfunction of neurologic cause. During sexual stimulation, it enhances the effect of local nitric oxide on the smooth muscle of the corpus cavernosum; this results in relaxation of the smooth muscle and inflow of blood. The high rate of success of this drug in patients with spinal cord injury indicates that segmental innervation is all that is required for reflexive erection in response to tactile stimulation of the penis.

Diseases of the spinal cord may abolish psychogenic erections but leave reflexive ones intact. In fact, the latter may become overactive, giving rise to sustained painful

erections (*priapism*). This indicates that the segmental mechanism for penile erection is relatively intact. There are many other nonneurologic causes for priapism, among them are sickle cell anemia and other thrombotic states and perineal trauma.

Other sexual difficulties include the premature ejaculation of semen. After lumbar sympathectomy, the semen may be ejected back into the bladder because of paralysis of the periurethral muscle within the prostate, at the verumontanum (*colliculus seminalis*). Polyneuropathies, such as those caused by diabetes, may be responsible; acute or chronic prostatitis may have a similar effect.

Cerebral disorders of sexual function are discussed further in Chap. 25 (see section on “Altered Sexuality”) and the development of sexual function, in Chap. 28.

NERVOUS SYSTEM CONTROL OF RESPIRATION

Considering that the act of breathing is directed entirely by the nervous system, it is surprising how little attention it has received other than from physiologists. Every component of breathing—the lifelong automatic cycling of inspiration, the transmission of coordinated nerve impulses to and from the respiratory muscles, the translation of systemic influences such as acidosis to the neuromuscular apparatus of the diaphragm—is under neural control. Moreover, respiratory failure is one of the most serious disturbances of neurologic function in comatose states and in neuromuscular diseases such as myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis, muscular dystrophy, and poliomyelitis. Finally, death—or brain death—is now virtually defined in terms of the ability of the nervous system to sustain respiration, a reversion to ancient methods of determining the cessation of all vital forces. Neurologists should be familiar with the alterations of respiration caused by diseases in different parts of the nervous system, the effects of respiratory failure on the brain, and the rationale that underlies modern methods of treatment. A full understanding of respiration requires knowledge of the mechanical and physiologic workings of the lungs as organs of gas exchange; but here we limit our remarks to the nervous system control of breathing.

The Central Respiratory Motor Mechanisms

It has been known for more than a century that breathing is controlled mainly by the lower brainstem, and that each half of the brainstem is capable of producing an independent respiratory rhythm. In patients with poliomyelitis, for example, the occurrence of respiratory failure was associated with lesions in the ventrolateral tegmentum of the medulla (Feldman; Cohen). Until fairly recently, thinking on this subject was dominated by Lumsden’s scheme of the breathing patterns that resulted from sectioning the brainstem of cats at various levels. He postulated the existence of several centers in the pontine tegmentum, each corresponding to an abnormal

breathing pattern—a pneumotaxic center, an apneustic center, and a medullary gasping center. This scheme proves to be oversimplified when viewed in the light of modern physiologic findings. Instead, neurons in several discrete regions discharge with each breath and, together, generate the respiratory rhythm. In other words, these sites do not function in isolation, as individual oscillators, but interact with one another to generate the perpetual respiratory cycle and they each contain both inspiratory and expiratory components.

Three paired groups of respiratory nuclei are oriented more or less in columns in the pontine and medullary tegmentum (Fig. 26-7). They comprise (1) a ventral respiratory group (referred to as VRG), extending from the lower to the upper ventral medulla, in the region of the nucleus retroambiguus; (2) a dorsal medullary respiratory group (DRG), located dorsal to the obex and immediately ventromedial to the NTS; and (3) two clusters of cells in the dorsolateral pons in the region of the parabrachial nucleus. From electrical-stimulation experiments, it appears that paired neurons in the dorsal pons may act as “on-off” switches in the transition between inspiration and expiration.

Inspiratory neurons are concentrated in the dorsal respiratory group and in the rostral portions of the ventral group, some of which have monosynaptic connections to the motor neurons of the phrenic nerves and the nerves to the intercostal muscles. Normal breathing is actively inspiratory and only passively expiratory; however, under some circumstances of increased respiratory drive, the internal intercostal muscles and abdominal muscles actively expel air. The expiratory neurons that mediate this activity are concentrated in the caudal portions of the ventral respiratory group and in the most rostral parts of the dorsal group. On the basis of both neuroanatomic tracer and physiologic studies, it has been determined that these expiratory neurons project to spinal motor neurons and have an inhibitory influence on inspiratory neurons.

The pathway of descending fibers that arises in the inspiratory neurons and terminates on phrenic nerve motor neurons lies just lateral to the anterior horns of the upper cervical cord segments. When these tracts are damaged, automatic but not voluntary diaphragmatic movement is lost. As noted later, the fibers carrying voluntary motor impulses to the diaphragm course more dorsally in the cord. The phrenic motor neurons form a thin column in the medial parts of the ventral horns, extending from the third through fifth cervical cord segments. Damage to these neurons, of course, precludes both voluntary and automatic breathing.

As mentioned, the exact locus from which the breathing rhythm is generated, if there is such a site, is not known. The conventional understanding has been that the DRG was the dominant generator of the respiratory rhythm but the situation is certainly more complex. Animal experiments have focused attention instead on the rostral ventrolateral medulla (VRG). This region contains a group of neurons in the vicinity of the “Botzinger complex” (which itself contains neurons that fire mainly

Figure 26-7. The location of the main centers of respiratory control in the brainstem as currently envisioned from animal experiments and limited human pathology. There are three paired groups of nuclei: (1) The dorsal respiratory group (DRG), containing mainly inspiratory neurons, located in the ventrolateral subnucleus of the nucleus of the tractus solitarius; (2) a ventral respiratory group (VRG), situated near the nucleus ambiguus and containing in its caudal part neurons that fire predominantly during expiration and in its rostral part neurons that are synchronous with inspiration—the latter structure merges rostrally with the Botzinger complex, which is located just behind the facial nucleus and contains neurons that are active mostly during expiration; and (3) a pontine pair of nuclei (PRG), one of which fires in the transition between inspiration and expiration and the other between expiration and inspiration. The intrinsic rhythmicity of the entire system probably depends on interactions between all these regions, but the “pre-Botzinger” area in the rostral ventromedial medulla may play a special role in generating the respiratory rhythm. (Adapted by permission from Duffin et al.)

during expiration). Cooling of this area or injection with neurotoxins in animals causes the respiratory rhythm to cease (see the review by Duffin et al). It has also been shown that the paired respiratory nuclei in the pons that are thought to act as switches between inspiration and expiration possess a degree of autonomous rhythmicity but their role in engendering cyclic breathing has not been clarified. Some workers are of the opinion that two or more sets of neurons in the VRG create a rhythm by their reciprocal activity or that oscillations arise within even larger networks (see Blessing for details).

There are also centers in the pons that do not generate respiratory rhythms but may, under extreme circumstances, greatly influence them. One pontine group, the “pneumotaxic center,” modulates the response to hypoxia, hypocapnia, and lung inflation. In general, expiratory neurons are located laterally and inspiratory neurons medially in this center, but there is an additional group that lies between them and remains active during the transition between respiratory phases. Also found in the lower pons is a group of neurons that prevent unrestrained activity of the medullary inspiratory neurons (“apneustic center”). In addition to these ambiguities regarding a “center” for the generation of respiratory rhythm, there is the difficulty that the nuclei described earlier are not well defined in humans.

As to the effects of a unilateral brainstem lesion on ventilation, numerous cases of hypoventilation or total loss of automatic ventilation (“Ondine’s curse”—see further on) have been recorded (Bogousslavsky and colleagues). We have observed several such remarkable cases as well, in most instances caused by a large lateral medullary infarction. If the neural oscillators on each side were totally independent, such a syndrome should not be possible. The likely explanation is that a unilateral lesion interrupts the connections between each of the paired groups of nuclei, which normally synchronize the two sides in the generation of rhythmic bursts of excitatory impulses to spinal motor neurons. It is of interest that in a case of a very delimited metastasis to the NTS there was no apparent impact on the breathing pattern until a terminal respiratory arrest (Rhodes and Wightman).

Voluntary Control of Breathing

During speech, swallowing, breathholding, or voluntary hyperventilation, the automaticity of the brainstem mechanisms of respiration is arrested in favor of reflexive or of conscious control of diaphragmatic contraction. The observations of Colebatch and coworkers, using PET scanning, indicate that voluntary control of breathing is associated with activity in the motor and premotor cortex. The experiments of Maskill and associates demonstrated

that magnetic cortical stimulation of a region near the cranial vertex activates the diaphragm. Although automatic and voluntary breathing utilize the same pools of cervical motor neurons that give rise to the phrenic nerves, the descending cortical pathways for voluntary breathing are distinct from those utilized by automatic brainstem mechanisms as noted earlier. It is not known whether the voluntary signal bypasses the brainstem mechanisms or is possibly integrated there. When both dorsal descending tracts subserving voluntary control are interrupted, as in the “locked-in syndrome,” the independent, automatic respiratory system in the medulla is capable of maintaining an almost perfectly regular breathing rate of 16 per minute with uniform tidal volumes.

These essential facts do not fully depict the rich interactions between the neuronal groups governing respiration and those for laryngeal and glottic activity that come into play during such coordinated acts as swallowing, sneezing, coughing, and speaking. The brainstem regions that hold breathing in abeyance while swallowing occurs are pertinent to aspiration, a common feature of many neurologic diseases, as discussed further on. The drive applied to these systems is damped in processes such as Parkinson disease, causing discoordination between breathing and swallowing, and may contribute to the problem of aspiration, as also discussed further on.

Afferent Respiratory Influences

A number of signals that modulate respiratory drive originate in chemoreceptors located in the carotid artery. These receptors are influenced both by changes in pH and by hypoxia. Chemoreceptor afferents pass along the carotid sinus nerves, which join the glossopharyngeal nerves and terminate in the NTS. Aortic body receptors, which are less important as detectors of hypoxia, send afferent volleys to the medulla through the aortic nerves, which join the vagus nerves. There are also chemoreceptors in the brainstem, but their precise location is uncertain. Their main locus is thought to be in the ventral medulla, but other areas that are responsive to changes in pH have been demonstrated in animals. What is clear is that these regions are sensitive not to the pH of CSF, as had been thought, but to the pH of the extracellular fluid of the medulla.

Numerous stretch receptors within smooth muscle cells of the airways also project via the vagus nerves to the NTS and influence the depth and duration of breathing. Afferent signals from these specialized nerve endings mediate the Hering-Breuer reflex, described in 1868—a shortened inspiration and decreased tidal volume triggered by excessive lung expansion. The Hering-Breuer mechanism seems not to be important at rest, as bilateral vagal section has no effect on the rate or depth of respiration. These aspects of afferent pulmonary modulation of breathing have been reviewed by Berger and colleagues. It is interesting, however, that patients with high spinal transections and inability to breathe can still sense changes in lung volume, attesting to a nonspinal afferent route to the brainstem from lung receptors, probably through the vagus nerves. In addition, there are receptors located between pulmonary epithelial cells that respond

to irritants such as histamine and smoke. They have been implicated in the genesis of asthma. There are also “J-type” receptors in the lung interstitium that are activated by substances in the interstitial fluid of the lungs. These are capable of inducing hyperpnea and probably play a role in driving ventilation under conditions such as pulmonary edema.

Both the diaphragm and the accessory muscles of respiration contain conventional spindle receptors, but their role is not clear; all that can be said is that the diaphragm has a paucity of these receptors compared with other skeletal muscles (a property shared with extraocular muscles) and is therefore not subject to spasticity with corticospinal lesions or to the loss of tone in states such as REM sleep, in which gamma motor neuron activity is greatly diminished.

Dyspnea

The common respiratory sensations of breathlessness, air hunger, chest tightness, or shortness of breath, all of which are subsumed under the term *dyspnea*, have defied neurophysiologic interpretation. In animals, Chen and colleagues from Eldridge’s laboratory have demonstrated that neurons in the thalamus and central midbrain tegmentum discharge in a graduated manner as respiratory drive is increased. These neurons are influenced greatly by afferent information from the chest wall, lung, and chemoreceptors and are postulated to be the thalamic representation of sensation from the thorax that is perceived at a cortical level as dyspnea. However, functional imaging studies indicate that various areas of the cerebrum are activated by dyspnea, mainly the insula and limbic regions.

Aberrant Respiratory Patterns

Many of the most interesting respiratory patterns observed in neurologic disease are found in comatose patients, and several of these patterns have been assigned localizing value, some of uncertain validity: *central neurogenic hyperventilation, apneusis, and ataxic breathing*. These are discussed in relation to the clinical signs of coma (see Chap. 17) and sleep apnea (see Chap. 19). Some of the most bizarre cadences of breathing—those in which unwanted breaths intrude on speech or those characterized by incoordination of laryngeal closure, diaphragmatic movement, or swallowing or by respiratory tics—have occurred in paraneoplastic brainstem encephalitis. Similar incoordinated patterns occur in certain extrapyramidal diseases. Patterns such as episodic tachypnea up to 100 breaths per minute and loss of voluntary control of breathing were, in the past, noteworthy features of post-encephalitic parkinsonism.

In *Leeuwenhoek’s disease*, named for the discoverer of the microscope who described and was afflicted with the problem, there is an almost continuous epigastric pulsation and dyspnea in association with rhythmic bursts of activity in the inspiratory muscles—a respiratory myoclonus akin to palatal myoclonus (Phillips and Eldridge). Two such cases in our clinical material followed influenza-like illnesses and resolved slowly over months. Another patient with similar movements intermittently causing

gasping sounds gave us the impression of having a psychogenic disease.

Cheyne-Stokes breathing, the common and well-known waxing and waning type of cyclic ventilation reported by Cheyne in 1818 and later elaborated by Stokes, has for decades been ascribed to a prolongation of circulation time, as in congestive heart failure; but there are data that support a primary neural origin of the disorder, particularly the observation that it occurs most often in patients with deep hemispherical lesions of the cerebral hemispheres or advanced stages of metabolic encephalopathy. The level of consciousness in these circumstances parallels the respiratory pattern. During the apneic period the patient is less responsive. The onset of respiration is heralded by arousal, marked by eye opening and sometimes vocalization. At the peak of the hyperventilation phase, the patient is maximally awake. Consciousness then wanes followed by slowing of the respiratory rate and finally coma to complete a full cycle. The fact that the level of consciousness changes before the respiratory rate is altered implies that Cheyne-Stokes breathing is only one component of a cyclic autonomic brainstem phenomenon. (See Chap. 17 for further comments on the physiologic explanation for this pattern.)

Another striking aberration of ventilation is a loss of automatic respiration during sleep, with preserved voluntary breathing (*Ondine's curse*). The term stems from the German myth in which Ondine, a sea nymph, condemns her unfaithful lover to a loss of all movements and functions that do not require conscious will. Patients with this condition are compelled to remain awake lest they stop breathing, and they must have nighttime mechanical ventilation to survive. Presumably the underlying pathology is one that selectively interrupts the ventrolateral descending medullocervical pathways that subservise automatic breathing. The syndrome has been documented mostly in cases of unilateral and bilateral brainstem infarctions, hemorrhage, encephalitis (neoplastic or infectious—for example, due to *Listeria*), in Leigh syndrome (a destructive process in the lower brainstem of mitochondrial origin), and with traumatic Duret hemorrhages in the lower brainstem. The issue of a loss of automatic ventilation as a result of a unilateral brainstem lesion has been addressed earlier. A state in which there is complete loss of voluntary control of ventilation but preserved automatic monorhythmic breathing has also been described (Munschauer et al). Incomplete variants of this latter phenomenon are regularly observed in cases of brainstem infarction or severe demyelinating disease, and may be a component of the “locked-in state.”

Often neglected is the dyspnea that patients experience with orthostatic hypotension (*orthostatic dyspnea*). In a questionnaire given to patients in an autonomic laboratory, Gibbons and Freeman reported that one-third had this symptom. They proposed that some form of mismatch between lung ventilation and perfusion was the cause.

The *congenital central hypoventilation syndrome* is thought to be an idiopathic version of the loss of automatic ventilation (see Shannon et al). This rare condition begins in infancy with apneas and sleep disturbances

of varying severity or later in childhood with signs of chronic hypoxia leading to pulmonary hypertension. As mentioned in “Sleep Apnea and Excessive Daytime Sleepiness” in Chap. 19, several subtle changes in the arcuate nucleus of the medulla and a depletion of neurons in regions of the respiratory centers have been found in this condition, but further study is necessary.

Neurologic lesions that cause *hyperventilation* are diverse and widely located throughout the brain, not just in the brainstem. In clinical practice, episodes of hyperventilation are most often seen in anxiety and panic states. The traditional view of “central neurogenic hyperventilation” as a manifestation of a pontine lesion has been brought into question by the observation that it may occur as a sign of primary cerebral lymphoma, in which postmortem examination has failed to show involvement of the brainstem regions controlling respiration (Plum).

Hiccup (singultus) is a poorly understood phenomenon. It does not seem to serve any useful physiologic purpose, existing only as a nuisance, and is typically not associated with any particular disease. It may occur as a component of the lateral medullary syndrome (see Chap. 34) as in 7 of 51 cases studied by Park and colleagues, with masses in the posterior fossa or medulla, and occasionally with generalized elevation of intracranial pressure, brainstem encephalitis, or with metabolic encephalopathies such as uremia. Rarely, singultation may be provoked by medication, one possible offender in our experience being dexamethasone. Because the triggers of hiccup often seem to arise in epigastric organs adjacent to the diaphragm, it is considered to be a gastrointestinal reflex, more than a respiratory one. A physiologic study by Newsom Davis demonstrated that hiccup is the result of powerful contraction of the diaphragm and intercostal muscles, followed immediately by laryngeal closure. This results in little or no net movement of air. He concluded that the projections from the brainstem responsible for hiccup are independent of the pathways that mediate rhythmic breathing.

Within a single burst or run of hiccups, the frequency remains relatively constant, but at any one time it may range anywhere from 15 to 45 per minute. The contractions are most liable to occur during inspiration and they are inhibited by therapeutic elevation of arterial carbon dioxide (CO₂) tension. We cannot vouch for the innumerable home-brewed methods that are said to suppress hiccups (breathholding, induced fright, anesthetization, or stimulation of the external ear canal or concha, etc.), but where the neurologist is asked to help in an intractable case (usually in a male), baclofen is sometimes effective. Drugs that act to empty the stomach (e.g., metoclopramide) may work as well.

Disorders of Ventilation Caused by Neuromuscular Disease

Failure of ventilation in the neuromuscular diseases causes one of two symptom complexes: an acute one occurs in patients with rapidly evolving generalized weakness, such as Guillain-Barré syndrome and myasthenia gravis, and the other in patients with subacute or

chronic diseases, such as motor neuron disease, myopathies (acid maltase, nemaline), and muscular dystrophy. The review by Polkey and colleagues provides a more extensive list of diseases that cause these problems. Patients in whom respiratory failure evolves in a matter of hours become anxious, tachycardic, and diaphoretic. They may display *paradoxical respiration*, in which the abdominal wall retracts during inspiration, owing to the failure of the diaphragm to contract, while the intercostal and accessory muscles create a negative intrathoracic pressure. Or, there is *respiratory alternans*, a pattern of diaphragmatic descent only on alternate breaths (this is more characteristic of airway obstruction). These signs appear in the acutely ill patient when the vital capacity has been reduced to approximately 10 percent of normal, or 500 mL in the average adult.

Patients with chronic but stable weakness of the respiratory muscles, demonstrate signs of CO₂ retention, such as daytime somnolence, headache upon awakening, nightmares, and, in extreme cases, papilledema. The accessory muscles of respiration are recruited in an attempt to maximize tidal volume, and there is a tendency for the patient to gulp or assume a rounded “fish mouth” appearance in an effort to inhale additional air. In general, patients with chronic respiratory difficulty tolerate lower tidal volumes without dyspnea than do patients with acute disease, and symptoms in the former may occur only at night, when respiratory drive is diminished and compensatory mechanisms for obtaining additional air are in abeyance.

Treatment of the two conditions differs. The chronic type of respiratory failure may require only nighttime support of ventilation, which can be provided by negative pressure devices such as a cuirass or preferably, by intermittent positive pressure applied by a tight-fitting mask over the nose (bilevel positive airway pressure [BIPAP] or continuous positive airway pressure [CPAP]). These measures may also be used temporarily in acute situations, but in many cases there will be need of a positive-pressure ventilator that provides a constant volume with each breath. This can be effected only through an endotracheal tube.

Typical ventilator settings in cases of acute mechanical respiratory failure, if there is no pneumonia, are for tidal volumes of 6 to 8 mL/kg, depending on the compliance of the lungs and the patient's comfort, at a ventilator rate between 4 and 12 breaths per minute, adjusted to the degree of respiratory failure. The tidal volume is kept relatively constant so as to prevent atelectasis, and only the rate is changed as the diaphragm becomes weaker or stronger. Decisions regarding the need for these mechanical devices are frequently difficult, particularly as patients with chronic neuromuscular illnesses often become dependent on a ventilator. Further details regarding the management of ventilation in acute neuromuscular weakness are given in the section on Guillain-Barré syndrome in Chap. 46.

The presence of oropharyngeal weakness as a result of the underlying neuromuscular disease may leave the patient's airway unprotected and require endotracheal intubation before mechanical ventilation becomes necessary. It is even difficult to decide when to remove an

endotracheal tube in a patient with oropharyngeal weakness. Because the safety of the swallowing mechanism cannot be assessed with the tube in place, one must be prepared to reintubate the patient or to have a surgeon prepared to perform a tracheostomy after extubation, in the event that aspiration occurs.

We frequently encounter patients in whom the earliest feature of neuromuscular disease is *subacute respiratory failure*; this is manifest as dyspnea and exercise intolerance but *without other overt signs of neuromuscular disease*. Most such cases prove to be motor neuron disease, but rare instances of myasthenia gravis (especially the type associated with the MUSK autoantibody), acid maltase deficiency, polymyositis, nemaline myopathy, Lambert-Eaton syndrome, or chronic inflammatory demyelinating polyneuropathy may present in this way. The neurologist may be consulted in these cases after other physicians have found no evidence of intrinsic pulmonary disease. The spirometric flow-volume loop in cases of neuromuscular respiratory failure shows low airflow rates with diminished lung volumes that together simulate restrictive lung disease. Among such patients we have also found instances of isolated unilateral or *bilateral phrenic nerve paresis* that followed abdominal or cardiac surgery or an infectious illness. The least of these is probably a form of brachial neuritis (see Chap. 46 for a discussion of brachial neuritis).

Neuromuscular Respiratory Failure in Critically Ill Patients Neurologists increasingly are being called upon to determine if there is an underlying neuromuscular cause for respiratory failure in a critically ill patient. Malnutrition, hypophosphatemia (induced by hyperalimentation), and hypokalemia always need to be kept in mind as causes of muscular weakness. Aside from the acute neuromuscular diseases listed above, Bolton and colleagues have delineated a *critical illness polyneuropathy*, which accounts for as many as 40 percent of cases of an inability to wean a patient from the ventilation. Most of these patients have had an episode of sepsis or have multiple organ failure (see Chap. 46). The EMG demonstrates widespread denervation with relative sparing of sensory potentials. Less often, a *critical illness myopathy* occurs in relation to the administration of high-dose corticosteroids (see Chap. 51). This myopathy occurs mainly in patients who are receiving neuromuscular postsynaptic blocking drugs such as pancuronium simultaneously with high-dose steroids but corticosteroids alone have been implicated (see Chap. 51).

The Neurologic Basis of Swallowing

The act of swallowing, like breathing, continues periodically through waking and sleep, largely without conscious will or awareness. Swallowing occurs at a natural frequency of about once per minute while an individual is idle; it is suppressed during concentration and emotional excitement.

The fundamental role of swallowing is to move food from the mouth to the esophagus and thereby to begin the process of digestion, but it also serves to empty the oral cavity of saliva and prevent its entry into the

respiratory tract. Because the oropharynx is a shared conduit for breathing and swallowing, obligatory reflexes exist to assure that breathing is held in abeyance during swallowing. Because of this relationship and the frequency with which dysphagia and aspiration complicate neurologic disease, the neural mechanisms that underlie swallowing are of considerable importance to the neurologist and are described here. The reader is also referred to other parts of this book for a discussion of derangements of swallowing consequent upon diseases of the lower cranial nerves (see Chap. 47), of muscle (see Chap. 48), and of the neuromuscular junction (see Chap. 53).

Anatomic and Physiologic Considerations

A highly coordinated sequence of muscle contractions is required to move a bolus of food smoothly and safely through the oropharynx. This programmed activity may be elicited voluntarily or by reflex movements that are triggered by sensory impulses from the posterior pharynx. Swallowing normally begins as the tongue, innervated by cranial nerve XII, sweeps food to the posterior oral cavity, and brings the bolus into contact with the posterior wall of the oropharynx. As the food passes the pillars of the fauces, tactile sensation, carried through nerves IX and X, reflexly triggers (1) the contraction of levator and tensor veli palatini muscles, which close the nasopharynx and prevent nasal regurgitation, followed by (2) the upward and forward movement of the arytenoid cartilages toward the epiglottis (observed as an upward displacement of the hyoid and thyroid cartilages), which closes the airway. With these movements, the epiglottis guides the food into the valleculae and into channels formed by the epiglottic folds and the pharyngeal walls. The airway is closed by sequential contractions of the arytenoid–epiglottic folds, and below them, the false cords, and then the true vocal cords, which seal the trachea.

All of these muscular contractions are effected largely by cranial nerve X (vagus). The palatopharyngeal and pharyngeal muscles pull the pharynx up over the bolus and the stylopharyngeal muscles draw the sides of the pharynx outward (nerve IX). At the same time, the upward movement of the larynx opens the cricopharyngeal sphincter. A wave of peristalsis then begins in the pharynx, pushing the bolus through the sphincter into the esophagus. These muscles relax as soon as the bolus reaches the esophagus. The entire swallowing ensemble can be elicited by stimulation of the superior laryngeal nerve (this route is used in experimental studies.)

Reflex swallowing requires only medullary functioning and is retained in the vegetative and locked-in states as well as in normal and anencephalic neonates. The integrated sequence of muscle activity for swallowing is organized in a region of brainstem that roughly comprises a swallowing center, located in the region of the NTS, close to the respiratory centers. This juxtaposition ostensibly allows the refined coordination of swallowing with the cycle of breathing. Besides a programmed period of apnea, there is a slight forced exhalation after each swallow that further prevents aspiration. The studies of Jean, Kessler, and others (cited by Blessing), using microinjections of excitatory neurotransmitters, have

localized the swallowing center in animals to a region adjacent to the termination of the superior laryngeal nerve. Unlike the generators of respiratory rhythm, the entire reflex apparatus for swallowing may be located in the NTS. There is, however, no direct connection between the NTS and the cranial nerve motor nuclei. Thus it is presumed that control must be exerted through premotor neurons located in adjacent reticular brainstem regions. There have been few comparable anatomic studies of the structures responsible for swallowing in humans. As to the cortical regions that are involved in swallowing, it appears from PET studies that the inferior precentral gyrus and the posterior inferior frontal gyrus are activated, and lesions in these parts of the brain give rise to the most profound cases of dysphagia.

Dysphagia and Aspiration

Weakness or incoordination of the swallowing apparatus is manifest as dysphagia and, at times, aspiration. The patient himself is often able to discriminate one of several types of defects: (1) difficulty initiating swallowing, which leaves solids stuck in the oropharynx; (2) nasal regurgitation of liquids; (3) frequent coughing and choking immediately after swallowing and a hoarse, “wet cough” following the ingestion of fluids; or (4) some combination of these. Extrapyramidal diseases, notably Parkinson disease, reduce the frequency of swallowing and cause an incoordination of breathing and swallowing, as noted later.

It is surprising how often the tongue and the muscles that cause palatal elevation appear on direct examination to act normally despite an obvious failure of coordinated swallowing. Similarly, the use of the gag reflex as a neurologic sign is quite limited, being most helpful when there is a medullary lesion or the lower cranial nerves are damaged. In our experience, palatal elevation in response to touching the posterior pharynx only demonstrates that cranial nerves IX and X and the local musculature are not entirely dysfunctional; in other words, the presence of the reflex does not assure the smooth coordination of the swallowing mechanism and, more importantly, does not obviate aspiration. Difficulties with swallowing may begin subtly and express themselves as weight loss or as a noticeable increase in the time required to eat a meal. Nodding or sideways head movements to assist the propulsion of the bolus, or the need to repeatedly wash food down with water, are other clues to the presence of dysphagia. Often, recurrent minor pneumonias are the only manifestation of intermittent (“silent”) aspiration.

A defect in the initiation of swallowing is usually attributable to weakness of the tongue and may be a feature of myasthenia gravis, motor neuron disease or rarely, inflammatory disease of the muscle; it may be caused by palsies of the twelfth cranial nerve (metastases at the base of the skull or meningoradiculitis, carotid dissection), or to a number of other causes. In all these cases there is usually an associated dysarthria with difficulty pronouncing lingual sounds. The second type of dysphagia, associated with nasal regurgitation of liquids, indicates a failure of velopalatine closure and is characteristic of myasthenia gravis, tenth nerve palsy of any cause, or incoordination

of swallowing because of bulbar or pseudobulbar palsy. A nasal pattern of speech with air escaping from the nose is a usual accompaniment.

Viewed from a physiologic perspective, the causes of aspiration fall into four main categories: (1) weakness of the pharyngeal musculature because of lesions of the vagus on one or both sides; (2) myopathy (polymyositis, myotonic and oculopharyngeal dystrophies) or neuromuscular disease (amyotrophic lateral sclerosis and myasthenia gravis); (3) a medullary lesion that affects the NTS or the cranial motor nuclei (lateral medullary infarction is the prototype)—but syringomyelia-syringobulbia and, rarely, multiple sclerosis, polio, and brainstem tumors may have the same effects; or (4) less-well-defined mechanisms of slowed or disorganized swallowing arising from corticospinal disease (pseudobulbar palsy, hemispherical stroke) or from diseases of the basal ganglia (mainly Parkinson disease) that alter the timing of breathing and swallowing and permit the airway to remain open as food passes through the posterior pharynx. In the latter cases, a decreased frequency of swallowing also causes saliva to pool in the mouth (leading to drooling) and adds to the risk of aspiration.

Because of its frequency, the neurologist will encounter stroke in a cerebral hemisphere as a cause of disorganized swallowing. The problem is most evident during the first few days after a hemispherical stroke on either side of the brain (Meadows). These effects last days or weeks and render the patient subject to pneumonia and fever. In the clinical and fluoroscopic study by Mann and colleagues, half of patients still had manifest abnormalities of swallowing 6 months after their strokes. For this reason, it has become customary for patients to have swallowing evaluations in the days after acute stroke. Some insight into the nature of swallowing dysfunction after stroke is provided by Hamdy and colleagues, who correlated the presence of dysphagia with a lesser degree of motor representation of pharyngeal muscles in the unaffected hemisphere, as assessed by magnetic stimulation of the cortex.

Pain on swallowing occurs under a different set of circumstances, the one of most neurologic interest being glossopharyngeal neuralgia as discussed in Chaps. 10 and 47.

Videofluoroscopy has become a useful tool in determining the presence of aspiration during swallowing and in differentiating the several types of dysphagia. The movement of the bolus by the tongue, the timing of reflex swallowing, and the closure of the pharyngeal and palatal openings are judged directly by observation of a bolus of food mixed with barium or of liquid barium alone. However, authorities in the field, such as Wiles, whose reviews are recommended (see also Hughes and Wiles), warn that unqualified dependence on videofluoroscopy is unwise. They remark that observation of the patient swallowing water and repeated observation of the patient while eating can be equally informative. Having the patient swallow water is a particularly effective test of laryngeal closure; the presence of coughing, wet hoarseness or breathlessness, and the need to

swallow small volumes slowly are indicative of a high risk of aspiration.

Based on bedside observations and on videofluoroscopy studies, an experienced therapist can make recommendations regarding the safety of oral feeding, changes in the consistency and texture of the diet, postural adjustments, and the need to insert a tracheostomy or feeding tube.

Vomiting

Vomiting is a complex, sequential act that may be triggered by numerous external, gastrointestinal, and neural stimuli. The main central nervous system structure of interest in eliciting the vomiting reflex is the *area postrema*, which is located at the base of the fourth ventricle. The neurons within the area postrema are chemosensitive and are activated by circulating toxins, which have direct access to these neurons because of the absence of a blood-brain barrier. Axons from the area postrema project to the *nucleus of the solitary tract* (NTS), which is also a convergence point of input from the pharynx, larynx, and gastrointestinal tract. The NTS engages groups of neurons in the medulla, which coordinates the sequential elements of vomiting; there is no “vomiting center,” as reviewed by Hornby. In addition to stimulation of the area postrema, vestibular, pharyngeal (gag reflex), and psychic stimuli can induce vomiting.

The final expulsion of gastric contents is effected through a combination of lowering of intrathoracic pressure by inspiration against a closed glottis and an increase in abdominal pressure during abdominal muscle contraction. Retroperistalsis begins in the small intestine and there is relaxation of the lower esophageal and pyloric sphincters; the stomach itself does not contract.

The vagus carries afferent information from the enteric system as well as conducting efferent signals from the NTS to the gastrointestinal structures. The neurons in the area postrema contain D2 dopamine, 5-HT₃ serotonin, opioids, substance P, and acetylcholine receptors, as well as the aquaporin channel. This affords an explanation for the emetic properties of dopaminergic agents and the antiemetic activity of dopamine and serotonin antagonists. However, other potent antiemetics such as ondansetron, a 5-HT₃ receptor antagonist, have their effect on vagal afferents.

Lesions near the area postrema, including tumors, hemorrhage, infarctions, and demyelination are the usual neurologic causes of vomiting. We have seen, and it has been reported in the literature, that vomiting may have a relation to the periventricular lesions of neuromyelitis optica due the enrichment of aquaporin-4 channels in this area (Iorio and colleagues). The mechanism of vomiting from raised intracranial pressure has not been fully explored but could be the result of transmission of pressure to the dorsal medulla.

Cyclic Vomiting Syndrome This syndrome of obscure cause is associated with abdominal migraine in children (see Chap. 10), and is a prominent component of Riley-Day dysautonomia. It is also well known as a factitious self-induced disorder, for example, in bulimia.

The Hypothalamus and Neuroendocrine Disorders

The hypothalamus plays three roles in the actions of the nervous system. The first, as the “head ganglion” of the autonomic nervous system, was described in the preceding chapter; the second, as the circadian and seasonal clock for behavioral and sleep–wake functions, was considered in Chap. 19 on sleep; and the third, as the neural center of the endocrine system, is the subject of this chapter. In the hypothalamus, these systems are integrated with one another as well as with neocortical, limbic, and spinal influences. Together, they maintain homeostasis and participate in the substructure of emotion and affective behavior.

The expansion of knowledge of neuroendocrinology during the past few decades stands as one of the significant achievements in neurobiology. It has been learned that neurons, in addition to transmitting electrical impulses, can synthesize and secrete complex molecules locally and into the systemic circulation, and that these molecules are capable of activating or inhibiting endocrine, renal, and vascular cells at distant sites.

The concept of neurosecretion probably had its origins in the observations of Speidel, in 1919, who noted that some of the hypothalamic neurons had the morphologic characteristics of glandular cells. Their suggestion that such cells might secrete hormones into the bloodstream was so novel, however, that it was rejected by most biologists at the time. This seems surprising now that neurosecretion is viewed as a fundamental part of the science of endocrinology.

Following these early observations, it was found that peptides secreted by neurons in the central and peripheral nervous systems were also contained in glandular cells of the pancreas, intestines, and heart. This seminal observation was made in 1931 by Euler and Gaddum, who isolated a substance from the intestines that was capable of acting on smooth muscle and called it “P” (from powder). But it was not until some 35 years later that Leeman and her associates purified an 11-amino-acid peptide that is now called substance P (see Aronin et al). Then followed the discovery of six hypothalamic mediators of anterior pituitary hormone secretion: TRH, and somatostatin 1973, GnRH, CRH, and GHRH. In the background was always dopamine that acted as an inhibitor of pituitary hormone secretion. Subsequently, a number

of other neuropeptides including enkephalin, neuropeptide Y, orexin as discussed in Chap. 19.

THE HYPOTHALAMUS

Anatomic Features

The hypothalamus lies on each side of the third ventricle and is continuous across the floor of the ventricle. It is bounded posteriorly by the mammillary bodies, anteriorly by the optic chiasm and lamina terminalis, superiorly by the hypothalamic sulci, laterally by the optic tracts, and inferiorly by the hypophysis. It comprises three main nuclear groups: (1) the anterior group, which includes the preoptic, supraoptic, and paraventricular nuclei; (2) the middle group, which includes the tuberal, arcuate, ventromedial, and dorsomedial nuclei; and (3) the posterior group, comprising the mammillary and posterior hypothalamic nuclei.

Nauta and Haymaker have subdivided the hypothalamus sagittally. The *lateral part* lies lateral to the fornix; it is sparsely cellular and its cell groups are traversed by the medial forebrain bundle—which carries finely myelinated and unmyelinated ascending and descending fibers to and from the rostrally placed septal nuclei, substantia innominata, nucleus accumbens, amygdala, and piriform cortex—and the caudally placed tegmental reticular formation. The *medial hypothalamus* is rich in cells, some of which are the neurosecretory cells for pituitary regulation and visceral control. It contains two main efferent fiber systems—the mammillothalamic tract of Vicq d’Azyr (named for the physician to Louis XIV, a paramour of Marie Antoinette), which connects the mammillary nuclei with the anterior thalamic nucleus (which, in turn, projects to the cingulate gyrus), and the mammillotegmental tract. Additional structures of importance are the stria terminalis, which runs from the amygdala to the ventromedial hypothalamic nucleus, and the fornix, which connects the hippocampus to the mammillary body, septal nuclei, and periventricular parts of the hypothalamus. The lateral and medial parts of the hypothalamus are interconnected and their functions are integrated.

Figure 27-1. Diagram of the hypothalamic–pituitary axis. Indicated on the left is the hypothalamic–neurohypophysial system, consisting of supraoptic and paraventricular neurons, axons of which terminate on blood vessels in the posterior pituitary (neurohypophysis). The hypothalamic–adenohypophysial system is illustrated on the right. Tuberoinfundibular neurons, the source of the hypothalamic regulatory hormones, terminate on the capillary plexus in the median eminence. (Courtesy of Dr. J.B. Martin.)

The inferior surface of the hypothalamus bulges downward from the floor of the fourth ventricle; this region is known as the tuber cinereum. The infundibulum is a critical structure that arises from the tuber cinereum. The superior hypophyseal artery, derived from the internal carotid artery, forms a network of capillaries in the *median eminence*, the veins of which are the critical *portal system* (Fig. 27-1).

The median eminence assumes special importance because of the intimate relation of its cells to the vessels of the portal system that bathe the anterior lobe of the pituitary gland. The releasing hormones of the hypothalamus are delivered directly to their target cells in the anterior

pituitary via the portal vessels extending through the stalk, thereby avoiding systemic dilution of these factors. In this way the portal system represents the interface between converging pathways from the brain and the pituitary. The tuberoinfundibular neurons of the arcuate nucleus and anterior periventricular nuclei synthesize most of the releasing factors described in Fig. 27-1.

The infundibulum extends into the pituitary stalk, which in turn, enters the neurohypophysis. The infundibulum is a structure that stands out because it contains the median eminence as well as the neurohypophysial fibers, containing vasopressin and oxytocin, which course through the infundibulum on their way to the posterior pituitary. The main blood supply to the posterior pituitary is from the inferior hypophyseal artery that is a branch of the cavernous part of the internal carotid artery.

The abundant blood supply of the hypothalamus (from several feeding arteries) is of importance to neurosurgeons who attempt to obliterate aneurysms that derive from adjacent vessels. Many small radicles, arising, not just from the carotid arteries, but also the posterior and anterior communicating arteries as well as from the most proximal portions of the anterior and posterior cerebral arteries, form a network of such redundancy that infarction of the hypothalamus is infrequent. The venous drainage from the portal system is to the petrosal sinus, where hormone levels can be sampled.

Readers requiring a more extensive source of information on anatomic and other aspects of the hypothalamus are directed to the comprehensive material by Swaab in the two-volumes of the *Handbook of Clinical Neurology* devoted to this subject, and to the monograph by Martin and Reichlin.

The Hypothalamic-Releasing Hormones

(Table 27-1)

Thyrotropin-Releasing Hormone (TRH)

This was the first of the releasing hormones to be identified; its tripeptide structure was determined in 1968. The hormone is elaborated by the anterior periventricular, paraventricular, arcuate, ventromedial, and dorsomedial

Table 27-1

ANTERIOR PITUITARY HORMONES

HORMONE	TARGET GLAND	SECRETORY CELL DESIGNATION	AMINO ACIDS	NORMAL RANGE
Growth hormone (GH)	Liver, other organs	Somatotrope	191	<0.5 µg/L per 24 h
ACTH ^a	Adrenal	Coricotrope	39	4–22 pg/L
Prolactin (PRL)	Breast, other tissues	Lactotrope	199	M <15 µg/L; F <20 µg/L
Thyroid-stimulating hormone (TSH)	Thyroid	Thyrotrope	211	0.1–0.5 mU/L
FSH and LH ^b	Ovary, testes	Gonadotrope	210; 201	M 5–20 IU/L; F 2–20 IU/L (basal level)

^aAdrenocorticotropic hormone.

^bFollicle-stimulating hormone (FSH) and luteinizing hormone (LH).

IU, international units.

For tests of pituitary sufficiency, see Table 31-4 and Melmed S, Jameson JL: Disorders of the anterior pituitary and hypothalamus, in Longo DL, Fauci AS, Kasper DL et al (eds): *Harrison's Principles of Internal Medicine*, 18th ed. New York, McGraw-Hill, 2012, Table 339-3, p. 2881.

neurons, but not by those of the posterior hypothalamic or thalamic nuclei. It stimulates the release of thyroid-stimulating hormone (TSH) from the pituitary gland. TSH, in turn, increases the activity of every step of the synthesis of thyroid hormone and stimulates the release of T_4 (thyroxine) and T_3 (triiodothyronine). Pituitary cells that release dopamine and somatostatin are also stimulated to a slight degree; the latter has an inhibitory effect on TSH. There is also an inhibitory feedback of T_3 on TSH and TRH. Actually, more than half of brain TRH is found outside the hypothalamus—in brainstem raphe nuclei, tractus solitarius, and the anterior and lateral horn cells of spinal cord—suggesting that TRH may function as a central regulator of the autonomic nervous system.

Growth Hormone-Releasing Hormone (GHRH)

This hormone and somatostatin (also known as growth hormone release-inhibiting hormone, or SRIH) are both secreted by specialized tuberoinfundibular neurons and released into the hypophyseal–portal circulation, by which they are carried to specific growth hormone (GH) secreting cells of the anterior pituitary gland (somatotropes). Immunohistochemical staining has shown the sources of GHRH and somatostatin to be neurons of the posterior part of the arcuate and ventromedian hypothalamic nuclei and other neurons of the median eminence and premammillary area. Somatostatin, a 14-amino-acid peptide, is produced more anteriorly by neurons in the periventricular area and small cell part of the paraventricular nucleus. The amygdala, hippocampus, and other limbic structures project to the arcuate nuclei via the medial corticohypothalamic tract (in the stria terminalis) and are believed to account for the sleep- and stress-induced fluctuations of GH and somatostatin. Also, it has been demonstrated that all 4 biogenic amines (dopamine, norepinephrine, epinephrine, and serotonin) influence GH regulation, as does acetylcholine, either by direct action on pituitary somatotrophic cells or on hypothalamic regulatory neurons. TRH also increases GH from somatotropes. Many of the latter pituitary cells contain large eosinophilic granules, but others, previously identified incorrectly as chromophobe cells, also contain GH. Somatomedin C, a basic peptide that is synthesized in the liver, exerts feedback control of GH by inhibiting the pituitary somatotropes and stimulating the release of somatostatin. Growth hormone enhances skeletal growth by stimulating the proliferation of cartilage and growth of muscle. It also regulates lipolysis, stimulates the uptake of amino acids in cells, and has anti-insulin effects. The blood concentrations of GH fluctuate from 1 or 2 ng/mL to more than 60 ng/mL, being highest within the first hour or two after the onset of sleep.

Corticotropin-Releasing Hormone (CRH)

This hormone, a 14-amino-acid peptide, acts synergistically with vasopressin to release adrenocorticotropic hormone (ACTH) from basophilic cells in the pituitary. ACTH stimulates the synthesis and release of the hormones of the adrenal cortex, mainly glucocorticoids (cortisol or hydrocortisone) but also mineralocorticoids (aldosterone) and androcorticoids (converted in the tissues

to testosterone). The neurons of origin of CRH lie in a particular part of the paraventricular nucleus, other cells of which form the paraventricular–supraopticohypophysial tract (neurohypophysis) and elaborate vasopressin, oxytocin, and several other substances (neurotensin, dynorphin, vasoactive intestinal peptide). These hypothalamic cells receive an extensive input from other regions of the nervous system, particularly via the noradrenergic pathways (from reticular neurons in the medulla and those of the locus ceruleus and tractus solitarius) and from many of the limbic structures. Presumably, these extrahypothalamic connections provide the mechanism by which stress and pain activate the secretion of ACTH and cortisol. CRH itself is widely distributed in the brain. There is feedback control of CRH and ACTH via glucocorticoid receptors in the hypothalamus and anterior lobe of the pituitary. Serotonin and acetylcholine enhance ACTH secretion, whereas the catecholamines are inhibitory.

Gonadotropin-Releasing Hormone (GnRH)

This 10-amino-acid peptide originates in the arcuate nucleus and is present in highest concentration near the median eminence. It effects the release of the two gonadotropic hormones—luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The ovary and testis, by secreting a peptide called *inhibin*, are able to suppress FSH, as do gonadal steroids—i.e., estrogens. GnRH is under the influence of other neuronal systems, which are modulated by catecholamines, serotonin, acetylcholine, and dopamine. Puberty, menstruation, ovulation, lactation, and menopause are all related to the effects of GnRH, FSH, and LH on the ovaries, uterus, breasts, and testes. Normal levels of blood FSH are 2.5 to 49 ng/mL in prepuberty and 7.5 to 11 ng/mL in the adult; levels of blood LH are 2.8 to 9.6 ng/mL in prepuberty and 10 to 18 ng/mL in the adult.

Prolactin Inhibition (Dopamine)

Dopamine is released by neurons in the region of the arcuate nucleus and inhibits lactotrophic cells of the anterior pituitary. The hypothalamopituitary axis is responsive to sensory stimuli from the nipples, via pathways in the spinal cord and brainstem, accounting for the effect of suckling on milk production. Nipple stimulation is also an important influence on oxytocin secretion, as described later. The normal blood levels of prolactin are 5 to 25 ng/mL.

This inhibitory action of dopamine on prolactin secretion accounts for galactorrhea and reproductive disorders, which occur with tumors that compress the pituitary stalk. These interrupt the venous portal transport of dopamine from the hypothalamus to the dopamine-sensitive lactotrophs in the pituitary. This mechanism also explains galactorrhea following the administration of dopamine-blocking medications such as Haldol.

The Neurohypophysis: Vasopressin and Oxytocin

The oligopeptides *vasopressin* and *oxytocin* are elaborated by cells of the supraoptic and paraventricular nuclei and are transported, via their axons, through the stalk of the

pituitary to its posterior lobe, where these substances are stored. Together, these elements constitute the neurohypophysis (posterior pituitary), which develops as an evagination of the floor of the third ventricle. Some of the vasopressin-containing nerve endings also terminate on cells of origin of the autonomic nervous system and on the capillary plexus of the hypophyseal portal circulation, through which they influence the secretion of CRH and GH. The delivery to the posterior pituitary of oxytocin and vasopressin is therefore through the nerve endings that originate in the hypothalamus and terminate in the neurohypophysis. There is some influence of anterior pituitary hormones. The peptide parts of vasopressin and oxytocin, whose chemical nature was determined by DuVigneaud, are almost identical, differing from one another by only two amino acids.

Vasopressin, acting on the V2 receptors in kidney tubules, serves as the antidiuretic hormone (ADH) and, complemented by thirst mechanisms, maintains the osmolality of the blood. Plasma osmolality modifies vasopressin secretion by acting directly on the supraoptic and paraventricular neurons or on separate osmoreceptors in the hypothalamus. The sensitivity of the vasopressin-ADH mechanism is demonstrated by the absence of antidiuretic effect when vasopressin is below 1 pg/mL and by maximal antidiuresis when plasma levels reach 5 pg/mL. If serum osmolality falls below 280 mOsm/L, the release of ADH is completely inhibited. This system is most effective in maintaining homeostasis when serum osmolality is relatively close to the normal range, between 280 and 295 mOsm/L.

Alterations in blood volume and pressure also affect vasopressin release through neural mechanisms that have their origin in baro- and mechanoreceptors of the aortic arch, carotid sinus, and right atrium. Afferent signals from these regions are conveyed in the vagus and glossopharyngeal nerves, which synapse in the nucleus of the tractus solitarius; the precise pathways to the hypothalamus have not been delineated, however. With severe hypotension, ADH release will continue even if there is a low serum osmolality, i.e., pressure predominates over osmolality as a stimulus. Vasopressin secretion is also influenced by nonosmotic factors. Nausea, for example, is a potent stimulus, raising levels of the hormone 100-fold. Hypoglycemia has a less-profound effect. Drugs such as morphine, nicotine, alcohol, and certain chemotherapeutic agents (cyclophosphamide) also cause release of the stored peptide. Pain, emotional stress, and exercise have long been thought to cause release of vasopressin, but it is unclear whether this is a direct effect or is mediated through hypotension or nausea.

Oxytocin initiates uterine contraction and has milk-ejecting effects. Its release is stimulated by distention of the cervix, labor, breastfeeding, and estrogen. The effects of oxytocin are inhibited by alcohol.

In summary, it is apparent that the regulatory system of hypothalamic-releasing hormones is complex. The releasing factors have overlapping functions, and the hypothalamic nuclei act on many parts of the brain in addition to the pituitary. Conversely, many parts of the brain influence the hypothalamus through neural

connections or modulate its activity and that of the pituitary gland through the action of neurotransmitters and modulators (catecholamines, acetylcholine, serotonin, and dopamine). There is feedback control between every part of the hypothalamus and the endocrine structures on which it acts. The factors that influence hypothalamic neurons have been reviewed in detail by Reichlin. Some of these relationships have been mentioned and others will emerge further on in this chapter and in later chapters, particularly as they relate to behavioral and psychiatric disorders.

Of particular significance is the role of the hypothalamus in the integration of the endocrine and autonomic nervous systems at both the peripheral and central levels. The best-known example of this interaction is in the adrenal medulla, as indicated in Chap. 26. Similarly, the juxtaglomerular apparatus of the kidney and the islets of Langerhans of the pancreas function as neuroendocrine transducers, in that they convert a neural stimulus (in these cases adrenergic) to an endocrine secretion (renin from the kidney and glucagon and insulin from the islet cells).

Role of the Hypothalamus in Sexual Development (See also Chap. 28)

The hypothalamus also plays a critical role in the development of human sexuality and its expression, a theme elaborated in the next chapter. The suprachiasmatic nucleus and the number of neurons it contains are considerably larger in men than in women, a dimorphism that becomes evident during postnatal development. The interstitial nucleus of the hypothalamus is reportedly smaller in the homosexual male, evidence perhaps that homosexuality has a recognizable morphologic basis (Levay). This biologic evidence has been sharply challenged (Byne). These issues are addressed further in the section on sexual development in Chap. 28. The intimate relationship of the hypothalamus with the development of sexual characteristics at all stages of life is shown by the appearance, in the infundibular area, of hypertrophic neurons that are rich in estrogen receptors; it has been proposed that some of the symptoms of menarche are timed and mediated by these hypothalamic neurons. With aging, and more so in Alzheimer disease, the neuronal population in this region decreases markedly; the sleep disturbances of senescence and some aspects of the "sundowning" syndrome (confusion and delirium occurring in the evening) have also been attributed to this cell loss.

Regulation of Sympathetic and Parasympathetic Activity

Finally, the central role of the hypothalamus in the regulation of both sympathetic and parasympathetic activities must be emphasized. This aspect of hypothalamic function is discussed in the preceding chapter.

The Pineal Gland and Melatonin

The pineal gland, or pineal body, is a small glandular structure (about 9 mm in diameter) that projects from the

dorsal diencephalon and lies just posterior to the third ventricle. In the past, the pineal body figured prominently in philosophic and religious writings; for Descartes, it was the seat of the soul. When this idea was discredited, the pineal gland was relegated to the status of a vestigial organ. The identification of melatonin, the pineal hormone—followed by recognition of its role in maintaining biologic rhythms and the modulating effects on its secretion by the circadian light–dark cycle—revived scientific interest in the structure. Even though the hormone was found to have an indirect effect on several other neuroendocrine systems, neurologists took little interest in pineal function because ablation of the gland in humans, with attendant loss of most of its circulating melatonin, leads to few if any clinical changes.

It is the cyclic secretion of melatonin that appears to be the most important activity of the pineal gland. However, melatonin secretion is more accurately regarded as a linked manifestation of the circadian rhythm than as its controlling mechanism. The main cellular element of the gland, the pinealocyte, is thought to be derived from neural photoreceptors in lower vertebrates. The latter cells, structurally analogous to retinal cones, transduce light directly into neural impulses and are among the mechanisms for circadian entrainment of hormonal rhythms. In humans, the pineal no longer possesses the ability to transduce light directly. However, it does retain an input from photic stimuli and influences the circadian light–dark cycle through a pathway that originates in the retina, synapses in the suprachiasmatic nucleus, passes through descending sympathetic tracts to the intermediolateral cell columns and superior cervical ganglia, and then ascends to innervate noradrenergic terminals on the pinealocytes. Darkness elicits a release of norepinephrine from the photoreceptors, stimulating the synthesis and release of melatonin. During daylight the retinal photoreceptor cells are hyperpolarized, norepinephrine release is inhibited, and there is little melatonin production. The concentration of the hormone peaks between 2 and 4 A.M. and gradually falls thereafter. An approximate circadian rhythmicity to melatonin release is preserved in continuous darkness and, inexplicably, the blind maintain a light suppression of secretion. It is readily appreciated that, in humans, it is difficult to separate the changes that occur in the suprachiasmatic nucleus from those of the pineal gland.

Like other neuroendocrine cells, pinealocytes release peptides that are produced in the Golgi apparatus and packaged in secretory granules. Whether secretion is the main mechanism for melatonin release is unclear, as these cells can use an alternative ependymal type of vacuolar secretion. The entire gland is invested by a rich vasculature to receive the released peptide (in some mammals the blood flow per gram of pineal tissue is surpassed only by that of the kidney). The biochemistry and physiology of melatonin have been extensively reviewed by Brzezinski.

In humans, a regular feature of pineal pathology is the accumulation of calcareous deposits in structures termed *acervuli* (“brain sand”). These have a more complex composition than simply calcium; they are actually

composed of carbonate-containing hydroxyapatite that is linked to calcium and other metals. A review of the mineralization of the pineal can be found in the text by Haymaker and Adams. These concretions are formed within vacuoles of pinealocytes and released into the extracellular space. The mineralization of the pineal body provides a convenient marker for its position in plain films and on various imaging studies.

It is of significance that pineal tumors do not secrete melatonin, but the loss of melatonin may be used as a marker for the completeness of surgical pinealectomy. Most interest in the past several years has centered on melatonin as a soporific agent and its potential to reset sleep rhythms. Its concentration in depressive illnesses, especially in the affected elderly, is also decreased. The subject of pineal tumors is discussed later and is contained in Chap. 31, with discussion of other brain tumors.

HYPOTHALAMIC SYNDROMES

Hypothalamic syndromes are of two distinct types (Martin and Reichlin). In one, all or many hypothalamic functions are disordered, often in combination with signs of disease in contiguous structures (“global hypothalamic syndromes,” as described below). The second type is characterized by a selective loss of hypothalamic–hypophyseal function, attributable to a discrete lesion of the hypothalamus and often resulting in a deficiency or overproduction of a single hormone—a *partial hypothalamic syndrome*.

Global Hypothalamic Syndromes

A variety of lesions can invade and destroy all or a large part of the hypothalamus. These include sarcoid and other granulomatous diseases, an idiopathic inflammatory disease, and germ-cell and other tumors. The hypothalamus is involved in approximately 5 percent of cases of sarcoidosis, sometimes as the primary manifestation of the disease, but more often in combination with facial palsy and hilar lymphadenopathy. The lesion may be visible by MRI (see Fig. 32-2).

Tumors that involve the hypothalamopituitary axis include metastatic carcinoma, lymphoma, craniopharyngioma, and a variety of germ-cell tumors. The last category (reviewed by Jennings et al) includes germinomas, teratomas, embryonal carcinoma, and choriocarcinoma. They develop during childhood, tend to invade the posterior hypothalamus, and are accompanied in some instances by an increase in serum alpha-fetoprotein or the beta subunit of chorionic gonadotropin. A unique syndrome of gelastic epilepsy is caused by a hamartoma of the hypothalamus (see Chap. 16).

Among the inflammatory conditions, infundibuloneurohypophysitis, or *infundibulitis*, is a cryptogenic inflammation of the neurohypophysis and pituitary stalk, with thickening of these parts by infiltrates of lymphocytes (mainly T cells) and plasma cells (Imura et al). It is thought to be an autoimmune disorder. Histiocytosis X—a group of diseases comprising Letterer-Siwe

disease, Hand-Schüller-Christian disease, and eosinophilic granuloma—implicates multiple organs, including the hypothalamus and neighboring structures and leptomeninges (often causing cells to appear in the cerebrospinal fluid [CSF]). These conditions of children pursue an indolent course. The cell type is a proliferating histiocyte. The obscure infiltrative and inflammatory condition, Erdheim-Chester disease, can also involve this region sometimes with proptosis, but is primarily a bone disease.

Partial Hypothalamic Syndromes

Diabetes Insipidus (DI)

This is a state of polyuria with dilute urine and polydipsia that results in the loss of action of antidiuretic hormone. As long ago as 1913, Farini of Venice and von den Velden of Dusseldorf (quoted by Martin and Reichlin) independently discovered that diabetes insipidus was associated with destructive lesions of the hypothalamus. They showed, moreover, that in patients with this disorder, the polyuria could be corrected by injections of extracts of the posterior pituitary. Ranson elucidated the anatomy of the neurohypophysis; the Scharrers traced the posterior pituitary secretion to granules in the cells of the supraoptic and paraventricular nuclei and followed their passage to axon terminals in the posterior lobe of the pituitary. As mentioned in the introductory section, DuVigneaud and colleagues determined the chemical structure of the two neurohypophyseal peptides, vasopressin and oxytocin, of which these granules were composed.

As already stated, the usual cause of DI is a lack of vasopressin (ADH) as a result of a lesion of the neurohypophysis. This leads to a reduction in its action in the kidneys, where it normally promotes the absorption of water. As a consequence, there is diuresis of low-osmolar urine (polyuria), reduction in blood volume, and increased thirst and drinking of water (polydipsia) in an attempt to maintain osmolality. A congenital abnormality of renal tubular epithelium or destruction of the epithelium has a similar effect—nephrogenic DI. DI is also of interest to the neurologist because of its association with lithium toxicity, which impairs renal tubular water absorption.

Among the established causes of acquired DI, the most important are brain tumors, infiltrative granulomatous diseases, head injury, and intracranial surgical trauma (which has become less frequent with the transsphenoidal approach to pituitary tumors). In a series of 135 cases of persistent DI reported by Moses and Stretten, 25 percent were idiopathic, 15 percent complicated primary brain tumors, 24 percent were postoperative (mostly after hypophysectomy or surgery for craniopharyngioma), 18 percent were caused by head trauma, and fewer than 10 percent were associated with intracranial histiocytosis, metastatic cancer, sarcoidosis, and ruptured aneurysm. Granulomatous infiltration of the base of the brain by sarcoid, eosinophilic granuloma, Letterer-Siwe disease, or Hand-Schüller-Christian disease, is a more frequent cause of DI in young patients. Of the primary tumors, glioma, hamartoma and craniopharyngioma, granular

cell tumor (choristoma), large chromophobe adenomas, and pinealoma are notable. The primary tumors can present with DI alone, whereas the granulomatous infiltrating processes generally exhibit other systemic manifestations before polydipsia and polyuria appear. Metastatic tumors originating in the lung or breast or leukemic and lymphomatous infiltration may also cause DI, sometimes in conjunction with pituitary disturbances and impairment of vision. The mild global hypothalamic dysfunction that often follows brain irradiation for glioma may occasionally include DI as a feature. The most extreme cases of hypothalamic destruction occur in brain death, in which DI is a regular component, although it is not always evident at the time brainstem reflexes are lost.

Pituitary tumors are infrequently associated with DI unless they become massive and invade the stalk of the pituitary and the infundibulum. This anatomic relationship was substantiated in past years by surgical sections of the stalk for metastatic carcinoma and for retinitis proliferans, which result in DI only if the section is high enough to produce retrograde degeneration of supraoptic neurons.

Among the idiopathic forms of DI, there also exists a congenital type of hypothalamic DI, of which only a small number of familial cases have been described. The disorder is evident at an early age and persists throughout life owing to a developmental defect of the supraoptic and paraventricular nuclei and smallness of the posterior lobe of the pituitary. This defect has been related in some cases to a point mutation in the vasopressin-neurophysin-glycopeptide gene. It may be combined with other genetic disorders such as diabetes mellitus, optic atrophy, deafness (Wolfram syndrome), and Friedreich ataxia.

Acquired idiopathic DI may occur at any age, most often in childhood or early adult life and more often in males, and by definition has no apparent cause. Other signs of hypothalamic or pituitary disease are lacking in 80 percent of such patients, but steps must be taken to exclude other disease processes by repeating endocrine and radiologic studies periodically. In some cases of idiopathic DI, there are serum antibodies that react with the supraoptic neurons, raising the question of an autoimmune disorder. In a few such instances, postmortem examination has disclosed a decreased number of neurons in the supraoptic and paraventricular nuclei. Also, anorexia nervosa is often associated with mild DI.

Finally, it should be mentioned that certain drugs used in neurologic practice—for example, carbamazepine—may be the cause of reversible DI (excessive secretion of ADH is more common in relation to this drug) and, as mentioned, lithium regularly causes DI, even at times at the upper range of its therapeutic serum concentration.

In all these conditions, the severity and permanence of the DI are determined by the nature of the lesion. In cases of acute onset, three phases have been delineated: First, a severe DI lasting days; then, as the neurohypophysis degenerates, a reduction in severity of DI or even the opposite, hyponatremia from excessive hormone, as a result of the release of stored ADH and, finally, a persistent pattern, usually lifelong. The neurohypophyseal

axons can regenerate, allowing for some degree of recovery even after years.

Diagnosis of Diabetes Insipidus This is always suggested by the passage of large quantities of dilute urine accompanied by polydipsia and polyuria lasting throughout the night. The thirst mechanism and drinking usually prevent dehydration and hypovolemia, but if the patient is stuporous or the thirst mechanism is inoperative, severe dehydration and hypernatremia can occur, leading to coma, seizures, and death. In an unresponsive patient careful measurement of fluid output and input are needed to expose the disorder.

A low urine osmolality and specific gravity are found in DI, in conjunction with high serum osmolality and sodium values. Osmotic dehydration as a cause of the polydipsia–polyuria syndrome, such as occurs with the glycosuria of diabetes mellitus must, of course, be excluded. A period of 6 to 8 h of dehydration increases urinary osmolality in a person with normal kidneys and neurohypophysis; it is this change in urine concentration that is most useful in the differential diagnosis of polyuria, particularly in distinguishing compulsive water drinkers from those with DI; in the latter group, urinary volume and serum electrolytes normalize with dehydration. Proof that the patient has a central cause of DI and not nephrogenic unresponsiveness to vasopressin is obtained by injecting 5 U of vasopressin (Pitressin) subcutaneously; this will diminish urine output and increase osmolality when there is a central cause of DI. Diagnosis is also aided by the radioimmunoassay for plasma ADH; ADH is usually reduced to less than 1.0 pg/mL in patients with central DI (normal: 1.4 to 2.7 pg/mL).

Treatment of Diabetes Insipidus Vasopressin tannate in oil, synthetic vasopressin nasal spray, and a long-acting analogue of arginine vasopressin (desmopressin [DDAVP]) administered by nasal insufflation (10 to 20 mg or 0.1 to 0.2 mL) are used to control chronic DI. The nasal form is generally preferred because of its long antidiuretic action and few side effects. In unconscious patients, aqueous vasopressin, 5 to 10 U given subcutaneously, is effective for 3 to 6 h; DDAVP, 1 to 4 mg subcutaneously, is effective for 12 to 24 h. These drugs must be given repeatedly, guided by urine output and osmolality (we have given these drugs intravenously in critical situations). The brief duration of action of the medication is advantageous in postoperative states and after head injury, for it allows the recognition of recovery of neurohypophyseal function and the avoidance of water intoxication. If a longer duration of treatment is anticipated, one uses vasopressin tannate in oil (2.5 U), the action of which persists for 24 to 72 h. In the unconscious patient, great care must be taken in the acute stages to replace the fluid lost in the urine, but not to the point of water intoxication. These problems can be avoided by matching the amount of intravenous fluids to the urinary volume and by evaluating serum and urine osmolalities every 8 to 12 h. This pertains even if a patient is receiving concurrent ADH analogues. For patients with partial preservation of ADH function, chlorpropamide, clofibrate, or carbamazepine can be used to stimulate release of the hormone.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

As mentioned, blood volume and osmolality are normally maintained within narrow limits by the secretion of ADH and the thirst mechanism. A reduction in osmolality of even 1 percent stimulates osmoreceptors in the hypothalamus to decrease ADH and to suppress thirst and drinking; increased osmolality and reduced blood volume do the opposite. Normally, blood osmolality is about 282 mmol/kg and is maintained within a very narrow range. Release of ADH begins when osmolality reaches 287 mmol/kg (the “osmotic threshold”). At this point, plasma ADH levels are 2 pg/mL and increase rapidly as the osmolality rises. The response of ADH secretion to hyperosmolality is not the same for all plasma solutes; in contrast to hypernatremia, for example, hyperosmolality induced by elevations in urea nitrogen or endogenous glucose produce minimal or no elevations in ADH.

Derangement of this delicately regulated mechanism, taking the form of dilutional hyponatremia and water retention without edema, is observed under a variety of clinical circumstances in which the plasma ADH is above normal or inappropriately normal despite plasma hypoosmolality. The term *inappropriate secretion of antidiuretic hormone* (SIADH) was applied to this syndrome by Schwartz and Bartter because of its similarity to that produced in animals by the chronic administration of ADH. The same syndrome can arise from ectopic production of the hormone by tumor tissue. In such cases, the thirst mechanism is not inhibited by decreased osmolality, and continued drinking further increases blood volume and reduces its solute concentration; ADH levels are found to be persistently elevated. The physiologic hallmarks of this condition are a concentrated urine, usually with an osmolality above 300 mOsm/L, and low serum osmolality and sodium concentrations. Because of the dilutional effects, urea nitrogen and uric acid are reduced in the blood and serve as markers for excessive total body water. Tissue edema is not seen because sodium excretion in the urine is maintained by suppression of the renin–angiotensin system and by an increase in atrial natriuretic peptide secretion (see below).

SIADH is observed frequently with a variety of cerebral lesions (infarct, tumor, hemorrhage, meningitis, encephalitis) that do not involve the hypothalamus directly and with many types of local hypothalamic diseases (trauma, surgery, vascular lesions). In most cases, it tends to be a transient feature of the underlying illness. The acute dysautonomia of Guillain-Barré syndrome is a common neurologic cause of SIADH; it is ostensibly the result of the neuropathy affecting the afferent nerves from volume receptors in the right atrium and jugular veins. (Hyponatremia is particularly likely to occur in such patients on positive-pressure ventilation.) The increased thoracic pressure induced by positive-pressure ventilation promotes SIADH in susceptible patients. Acute porphyric episodes have the same effect. Neoplasms, particularly small cell tumors, and sometimes inflammatory lesions of the lung, may elaborate an ADH-like substance, and certain drugs—such as

carbamazepine, chlorpromazine, chlorothiazide, chlorpropamide, clofibrate, nonsteroidal antiinflammatory agents, and vincristine—also stimulate ADH release and may lead to hyponatremia. In some cases, no cause or associated disease is apparent.

A fall in serum sodium to 125 mEq/L usually has few clinical effects, although signs of an associated neurologic disease, such as a previous stroke or a subdural hematoma, may worsen. Sodium levels of less than 120 mEq/L are attended by nausea and vomiting, inattentiveness, drowsiness, stupor, and generalized seizures. There may be asterixis. As is characteristic of most metabolic encephalopathies, the more rapid the decline of the serum sodium, the more likely there will be accompanying neurologic symptoms.

Treatment of SIADH The rapid restitution of serum sodium to normal or above-normal levels carries a risk of producing an osmotic demyelination (also called central pontine myelinolysis; see Chap. 40). Our usual procedure in patients with serum sodium concentrations of 117 to 125 mEq/L is to slowly correct the sodium concentration by restricting water to 400 to 800 mL/d and to verify the desired urinary loss of water by checking the patient's weight and serum sodium until it reaches approximately 130 mEq/L. If there is drowsiness, confusion, or seizures that cannot be confidently attributed to the underlying neurologic illness, or if the serum sodium is in the range of 100 to 115 mEq/L, isotonic or 3 percent NaCl should be infused over 3 to 4 h and furosemide 20 to 40 mg administered to prevent fluid overload. A safe clinical rule is to raise the serum sodium by no more than 12 mEq/L in the first 24 h and by no more than 20 mEq/L in 48 h so as to prevent myelinolysis.

Neurogenic (Cerebral) Salt Wasting (Nelson Syndrome)

A moderate reduction in the serum sodium concentration is a common finding in patients with acute intracranial diseases and postoperatively in neurosurgical patients. Originally it was described as a "cerebral salt-wasting" syndrome by Peters and colleagues and later was erroneously identified with the then newly described Schwartz-Bartter syndrome of SIADH. In recent years it has again come to be recognized as being a result of natriuresis and not of water retention caused by ADH secretion. As Nelson and colleagues demonstrated many years ago, neurosurgical patients with hyponatremia have a reduction in blood volume, suggesting sodium loss rather than water retention. This distinction has important clinical implications because the use of fluid restriction with the intention to treat SIADH can have disastrous results if a state of volume contraction exists from salt wasting.

One leading hypothesis concerning the mechanism of hyponatremia in these cases is secretion of another oligopeptide, atrial natriuretic factor (ANF) that is found mainly in the walls of the cardiac atria but also in neurons surrounding the third ventricle in the anteroventral hypothalamic region. Physiologically, ANF activity opposes that of ADH in the kidney tubules and also has a potent inhibitory effect on ADH release from the hypothalamus; i.e., it causes a natriuresis (see review by Samson). ANF,

like some other neural peptides, is secreted in bursts, and the natriuresis is evident only if total urinary sodium content is measured over many hours or days.

The role of ANF in causing the hyponatremia that follows subarachnoid hemorrhage is controversial (see Wijdicks et al and Diringier et al for opposing views), but it is our experience that the hyponatremia in this condition is the result mainly of salt loss, not water retention. Because fluid restriction after subarachnoid hemorrhage may precipitate cerebral ischemia from vasospasm, the proper approach is to maintain normal intravascular volume with intravenous fluids and to correct hyponatremia by infusion of normal saline.

In addition to head trauma, salt wasting has also been reported with cerebral tumors, after pituitary surgery, and in the dysautonomia of Guillain-Barré syndrome, conditions that have also been associated at times with SIADH. As already stated, in each of these disorders, should the patient be hyponatremic, it is desirable to determine the intravascular volume and the urine sodium output before instituting treatment.

Other Disturbances of Antidiuretic Hormone and Thirst

Conditions have been described in which the osmoreceptor control of ADH and of thirst appear to be dissociated. As reported by Hayes and coworkers, one of our colleagues' patients repeatedly developed severe hypernatremia (levels as high as 180 to 190 mEq/L), at which time he became confused and stuporous. Although the patient was able to initiate a release of ADH, his thirst mechanism was nonfunctional. Only when the patient was compelled to drink water at regular intervals did his serum sodium fall. Robertson and others have described similar cases with abnormalities of thirst. These have been reported under the title of "central" or "essential" hypernatremia.

Pituitary Insufficiency

Loss of function of the anterior pituitary gland may result from disease of the pituitary itself or from hypothalamic disease. In either event, it leads to a number of clinical abnormalities, each predicated on the deficiency of one or more hormones that depend on the pituitary trophic factors described earlier. The condition of *panhypopituitarism* represents the more serious illness in that it requires supplementation with multiple hormones. Hypopituitarism may have its onset in childhood, either as an inherited process that affects individual or multiple hormones or as a secondary process caused by a destructive lesion of the pituitary or the hypothalamus from tumor, e.g., craniopharyngioma. Later in life the causes vary, but the most common are pituitary surgery, infarct of the gland from a rapidly growing adenoma (*pituitary apoplexy*, see "Pituitary Apoplexy" in Chap. 31), involutional changes that occur at the end of pregnancy (Sheehan syndrome), cranial irradiation for cerebral tumors other than those in the pituitary fossa, lymphocytic hypophysitis, and granulomatous and neoplastic invasion.

The clinical features of pituitary failure vary, but impairments of thyroid function tend to be more prominent than those of adrenal failure. The neurologic accompaniments of pituitary failure depend on the underlying cause; Lamberts and colleagues have reviewed the endocrinologic aspects and a detailed discussion can be found in *Harrison's Principles of Internal Medicine*.

Other Hypothalamic Syndromes

Apart from DI and SIADH, there are a variety of other special clinical phenomena resulting from disease of the hypothalamus. These usually occur not in isolation but in various combinations, comprising a number of rare, but well-characterized, syndromes.

Precocious Puberty

This term refers to the abnormally early onset of androgen secretion and spermatogenesis in boys and of estrogen secretion and cyclic ovarian secretion in girls. It is associated with the premature development of secondary sexual characteristics. The occurrence of precocious puberty always calls for a neurologic as well as an endocrine investigation. In the male, one searches for evidence of a teratoma of the pineal gland or mediastinum or an androgenic tumor of the testes or adrenals. In the female with early development of secondary sexual characteristics and menstruation, one seeks other evidence of hypothalamic disease, as well as an estrogen-secreting ovarian tumor.

A hamartoma of the hypothalamus (part of von Recklinghausen disease, or of polyostotic fibrous dysplasia of McCune-Albright syndrome) is a leading cause of precocious puberty in both boys and girls; in a number of such cases, so-called *gelastic seizures* have been conjoined (Brenningstall, see "Complex Partial Seizures" in Chap. 16). Neurologic study entails CT and MRI imaging of the hypothalamus, ovaries, and adrenals.

Failure of Puberty

Several genetic conditions can lead to failure of puberty. *Kallman syndrome* is a type of hypogonadotropic hypogonadism that is associated with anosmia. GnRH-secreting neurons formed in the olfactory placode migrate across the cribriform plate into the olfactory bulb and ultimately reside in the hypothalamus. In Kallman syndrome, the olfactory bulb does not develop normally, leading to loss of hypothalamic control of FSH and LH release, and failure of puberty to initiate, as well as anosmia. Several causative X-linked and autosomal dominant gene mutations have been discovered.

Prader-Willi syndrome, discussed in Chap. 38, is associated with hypogonadism and incomplete sexual development along with other endocrine abnormalities affecting growth and satiety. The *Bardet-Biedl syndrome* is a heterogenous disorder affecting multiple organ systems. Variable growth retardation, obesity, and diabetes mellitus are seen, along with hypogonadism and anosmia. The causative mutations affect ciliary function at several sites.

Adiposogenital Dystrophy (Froehlich Syndrome)

Under this title, in 1901, Froehlich first described the association of obesity and gonadal underdevelopment. He related the disorder to a pituitary tumor. But a few years later, Erdheim recognized that the same syndrome could be a manifestation of a lesion (a suprasellar cyst in his case) involving or restricted to the hypothalamus. Later it was determined that obesity and hypogonadism could occur together or separately and were often combined with a loss of vision and unprovoked rage, aggression, or antisocial behavior. DI may be added. In some patients, the clinical state is characterized by abulia, apathy, and reduced verbal output. The usual causes of the Froehlich syndrome are craniopharyngioma, adamantinoma, and glioma, but many other tumors have been reported (pituitary adenoma, cholesteatoma, lipoma, meningioma, glioma, angiosarcoma, and chordoma). The condition bears clinical similarities to the Prader-Willi syndrome, in which hypothalamic abnormalities are not found, as discussed in Chap. 38.

Hypothalamic Disorders Associated With Alterations in Weight

Neuroanatomic studies have localized a satiety center in the ventromedial nucleus of the hypothalamus and an appetite center in the ventrolateral nucleus. Lesions in the lateral hypothalamus may result in a failure to eat and, in the neonate, failure to thrive; lesions in the medial hypothalamus may result in overeating and obesity. Bray and Gallagher, who analyzed 8 cases of the latter type, concluded that the critical lesion was bilateral destruction of the ventromedial regions of the hypothalamus. Most of the reported cases of this type have been caused by tumors, particularly craniopharyngioma, and some to trauma, inflammatory disease, and hydrocephalus (Suzuki et al). In a case that was subject to clinicopathologic correlation, Reeves and Plum found that a hamartoma had destroyed the medial eminence and the ventromedial nuclei bilaterally but spared the lateral hypothalamus. Hyperphagia and rage reactions were the main clinical features; the associated polydipsia and polyuria were due to extension of the tumor to the anterior hypothalamus. It is evident that in only a tiny fraction of people can obesity be traced to a hypothalamic lesion. Of overriding importance are genetic factors, such as the number of lipocytes that one inherits and their ability to store fat.

A disorder of infants has been described under the name *diencephalic syndrome*. Progressive and ultimately fatal emaciation (failure to thrive), despite normal or near-normal food intake, in an otherwise alert and cheerful infant is the main clinical feature. The lesion has usually proved to be a low-grade astrocytoma of the anterior hypothalamus or optic nerve (Burr et al).

Extrahypothalamic parts of the brain, if diseased, may also be associated with increased food-seeking behavior, food ingestion, and weight gain. Examples are involvement of limbic structures, as in the Klüver-Bucy syndrome and basal frontal lobe lesions leading to gluttony. Indeed, the primacy of hypothalamic lesions in

causing pathologic weight gain has been challenged in a review of published cases by Uher and Treasure.

Anorexia Nervosa and Bulimia

The special syndromes called *anorexia nervosa* and *bulimia* have been difficult to classify and are mentioned in this chapter only because they are associated with alterations in several hypothalamic functions, including appetite, temperature control, and menstruation. In all likelihood, these alterations are not the result of a primary dysfunction of hypothalamic nuclei but are secondary to the extreme weight loss, which is the primary feature of the disease. However, a causal link between these idiopathic diseases and hypothalamic dysfunction has been suggested by the rare patients with an anorexia nervosa syndrome who were later found to have hypothalamic tumors (Bhanji and Mattingly; Berek et al; and Lewin et al).

Anorexia nervosa and bulimia are probably best regarded as disorders of behavior, in this case an obsession with thinness; consequently, they are discussed with the psychiatric disorders (see Chap. 56). But the developmental nature of the disease (arising in early adolescence), its virtual absence in men, and the hypothalamic alterations mentioned above do not allow the dismissal of a primary disorder of the brain's appetite centers.

Abnormalities of Growth

Presumably, in most instances of growth retardation, there is a deficiency of GHRH or of GH per se. In the *Prader-Willi syndrome* (obesity, hypogonadism, hypotonia, mental retardation, and short stature), Bray and Gallagher found the deficiency to be one of GHRH. In certain congenital and developmental diseases, the hypothalamus appears to be incapable of releasing GH. This appears to be the case in the de Morsier septooptic defect of the brain (median facial cleft, cavum septum pellucidum, optic defect), as Stewart and colleagues found an isolated deficiency of GH. In children with idiopathic hypopituitarism in whom stunting of growth is associated with other endocrine abnormalities, the deficiency is probably in the synthesis or release of GHRH. In some dwarfs (Laron dwarf, Seckel bird-headed dwarf), there are extremely high levels of circulating GH, suggesting either a defect in the GH molecule or an unresponsiveness of target organs. Many patients with the more severe forms of mental retardation are subnormal in height and weight, but the explanation for this has not been ascertained. It has not been reducible to changes in the level of GHRH or GH.

Of course, the vast majority of unusually short children who are otherwise healthy do not have a recognizable defect in GH or GHRH. Often their parents are short. The therapeutic use of GH in such children is a controversial matter. The hormone effects a spurt in growth during the first year of its administration, but whether it significantly influences growth in the long term is still under investigation. There is concern about the risk of transmitting prion or viral diseases through administration of the biologically derived hormone; this problem is obviated if a genetically produced hormone is used.

In *gigantism*, most of the reported cases have been caused by pituitary adenomas that secrete an excess of GH. This must occur prior to closure of the epiphyses. Hypersecretion of GH after closure of the epiphyses results in *acromegaly*. The notion of a purely hypothalamic form of gigantism or acromegaly (hypothalamic acromegaly) has been affirmed by Asa and associates, who described 6 patients with hypothalamic gangliocytomas that produced GHRH. The possibility of an ectopic source of GH must also be considered. The mentally retarded individuals with gigantism described by Sotos and coworkers were found to have no abnormalities of GHRH, GH, or somatomedin.

Disturbances of Temperature Regulation

Bilateral lesions in the anterior parts of the hypothalamus, specifically of temperature-sensitive neurons in the preoptic area, may result in *hyperthermia*. The heat-dissipating mechanisms of the body, notably vasodilatation and sweating, are impaired. This effect has followed operations or other trauma in the region of the floor of the third ventricle but we have seen it most often after massive rupture of an anterior communicating artery aneurysm. The temperature rises to 41°C (106°F) or higher and remains at that level until death some hours or days later, or it drops abruptly with recovery. Acetylsalicylic acid has little effect on central hyperthermia; the only way to control it is by active evaporative cooling of the body while administering sedation. A less-dramatic example of the loss of natural circadian temperature patterns is seen in patients with postoperative damage in the supra-chiasmatic area (Cohen and Albers) and supra-chiasmatic metastasis (Schwartz et al). These types of lesions are invariably associated with other disorders of intrinsic rhythmicity, including sleep and behavior. It should be emphasized, however, that instances of "central fever" are rare, and unexplained fever of moderate degree should not be attributed to an existing or putative brain lesion.

Hyperthermia is also part of the *malignant hyperthermia* syndrome, in which, in a limited number of cases, there is an inherited (autosomal dominant) susceptibility to develop hyperthermia and muscle rigidity in response to inhalation anesthetics and skeletal muscle relaxants ("Malignant Hyperthermia" in Chap 54). In some of these instances, it has been found to be caused by a defective ryanodine receptor. Closely related is the *neuroleptic malignant syndrome*, which is the result of an idiosyncratic reaction to neuroleptic drugs ("Neuroleptic Malignant Syndrome" in Chap. 43). Wolff and colleagues have described a syndrome of *periodic hyperthermia*, associated with vomiting, hypertension, and weight loss and accompanied by an excessive excretion of glucocorticoids; the symptoms had no apparent explanation, although there was a symptomatic response to chlorpromazine.

Lesions in the posterior part of the hypothalamus have had a different effect; i.e., they often produce *hypothermia* (a persistent temperature of 35°C [95°F] or less) or *poikilothermia* (equilibration of body and environmental temperatures). The latter may pass unnoticed unless the

patient's temperature is taken after lowering and raising the room temperature. Somnolence, confusion, and hypotension may be associated. *Spontaneous periodic hypothermia*, probably first described by Gowers, has been found in association with a cholesteatoma of the third ventricle (Penfield) and with agenesis of the corpus callosum (Noel et al). Episodically, there are symptoms of autonomic disturbance—salivation, nausea and vomiting, vasodilatation, sweating, lacrimation, and bradycardia; the rectal temperature may fall to 30°C (86°F), and seizures may occur. Penfield referred to these attacks incorrectly as “diencephalic epilepsy.” Between attacks, which last a few minutes to an hour or two, neurologic abnormalities are usually not discernible and temperature regulation is normal.

Chronic hypothermia is a more familiar state than hyperthermia, being recorded in cases of severe hypothyroidism, hypoglycemia, and uremia; after prolonged immersion or exposure to cold; and in cases of intoxication with barbiturates, phenothiazines, or alcohol. It tends to be more frequent among elderly patients, who are often found to have an inadequate thermoregulatory mechanism.

Cardiovascular Disorders With Hypothalamic Lesions

Ranson demonstrated a number of autonomic effects upon stimulation of the hypothalamus; these effects as well as hypertension were recorded in Penfield's case of “diencephalic epilepsy.” Since Byer and colleagues' description of large, upright T waves and prolonged QT intervals in patients with stroke, it has been appreciated that acute lesions of the brain—particularly subarachnoid hemorrhage and head trauma—may be accompanied by changes in the electrocardiogram (ECG) as well as by supraventricular tachycardia, ectopic ventricular beats, and ventricular fibrillation. Most of the same effects can be induced by very high levels of circulating norepinephrine and corticosteroids. Considering the numerous catastrophic lesions of the brain as well as extreme emotional states that can provoke arrhythmias and other changes in the ECG, the hypothalamus, with its limbic connections and ability to mount a massive sympathoadrenal discharge, is the likely source of these autonomic changes. Cropp and Manning found that the changes seen in the ECG, particularly “cerebral T waves” and other reversible repolarization abnormalities, could occur almost instantaneously (too quickly for attribution to circulating factors) during surgery for a cerebral aneurysm. Again, the hypothalamus is implicated, but as yet no direct evidence links this structure to direct cardiac control.

Gastric Hemorrhage

In experimental animals, lesions placed in or near the tuberal nuclei induce superficial erosions or ulcerations of the gastric mucosa in the absence of hyperacidity (Cushing ulcers). Gastric lesions of similar type are seen in patients with several types of acute intracranial disease (particularly subdural hematoma and other effects of

head injury, cerebral hemorrhages, and tumors). In seeking causative lesions, as in patients dying with cardiac changes after head injury or subarachnoid hemorrhage, one searches in vain for a lesion in the various hypothalamic nuclei. A functional disorder in this region is nonetheless suspected.

“Neurogenic” Pulmonary Edema

Following the original observations by Maire and Patton in humans, numerous cases of massive and often fatal pulmonary edema have been described in relation to catastrophic intracranial lesions—head injury, subarachnoid and intracerebral hemorrhage, bacterial meningitis, and status epilepticus being the usual ones. A sudden elevation in intracranial pressure is involved in most cases, usually accompanied by a brief bout of extreme systemic hypertension but without obvious left ventricular failure—which is one reason the pulmonary edema has been attributed to a “neurogenic” rather than a cardiogenic cause. Also, it has been shown that experimental lesions in the caudal hypothalamus are capable of producing this type of pulmonary edema, but almost always with the interposed event of brief and extreme systemic hypertension.

Both the pulmonary edema and hypertensive response can be prevented by sympathetic blockade at any level, suggesting that the adrenergic discharge and the hypertension it causes are essential for the development of pulmonary edema. The rapid rise in vascular resistance and systemic blood pressure is similar to the pressor reaction obtained by destruction of the nucleus of the tractus solitarius, as described in Chap. 26, making understandable the few instances of neurogenic edema that have followed acute lesions in the medullary tegmentum (as was seen in one of our patients [Brown et al]). At issue is whether the hypothalamus exerts a direct sympathetic influence on the pulmonary vasculature, allowing a leakage of protein-rich edema fluid, or if the edema is the result of sudden and massive overloading of the pulmonary circulation by a shift of fluid from the systemic vasculature. The latter theory, essentially one of momentary right-heart failure, is currently favored but does not explain all aspects of the syndrome. Likewise, the role of circulating catecholamines and adrenal steroids has not been fully elucidated. These issues have been summarized in the text on neurologic intensive care by Ropper and colleagues.

Disorders of Consciousness and Personality

Since Ranson's experimental work in monkeys, it has been appreciated that acute lesions in the posterior and lateral parts of the hypothalamus may be associated with stupor, although it has always been difficult to determine the precise structures that were involved. One can be certain that permanent coma from small lesions in the caudal diencephalon (thalamus) may occur in the absence of any changes in the hypothalamus and, conversely, that chronic hypothalamic lesions may be accompanied by no more than drowsiness or confusion or no mental change at all. In one of our cases, involving an infundibuloma

entirely confined to the hypothalamus, the patient lay for weeks in a state of torpor, drowsy and confused. His blood pressure was low, his body temperature was 34°C (93.2°F) to 35°C (95°F), and he had diabetes insipidus. When aroused, he was aggressive, like the patient of Reeves and Plum (see earlier).

Among the cases of acquired changes in personality and sleep patterns from ventral hypothalamic disease that we have seen, a few have been impressive because of a tendency to a hypomanic, hypervigilant state with insomnia, lasting days on end, and an impulsiveness and disinhibition suggestive of involvement of the frontal connections to the hypothalamus. In one recent case we examined following removal of a craniopharyngioma, a delirious, agitated state lasted 3 weeks during which the patient's attention could not be captured for even a moment. These and other cognitive disorders with hypothalamic lesions are difficult to interpret and are usually transient. Often the lesions are acute or postoperative and involve adjacent areas, making it impossible to attribute them to the hypothalamus alone.

Periodic Somnolence and Bulimia (Kleine-Levin Syndrome)

Kleine in 1925 and Levin in 1936 described an episodic disorder characterized by somnolence and overeating. For days or weeks, the patients, mostly adolescent boys, sleep 18 or more hours a day, waking only long enough to eat and attend to toilet needs. They appeared dull, often confused, and restless, and were sometimes troubled by hallucinations. The hypothalamus has been implicated on the basis of these symptoms, but without definite pathologic confirmation. We have had some experience with patients having this disorder; a further discussion can be found in "Kleine-Levin Syndrome" in Chap. 19.

Neuroendocrine Syndromes Related to the Adrenal Glands (See also Chap. 30)

Cushing Disease and Cushing Syndrome

The clinical features of Cushing disease, first described in Cushing's monograph in 1932, are familiar to everyone in medicine: truncal obesity with reddish purple cutaneous striae over the abdomen and other parts; dryness and pigmentation of the skin and fragility of skin vessels; excessive facial hair and baldness; cyanosis and mottling of the skin of the extremities; osteoporosis and thoracic kyphosis; proximal muscular weakness; hypertension; glycosuria; and a number of psychologic disturbances. Adrenal hyperplasia secondary to a basophil adenoma of the pituitary (*pituitary basophilia* was Cushing's term) was the established pathology in Cushing's cases. It is to the pituitary form of hyperadrenalism that the term *Cushing disease* has been applied. But the same combination of abnormalities may be associated with chronically increased production of cortisol from a primary adrenal tumor, ectopic production of ACTH by carcinoma of the lung or other carcinomas, and most commonly, with the prolonged administration of glucocorticoids (prednisone, methylprednisolone, or ACTH). For these latter

conditions, all but the last being associated with secondary adrenal hyperplasia, the term *Cushing syndrome* is appropriate. Some components of the syndrome may be lacking or less conspicuous than in florid Cushing disease; diagnosis is then facilitated by measurements of ACTH and cortisol in the blood and urine. Cushing syndrome of ectopic type differs clinically from primary pituitary Cushing disease with respect to its more rapid development and greater degrees of proximal limb weakness, skin pigmentation, hypokalemia, hypertension, and glycosuria. Plasma concentrations of ACTH are usually above 20 pg/ml and may exceed 50 pg/ml in the ectopic type and are not suppressed by dexamethasone.

In Orth's review of 630 cases of Cushing syndrome of endogenous cause, 65 percent were caused by hyperpituitarism (Cushing disease), 12 percent by ectopic production of ACTH, 10 percent by an adrenal adenoma, and 8 percent by adrenal carcinoma.

In *Cushing disease*, either hyperplasia of pituitary cells or a better-defined basophil or chromophobe adenoma produces ACTH, which stimulates the adrenals. Unlike the usual pituitary tumors, the corticotroph (basophil) type are usually microadenomas (<1 cm) and enlarge the sella in only 20 percent of cases. However, it is now appreciated by MRI or high-resolution CT through the sella, that either micro- or macroadenomas are the cause in approximately 80 percent of cases, higher than in the aforementioned series by Orth and all studies prior to the inception of modern brain imaging. There are only a few cases in which a hypothalamic tumor such as a gangliocytoma has caused Cushing syndrome.

For *diagnostic purposes*, measurement of the excretion of cortisol over 24 h in the urine is the most expeditious test and superior to serum sampling because of fluctuations in the serum levels of ACTH. If a 24-h urine collection is not feasible, it is advisable to obtain two or three daily urine determinations, as the values may vary from day to day in Cushing syndrome and patients are frequently unable to save all their urine. The normal value for urinary excretion of cortisol is approximately 12 to 40 mg in 24 h, but some assays that measure additional metabolites of the hormone may allow normal values up to 100 mg. This should be followed by low- or high-dose dexamethasone suppression testing. A test using high doses of dexamethasone (2 mg every 6 h orally for 2 d, or a single dose of 8 mg at midnight) is the most dependable screening method for separating Cushing disease from ectopic secretion of ACTH. In the latter condition, the urinary excretion of cortisol is not suppressed by the administration of dexamethasone, whereas there is a reduction of 90 percent in urinary excretion in 60 to 70 percent of patients with Cushing disease.

Treatment is governed by the cause of the syndrome. A pituitary adenoma, if not extending out of the sella and encroaching on the optic chiasm (microadenoma), is ideally treated by transsphenoidal pituitary microsurgery, as discussed in Chap. 31. The alternative is focused proton beam or gamma radiation, but the long latency of response to these forms of treatment, 6 months or more, makes them less desirable. If such indirect methods of treatment are used, hypercortisolism may be suppressed

in the interim by adrenal enzyme inhibitors such as ketoconazole, metapyrone, or aminoglutethimide. The rate of cure for pituitary microadenoma by transsphenoidal surgery approaches 80 percent, although operative complications—CSF leakage, transient diabetes insipidus, visual abnormalities, meningitis—occur in as many as 10 percent of patients. In approximately 20 percent of patients, removal of the tumor is incomplete and symptoms persist or recur. In such circumstances reoperation is often undertaken, with total excision of the gland and a consequent requirement for extensive hormone replacement in many cases. As an alternative, radiotherapy may be used after failed surgery. If there is an urgent need to suppress the effects of hypercortisolism, bilateral adrenalectomy is effective but has obvious limitations.

Depending on the functional status of the pituitary after any mode of successful treatment, replacement therapy may be needed for a variable period or for the patient's lifetime.

Adrenocortical Insufficiency (Addison Disease)

The classic form of adrenal insufficiency, described by Addison in the nineteenth century, is a result of primary disease of the adrenals. It is characterized by pigmentation of the skin and mucous membranes, nausea, vomiting, and weight loss, as well as muscle weakness, languor, and a tendency to faint. Since Addison's time, hypotension, hyperkalemia, hyponatremia, and low serum cortisol concentrations have come to be recognized as important laboratory features.

In the past, the most common cause of primary adrenal disease was tuberculosis. Now, most cases are designated as idiopathic and thought to represent an autoimmune disorder, often associated with Hashimoto thyroiditis and diabetes mellitus and rarely with other polyglandular autoimmune endocrine disorders. A less-frequent cause is a hereditary metabolic disease of the adrenals—in combination with a demyelinating disease of brain, spinal cord, and nerves and occurring predominantly in males (adrenoleukodystrophy; see Chap. 37). In primary adrenal disease, plasma concentrations of cortisol are low, in response to which the concentrations of ACTH rise. Adrenal insufficiency of whatever cause is a life-threatening condition; there is always a danger of collapse and even death, particularly during periods of infection, surgery, injury, and the like. Lifelong replacement therapy is usually required, with a glucocorticoid (cortisone, 25 to 50 mg, or prednisone, 7.5 to 15 mg daily) and a mineralocorticoid, such as fludrocortisone acetate (Florinef), 0.05 to 0.2 mg daily.

When adrenal insufficiency is secondary to disease of the pituitary, ACTH is low or absent and cortisol secretion is markedly reduced, but aldosterone levels are sustained. Hyperpigmentation is notably absent; it is the elevation of ACTH that causes melanoderma, such as occurs, for example, in patients subjected to bilateral adrenalectomy. Hypothalamic lesions, principally involving the paraventricular nuclei, may also cause adrenal insufficiency, but less frequently than do pituitary lesions.

PART 3

GROWTH AND DEVELOPMENT OF THE NERVOUS SYSTEM AND THE NEUROLOGY OF AGING

This page intentionally left blank

Normal Development and Deviations in Development of the Nervous System

In this chapter and the next one on aging, we consider the effects of growth, maturation, and aging on the nervous system. These are discussed in some detail because certain aspects of neurologic diseases are meaningful only when viewed against the background of these natural age-linked changes. Developmental diseases of the nervous system, e.g., malformations, genetic defects, and other forms of damage that are acquired in the intrauterine period of life, are considered in Chap. 38.

SEQUENCES OF NORMAL DEVELOPMENT

The establishment of a biologic timescale of human development requires observation of a large number of normal individuals of known ages and testing them for measurable items of behavior. Because of individual variations in the tempo of development, it is equally important to study the growth and development of any one individual over a prolonged period. If these observations are to be correlated with stages of neuroanatomic development, the clinical and morphologic data must be expressed in units that are comparable. Early in life, very precise age periods are difficult to ascertain because of the difficulty in fixing the time of conception. The average human gestational period is 40 weeks (280 days), but birth may occur with survival as early as about 24 or as late as 49 weeks (a time span of almost 5 months), and the extent of nervous system development varies accordingly.

After birth, any given item of behavior or structural differentiation must always have two reference points: (1) to a particular item of behavior that has already been achieved, and (2) to units of chronologic time or duration of life of the organism. The chronologic or biologic scale assumes special significance in early prenatal life. During that period development proceeds at such a rapid pace that small units of time weigh heavily and the organism appears to change literally day by day. In infancy, the tempo of development slows somewhat but is still very rapid in comparison with later childhood.

The neurologist will find it advantageous to organize knowledge of normal development and disease around the timetables for human growth and development listed in Tables 28-1 and 28-2. In addition, the last decade has

brought startling advances in the understanding of the genetic and molecular control of neural development. That topic is considered in Chap. 38.

Neuroanatomic Bases of Normal Development

A large body of knowledge has accumulated concerning the functional and structural status of the nervous system during each successive period of life. This information is reviewed briefly in the following paragraphs and is summarized in Table 28-2. It must be kept in mind that development of the nervous system does not proceed stepwise, from one period to the next, but is continuous from conception to maturity. The sequences of development are much the same in all infants, although the rate may vary slightly. Any given behavioral function, in order to be expressed, must await the development of its neural substrate. Furthermore, at any given moment in development, several measurable functions appear in parallel, and it is often a dissociation between them that acquires clinical significance.

Embryonal and Fetal Periods

What we know of the nervous system in the germinal and embryonal periods has been derived from the study of a relatively small number of fetuses that have come into the hands of anatomists. Neuroblastic differentiation, migration, and neuronal multiplication are already well under way in the first 3 weeks of embryonic life. The control of each of these phases (and, later, of connectivity of neurons) is determined by the genome of the organism. Primitive cells destined to become neurons originate in, or close to, the neuroepithelium of the neural tube. These cells proliferate at an astonishingly rapid rate (250,000 per minute, according to Cowan) for a circumscribed period (several days to weeks). They become transformed into bipolar neuroblasts, which migrate in a series of waves toward the marginal layer of what is to become the cortex of the cerebral hemispheres. The first glial cells also appear very early and provide the scaffolding along which the neuroblasts move. Each step in the differentiation and migration of the neuroblasts proceeds in an orderly fashion, and one stage progresses to the next with remarkable precision. The process of neuronal migration

Table 28-1

TIMESCALE OF STAGES IN HUMAN GROWTH AND DEVELOPMENT

GROWTH PERIOD	APPROXIMATE AGE
Prenatal	From 0 to 280 days
Ovum	From 0 to 14 days
Embryo	From 14 days to 9 weeks
Fetus	From 9 weeks to birth
Premature infant	From 27 to 37 weeks
Birth	Average 280 days
Neonate	First 4 weeks after birth
Infancy	First year
Early childhood (preschool)	From 1 to 6 years
Later childhood (prepubertal)	From 6 to 10 years
Adolescence	Girls, 8 or 10 to 18 years Boys, 10 or 12 to 20 years
Puberty (average)	Girls, 13 years Boys, 15 years

Source: Reproduced by permission from Lowrey GH: *Growth and Development of Children*, 8th ed. Chicago, Year Book, 1986.

is largely completed by the end of the fifth fetal month but continues at a much slower rate up to 40 weeks of gestation, according to the classic studies of Conel and of Rabinowicz. Because the migration of most neurons involves postmitotic cells, the cerebral cortex by this time has presumably acquired its full complement of nerve cells, numbered in the many billions. This concept has been revised in recent years with the discovery that active stem cells in the adult brain generate neurons in the hippocampal formation and in the subventricular matrix zones, giving rise most evidently to olfactory neurons in the adult brain but possibly also to other nerve cells (see Kempermann and also Alvarez-Buylla and Garcia-Verdugo).

Table 28-2

TIMETABLE OF GROWTH AND NERVOUS SYSTEM DEVELOPMENT IN THE NORMAL EMBRYO AND FETUS

FETAL AGE, DAYS	SIZE	
	(CROWN-RUMP LENGTH), MM	NERVOUS SYSTEM DEVELOPMENT
18	1.5	Neural groove and tube
21	3.0	Optic vesicles
26	3.0	Closure of anterior neuropore
27	3.3	Closure of posterior neuropore; ventral horn cells appear
31	4.3	Anterior and posterior roots
35	5.0	Five cerebral vesicles
42	13.0	Primordium of cerebellum
56	25.0	Differentiation of cerebral cortex and meninges
150	225.0	Primary cerebral fissures appear
180	230.0	Secondary cerebral sulci and first myelination appear in brain
8-9 months	240.0	Further myelination and growth of brain (see text)

Despite the almost universal acceptance of the presence of neuron genesis in the human brain, the methodology that demonstrates it is complex and has been questioned by authoritative individuals such as Rakic, whose perspective should be consulted for a complete portrait of the subject. Actually, we have little idea of the number of nerve cells in the cerebral and cerebellar cortices at different ages. Many more are formed than survive, as programmed cell death (apoptosis) constitutes an important component of development.

Within a few months of mid-fetal life, the cerebrum, which begins as a small bihemispheric organ with hardly a trace of surface indentation, evolves into a deeply sulcated structure. Every step in the folding of the surface to form fissures and sulci follows a temporal pattern of such precision as to permit a reasonably accurate estimation of fetal age by this criterion alone. The major sylvian, rolandic, and calcarine fissures take on the adult configuration during the fifth month of fetal life, the secondary sulci in the sixth and seventh months, and the tertiary sulci, which vary slightly in location from one individual to another, in the eighth and ninth months (see Fig. 28-1 and Table 28-2).

Concomitantly, subtle changes in neuronal organization are occurring in the cerebral cortex and central ganglionic masses. Involved here are the processes of synaptogenesis and axonal pathfinding. Neurons become more widely separated as differentiation proceeds, owing to an increase in the size and complexity of dendrites and axons and enlargement of synaptic surfaces (Fig. 28-2). The cytoarchitectural patterns that demarcate one part of the cerebral cortex from another (as described in Chap. 22) are already in evidence by the thirtieth week of fetal life and become definitive at 40 weeks and in succeeding months. As the maturational process of cortical neurons proceeds, the patterns of neuronal organization in different regions of the brain (motor, premotor, sensory, and striate cortices, Broca and Wernicke areas) continue to change.

Myelination provides another parallel index of development and maturation of the nervous system and is apparently related to the functional activity of the fiber systems. The timing and precision of these connecting pathways are no less precise and time locked than is neuronal development (see Flechsig's myelinogenic cycle as shown in Fig. 28-3). The acquisition of myelin sheaths by the spinal nerves and roots by the tenth week of fetal life is associated with the beginning of reflex motor activities. Segmental and intersegmental fiber systems in the spinal cord myelinate soon afterward, followed by ascending and descending fibers to and from the brainstem (reticulospinal, vestibulospinal). The acoustic and labyrinthine systems stand out with singular clarity in myelin-stained preparations by the twenty-eighth to thirtieth weeks, and the spinocerebellar and dentatorubral systems by the thirty-seventh week.

Neonatal Period and Infancy

After birth, the brain continues to grow dramatically. From an average weight of 375 to 400 g at birth (40 weeks), it reaches about 1,000 g by the end of the first postnatal year.

Figure 28-1. Lateral views of the fetal brain, from 10 to 40 weeks of gestational age. (Reproduced by permission from Feess-Higgins and Larroche.)

Glial cells (oligodendrocytes and astrocytes) derived from the matrix zones continue to divide and multiply during the first 6 months of postnatal life. The visual system begins to myelinate about the fortieth gestational week; its myelination cycle proceeds rapidly, being nearly complete a few months after birth. The corticospinal tracts are not fully myelinated until halfway through the second postnatal year. Most of the principal tracts are myelinated by the end of this period. In the cerebrum, the first myelin is seen at 40 weeks in the posterior frontal and parietal lobes, and the occipital lobes (geniculocalcarine tracts) myelinate soon thereafter. Myelination of the anterior frontal and temporal lobes occurs later, during the first year of postnatal life. By the end of the second year, myelination of the cerebrum is largely complete (see Fig. 28-3). These steps in myelination can be followed by MRI. Despite these careful anatomic observations, their correlation with developmental clinical and electroencephalographic data has not been precise.

Childhood, Puberty, and Adolescence

Growth of the brain continues, at a much slower rate than before, until 12 to 15 years, when the average adult weight of 1,230 to 1,275 g in females and 1,350 to 1,410 g in males is attained. Myelination also continues slowly during this period. Yakovlev and Lecours, who reexamined Flechsig's classic findings on the ontogeny of myelination (the term *Flechsig's myelinogenic cycle* is still used), traced

the progressive myelination of the middle cerebellar peduncle, acoustic radiation, and bundle of Vicq d'Azyr (mammillothalamic tract) beyond the third postnatal year; the nonspecific thalamic radiations continued to myelinate beyond the seventh year and fibers of the reticular formation, great cerebral commissures, and intracortical association neurons to at least the tenth year and beyond (see Fig. 28-3). These investigators noted that there was an increasing complexity of fiber systems through late childhood and adolescence, and perhaps even into middle adult life. Similarly, in the extensive studies of Conel and Rabinowicz, depicting the cortical architecture at each year from mid-fetal life to the twentieth year, the dendritic arborizations and cortical interneuronal connections were observed to increase progressively in complexity; the "packing density" of neurons, i.e., the number of neurons in any given volume of tissue increases through the age of approximately 15 months and then decreases (see Fig. 28-2).

Interesting questions are whether neurons begin to function only when their axons have acquired a myelin sheath; whether myelination is under the control of the cell body, the axon, or both; and whether the usual myelin stains yield sufficient information as to the time of onset and degree of the myelination process. At best these correlations can be only approximate. It seems likely that systems of neurons begin to function before the first appearance of myelin, at least insofar as shown

Figure 28-2. Cox-Golgi preparations of the leg area of the motor cortex (area 4). *Upper row, left to right:* 1 month premature (8 months gestation); newborn at term; 1 month; 3 months; and 6 months. *Lower row, left to right:* 15 months; 2 years; 4 years; 6 years. Apical dendrites of Betz cells have been shortened, all to the same degree, for the purposes of display. (Courtesy of T. Rabinowicz, University of Lausanne.)

in conventional myelin stains. These correlations will undoubtedly be restudied using more delicate measures of function and finer staining techniques, as well as the techniques of quantitative biochemistry and phase and electron microscopy.

Physiologic and Psychologic Development

Neural Development in the Fetus

The human fetus is capable of a complex series of reflex activities, some of which appear as early as 5 weeks of postconceptional age. Cutaneous and proprioceptive stimuli evoke slow, generalized, patterned movements of the head, trunk, and extremities. More discrete movements appear to differentiate from these generalized activities. Reflexes subserving blinking, sucking, grasping, and visceral functions, as well as tendon and plantar reflexes, are all elicitable in late fetal life. They seem to develop along with the myelination of peripheral nerves,

spinal roots, spinal cord, and brainstem. By the twenty-fourth week of gestation, the neural apparatus is functioning sufficiently well to give the fetus some chance of survival should birth occur at this time. However, most infants fail to survive birth at this age, usually owing to an inadequacy of pulmonary function. Thereafter, the basic neural equipment matures so rapidly that, by the thirtieth week, postnatal viability is relatively common. It seems that nature prepares the fetus for the contingency of premature birth by hastening the establishment of vital functions necessary for extrauterine existence.

It is in the last trimester of pregnancy that a complete timetable of fetal movements, posture, and reflexes would be of the greatest value, for mainly during this period does the need for a full clinical evaluation arise. That there are recognizable differences between infants born in the sixth, seventh, eighth, and ninth months of fetal life has been documented by Saint-Anne Dargassies, who applied the neurologic tests earlier devised by André-Thomas and herself. Her observations document

Figure 28-3. The myelogenetic chronology. (Reproduced from Yakovlev and Lecours.)

prevailing postures; control and attitude of head, neck, and limbs; muscle tonus; and grasp and sucking reflexes. These findings are of interest and may well be a means of determining exact age, but many more observations are needed with follow-up data on later development before they can be fully accepted. Part of the difficulty here is the variability of the premature infant's neurologic functions, which may change literally from hour to hour. Even at term there may be variability in neurologic functions from one day to the next. This variability reflects in part the effects of parturition and the effects of drugs given to the mother, as well as the inaccurate dating of conception and rapid developmental changes in the brain.

Development During the Neonatal Period, Infancy, and Early Childhood

At term, effective sucking, rooting, and grasping reactions are present. The infant is able to swallow and cry, and the startle reaction (e.g., Moro reflex, as described further on) can be evoked by loud sound and sudden extension of the neck. Support and steppage movements

can be demonstrated by placing the infant on its feet, and incurvation of the trunk by stroking one side of the back. Also present at birth is the placing reaction, wherein the foot or hand, brought passively into contact with the edge of a table, is lifted automatically and placed on the flat surface. These neonatal automatisms depend essentially on the functioning of the spinal cord, brainstem, and possibly diencephalon and pallidum. The *Apgar score*, a universally used but somewhat imprecise index of the well-being of the newly born infant, is in reality a numerical rating of the adequacy of brainstem-spinal mechanisms (breathing, pulse, color of skin, tone, and responsivity) (Table 28-3).

Studies of local cerebral glucose metabolism by positron emission tomography (PET) have provided interesting information about the functional maturation of the brain. There are remarkable differences between the newborn and the mature individual. Neonatal values, adjusted for brain weight, are only one-third those of the adult; except for the primary sensorimotor cortex, they are confined to brainstem, cerebellum, and thalamus.

Table 28-3

APGAR SCORING SYSTEM

Heart rate

- 0 No heart rate
- 1 Fewer than 100 beats per minute—the baby is not very responsive
- 2 More than 100 beats per minute—the baby is obviously vigorous

Respiration

- 0 Not breathing
- 1 Weak cry; may sound like whimpering or grunting
- 2 Good strong cry

Muscle tone

- 0 Limp
- 1 Some flexing (bending) of arms and legs
- 2 Active motion

Reflex response

- 0 No response to airways being suctioned
- 1 Grimace during suctioning
- 2 Grimace and cough or sneeze during suctioning

Color

- 0 The baby's whole body is completely blue or pale
- 1 Good color in body with blue hands or feet
- 2 Completely pink or good color

During infancy, there is a progressive evolution in the pattern of glucose metabolism in the parietal, temporal, striate, dorsolateral occipital, and frontal cortices, in this order. Only by the end of the first year do the glucose metabolic patterns qualitatively resemble those of the normal young adult (Chugani).

Behavior during *infancy and early childhood* is also the subject of a substantial literature, contributed more by psychologists than neurologists. In particular they have explored sensorimotor performance in the first year and language and social development in early childhood. In the first 6 years of life, the infant and young child traverse far more ground developmentally than they ever will again in a similar period. From the newborn state, when the infant demonstrates a few primitive feeding and postural reflexes, there are acquired, within a few months, smiling and head and hand-eye control; by 6 months, the ability to sit; by 10 months, the strength to stand; by 12 months, the muscle coordination required to walk; by 2 years, the ability to run; and by 6 years, mastery of the rudiments of a game of baseball or a musical skill. On the perceptual side, the neonate progresses, in less than 3 months, from a state in which ocular control is tentative and tonic deviation of the eyes occurs only in response to labyrinthine stimulation to one in which he is able to fixate on and follow an object. (This last corresponds to the development of the macula.) Later, the child is able to make fine discriminations of color, form, and size. Gesell has provided a graphic summation of the variety and developmental sweep of a child's behavior. He writes

At birth the child reflexly grasps the examiner's finger, with eyes crudely wandering or vacantly transfixed . . . and by the sixth year the child adaptively scans the perimeter of a square or triangle, reproducing each form with

directed crayon. The birth cry, scant in modulation and social meaning, marks the low level of language, which in two years passes from babbling to word formation that soon is integrated into sentence structure, and in six years to elaborated syntactic speech with questions and even primitive ideas of causality. In personality makeup . . . the school beginner is already so highly organized, both socially and biologically, that he foreshadows the sort of individual he will be in later years.

The studies of Gesell and Amatruda and of others represent attempts to establish age-linked standards of behavioral development, but the difficulties of using such rating scales are considerable. The components of behavior that have been chosen as a frame of reference for neurological development are not likely to be of uniform physiologic value or of comparable complexity, and they have seldom been standardized on large populations drawn from different cultures. Also, the examinations at specified ages are cross-sectional assessments, which give a limited idea of the dynamics of behavioral development. As already stated, temporal patterns of behavior reveal an extraordinary degree of variation in their emergence, increment, and decrement, as well as marked variation from one individual to another.

Indeed, the predictive value of developmental assessment has been the subject of a lively dispute. Gesell took the position that careful observation of a large number of infants, with accurate recording of the age at which various skills are acquired, permits the establishment of norms or averages. From such a framework one can determine the level of developmental attainment, expressed as the development quotient (DQ = developmental age/chronologic age), and thus ascertain whether any given child has superior, average, or inferior performance. Furthermore, after examining 10,000 infants over a period of 40 years, Gesell concluded that "attained growth is an indicator of past growth processes and a foreteller of growth yet to be achieved." In other words, the DQ predicts potential attainment.

The other position—taken by Anderson and others—is that developmental attainments are of no real value in predicting the level of intelligence but are measures of completely different functions. Illingworth and most clinicians, including the authors, have taken an intermediate position, that the developmental scale in early life is a useful source of information, but it must be combined with a full clinical assessment. When this is done, the clinician has a reasonably certain means of detecting delays in cognitive development and other forms of neurologic impairment.

The trajectory of rapid growth and maturation continues in late childhood and adolescence, although at a slower pace than before. Motor skills attain their maximal precision in the performances of athletes, artists, and musicians, whose peak development is at maturity (age 18 to 21 years). Intelligence and the capacity for reflective thought and the manipulation of mathematical symbols become possible for most individuals only in adolescence and later. Emotional control, precarious in the school age and all through adolescence, stabilizes in adulthood. We tend to think of all these phenomena as being achieved

through the stresses of human relations, which are conditioned and habituated by the powerful influences of social approval. In this extensive and pervasive interaction between the individual and the environment, which is the preoccupation of the child psychiatrist, it is well to remember that the processes of extrinsic and intrinsic organization can be separated only for the purpose of analytic discussion. There is always interdependence between them.

Motor Development

As indicated earlier and in Table 28-4, the wide variety and seemingly random movements displayed by the healthy neonate are from birth, and certainly within days, firmly organized into reflexive-instinctual patterns called *automatisms*. The most testable of the automatisms are blinking in response to light, tonic deviation of the eyes in response to labyrinthine stimulation (turning of the head), prehensile and sucking movements of the lips in response to labial contact, swallowing, avoidance movements of the head and neck, startle reaction (Moro response, see further on) in response to loud noise or dropping of the head into an extended position, grasp reflexes, and support, stepping, and placing movements. This repertoire of movements, as mentioned earlier, depends on reflexes organized mainly at the spinal and brainstem levels. Only the placing reactions, ocular fixation, and following movements (the latter are established by the third month) are thought to depend on emerging cortical connections, but even this is debatable. In the neonatal period, when little of the cerebrum has begun to function, extensive cerebral lesions may cause little derangement of motor function and may pass unnoticed unless special methods of examination—sensory evoked potentials, electroencephalography (EEG), CT, and MRI—are used. Of clinically testable neurologic phenomena in the neonatal period, disturbances of ocular movement, seizures, tremulousness of the arms, impaired arousal reactions and muscular tone, all of which relate essentially to upper brainstem and diencephalic mechanisms, provide the most reliable clues to the presence of neurologic disease. Prechtl and associates have affirmed the importance of disturbances of these neurologic functions at this early age as predictors of delayed development.

During early infancy, the motor system undergoes a variety of differentiations as visual, auditory, and tactile motor mechanisms develop. Bodily postures are modified to accommodate these complex sensorimotor acquisitions. In the normal infant, these emerging motor differentiations follow a time schedule prescribed by the maturation of neural connections. Normalcy is expressed by the age at which each of these appears, as shown in Table 28-4. It is also evident from this table that reflex and instinctual motor activities are the most dependable means of evaluating early development. Moreover, in the normally developing infant, some of these activities disappear as others appear. For example, the grasp reflex, extension of the limbs without a flexor phase, Moro response, tonic neck reflexes, and crossed adduction in response to eliciting the knee jerk gradually become less prominent

and are usually not elicitable by the sixth month. *The absence of these reflexes in the first few months of life and conversely, their persistence beyond this time indicate a defect in cerebral development*, as described in more detail further on, under “Delays in Motor Development.” By contrast, neck-righting reflexes, support reactions, the Landau reaction (extending neck and legs when held prone), the parachute maneuver, and the pincer grasp, which are absent in the first 6 months, begin to appear by the seventh to eighth months and are present in all normal infants by the twelfth month.

Because many functions that are classified as “mental” at a later period of life have a different anatomic basis than motor functions, it is not surprising that early motor achievements do not correlate closely with childhood intelligence. The converse does not apply, however; delay in the acquisition of motor milestones often correlates with developmental delay. In other words, *most cognitively delayed children sit, stand, walk, and run at a later age than normal children*, and deviations from this rule occur mainly in special diseases such as autism.

In the period of early childhood, the reflexive-instinctual activities are no longer of help in evaluating cerebral development, and one must turn to the examination of language functions and learned sensory and motor skills, which are outlined in Tables 28-5 and 28-6.

Quite apart from the early stage of motor development, in later childhood and adolescence one observes a remarkable variation in levels of muscular activity, strength, and coordination. Motor acquisitions of later childhood such as hopping on one foot, kicking a ball, jumping over a line, walking gracefully, dancing, and certain skills in sports are linked to age but there is wide variability in the finesse with which they are performed. Ozeretzki has combined these in a scale that putatively discloses arrests in motor development in the developmentally delayed. Also in later childhood, precocity in learning complex motor skills as well as skill in games and the development of an all-around interest in athletic activity becomes evident. By adolescence, high individual physical achievement is well recognized. At the other end of the spectrum are instances of motor underachievement, ineptitude, and intrinsic awkwardness; a member of this group will easily stand out and be designated as “an awkward child.” Such awkwardness is to be clearly distinguished from the motor impairment associated with a number of cerebral diseases.

Sensory Development

Under normal circumstances, sensory development keeps pace with motor development, and at every age sensorimotor interactions are apparent. However, under conditions of disease, this generalization may not hold; i.e., motor development may remain relatively normal in the face of a sensory defect, or vice versa. The sense organs are fully formed at birth. The neonate is crudely aware of visual, auditory, tactile, and olfactory stimuli, which elicit only low-level reflex responses. Moreover, any stimulus-related response is only to the immediate situation; there is no evidence that previous experience

Table 28-4

NEUROLOGIC FUNCTIONS AND DISTURBANCES IN INFANCY AND EARLY CHILDHOOD

AGE	NORMAL FUNCTIONS	PATHOLOGIC SIGNS
Newborn period	Blinking, tonic deviation of eyes on turning head, sucking, rooting, swallowing, yawning, grasping, brief extension of neck in prone position, incurvation response, Moro response, flexion postures of limbs Biceps reflexes present and others variable; infantile type of flexor plantar reflex; stable temperature, respirations, and blood pressure; periods of sleep and arousal: vigorous cry	Lack of arousal (stupor or coma) High-pitched or weak cry Abnormal (incomplete or absent) Moro response Opisthotonus Flaccidity or hypertonia Convulsions Tremulous limbs Failure of tonic deviation of eyes on passive movement of head or of head and body
2–3 months	Supports head Smiles Makes vowel sounds Adopts tonic asymmetrical neck postures (tonic neck reflexes) Large range of movements of limbs, tendon reflexes usually present Fixates on and follows a dangling toy Suckles vigorously Period of sleep sharply differentiated from awake periods Support and stepping unelicitable Vertical suspension—legs flex, head up Optokinetic nystagmus elicitable	Absence of any or all of the normal functions Convulsions Hypotonia or hypertonia of neck and limbs Vertical suspension—legs extend and adduct
4 months	Good head support, minimal head lag Coos and chuckles Inspects hands Tone of limbs moderate or diminished Turns to sounds Rolls over from prone to supine Grasping, sucking, and tonic neck reflexes subservient to volition	Lack of head support Motor deficits Hypertonia Lack of social reactions Tonic neck reflexes present Strong Moro response Absence of symmetrical attitude
5–6 months	Babbles Reaches and grasps Vocalizes in social play Discriminates between family and strangers Moro and grasp reflexes disappear Tries to recover lost object Begins to sit; no head lag on pull to sit Positive support reaction Tonic neck reflexes gone Landau response (holds head above horizontal, arches back when held horizontally) Begins to grasp objects with one hand; holds bottle	Altered tone Obligatory postures Cannot sit or roll over Hypo- or hypertonia Persistent Moro and grasp Persistent tonic neck reflexes No Landau response
9 months	Creeps and pulls to stand; stands holding on Sits securely Babbles "Mama," "Dada," or equivalent Sociable; plays "pat-a-cake," seeks attention Drinks from cup Landau response present Parachute response present Grasps with thumb to forefinger	Fails to attain these motor, verbal, and social milestones Persistent automatisms and tonic neck reflexes or hypo- or hypertonia
12 months	Stands alone May walk, or walks if led Tries to feed self May say several single words, echoes sounds Plantar reflexes definitely flexor Throws objects	Failure to attain 12-month milestones Persistence of automatisms
15 months	Walks independently (9–16 months), falls easily Moves arms steadily Says several words; scribbles with crayon Requests by pointing Interest in sounds, music, pictures, and animal toys	Retardation in reaching milestones expected at this age Persistent abnormalities of tone and posture Sensory discriminations defective

Table 28-5

DEVELOPMENTAL ACHIEVEMENTS OF THE NORMAL PRESCHOOL CHILD

AGE	OBSERVED ITEMS	USEFUL CLINICAL TESTS
2 years	Runs well Goes up and down stairs, 1 step at a time Climbs on furniture Opens doors Helps to undress Feeds well with spoon Puts 3 words together	Pencil-paper test: scribbles, imitates horizontal stroke Folds paper once Builds tower of 6 blocks
2.5 years	Listens to stories with pictures Jumps on both feet; walks on tiptoes if asked Knows full name; asks questions Refers to self as "I" Helps put away toys and clothes Names animals in book, knows 1 to 3 colors Can complete 3-piece form board	Pencil-paper test: copies horizontal and vertical line Builds tower of 8 blocks
3 years	Climbs stairs, alternating feet Talks constantly; recites nursery rhymes Rides tricycle Stands on one foot momentarily Plays simple games Helps in dressing Washes hands Identifies 5 colors	Builds 9-cube tower Builds bridge with 3 cubes Imitates circle and cross with pencil
4 years	Climbs well; hops and skips on one foot; throws ball overhand; kicks ball Cuts out pictures with scissors Counts 4 pennies Tells a story; plays with other children Goes to toilet alone	Copies cross and circle Builds gate with 5 cubes Builds a bridge from model Draws a human figure with 2 to 4 parts other than head Distinguishes short and long line
5 years	Skips Names 4 colors; counts 10 pennies Dresses and undresses Asks questions about meaning of words	Copies square and triangle Distinguishes heavier of 2 weights More detailed drawing of a human figure

USEFUL PSYCHOMETRIC TESTS FOR EVALUATING LEARNING AND BEHAVIORAL DISABILITIES IN CHILDREN^a

DEFICIT	TEST
Development	Denver Developmental Test; Vineland Social Maturity Test; Leiter International Performance Scale; Otis Group Intelligence Test
Achievement	Wide Range Achievement Test; Gates Primary Reading Test
Attentiveness	Dehoit Test of hearing aptitude
Calculation	Key Math Diagnostic Arithmetic Test
Vocabulary	Peabody Picture Vocabulary
Developmental Gerstmann syndrome (finger agnosia, right-left disorientation)	Finger Order Tests; Benton Right-Left Discrimination Test
Figure copying	Visual-Motor Integration Test
Visual memory	Benton Visual Retention Test
Error patterns	Boder Test of Reading-Spelling Patterns
Impulsiveness	Matching Familiar Figures Test

^aFor descriptions of individual tests, see Kinsbourne, 1995.

with the stimulus has influenced the response; i.e., that the newborn can learn and remember. The capacity to attend to a stimulus, to fixate on it for any period of time, also comes later. Indeed, the length of fixation time is a quantifiable index of perceptual development in infancy.

Information is available about the time at which the infant makes the first interpretable responses to each of the different modes of stimulation. The most nearly perfect senses in the newborn are those of touch and pain. A series of pinpricks cause distress, whereas an abrasion of the skin seems not to do so. The sense of touch clearly plays a role in feeding behavior. Newborn infants react vigorously to irritating odors such as ammonia and acetic acid, but discrimination between olfactory stimuli is not evident until much later. Sugar solutions initiate and maintain sucking from birth on, whereas quinine (bitter) solutions seldom do, and the latter stimulus elicits avoidance behavior. Hearing in the newborn is manifest within the first few postnatal days. Sharp, quick sounds elicit responsive blinking and sometimes startle. In some infants, the human voice appears to cause similar reactions by the second week. Strong light and objects held before the face evoke reactions in the neonate; later, visual searching is an integrating factor in most projected motor activities.

Sensation in the newborn infant must be judged largely by its motor reactions, so that sensory and motor developments seem to run in parallel but this may be partly artifactual. There are nonetheless discernible maturational stages that constitute sensory milestones, so to speak. This is most apparent in the visual system, which is more easily studied than the other senses. Sustained ocular fixation on an object is observable at term and even

in some preterm infants; at these ages it is essentially a reflexive phototropic reaction. It has been observed that the neonate will consistently gaze at some stimuli more often than others, suggesting, according to Fantz, that there must already be some elements of perception and differentiation at this early stage. Voluntary fixation (i.e., following a moving object) is a later development. Horizontal following occurs at about 50 days; vertical following, at 55 days; and following an object that is moving in a circle, at 75 days. Preference for a colored stimulus over a gray one was recorded by Staples by the end of the third month. By 6 months the infant discriminates between colors, and saturated colors can be matched at 30 months. Perception of form, at least as judged by the length of time spent in looking at different visual presentations, is evident at 2 or 3 months of age (Fantz). At this time infants are attracted more to certain patterns than to colors. At 3 months, most infants have discovered their hands and spend considerable time watching their movements. The ages at which infants begin to observe color, size, shape, and numbers can be determined by means of the Terman-Merrill and Stutzman intelligence tests (see Gibson and Olum). Perception of size becomes increasingly accurate in the preschool years. An 18-month-old child discriminates among pictures of familiar animals and recognizes them equally well if they are upside down.

Visual discrimination is reflected in manual reactions, just as auditory discrimination is reflected in vocal responses. Much of early visual development (first year) involves peering at objects, judging their position, reaching for them, and seizing and manipulating them. The inseparability of sensory and motor functions is never more obvious. Sensory deprivation impedes not only the natural sequences of perceptual awareness of the child's surroundings but also the development of all motor activities. *Auditory discrimination*—reflected in vocalizations such as babbling and, later, in word formation—is discussed further on in connection with language development.

The Development of Intelligence

(See also Chap. 21)

The subject of intellectual endowment and the development and testing of intelligence were touched upon in Chap. 21. There it was pointed out that although intelligence is modifiable by training, practice, and schooling, it is much more a matter of native endowment and not simply a question of environment and providing the stimulus to learn, although these are clearly factors. It is evident early in life that some individuals have a superior intelligence; they also clearly maintain this differentiation all through life, and the opposite pertains in others.

Much of the uncertainty about the relative influence of heredity and environment relates to our imprecise views of what constitutes intelligence. The authors tend to agree with those who view intelligence as a general mental capability, embracing a number of primary abilities: the capacity to comprehend complex ideas, learn from experience, think abstractly, reason, plan, draw

analogies, and solve problems. Thus intelligence includes a multiplicity of abilities, which probably accounts for a lack of consensus about its mechanism. Everyday experience teaches us that it is not always abstract tasks that suffer most when intelligence is impaired. Indeed, even abstraction is not likely to be a unitary function. Theoreticians, like Carl Spearman, believed that intelligence comprises a general (*g*), or core, factor and a series of special (*s*) factors. In contrast, Thurstone conceived of intelligence as a mosaic of factors such as drive and curiosity, verbal and arithmetic ability, memory, capacity for abstract thinking, practical skills in manipulating objects, geographic or spatial sense, and athletic and musical ability—each of which appears to be largely genetically determined. These and other theories concerning intellectual development in the child, such as those of Eysenck and of Gardner, and particularly those of Piaget, were considered briefly in Chap. 21, which may be read as an extension of this section.

The beginnings of the development of intelligence are difficult to discern. It is readily assessed at 8 to 9 months of life, when the infant begins to crawl and explore. Now, learning proceeds rapidly as adults attach names to objects and help the baby manipulate them. Gradually the child acquires verbal facility (learning what words mean), memory, color and spatial perception, a concept of number, and the practical use of tools, each at a particular time according to a schedule set largely by the maturational state of the brain. Nevertheless, in these early achievements individuals differ considerably, reflecting to some extent the influence of their parents and others around them. Also, the young child exhibits elementary modes of thinking but is highly suggestible and often incapable of separating imagination from reality.

Neurologists who need a quick and practical method of ascertaining whether an infant or preschool child is measuring up to normal standards for a particular age will find Table 28-4 useful. The main items are drawn from Gesell and Amatruda and from the Denver Developmental Test. In addition, a variety of intelligence tests have been designed to measure the child's special abilities and increasing success in learning in accordance with age (these are listed in Table 28-5). Starting at age 6 to 7 years, there is a steady improvement in intelligence scores that parallels chronologic age up to about age 13 years; thereafter the rate of advance diminishes. By age 16 to 17 years, performance reaches a plateau, but this is probably an artifact of the commonly used tests, which are designed to predict success in school. Only late in life do test scores begin to diminish, in a manner that is described in the next chapter on aging. Individuals with high or low IQs at 6 years of age tend to maintain their rank at 10, 15, and 20 years unless the early scores were impaired by anxiety, poor motivation, or a gross lack of opportunity to acquire the skills that are necessary to take such tests (language skill in particular). Even then, performance tasks, which largely eliminate verbal and mathematical skills, will disclose many individual differences.

The reliability of intelligence tests and their validity as predictive measures of scholastic, occupational, and

economic success have been heatedly debated for many years. This aspect of the subject is discussed in the section on Intelligence in Chap. 21 and need not be repeated here. The most persuasive argument for these tests as an index of some type of native ability is that individuals drawn from a fairly homogeneous environment tend to maintain the same rating on the intelligence scale throughout their lives. While native endowment may set some limits on learning and achievement; opportunity, personality traits, and other factors clearly determine how nearly the individual's full potential is realized.

The Development of Language

Closely tied to the development of intelligence is the acquisition of language. Indeed, facility with language is one of the best indices of intelligence (Lenneberg). The acquisition of speech and language by the infant and child has been observed methodically by a number of eminent investigators, and their findings provide a background for the understanding of a number of derangements in the development of these functions (Ingram; Rutter and Martin).

Early verbalizations consist of *babbling*, *cooing*, and *lalling stages*, during which the infant, a few weeks old, emits a variety of cooing and then, at about 6 months, babbling sounds in the form of vowel-consonant (labial and nasoguttural) combinations. Later, babbling becomes interspersed with pauses, inflections, and intonations drawn from what the infant hears. At first this appears to be a purely self-initiated activity, being the same in normal and deaf infants. However, study of the latter shows that auditory modifications begin within a period of 2 to 3 months; without an auditory sense, babblers do not produce the variety of random sounds of the normal infant, nor do they begin to imitate the sounds made by the mother. Thus motor speech is stimulated and reinforced mainly by auditory sensations, which become linked to the kinesthetic ones arising from the speech musculature. It is not clear whether the capacity to hear and understand the spoken word precedes or follows the first motor speech. Perhaps it varies from one infant to another, but the dependence of motor speech development on hearing is undeniable. Comprehension seems to postdate the first verbal utterance of words in most infants.

Soon babbling merges with *echo speech*, in which short sounds are repeated parrot-like; gradually longer syllable groups are repeated correctly as the praxic function of the speech apparatus develops. As a general rule, the first recognizable words appear by the end of 12 months. Initially these are attached directly to persons and objects and then are used increasingly to designate objects. The word then becomes the symbol, and this substitution greatly facilitates speaking and later thinking about people and objects. Nouns are learned first, then verbs and other parts of speech. Exposure to and correction by parents and siblings gradually shapes vocal behavior, including the development of a distinctive and enduring accent, to conform to that of the social group in which the child is raised.

During the second year of life, the child begins to use word combinations. They form the propositions, which, according to Hughlings Jackson, are the essence of language (a notion in part echoed by modern linguists as noted in Chap. 23). On average, at 18 months the child can combine an average of 1.5 words; at 2 years, 2 words; at 2.5 years, 3 words; and at 3 years, 4 words. Pronunciation of words undergoes a similar progression; 90 percent of children can articulate all vowel sounds by the age of 3 years. At a slightly later age the consonants *p*, *b*, *m*, *h*, *w*, *d*, *n*, *t*, and *k* are enunciated; *ng* by the age of 4 years; *y*, *j*, *zh*, and *wh* by 5 to 6 years; and *f*, *l*, *v*, *sh*, *ch*, *s*, *v*, and *th* by 7 years. Girls tend to acquire articulatory facility earlier than boys. The vocabulary increases, so that at 18 months the child knows 6 to 20 words; by 24 months, 50 to 200 words; by 3 years, 200 to 400 words. By 4 years, the child is normally capable of telling stories, but with little distinction between fact and imagination. By 6 years, the average child knows several thousand words. Also by that age, children can indicate spatial and temporal relationships and start to inquire about causality. The understanding of spoken language always exceeds the child's speaking vocabulary; that is to say, most children understand more than they can say.

The next stage of language development is reading. Here there must be an association of graphic symbols with the auditory, visual, and kinesthetic images of words already acquired. Usually the written word is learned by associating it with the spoken word rather than with the seen object. The integrity of the superior gyrus of the temporal lobe (Wernicke area) and contiguous parietooccipital areas of the dominant hemisphere are essential to the establishment of these crossmodal associations. Writing is learned soon after reading, the audiovisual symbols of words being linked to cursive movements of the hand. The tradition of beginning grade school at 5 or 6 years is based not on an arbitrary decision but on the empirically determined age at which the nervous system of the average child is ready to learn and execute the tasks of reading, writing, and, soon thereafter, calculating.

Once language is fully acquired, it is integrated into all aspects of complex action and behavior. Movements of volitional type are activated by a spoken command or the individual's inner phrasing of an intended action. Every plan for the solution of a problem must be cast into language, and the final result is analyzed in verbal terms. Thinking and language are, therefore, inseparable.

Anthropologists see in all this a grander scheme wherein the individual recapitulates the language development of the human race. They point out that in primitive peoples, language consisted of gestures and the utterance of simple sounds expressing emotion and that, over periods of time, movements and sounds became the conventional signs and verbal symbols of objects. Later these sounds came to designate the abstract qualities of objects. Historically, signs and spoken language were the first means of human communication; graphic records appeared much later. Native Americans, for instance, never reached the level of syllabic written language. Writing commenced as pictorial representation and only

much later in human evolution were alphabets devised. The reading and writing of words are comparatively late achievements. For further details concerning communicative and cognitive abilities and methods of assessment, the reader may consult the monograph by Minifie and Lloyd.

Sexual Development

The terms *sexual* and *sexuality* have several meanings in medical and nonmedical writings. The most obvious one relates to the functions of the male and female sexual organs through which procreation occurs and the survival of the species is assured as well as to behaviors that serve to attract the opposite sex and ultimately lead to mating. The terms refer also to a person's concern or preoccupation with sex or his erotic desires or activities. A more ambiguous meaning has been proposed by some psychologists, for whom the term is equated with all growth and development, the experience of pleasure, and survival.

Much of now discredited Freudian psychoanalytic theory centers on the sexual development of the child and, on the basis of questionable observations, espouses the view that repression of the sexual impulse and the psychic conflicts resulting therefrom are the main sources of neurosis and possibly psychosis.

The following are the main chronologic steps in sexual development, taken from the observations of Gesell and colleagues and itemized in de Ajuriaguerra's monograph. The timetable of menarche and other aspects of sexual development show considerable variation. If sexuality is not allowed natural expression, it often becomes a source of worry and preoccupation. Some 10 percent of the population fails to develop heterosexual orientation. Perverse derangements of psychosexual function are another matter entirely and are not addressed here.

Homosexuality

This denotes a preferential erotic attraction to members of the same sex. Most psychiatrists exclude from the definition of homosexuality those patterns of behavior that are not motivated by specific preferential desire, such as the incidental homosexuality of adolescents and the situational homosexuality of prisoners.

Figures on incidence are difficult to secure. According to the early reports of Kinsey and colleagues, approximately 4 percent of American males are exclusively homosexual and 8 percent have been "more or less exclusively homosexual for at least 3 years, sometime between the ages of 16 and 65." For females, the incidence is lower, perhaps half that for males. It was estimated, on the basis of the examination of large numbers of military personnel during World War II, that 1 to 2 percent of servicemen were exclusively or predominantly homosexual. More recent estimates, both in men and women, range from 1 to 5 percent (see LeVay and Hamer). These widely variable figures share a problem with all estimates derived from surveys and questionnaires: they cannot count people who do not wish to be counted.

The origins of homosexuality are obscure. The authors favor the hypothesis that differences or variations

in genetic patterning of the nervous system (possibly of the hypothalamus) set the sexual predilection during early life. Several morphologic studies of the hypothalamus are significant in this regard. Swaab and Hofman have reported that the preoptic zone is three times larger in heterosexual males than it is in females, but it is about the same size in homosexual males as it is in females. As mentioned in Chap. 27, LeVay found that an aggregate of neurons in the suprachiasmatic nucleus of the hypothalamus is two to three times larger in heterosexual men than it is in women, and also two to three times larger in heterosexual than in homosexual men. If confirmed, these findings, which have been disputed by Byne and others, would support the view that homosexuality has a biologic basis. Genetic studies point in the same direction. Pooled data from 5 studies in men show that approximately 57 percent of identical twins (and 13 percent of brothers) of homosexual men are also homosexual. The figures for lesbians are much the same. In most studies, the inheritance pattern of male homosexuality comes from the maternal side, implicating a gene on the X chromosome (LeVay and Hamer) but to suggest there is a simple genetic connection is oversimplified.

Psychoanalytic explanations of homosexuality have never been substantiated. Attempts to demonstrate an endocrine basis for homosexuality have also failed. The most widely held current view is that homosexuality is not a mental or a personality disorder, though it may at times lead to secondary reactive disturbances. The studies of Kinsey and colleagues indicate that a homosexual orientation cannot be traced to a single social or psychologic root. Instead, as indicated above, homosexuality seems to arise from a deep-seated predisposition, biologic in origin and as ingrained as heterosexuality. The status of bisexuality is undetermined.

The Development of Personality and Social Adaptation (See also Chap. 51)

Personality, the most inclusive of all psychologic terms, encompasses the entirety of psychologic traits that distinguish one individual from every other. The notion that one's physical characteristics are determined by inheritance is a fundamental tenet of biology. One has but to observe the resemblances between parent and child to confirm this view. Just as no two persons are physically identical, not even monozygotic twins, so, too, do they differ in any other refined quality one chooses to measure, particularly those that determine behavior and modes of thinking. Strictly speaking, the normal person is an abstraction, just as is a typical example of any disease.

It is in nonphysical attributes that individuals display the greatest differences. Here reference is made to their variable place on a scale of energy, capacity for effective work, sensitivity, temperament, emotional responsiveness, aggressivity or passivity, risk taking, ethical sense, flexibility, and tolerance to change and stress. The composite of these qualities constitutes the human personality or character. The current model of personality structure identifies 5 dimensions, which account for

the covariation of most personality traits: (1) neuroticism versus emotional stability; (2) extraversion versus introversion; (3) openness to experience versus aversion to change; (4) agreeableness versus irascibility; and (5) conscientiousness versus unscrupulousness, and all five of these are heritable, as discussed in Chap. 51.

In the formation of personality, especially the part concerned with feeling and emotional sensitivity, basic temperament surely plays a large part. By nature, some children from the beginning seem to be happy, cheerful, and unconcerned about immediate frustrations; others are the opposite. By the third month of life, Birch and Belmont recognized individual differences in activity-passivity, regularity-irregularity, intensity of action, approach-withdrawal, adaptivity-unadaptivity, high-low threshold of response to stimulation, positive-negative mood, high-low selectivity, and high-low distractibility. Ratings at this early age were found to correlate with the results of examinations made at age 5 years. Kagan and Moss recognized the trait of timidity as early as 6 months of age and noted that it persists lifelong.

The more common aspects of personality, i.e., anxiety or serenity, timidity or boldness, the power of instinctual drives and need of satisfaction, sympathy for others, sensitivity to criticism, and degree of disorganization resulting from adverse circumstances, are presumed to be genetically determined. Identical twins raised apart are remarkably alike in these and many other personality traits (and have the same IQs, within a few points; Moser et al). Scarr and associates have also demonstrated the strong genetic influence on personality development. The related subject of the development of a moral sense that can be said to be part of an individual's personality has been subject to several competing theories. The interested reader is referred to Damon's summary of the topic.

Chapter 51 discusses disorders of personality and the genetic predisposition to certain personality traits further.

Social behavior, like other neurologic and psychologic functions in general, depends to a great extent on the development and maturation of the brain. Involved also are genetic and environmental factors, for one cannot adapt to society except in the presence of other people; i.e., social interaction is necessary for the emergence of many basic biologic traits. The roots of social behavior are traceable to certain instinctive patterns that are progressively elaborated by conditioned emotional reactions. In the long series of human interactions—first with parents, then with siblings and other children, and finally with a widening circle of individuals in the classroom and community, the capacity to cooperate, to subjugate one's own egocentric needs to those of the group, and to lead or be led appear as secondary modes of response (i.e., secondary to some of the basic impulses of anger, fear, self-protection, love, and pleasure). The sources of these social reactions are even more obscure than those of temperament, character, and intelligence.

In children, difficulty in social adaptation tends first to be manifest by an inability to take their places in a classroom. However, the greatest demands and frustrations in social development are likely to occur in late

childhood and adolescence. The development of adult gonadal function and the further evolution of psychosexual impulses create a bewildering array of new challenges in social adaptation. These types of social adjustments continue as long as life continues. As social roles change, as intellectual and physical capacities first advance and later recede, new challenges demand new adaptations.

DELAYS AND FAILURES OF NORMAL NEUROLOGIC DEVELOPMENT

Delays in Motor Development

A delay in motor development is often accompanied by a delay in cognitive development, in which case both are parts of a developmental lag or immaturity of the entire cerebrum. The most severe forms of delayed motor development, those associated with spasticity and athetosis, are usually manifestations of prenatal and perinatal diseases of the brain subsumed under the term cerebral palsy; these are discussed in Chap. 38.

In assessing developmental abnormalities of the motor system in the neonate and young infant, the following maneuvers, which elicit certain postures and reflexive movements, are particularly useful:

1. The *Moro response* is the infant's reaction to startle and can be evoked by suddenly withdrawing support of the head and allowing the neck to extend. A loud noise, slapping the bed, or jerking one leg will have the same effect, causing an elevation and abduction of the arms followed by a clasping movement to the midline. This response is present in newborns and infants, it wanes after 2 months and is no longer elicitable after about 5 months of age, and its absence before that time or persistence afterwards indicates a disorder of the motor system. An absent or inadequate Moro response on one side is found in infants with hemiplegia, brachial plexus palsy, or a fractured clavicle. Persistence of the Moro response beyond 4 or 5 months of age is noted only in infants with severe neurologic defects.
2. The *tonic neck reflex* consisting of extension of the arm and leg on the side to which the head is passively turned and flexion of the opposite limbs, if obligatory and sustained, is a sign at any age of pyramidal or extrapyramidal motor abnormality. Barlow reports that he has obtained this reflex in 25 percent of developmentally delayed infants at 9 to 10 months of age. Fragments of the reflex, such as a brief extension of one arm, may be elicited in 60 percent of normal infants at 1 to 2 months of age and may be adopted spontaneously by the infant up to 6 months of age. As with the Moro response, persistence beyond this age represents a malfunction of the nervous system.
3. The *placing reaction* in which the foot or hand, brought into contact with the edge of a table, is lifted automatically and placed on the flat surface, is present in all normal newborns. Its absence or asymmetry in infants younger than 6 months of age indicates a motor abnormality.
4. In the *Landau maneuver*, the infant, if suspended horizontally in the prone position, will extend the neck and trunk and will break the trunk extension when the neck is passively flexed. This reaction is present by age 6 months; its delayed appearance in a hypotonic child is indicative of a faulty motor apparatus.
5. If an infant is held prone in the horizontal position and is then dropped toward the bed, an extension of the arms is evoked, as if to break the fall. This is known as the *parachute response* and is elicitable in most 9-month-old infants. If it is asymmetrical, it indicates a unilateral motor abnormality.

The detection of gross delays or abnormalities of motor development in the neonatal or early infantile period of life is aided little by tests of tendon and plantar reflexes. Arm reflexes are always rather difficult to obtain in infants, and a normal neonate may have a few beats of ankle clonus. The plantar response tends to be wavering and uncertain in pattern. However, a consistent extension of the great toe and fanning of the toes on stroking the side of the foot is abnormal at any age.

The early detection of cerebral palsy is hampered by the fact that the corticospinal tract is not fully myelinated until 18 months of age, allowing only quasivoluntary movements up to this time. For this reason, a *congenital hemiparesis* may not be evident until many months after birth. Even then it is manifest only by subtle signs, such as holding the hand in a fistful posture or clumsiness in reaching for objects and in transferring them from one hand to the other. Later, the leg is seen to be less active as the infant crawls, steps, and places the foot. Early hand dominance should always raise the suspicion of a motor defect on the opposite side. In the upper limb, the characteristic catch and yielding resistance of spasticity is most evident in passive abduction of the arm, extension of the elbow, dorsiflexion of the wrist, and supination of the forearm; in the leg, the change in tone is best detected by passive flexion of the knee. However, the time of appearance and degree of spasticity are variable from child to child. The stretch reflexes are hyperactive, and the plantar reflex may be extensor on the affected side. With bilateral hemiplegia, the same abnormalities are detectable, but there is a greater likelihood of pseudobulbar manifestations, with delayed, poorly enunciated speech.

Later, intelligence is likely to be impaired (in 40 percent of hemiplegias and 70 percent of bilateral hemiplegias). In *diparesis* or *diplegia*, hypotonia gives way to spasticity and the same delay in motor development except that it predominates in the legs. Aside from the hereditary spastic paraplegias, which may become evident in the second and third years, the common causes of weak spastic legs are prematurity and matrix hemorrhages. These various forms of cerebral palsy are described in Chap. 38.

Developmental motor delay and other abnormalities are present in a large proportion of infants with *hypotonia*. When the "floppy" infant is lifted and its limbs are passively manipulated, there is little muscle reactivity. In the supine position, the weakness and laxity result in a "frog-leg" posture, along with an increased mobility

at the ankles and hips. Hypotonia, if generalized and accompanied by an absence of tendon reflexes, is most often a result of Werdnig-Hoffmann disease (an early life loss of anterior horn cells, a type of spinal muscular atrophy), although the range of possible diagnoses is large and includes diseases of muscle, nerve, and the central nervous system (see Chaps. 38 and 48). The other causes of this type of neonatal and infantile hypotonia include muscular dystrophies and congenital myopathies, maternal myasthenia gravis, polyneuropathies, Down syndrome, Prader-Willi syndrome, and spinal cord injuries, each of which is described in its appropriate chapter. Hypotonia that arises in utero may be accompanied by congenital fixed contractures of the joints, termed *arthrogryposis*, as discussed in Chap. 48.

Infants who will later manifest a central motor defect can sometimes be recognized by the briskness of their tendon reflexes and by the postures they assume when lifted. In the normal infant, the legs are flexed, slightly rotated externally, and associated with vigorous kicking movements. The hypotonic infant with a defect of the motor projection pathways may extend the legs or rotate them internally, with dorsiflexion of the feet and toes. Exceptionally, the legs are firmly flexed, but in either instance relatively few movements are made.

When hypotonia is a forerunner of an extrapyramidal motor disorder (so-called double athetosis, another type of cerebral palsy), the first hint of abnormality may be opisthotonic posturing of the head and neck. However, involuntary choreic movements usually do not appear in the upper limbs before 5 to 6 months of age and often are so slight as to be overlooked. They worsen as the infant matures and by 12 months assume a more athetotic character, often combined with tremor. Tone in the affected limbs is by then increased but may be interrupted during passive manipulation.

Hypotonia may also be a prelude to a cerebellar motor defect. The ataxia becomes apparent when the infant makes the first reaching movements. Tremulous, irregular movements of the trunk and head are seen when the infant attempts to sit without support. Still later, as the infant attempts to stand, there is unsteadiness of the entire body.

In distinction to the gross deficits in motor development described earlier, there is a distinct group of young children who exhibit only mild abnormalities of muscle tone, clumsiness or unusual postures or rhythmic movements of the hands, tremor, and ataxia ("fine motor deficit"), or "developmental coordination disorders." Such awkwardness in the somewhat older child is referred to as a "soft sign" and has been reviewed by Gubbay and colleagues in what they have called "the clumsy child." Like speech delay and dyslexia, fine motor deficits of this sort are more frequent in males. Tirosh found that intranatal problems were more prevalent among children with fine motor deficits (compared to those with gross motor deficits), as were minor physical anomalies and seizures.

Systemic diseases in infancy pose special problems in evaluation of the motor system. The achievement of motor milestones is delayed by illnesses such as congenital heart disease (especially cyanotic forms), cystic fibrosis,

renal and hepatic diseases, infections, and surgical procedures. Under such conditions one does well to deal with the immediate illnesses and defer pronouncements about the status of cerebral function. The brain proves to be simultaneously affected in 25 percent of patients with serious forms of congenital heart disease and an even higher proportion of patients with rubella and coxsackie B viral infections. In a disease such as cystic fibrosis, where the brain is not affected, it is advisable to depend more on the analysis of language development than on assessment of motor function, because muscular activity may be generally enfeebled.

Delays in Sensory Development

Failure to see and to hear are the most important sensory defects affecting the infant and child. When *both* senses are affected, a severe cerebral defect is usually responsible; only at a later age, when the child is more testable, does it become apparent that the trouble is not with the peripheral sensory apparatus but with the central integrating mechanisms of the brain.

Failure of development of visual function is usually revealed by strabismus and by disorders of ocular movements, as described in Chap. 13. Any defect of the refractive apparatus or the acuity of the central visual pathways results in wandering, jerky movements of the eyes. The optic discs may be atrophic in such cases, but it should be pointed out that the discs in infants tend naturally to be paler than those of an older child. In congenital hypoplasia of the optic nerves, the nerve heads are extremely small. Defects in the retina and choroid are detectable by funduscopy. Faulty vision becomes increasingly apparent in older infants when the normal sequences of hand inspection and visuomanual coordination fail to emerge. Retention of pupillary light reflexes in a sightless child signifies a defect in the geniculocalcarine tracts or occipital lobes—conditions that may be confirmed by MRI and testing of visual evoked responses.

With respect to hearing, again there is the difficulty in evaluating this function in an infant. Normally, after a few weeks of life, alert parents notice that the child makes a brisk startle to loud noises and a response to other sounds. A tinkling bell brought from behind the infant usually results in hearkening or head turning and visual searching, but a lack of these responses warns only of the most severe hearing defects. The detection of slight degrees of deafness, enough to interfere with auditory learning, requires special testing. To make the problem even more difficult, both a peripheral and a central disorder may be present in some conditions, such as the now infrequent disorder of kernicterus. Brainstem auditory evoked responses are particularly helpful in confirming peripheral (cochlear and eighth nerve) abnormalities in the infant and young child. After the first few months, impaired hearing becomes more obvious and interferes with language development, as described further on. It is of interest that the identification and remediation of early (infants) hearing defects by screening leads to higher scores on language tests later in childhood but not improved speech, according to a study by Kennedy and colleagues.

RESTRICTED DEVELOPMENTAL ABNORMALITIES

A considerable portion of neuropsychiatric practice is committed to the diagnosis and management of children with learning disabilities. These problems usually come to light in the school-age child (hence the term *school dysfunction*), whose aptitude for classroom learning is poorer than the child's general intelligence. The medical referral may be from a parent, teacher, or psychologist. The clinician's objective is to determine by history and examination whether there is (1) a general congenital developmental abnormality impairing intelligence; (2) a specific deficit in reading, writing, arithmetic, or attention, any one of which may interfere with the child's ability to learn; (3) a primary sensory defect, particularly in audition; or (4) neither of these—for example, a behavior disorder or home situation that interferes with schooling.

Once diagnosis is achieved, the goal of management, undertaken in collaboration with psychologists and educators, is to fashion a program of remedial exercises that will maximize the child's skills to a point commensurate with his talent and aptitude, and restore his self-confidence.

Disorders in the Development of Speech and Language

In the pediatric age period and extending into adult life, one encounters an interesting assortment of developmental disorders of speech and language. Many patients with such disorders come from families in which similar speech defects, ambidexterity, and left-handedness are also frequent. Males predominate; in some series, male-to-female ratios as high as 10:1 have been reported.

Developmental disorders of speech and language are far more frequent than acquired disorders, e.g., aphasia. The former include developmental speech delay, congenital deafness with speech delay, developmental word deafness, dyslexia (special reading disability), cluttered speech, infantilisms of speech, and stuttering or stammering, and mechanical disorders such as cleft-palate speech. Often in these disorders, the various stages of language development described earlier are not attained at the usual age and may not be achieved even by adulthood. Disorders of this type, especially those restricted to the language areas of the cerebrum, are far more frequently a result of slowness in the normal processes of maturation than to an acquired disease. With the possible exception of developmental dyslexia (see further on), cerebral lesions have not been described in these cases, although it must be emphasized that only a small number of brains of such individuals have been thoroughly studied by proper methods.

In discussing the developmental disorders of speech and language, we have adopted a conventional classification. Not usually included in such a classification are the many mundane peculiarities of speech and language that are usually accepted without comment: lack of fluency, inability to speak uninterruptedly in complete sentences,

and lack of proper intonation, inflection, and melody of speech (dysprosody).

Developmental Speech Delay

Fully two-thirds of children say their first words between 9 and 12 months of age and their first word combinations before their second birthday; when this does not happen, it becomes a matter of parental concern. Children who fail to reach these milestones at the stated times fall into two general categories. In one group there is no clear evidence of cognitive delay or impairment of neurologic or auditory function. In a second group, the speech delay has an overt pathologic basis.

The first group, comprising *otherwise normal children who talk late*, is the more puzzling. It is virtually impossible to predict whether such a child's speech will eventually be normal in all respects and just when this will occur. Prelanguage speech continues into the period when words and phrases should normally be used in propositional speech. The combinations of sounds are close to the standard of normal vowel-consonant combinations of the 1- to 2-year-old, and they may be strung together as if forming sentences. Yet, as time passes, the child may utter only a few understandable words, even by the third or fourth year. Three of 4 such patients will be boys and often one discovers a family history of delayed speech. When the child finally begins to talk, he may skip the early stages of spoken language and progress rapidly to speak in full sentences and to develop fluent speech and language in weeks or months. During the period of speech delay, the understanding of words and general intelligence develop normally, and communication by gestures may be remarkably facile. In such children, motor speech delay does not presage mental backwardness. (It is said that Albert Einstein did not speak until the age of 4 and lacked fluency at age 9.)

Nevertheless, the eventual acquisition of fluent speech is no guarantee of normalcy (Rutter and Martin). Many such children do have later educational difficulties, mainly because of dyslexia and dysgraphia, a combination that is sometimes inherited as an autosomal dominant trait, again more frequently in boys (see further on). In a smaller subgroup, articulation remains infantile and the content of speech is impoverished semantically and syntactically. Yet others, as they begin to speak, express themselves fluently, but with distortions, omissions, and cluttering of words, but such patients usually acquire normal speech patterns with development.

A second broad group of children with speech delay or slow speech development (no words by 18 months, no phrases by 30 months) comprises those in whom an overt pathologic basis is evident. In clinics where children of the latter type are studied systematically, 35 to 50 percent of cases occur in those with global developmental delay or "cerebral palsy." Hearing deficit explains many of the other cases, as discussed later, and a few represent what appears to be a specific lack of maturation of the motor speech areas or an acquired lesion in these parts. Only in this small, latter group is it appropriate to refer to the language disorder as aphasia, i.e., a derangement or loss of language caused by a cerebral lesion.

Aphasia, when it occurs as the result of an acquired lesion (vascular, traumatic) is essentially of the motor variety and typically lasts but a few months in the child. It may be accompanied by a right-sided hemiplegia. An interesting type of acquired aphasia, possibly encephalitic, has been described by Landau and Kleffner in association with seizures and bitemporal focal discharges in the EEG (see "Seizures Presenting in Early Childhood" in Chap. 16).

Congenital Deafness

Speech delay caused by congenital deafness, whether peripheral (loss of pure-tone acuity) or central (pure-tone threshold normal by audiogram), is a most important condition but may at first be difficult to discern. One suspects that faulty hearing is causal when there is a history of familial deaf mutism, congenital rubella, erythroblastosis fetalis, meningitis, chronic bilateral ear infections, or the administration of ototoxic drugs to the pregnant mother or newborn infant—the well-known antecedents of deafness. It is estimated that approximately 3 million American children have hearing defects; 0.1 percent of the school population are deaf and 1.5 percent are hard of hearing. The parents' attention may be drawn to a defect in hearing when the infant fails to heed loud noises, to turn the eyes to sound sources outside the immediate visual fields, and to react to music; but in other instances, it is the delay in speaking that calls attention to it.

As already mentioned, the deaf child makes the transition from crying to cooing and babbling at the usual age of 3 to 5 months. After the sixth month, however, the child becomes much quieter, and the usual repertoire of babbling sounds becomes stereotyped and unchanging, though still uttered with pleasant voice. A more conspicuous failure comes somewhat later, when babbling fails to give way to word formation. Should deafness develop within the first few years of life, the child gradually loses such speech as had been acquired but can be retaught by the lipreading method. Speech, however, is harsh, poorly modulated, and unpleasant, and accompanied by many peculiar squeals and snorting or grunting noises. Social and other acquisitions appear at the expected times in the congenitally deaf child, unlike in the developmentally delayed child. The deaf child seems eager to communicate and makes known all his needs by gesture or pantomime, often very cleverly. The deaf child may attract attention by vivid facial expressions, motions of the lips, nodding, or head shaking. The Leiter performance scale, which makes no use of sounds, will show that intelligence is normal. Deafness can be demonstrated at an early age by careful observation of the child's responses to sounds and by free-field audiometry, but the full range of hearing cannot be accurately tested before the age of 3 or 4 years. Recording of brainstem auditory evoked potentials and testing of the labyrinths, which are frequently unresponsive in deaf mutes, may be helpful. Early diagnosis is important so as to fit the child with a hearing aid and to begin appropriate language training.

In contrast to the child in whom deafness is the only abnormality, the developmentally delayed child generally talks little but may display a rich personality. Autistic children may also be mute; if they speak, echolalia is

prominent and the personal "I" is avoided. Blind children of normal intelligence tend to speak slowly and fail to acquire imitative gestures.

Congenital Word Deafness

This disorder, also called *developmental receptive dysphasia*, *verbal auditory agnosia*, or *central deafness*, is rare and may be difficult to distinguish from peripheral deafness. Usually the parents have noted that the word-deaf child responds to loud noises and music, but obviously this does not assure perfect hearing, particularly for high tones. The word-deaf child does not understand what is said, and delay and distortion of speech are evident.

Presumably, the receptive auditory elements of the dominant temporal cortex fail to discriminate the complex acoustic patterns of words and to associate them with visual images of people and objects. Despite intact pure-tone hearing, the child does not seem to hear word patterns properly and fails to reproduce them in natural speech. In other ways the child may be bright, but more often this auditory imperception of words is associated with hyperactivity, inattentiveness, bizarre behavior, or other perceptual defects incident to focal brain damage, particularly of the temporal lobes. Word-deaf children may chatter incessantly and often adopt a language of their own design, which the parents come to understand. This peculiar type of speech is known as *idioglossia*. It is also observed in children with marked articulatory defects.

Speech rehabilitation of the bright word-deaf child follows along the same lines as that of the congenitally deaf one. Such a child learns to lip-read quickly and is very facile at acting out his or her own ideas.

Congenital Inarticulation

In this developmental defect the child seems unable to coordinate the vocal, articulatory, and respiratory musculature for the purpose of speaking. Again, boys are affected more often than girls, and there is often a family history of the disorder, although the data are not quite sufficient to establish the pattern of inheritance. The incidence is 1 in every 200 children. The motor, sensory, emotional, and social attainments correspond to the norms for age, although in a few cases, a minority in the authors' opinion, there has been some indication of cranial nerve abnormality in the first months of life (ptosis, facial asymmetry, strange neonatal cry, and altered phonation).

In children with congenital inarticulation, the prelanguage sounds are probably abnormal, but this aspect of the speech disorder has not been well studied. Babbling tends to be deficient, and, in the second year, in attempting to say something, the child makes noises that do not sound at all like language; in this way the child is unlike the late talker already described. Again, the understanding of language is entirely normal; the comprehension vocabulary is average for age, and the child can appreciate syntax, as indicated by correct responses to questions by nodding or shaking the head and by the execution of complex spoken commands. Usually such patients are shy but otherwise quick in responding, cheerful, and without other behavioral disorders. Some are bright,

but a combination of congenital inarticulation and mild mental slowness is also not uncommon. If many of the spontaneous utterances are intelligible, speech correction should be attempted (by a trained therapist). However, if the child makes no sounds that resemble words, the therapeutic effort should be directed toward a modified school program, and speech rehabilitation usually waits until some words are acquired.

Studies of the cerebra of such patients are not available, and it is doubtful if they would show any abnormality by the usual techniques of neuropathologic examination. Occasionally, suspicion of a lesion is raised by focal changes in the EEG or a slight widening of the temporal horn of the left ventricle. All manner of delayed speech is often attributed to being "tongue-tied," i.e., a short lingual frenulum, but this idea now seems outdated. Also, psychologists have attributed incomplete development of speech to overprotectiveness or excessive pressure by the parents but these are certainly the result rather than the cause of the delay.

A fuller review of this subject can be found in the text *The Child with Delayed Speech*, edited by Rutter and Martin.

Stuttering and Stammering

These difficulties occur in an estimated 1 to 2 percent of the school population. Often the conditions disappear in late childhood and adolescence; by adulthood, only about 1 in 300 individuals suffer from a persistent stammer or stutter. Mild degrees are to some extent cultivated and permit a pause in speech for collecting one's thoughts, and stammering appears to be an affectation in certain social circles, as in the past among educated Englishmen (and some Americans).

Stammering and stuttering are difficult to classify. In some respects they belong to and are customarily included in the developmental language disorders, but they differ in being largely centered in articulation. There is no valid reason to distinguish between these two forms of the inarticulation, as they are intermingled, and the terms *stammer* and *stutter* are now used synonymously. Essentially they represent a disorder of rhythm—an involuntary, repetitive prolongation of speech because of an insuppressible *spasm of the articulatory muscles*. The spasm may be tonic and result in a complete blocking of speech (at one time referred to specifically as stammering) or clonic speech, i.e., a rapid series of spasms interrupting the emission of consonants, usually the first letter or syllable of a word (stuttering). Certain sounds, particularly *p* and *b*, offer greater difficulty than others; *paperboy* comes out *p-p-paper b-b-boy*. The problem is usually not apparent when single words are being spoken and dysfluency tends to be worse at the beginning of a sentence or an idea. The severity of the stutter is increased by excitement and stress, as when speaking before others, and is reduced when the stutterer is relaxed and alone or when singing in a chorus. When severe, the spasms may overflow into other groups of muscles, mainly of the face and neck and even of the arms. The muscles involved in stuttering show no fault in actions other than speaking, and all gnostic and semantic aspects of receptive language are intact.

Males are affected four times as often as females. The time of onset of stuttering is mainly at two periods in life: between 2 and 4 years of age, when speech and language are evolving, and between 6 and 8 years of age, when these functions extend to reciting and reading aloud in the classroom. However, there may be a later onset. Many afflicted children have an associated difficulty in reading and writing. If stuttering is mild, it tends to develop or to be present only during periods of emotional stress, and in 4 of 5 children it disappears entirely or almost so during adolescence or the early adult years (Andrews and Harris). If severe, it persists throughout life regardless of treatment but tends to improve as the patient grows older.

Theories of causation are legion, attesting to a lack of actual explanation. Slowness in developing hand and eye preference, ambidexterity, or an enforced change from left- to right-hand use have been popular explanations, of which Orton and Travis were leading advocates. According to their theory, stuttering results from a lack of the necessary degree of unilateral control in the synchronization of bilaterally innervated speech mechanisms. Fox and colleagues support a theory of failure of left hemisphere dominance. By performing PET studies while a subject was reading, they found that the auditory and motor areas of the right hemisphere are activated instead of those of the left hemisphere. However, these explanations probably apply to only a minority of stutterers (Hécaen and de Ajuriaguerra). It is of interest that stutterers activate the motor cortex prematurely when reading words aloud and, as noted by Sandak and Fiez, affected individuals seem to initiate motor programs before the articulatory code is prepared. Recently, several groups have reported subtle structural anomalies in the gray matter of the perisylvian region, but no common theme has emerged, and others are skeptical of these findings (see editorial by Packman and Onslow). It has been commented in the literature on this subject that speech production is a highly distributed system and that compensatory mechanisms used by stutterers may confound interpretation of functional imaging studies.

The disappearance of mild stuttering with maturation has been attributed incorrectly to all manner of treatment (hypnosis, progressive relaxation, speaking in rhythms, etc.) and used to bolster particular theories of causation. Because stuttering may reappear at times of emotional strain, a psychogenesis has been proposed, but—as pointed out by Orton and by Baker and colleagues—if there are any psychologic abnormalities in the stutterer, they are secondary rather than primary. We have observed that many stutterers, probably as a result of this impediment to free social interaction, do become increasingly fearful of talking and may become very self-conscious. By the time adolescence and adulthood are reached, emotional factors are so prominent that many physicians still mistake stuttering for a psychogenic disorder. Usually there is little or no evidence of any personality deviation before the onset of stuttering, and psychotherapy has not had a significant effect on the underlying defect. (The eminent Dr. Stanley Cobb undertook Jungian psychoanalysis for the condition according

to R.D. Adams, with no benefit whatsoever.) A strong family history in many cases and male dominance point to a genetic origin, but the inheritance does not follow a readily discernible pattern.

Stuttering is not associated with any detectable weakness or ataxia of the speech musculature. The muscles of speech go into spasm *only* when called upon to perform the specific act of speaking. The spasms are not invoked by other actions (which may not be as complex or voluntary as speaking), differing in this way from an apraxia and the intention spasm of athetosis. Also, palilalia is a different condition in which a word or phrase, usually the last one in a sentence, is repeated many times with decreasing volume. We are inclined toward a tentative view that stuttering represents a special category of extrapyramidal dystonic movement disorder, much like writer's cramp.

Rarely, in adults as well as in children, stuttering may be acquired as a result of a lesion in the motor speech areas. A distinction has been drawn between developmental and acquired stuttering. The latter is said to interfere with the enunciation of any syllable of a word (not just the first), to favor involvement of grammatical and substantive words, and to be unaccompanied by anxiety and facial grimacing. Such distinctions are probably illusory. The reported lesion sites in acquired stuttering are so variable (right frontal, corpus striatum, left temporal, left parietal) as to be difficult to reconcile with proposed theories of developmental stuttering (see Fleet and Heilman).

Another form of acquired stuttering is more manifestly an expression of an extrapyramidal disorder. Here there occurs a prolonged repetition of syllables (vowel and consonant), which the patient cannot easily interrupt. The abnormality involves throat-clearing and other vocalizations, similar to what is seen in tic disorders.

Treatment The therapy of stuttering is difficult to evaluate and, on the whole, the therapy of speech-fluency disorders has been a frustrating effort. As remarked earlier, all these disturbances are modifiable by environmental circumstances. Thus a certain proportion of stutterers will become more fluent under certain conditions, such as reading aloud; others will stutter more severely at this time. Again, a majority of stutterers will be adversely affected by talking on the telephone; a minority are helped by this device. Some stutterers are more fluent under conditions of mild alcohol intoxication. Nearly every stutterer is fluent while singing. Schemes such as the encouragement of associated muscular movements ("penciling," etc.) and the adoption of a "theatrical" approach to speaking have been advocated. Common to all such efforts has been the difficulty of achieving carry-over into the natural speaking environment. Progressive relaxation, hypnosis, delayed auditory feedback, loud noise that masks speech sounds, and many other ancillary measures may help, but only temporarily. Canevini and colleagues have made the interesting observation that stuttering improved in an epileptic treated with levetiracetam, and Rosenberger has commented on other drug therapies.

Cluttering, or Cluttered Speech

This is another special developmental disorder. It is characterized by uncontrollable speed of speech, which results in truncated, dysrhythmic, and often incoherent utterances. Omissions of consonants, elisions, improper phrasing, and inadequate intonation occur. It is as though the child were too hurried to take the trouble to pronounce each word carefully and to compose sentences. Cluttering is frequently associated with other motor speech impediments. Speech therapy (elocutionary) and maturation may be attended by a restoration of more normal rhythms.

Other Articulatory Defects

Milder speech defects are common in preschool children, having an incidence of up to 15 percent. There are several varieties. One is *lisping*, in which the *s* sound is replaced by *th*, e.g., *thimble* for *simple*. Another common condition, *lallation*, or *dyslalia*, is characterized by multiple substitutions or omissions of consonants. Milder degrees consist of difficulty in pronouncing one or two consonants that give the impression of "baby talk" and are referred to as "infantilisms." For example, the letter *r* may be incorrectly pronounced, so that it sounds like *w* or *y*; *running a race* becomes *wunning a wace* or *yunning a yace*. In severe forms, speech may be almost unintelligible. The child seems to be unaware that his or her speech differs from that of others and is distressed at not being understood. More important is the fact that in more than 90 percent of cases, the articulatory abnormalities disappear by the age of 8 years, either spontaneously or in response to speech therapy. The latter is usually started if these conditions persist into the fifth year. Presumably the natural cycle of motor speech acquisition has only been delayed, not arrested. Such abnormalities, however, are more frequent among developmentally delayed children than in normal children; with cognitive defects in general, many consonants are persistently mispronounced.

Another disorder is a congenital form of spastic bulbar speech, described by Worster-Drought, in which words are spoken slowly, with stiff labial and lingual movements, hyperactive jaw and facial reflexes, and, sometimes, mild dysphagia and dysphonia. The limbs may be unaffected, in contrast to cerebral palsy.

The mechanical speech disorder resulting from *cleft palate* is easily recognized. Many of these patients also have a harelip; the two abnormalities together interfere with sucking and later in life with the enunciation of labial and guttural consonants. The voice has an unpleasant nasality; often, if the defect is severe, there is an audible escape of air through the nose.

The aforementioned developmental abnormalities of speech pattern are only sometimes associated with disturbances of higher-order language processing. Rapin and Allen have described a number of such disturbances. In one, which they call the "semantic pragmatic syndrome," a failure to comprehend complex phrases and sentences is combined with fluent speech and well-formed sentences lacking in content. The syndrome resembles Wernicke

or transcortical sensory aphasia (Chap. 23). In another, “semantic retrieval-organization syndrome,” a severe anomia blocks word finding in spontaneous speech. A mixed expressive–receptive disorder may also be seen as a developmental abnormality; it contains many of the elements of acquired Broca’s aphasia (Chap. 23). Recently, a category of “specific language impairment” has been created to encompass all failures to acquire language competence despite normal intelligence.

The role of certain genes, particularly *FOXP2*, in the development of language is mentioned in Chap. 23. Here it is pointed out that there is an isolated developmental verbal dyspraxia that is caused by a point mutation in this gene but that other disorders, such as dyslexia, have not yielded clearly to genetic analysis as discussed below. However, Vernes and colleagues have found that *FOXP2* downregulates a gene (*CNTNAP2*) that encodes neurexin in the developing cortex. Polymorphisms of the gene are found in children with a number of specific but seemingly unrelated language deficits. They propose that this is a mechanistic link between different developmental language syndromes.

Developmental Dyslexia (Congenital Word Blindness)

This condition, first described by Hinshelwood in 1896, becomes manifest in an older child who is found to lack the aptitude for one or more of the specific skills necessary to derive meaning from the printed word. Also defined as a significant discrepancy between “measured intelligence” and “reading achievement” (Hynd et al), it has been found in 3 to 6 percent of all schoolchildren. There have been several excellent writings on the subject over the past century, to which the interested reader is referred for a detailed account (Orton; Critchley and Critchley; Rutter and Martin; Shaywitz; Rosenberger).

The main problem is an inability to read, spell, and to write words despite the ability to see and recognize letters. There is no loss of the ability to recognize the meaning of objects, pictures, and diagrams. According to Shaywitz, these children lack an awareness that words can be broken down into individual units of sound and that each segment of sound is represented by a letter or letters. This has been summarized as a problem in “phonologic processing,” referring to the smallest unit of spoken language, the phoneme, and as a parallel inability of dyslexic individuals to appreciate a correspondence between phonemes and their written representation (graphemes). A defect in the decoding of acoustic signals is one postulated mechanism. In addition to the essential visuospatial defect, some individuals also manifest a failure of sequencing ability and altered cognitive processing of language. De Renzi and Luchelli have found a deficit of verbal and visual memory in some affected children as noted below.

Much of what has been learned about dyslexia applies to native speakers of English more than to those who speak Romance languages. English is more complex phonologically than most other languages; e.g., it uses 1,120 graphemes to represent 40 phonemes, in contrast to Italian, which uses 33 graphemes to represent

22 phonemes (see Paulesu et al). Children with native orthographic languages, such as Chinese and Japanese, apparently have a far lower incidence of dyslexia.

Often, before the child enters school, reading failure can be anticipated by a delay in attending to spoken words, difficulty with rhyming games, and speech characterized by frequent mispronunciations, hesitations, and dysfluency; or there may be a delay in learning to speak or in attaining clear articulation. In the early school years there are difficulties in copying, color naming, and formation of number concepts as well as the persistent reversal of letters. The child’s writing reflects faulty perception of form and a kind of constructional and directional apraxia. Often, there is an associated vagueness about the serial order of letters in the alphabet and months in the year, as well as difficulty with numbers (acalculia) and an inability to spell and to read music. The complex of dyslexia, dyscalculia, finger agnosia, and right-left confusion is found in a small number of these children and is interpreted as a developmental form of the Gerstmann syndrome described in Chap. 22.

Lesser degrees of dyslexia are found in a large segment of the school population and are more common than the severe ones. Approximately 10 percent of schoolchildren in some surveys have some degree of this disability. The disorder is stable and persistent; however, as a result of effective methods of training, only a few children are unable to read at all after many years in school.

This form of language disorder, unattended by other neurologic signs, is strongly familial, in various series being almost in conformity with an autosomal dominant or sex-linked recessive pattern. Loci on chromosomes 6 and 15 have been implicated but not confirmed. There is also a higher incidence of left-handedness among these persons and members of their families. Shaywitz et al have suggested that the reported predominance of reading disabilities in boys (male-to-female ratios of 2:1 to 5:1) represents a bias in subject selection—many more boys than girls being identified because of associated hyperactivity and other behavioral problems; but to us this does not seem the entire explanation. Our casual clinical experience suggests that there is a genuine and substantial male preponderance. Nonetheless, an estimated 12 to 24 percent of dyslexic children will also have an attention-deficit hyperactivity disorder (ADHD) (see further on).

In the study of dyslexic and dysgraphic children, a number of other apparently congenital developmental abnormalities were documented, such as inadequate perception of space and form (poor performance on form boards and in tasks requiring construction); inadequate perception of size, distance, and temporal sequences and rhythms; and inability to imitate sequences of movements gracefully, as well as slight degrees of clumsiness and reduced proficiency in all motor tasks and games (the *clumsy child syndrome* as described by Gubbay et al and also by Denckla et al as mentioned earlier in the chapter under “Delays in Motor Development”). These disorders may also occur in brain-injured children; hence there may be considerable difficulty in separating simple delay or arrest in development from a pathologic process in the brain. However, in the majority of dyslexic children these

additional features are absent or so subtle as to require special testing for their detection.

A few careful morphometric studies have provided insight into the basis of this disorder. Galaburda and associates have studied the brains of 4 males (ages 14 to 32 years) with developmental dyslexia. In each case there were anomalies of the cerebral cortex consisting of minor neuronal ectopias and architectonic dysplasias, located mainly in the perisylvian regions of the left hemisphere. More in conformity with imaging studies noted below, all of the brains were characterized by relative symmetry of the planum temporale, in distinction to the usual pattern of cerebral asymmetry that favors the planum temporale of the left side. Similar changes have been described in 3 women with developmental dyslexia (Humphreys et al). CT and MRI scanning of large numbers of dyslexic patients (as well as some patients with autism and developmental speech delay) have demonstrated an increased prevalence of relative symmetry (reversed or "atypical" asymmetry) of the temporal planes of the two hemispheres (Rosenberger; Hynd et al). It is important to note, however, that not all patients with developmental dyslexia show this anomalous anatomic asymmetry (Rumsey et al). In other studies, a number of variable alterations of cortical organization were found by Casanova and colleagues, most notably, in one case, an enlargement of the minicolumns in the temporal cortex. (A similar developmental change has been found in the brains of individuals with Down syndrome and with autism.)

Leonard and colleagues, using MRI, demonstrated several other gyral anomalies in dyslexic subjects: in the planum temporale and neighboring parietal operculum of both hemispheres, some gyri were missing and others were duplicated. In some dyslexic individuals, the visual evoked to rapid low-contrast stimuli are diminished. This abnormality has been related to a deficit of large neurons in the lateral geniculate bodies (see Livingstone et al).

Specific *spelling difficulty* probably represents another developmental language disorder, distinct from dyslexia.

Additional physiologic data from functional imaging studies support the presence of an abnormal temporoparietal cortex in dyslexics. These regions, particularly the posterior portion of the superior temporal, angular, and supramarginal gyri, are selectively activated during reading in normal individuals but not in dyslexics, who activate very restricted regions of the cerebral hemisphere, mainly the Broca area. In addition, they recruit other areas not normally activated during reading, such as the inferior frontal regions. It is noteworthy that Simos and coworkers were able to show that these aberrant patterns (using functional MRI) normalized after several weeks of intensive training. If nothing else, these findings validate the localization of the functional problem in the dominant temporoparietal area, and support the notion that developmental dyslexia is susceptible to improvement by proper training.

Treatment The steady practice (many hours per week) of a cooperative and motivated child by a skillful teacher over an extended period slowly overcomes the handicap and enables an otherwise intelligent child to

read at grade level and to follow a regular program of education. The Orton phonologic method has been one of the most widely used over the years (for details, see Rosenberger). Secondary school and college students with reading deficits successfully resort to tape recorders, tutorial aids, and laptop computers that allow for review of material after classes.

Developmental Dysgraphia

Developmental writing disorders differ from dyslexia in having both linguistic and motor (orthographic) aspects. As indicated earlier, dysgraphias are present in many dyslexic children and may be combined with difficulty in calculation (so-called developmental Gerstmann syndrome). Two forms of dysgraphia have been distinguished. In one there is good spontaneous handwriting and formation of letters and spacing but miswriting of dictated words (*linguistic dysgraphia*). In the other, there are reversals of letters and letter order and poor alignment (*mechanical dysgraphia*). It is this latter type that seems to us to be the genuine, or at least the purer, dysgraphia.

Developmental Dyscalculia

This disorder, like dyslexia, usually becomes evident in the first few years of grade school, when the child is challenged by tasks of adding and subtracting and, later, multiplying and dividing. In some instances there is an evident disorder in the spatial arrangements of numbers that has been termed "anarithmetia" as noted in Chap. 22 (supposedly a right hemispherical fault). In others, there is a lexical-graphical abnormality (naming and reading the names of numbers) akin to aphasia.

Probably most of what has been said about the treatment of developmental dyslexia applies to *acalculia* and *agraphia*. The usual type of conventional classroom work does little to increase the child's proficiency in writing and arithmetic, but special tutoring and drills aid the student to some extent. All of these impairments may be associated with hyperactivity and attentional defects, as described below (Denckla et al).

Precocious Reading and Calculating

In direct contrast to the conditions discussed above, precocious reading and calculating abilities have also been identified. A 2- or 3-year old child may read with the skill of an average adult. Extraordinary facility with numbers (mathematical prodigies) and memorization ability (eidetic imagery) are comparable traits. One of these special abilities may be observed in a child with a mild form of autism (Asperger syndrome, see Chap. 38). Such children exhibit great skill in performing particular mathematical tricks but are unable to solve simple arithmetical problems or to understand the meaning of numbers ("idiot savant"). In the child with *Williams syndrome*, language and sometimes musical skills are not so much precocious as relatively normal in comparison to the overall mental deficiency, indicating that not all forms of cognitive delay impair language skills.

Congenital Amusia

One would expect that developmental deficiencies similar to those found for language would exist for music. This uncommon condition, commonly known as *tone deafness*, has only recently been studied. According to the careful studies of Ayotte and colleagues, there are deficits not only in appreciating pitch variation but also in music memorization, singing, and rhythmicity. These authors propose that the defect in pitch perception is at the root of the other abnormalities. What is also interesting is that amusia occurs without any difficulty in the processing of speech and language, specifically, prosody and prosodic interpretation are preserved. (See Chap. 22 for a discussion of the acquired defects of musical appreciation.)

Attention-Deficit Hyperactivity Disorder

A large portion of ambulatory pediatric neurology practice consists of children who are referred because of failure in school related to overactivity, impulsivity, and inattentiveness. The question often asked is whether they have an identifiable brain disease. According to Barlow, when a large number of such cases is analyzed, fully 85 percent prove to have no major signs of neurologic disease. Perhaps 5 percent are mentally subnormal and another 5 to 10 percent show some evidence of a minimal brain disorder. Many are clumsy. In the larger group without neurologic signs, the IQ is normal, although there are also cases of borderline intelligence. Boys are more often found to be hyperactive and inattentive than girls, just as they often have more trouble in learning to read and write. Dyslexia is frequently associated, as noted earlier. Girls with ADHD tend to have more trouble with numbers and arithmetic.

Human infants exhibit astonishing differences in amount of activity almost from the first days of life. Some babies are constantly on the move, wiry, and hard to hold; others are placid and slack as a sack of meal. Irwin, who studied motility in the neonate, found a difference of 290 times between the most and least active in terms of amount of movement per 24 h.

Once walking and running begin, children normally enter a period of extreme activity, more so than at any other period of life. The degree of activity, which varies widely from one child to another, seems not to be correlated with the age of achieving motor milestones or with motor skill at a later time.

Again, two groups of overactive children can be discerned early in life. In one, infants are constitutionally overactive from birth, sleeping less and feeding poorly; by the age of 2 years, the syndrome is obvious. In the other group, an inability to sit quietly only becomes apparent at the preschool age (4 to 6 years). Seldom do such children remain in one position for more than a few seconds, even when watching television. They are seen as fidgety, constantly in motion, and a bit wild in public places such as restaurants. Attention to any task cannot be sustained, hence the term *attention-deficit hyperactivity disorder*. As a rule, there is also an abnormal impulsivity and often an intolerance of all measures of restraint.

Currently, three clinical subsyndromes have been delineated: (1) combined hyperactivity, impulsivity, and inattention, which describes approximately 80 percent of affected children; (2) a predominantly inattentive syndrome; and (3) a small group that display only hyperactivity. It is also valuable to point out that a syndrome with most of the features of ADHD can be embedded in several forms of overarching cognitive and developmental delay, including in children with autistic traits. This takes on special significance in the exploration of a genetic basis for attention-deficit disorder, as noted below.

Once the child is in school, the attention deficit becomes a more troubling, practical problem. Now these children must sit still, watch and listen to the teacher when she speaks to another child, and not react to distracting stimuli. They cannot stay at their desks, take turns in reciting, be quiet, or control their impulsivity. The teacher finds it difficult to discipline them and the school often insists that the parents seek medical consultation for the child. A few are so hyperactive that they cannot attend regular classes. Their behavior verges on the "organic drivenness" that has been known to occur in children whose brains have been injured by encephalitis. In certain families, the disorder is probably inherited (Biederman et al). In about half the hyperactivity subsides gradually by puberty or soon thereafter, but in the remainder the symptoms persist in modified form into adulthood (Weiss et al).

It has also become clear that there are a large group of children who have difficulty sustaining concentration but do not manifest hyperactivity or behaviors that betray the attention deficit. It is presumed that they share a similar core problem with hyperkinetic children, and it has been observed that they may be helped in studying and school performance by the same stimulant drugs that are used for the treatment of more overt ADHD. A precise relationship between motor hyperactivity and the inability to concentrate and stay focused on a series of tasks has not been established. It would seem that these are but two aspects of the same fundamental disorder of drive and attention, but it is clear that there are individuals who have difficulty concentrating but who are not manifestly hyperactive. This becomes a particular issue in adults with ostensible ADHD who feel they have always had trouble focusing as discussed further on.

For a number of years there was a tendency to consider children with the hyperkinetic syndrome as having a form of minimal brain disease. "Soft neurologic signs" such as right-left confusion, mirror movements, minimal "choreic" instability of the hands, awkwardness, finger agnosia, tremor, and borderline hyperreflexia were said to be more frequent among them. The issue of mild developmental disorders of coordination constitutes its own subject independent of ADHD. The notion of this type of clumsiness has been known for over a century and was called *debilitate motrice* by Dupre. The connection to ADHD, however, is evident in Annell's description (taken from the review by Kirby and Sugden) ". . . awkward in movements, poor at games, hopeless in dancing and gymnastics, a bad writer and defective in communication. He is inattentive, cannot sit still, leaves his shoelaces untied, does buttons wrongly, bumps into furniture,

breaks glassware, slips off his chair, kicks his legs against the desk, and perhaps reads badly." Dyslexia is found in approximately 20 percent and a similar clumsiness is known to occur in many developmental disorders and forms of cognitive delay. These signs, however, are seen so often in normal children that their attribution to disease is invalid. Consequently, Schain and others substituted the term *minimal brain dysfunction*, which is no more accurate and simply restates the problem and, furthermore, may not be accurate in many cases.

Lacking altogether are clinicoanatomic and clinico-pathologic correlative data, but some morphologic and physiologic data are available. In an MRI study of the brains of 10 children with ADHD, Hynd and colleagues found the width of the right frontal lobe to be smaller than normal; also fairly consistently, there was a reduction in the volume of the dorsolateral, cingulate, and striatal regions. Unlike dyslexics, in whom the planum temporale tends to be equal in the two hemispheres, the left planum was larger in the attention-deficit cases, just as it is in normals. Also, functional imaging studies have suggested that changes in the striatum underlie the inability of these children to block impulsive reactions and the improvement that is seen with methylphenidate. One would expect the prefrontal cortex to be implicated in such a disinhibitory syndrome but what data exist have been complex and difficult to interpret.

Another approach to understanding the process has been to study a strain of mice that have been genetically altered to eliminate a dopamine transporter gene. These animals display behavioral symptoms that are said to replicate those of ADHD in children and also to respond to stimulants, observations that implicate an abnormality of dopamine and serotonin. This idea is provocative because several genetic linkage studies have suggested an association between ADHD and a polymorphism of the gene that codes for the same dopamine transporter gene. Furthermore, copy number variations in genes that relate to development, a rich field for study in autism, give rise to global forms of cognitive delay that display prominent features of ADHD. Most of these are duplications or deletions that congregate on chromosomes 15 and 16.

Apart from the reports of parents and teachers and observation of the child, one is aided in the diagnosis of ADHD (and other learning disabilities) by psychometry. An observant psychologist, in performing intelligence tests, notes distractibility and difficulty in sustaining any activity. Erratic performance that is not the result of a defect in comprehension is also characteristic. The Vanderbilt Assessment Scale is a checklist that is completed with parents or teachers.

Treatment of ADHD The treatment of the hyperactive child can proceed reasonably only after medical and psychological evaluations have clarified the context in which the hyperactivity occurs. If the child is hyperactive and inattentive mainly in school and less so in an unstructured environment, it may be that mild developmental delay or a specific cognitive deficiency or dyslexia, which prevents scholastic success, is a source of frustration and boredom. The child then turns to other activities that may happen to disturb the classroom. Or the hyperactive

child may have failed to acquire self-control because of a disorganized home life, and the overactivity may be but one manifestation of anxiety or intolerance of constraint. Clearly problems such as these require a modification of the educational program.

For overactive children of normal intelligence who have failed to control their impulses, who at all times have boundless energy, require little sleep, exhibit a wriggling restlessness (the "choreiform syndrome" of Prechtl and Stemmer), and manifest incessant exploratory activity that repeatedly gets them into mischief, even to their own dismay, medical therapy is justified. Paradoxically, stimulants have a quieting effect on these children, whereas sedatives may do the opposite.

Methylphenidate is the drug most widely used and its use has been validated in several studies. Children weighing less than 30 kg are given 5 mg each morning on school days for 2 weeks, after which the dose can be raised to 5 mg morning and noon. Children weighing more than 30 kg can be given a single 20-mg sustained-release tablet each morning. If methylphenidate proves ineffective after several weeks or cannot be tolerated, dextroamphetamine 2.5 to 5 mg three times daily or a mixed amphetamine-dextroamphetamine are suitable substitutes. Atomoxetine, a norepinephrine inhibitor, is also effective and is not classified as a stimulant but has caused a few cases of liver failure. If these agents control the activity and improve school performance (they can be continued for a number of years), there is then no need to alter the child's school program. It is not clear if there should be a long-term concern about hypertension, but the blood pressure is not generally measured at frequent intervals. If stimulants are ineffective, tricyclic antidepressants, particularly desipramine, may be tried. Multiple medications should be generally avoided. Classroom behavioral conditioning techniques and psychotherapy may be needed for brief periods but are not as effective as medication. Remedial education is reserved for recalcitrant cases. Biederman and Faraone have summarized approaches to treatment.

Adult Attention-Deficit Disorder

Certainly this disease is a lifelong problem for a proportion of children, although it is just as clear that many "outgrow" the hyperactivity and attention deficit. Hill and Schoener estimate that there is a 50 percent decline in prevalence with each 5 years that pass. Other authorities state that the problem persists in 80 percent. In addition to the child with ADHD who grows to adulthood with persistent problems, there recently has emerged an emphasis on a group of adults who present for the first time with features of difficulty focusing or concentrating that they or their physicians attribute to ADHD. The hyperactivity component is generally absent and may not have occurred in childhood, making the validity of the diagnosis uncertain in adults who were not identified as having ADHD in childhood. A study by Kessler and colleagues suggests that 4.4 percent of adults in the United States have the disorder. European investigators use more restrictive criteria for diagnosis and find far lower frequencies in both children and adults, with

consequentially far fewer prescriptions being written for stimulant drugs.

An approach to screening in adults has been given by McCann and Roy-Byrne. Most often these adults come to realize they have had a lifelong problem that is similar to the motor restlessness and wandering attention that led to the diagnosis of ADHD in their own children. The efficacy and safety of stimulant drugs in the adult group are not known with certainty, but this class of medications has been tried with some benefit according to many patients. Some data have emerged that the cardiovascular risks are greater in adults than in children; reports of anxiety and palpitations, as well as elevations in blood pressure, are common among adults taking the medications.

Many such individuals are of above-average intelligence and have attained high degrees of professional success, perhaps as a result of strategies developed implicitly over the years, such as note taking, organizers, mental reminders to focus, etc. These same adjustments can be quite useful to others who are struggling with the disorder so that medication is not the only alternative to surmount the cognitive problem. In relation to persistent traits of ADHD from childhood, several psychiatrists have pointed out that there may be an increase in drug and alcohol dependence among adolescents with the disorder (Zametkin and Ernst) and a slight overrepresentation of tic disorders such as Gilles de la Tourette syndrome. Our general clinical experience suggests that these additional problems do not arise in the great majority of such children. Recent studies have been reassuring in this regard, but the concern regarding tics has remained.

Enuresis

Voluntary sphincteric control develops according to a predetermined time scale. Usually normal children stop soiling themselves before they can remain dry, and day control precedes night control. Some children are toilet trained by their second birthday, but many do not acquire full sphincteric control until the fourth year. Constant dribbling usually indicates spina bifida, another form of dysraphism, or a tethered cord, but in the boy, one must look also for obstruction of the bladder neck, and in the girl, for an ectopic ureter entering the vagina.

When a child 5 years of age or older wets the bed nearly every night and is dry by day, the child is said to have *nocturnal enuresis*. This condition afflicts approximately 10 percent of children between 4 and 14 years of age, boys more than girls, and continues in many cases to be a problem even into adolescence and adulthood. Although developmentally delayed children are notably late in acquiring sphincter control (some never do), the majority of enuretic individuals are normal in other respects.

The cause of this condition is disputed. Often there is a family history of the same complaint. Some psychiatrists have insisted that overzealous parents “pressure” the child until he develops a “complex” about his bedwetting; this is highly doubtful. The underlying condition is believed by most neurologists to be a delay in the maturation of higher control of spinal reflex centers

during sleep. These and other abnormalities of bladder function in the enuretic child, as well as treatment, are also discussed Chap. 19 in relation to sleep.

Sociopathy

Extremes of egocentricity, lack of understanding of the feelings, needs, and actions of others, and an inability to judge one’s own strengths and weaknesses stand as the central issues in a certain type of personality disorder. Such difficulties usually become manifest by adolescence. The complete detachment of the child with psychosis, the amorality of the constitutional sociopath, the major disturbances in thinking of the schizophrenic, and the mood swings of the bipolar also express themselves in many, if not most, instances by adolescence and sometimes by late childhood. Here one confronts a key problem in psychiatry—the extent to which sociopathy has its roots in genetically determined personality traits or in derangements in the affective and social life of the individual consequent to a harmful environment. The answers to these questions cannot be given with finality but most clinicians believe that genetic factors are more important than environmental ones. The discovery that unusually tall males with severe acne vulgaris and aggressive sociopathic behavior may have a karyotype of XYY chromosomes is an extreme but instructive example of a genetic relationship. The patients with Turner syndrome in whom competent social adaptation is linked closely to an X chromosome of paternal origin is another example. Furthermore, there is no critical evidence to show that deliberate alteration of the familial and social environmental measures now so popular have ever prevented sociopathy.

It is during the period of late childhood and adolescence, when the personality is evolving and least stable, that transient symptoms resembling the psychopathologic states of adult life are most frequent and difficult to interpret. Some of these disorders represent the early signs of schizophrenia or bipolar disease. Others are forerunners of sociopathy. But many of these traits have a way of disappearing as adult years are reached so that one can only surmise that they represented either a maturational delay in the attainment of mature social behavior or were expressions of adolescent turmoil, or what has been called “adolescent adjustment reaction.”

Many issues that have been touched upon in the preceding discussion are considered more fully in the section on psychiatric disorders (particularly Chap. 51).

INTELLECTUAL AND DEVELOPMENTAL DISABILITY

(See also Chap. 38)

A symptom complex of incomplete development of global cognitive capacities and certain associated behavioral changes combines many of the developmental abnormalities already discussed. What has been called mental retardation and now, intellectual and developmental delay, stands as the single largest neuropsychiatric disorder in every industrialized society. In deference changed

Figure 28-4. Gaussian or bell-shaped curve of intelligence and its skewing by the group of mentally retarded individuals with diseases of the brain. The shaded areas indicate the two groups of developmentally delayed. The hump representing the pathologically retarded is purely diagrammatic, illustrating its overlap with the subculturally delayed discussed in the text and in Chap. 38. When the population plotted is limited to “mental defectives,” a truly bimodal distribution is seen, segregating the two groups of retarded.

attitudes towards the formerly used term “mental retardation,” we employ alternatives in this text. The overall frequency of the problem cannot be stated precisely but rough estimates are that in children between 9 and 14 years of age, approximately 2 percent or slightly more will be unable to profit from conventional education or to adapt socially and, when grown, to live independently.

Using any one of a number of indices of social and cognitive delay, two somewhat overlapping groups are recognized: (1) the *mildly impaired* (IQ 45 to 70), and (2) the *severely impaired*, corresponding to an IQ below 45. The second group, called the *pathologically delayed*, makes up approximately 10 percent of the mental retardation population. The more mildly affected first group, includes a group of the *familial developmentally delayed*, is much larger.

Within the severely delayed there are gradations. Because of the objectionable implications of the previously used terms *idiot*, *imbecile*, and *moron*, the developmentally delayed can be grouped instead into four categories: (1) those with *profound deficiency*, incapable of self-care (IQ below 25); (2) those with *severe deficiency*, incapable of living an independent existence and essentially untrainable (IQ 25 to 39); (3) those with *moderate deficiency*, trainable to some extent (IQ 40 to 54); and (4) those with *mild deficiency*, who are impaired but trainable and to some extent educable. The above terms, while in common use, satisfy neither neurologists nor psychologists because of their generality, embracing as they do any lifelong global deficit in mental capacities. The terms convey no information of the particular type of intellectual impairment, their causes and mechanisms, or their anatomic and pathologic bases. Moreover, they express only one aspect of impaired mental function—the cognitive—and ignore the inadequate development of personality, social adaptation, and behavior. A more comprehensive view is provided by assessing the individual’s adaptive abilities along the lines of conceptual, social, and practical skills that allow planning for maximizing independence and productivity.

When the brains of severely affected people are examined by conventional methods, gross lesions are found in

approximately 90 percent of cases. Just as noteworthy is the fact that among the remaining 10 percent of the severely delayed, the brains are grossly and microscopically normal. Despite the recent discovery of many mutations that may give rise to a delay in cognitive development only a modest proportion of cases of those with milder deficiency can presently be traced to one of the congenital abnormalities of development that are described in Chap. 38 and the vast majority of the less-severely delayed also lack a recognizable tissue pathology and have not exhibited any of the conventional signs of cerebral disease.

In our view, a more acceptable view of the mildly affected group is that they represent the proportion of the population that is on the low end of the Gaussian curve of intelligence, i.e., they constitute the group that falls between 2 to 3 standard deviations (SD) below the mean (Fig. 28-4) and are the opposite in this respect to genius. Lewis was one of the first to call attention to this large group of mildly delayed individuals and he referred to them by the ambiguous term *subcultural*. The term *familial retardation* was in the past applied to this group, because in some of the families, members of the same and previous generations have reduced cognitive ability.

An important advance in the understanding of developmental delay has now emerged from careful genetic studies that have identified specific loci that at which deletions or duplications result in intellectual disability. Some of these express particular syndromes such as cognitive delay with autism or epilepsy; however, the same genetic changes can be found among individuals who have only autism or schizophrenia. While a unifying explanation for these disparate disorders has yet to be defined, they probably have subcellular and synaptic changes in common as summarized by Mefford, Batshaw, Hoffman in their review that is recommended to the reader.

Both the milder and more-severe forms of developmental delay that are associated with physical abnormalities and diseases of the brain, as well as nondysmorphic and genetic forms of delayed development are discussed in Chap. 38.

The Neurology of Aging

As indicated in the preceding chapter, standards of growth, development, and maturation provide a frame of reference against which every pathologic process in early life must be viewed. It has been less appreciated, however, that at the other end of the life cycle, neurologic deficits must be judged in a similar way, against a background of normal aging changes (senescence). The earliest of these changes begins long before the acknowledged period of senescence and continues throughout the remainder of life. Most authors use the terms *aging* and *senescence* interchangeably, but some draw a fine semantic distinction between the purely passive and chronologic process of aging and the composite of bodily changes that characterize this process (senescence).

Biologists have measured many of these changes. Table 29-1 gives estimates of the structural and functional decline that accompanies aging between ages 30 and 80 years. It appears that all structures and functions share in the aging process. Some persons withstand the onslaught of aging far better than others, and this constitutional resistance to the effects of aging seems to be familial. It can also be said that such changes are unrelated to Alzheimer disease and other degenerative diseases but that in general, the changes of aging reduce the capacity to recover from virtually any illness or trauma. An entity of "frailty" has been conceived to encompass the sum of breakdown in multiple organ systems as a result of aging. The review by Clegg and colleagues is recommended on this subject. With respect to the nervous system, it entails loss of muscle mass, strength and endurance, decreased appetite, unintentional weight loss, and reduced mobility and balance. A working definition of frailty has been given by Fried and is summarized in Table 29-2. In the past, this was referred to as "failure to thrive," a term adopted from pediatrics.

Effects of Aging on the Nervous System

Of all the age-related changes, those in the nervous system are of paramount importance. Actors portray old people as being feeble, idle, obstinate, given to reminiscing and having tremulous hands, quavering voices, stooped posture, and slow, shuffling steps. In so doing, they have selected some of the most obvious effects of aging on the nervous system. The lay observer, as well as the medical one, often speaks glibly of the changes of advanced age as a kind of second childhood. "Old men are boys again," said Aristophanes.

Critchley, in 1931 and 1934, drew attention to a number of neurologic abnormalities that he had observed in octogenarians and for which no cause could be discerned other than the effects of aging itself. Several reviews of this subject have appeared subsequently (see especially those of Jenkyn, of Benassi, and of Kokmen [1977] and their associates). The most consistent of the neurologic signs of aging are the following:

- *Neuroophthalmic signs*: progressive smallness of pupils, decreased reactions to light, and near farsightedness (hyperopia) as a result of impairment of accommodation (presbyopia), insufficiency of convergence, restricted range of upward conjugate gaze, frequent loss of the Bell phenomenon, diminished dark adaptation, and increased sensitivity to glare.
- *Progressive hearing loss* (presbycusis), especially for high tones, and commensurate decline in speech discrimination. Mainly these changes are a result of a diminution in the number of hair cells in the organ of Corti.
- *Diminution in the sense of smell* and, to a lesser extent, of taste (see Chap. 12).
- *Motor signs*: reduced speed and amount of motor activity, slowed reaction time, impairment of fine coordination and agility, reduced muscular power (legs more than arms and proximal muscles more than distal ones) and thinness of muscles (sarcopenia), particularly the dorsal interossei, thenar, and anterior tibial muscles. A progressive decrease in the number of anterior horn cells is partially responsible for these changes, as described further on.
- *Changes in tendon and frontal reflexes*: A depression of tendon reflexes at the ankles in comparison with those at the knees is observed frequently in persons older than 70 years of age, as is a loss of Achilles reflexes in those older than 80 years of age. The snout or palmo-mental reflexes, which can be detected in mild form in a small proportion of healthy adults, are frequent findings in the elderly (in as many as half of normal subjects older than 60 years of age, according to Olney). However, other so-called cortical release signs, such as suck and grasp reflexes, when prominent, are indicative of frontal lobe disease but sometimes are expected simply as a result of aging.
- *Impairment or loss of vibratory sense* in the toes and ankles. Proprioception, however, is impaired very

Table 29-1

PHYSIOLOGIC AND ANATOMIC DETERIORATION AT 80 YEARS OF AGE

	PERCENT DECREASE
Brain weight	10–15
Blood flow to brain	20
Speed of return of blood acidity to equilibrium after exercise	83
Cardiac output at rest	35
Number of glomeruli in kidney	44
Glomerular filtration rate	31
Number of fibers in nerves	37
Nerve conduction velocity	10
Number of taste buds	64
Maximum O ₂ utilization with exercise	60
Maximum ventilation volume	47
Maximum breathing capacity	44
Power of hand grip	45
Maximum work rate	30
Basal metabolic rate	16
Body water content	18
Body weight (males)	12

little or not at all. Thresholds for the perception of cutaneous stimuli increase with age but require the use of refined methods of testing for their detection. These changes correlate with a loss of sensory fibers on sural nerve biopsy, reduced amplitude of sensory nerve action potentials, probably as a result of loss of dorsal root ganglion cells.

- The most obvious neurologic aging changes—those of *stance, posture, and gait*—are fully described in Chap. 7 and further on in this chapter.

Table 29-2

CRITERIA FOR FRAILTY (THE PRESENCE OF 3 OR MORE OF THE 5 FEATURES MAY BE USED TO DEFINE FRAILTY)

MEN		WOMEN	
1. <i>Weight loss</i>			
Greater than 10 lb or 5% of weight loss in the last year			
2. <i>15-ft walk time</i>			
Height ≤173 cm	≥7 s	Height ≤159 cm	≥7 s
Height >173 cm	≥6 s	Height >159 cm	≥6 s
3. <i>Grip strength (lb)</i>			
BMI ≤24	≤29	BMI ≤23	≤17
BMI 24.1–26	≤30	BMI 23.1–26	≤17.3
BMI 26.1–28	≤30	BMI 26.1–29	≤18
BMI >28	≤32	BMI >29	≤21
4. <i>Physical activity</i>			
<383 kcal/wk		<270 kcal/wk	
5. <i>Exhaustion</i>			
A score of 2 or 3 on either question on the CES-D			

BMI, body mass index; CES-D, Center for Epidemiologic Studies Depression Scale.

Source: Adapted from Fried.

Jenkyn and colleagues, based on their examinations of 2,029 individuals aged 50 to 93 years, have determined the incidence of certain common neurologic signs of aging. Notable again is the high frequency of snout and glabellar responses, but also limited downgaze and upgaze in approximately one-third of persons older than age 80 years. Table 29-3 summarizes these data.

With regard to the interesting population of the “oldest old,” those older than 85 years of age, Kaye and colleagues reported that deficits in balance, olfaction, and visual pursuit are distinctly worse than in younger elderly persons. Also of interest is the observation by van Exel and colleagues that women in this age group perform better than men on cognitive tests.

Effects of Aging on Memory and Other Cognitive Functions

Probably the most detailed information as to the effects of age on the nervous system comes from the measurement of cognitive functions. In the course of standardization of the original Wechsler-Bellevue Intelligence Scale (1955), cross-sectional studies of large samples of the population indicated that there was a steady decline in cognitive function starting at 30 years of age and progressing into old age. Apparently all forms of cognitive function partake of this decline—although in general certain elements of the verbal scale (vocabulary, fund of information, and comprehension) withstand the effects of aging better than those of the performance scale (block design, reversal of digits, picture arrangement, object assembly, and the digit symbol task).

However, the concept of a linear regression of cognitive function with aging has had to be modified in the light of subsequent longitudinal studies. If the same individual is examined over a period of many years, there is virtually no decline in his performance, as measured by tests of verbal function, until 60 years of age. Beyond this age, verbal intelligence does decline, but very slowly—by an average of less than 5 percent through the seventh decade and by less than 10 percent through the eighth decade (Schaie and Hertzog). Also, in a series of 460 community-dwelling individuals (55 to 95 years of age) studied by Smith and coworkers (1992), there was no significant decline with age in verbal memory and in registration-attention; similar results were found by Peterson and colleagues in 161 normal, community-dwelling individuals 62 to 100 years of age. The most definite effects of age were in learning and memory and in problem solving—cognitive impairments probably attributable to a progressive reduction in the speed of processing information. The latter may be reflected in the slowing of event-related evoked potentials and by a number of special psychologic tests (see Verhaeghen et al).

As regards these cognitive functions, the ability to memorize, acquire, and retain new information, recall of names, and avoidance of distraction once set on a course of action, diminishes with advancing age, particularly in those older than 70 years of age. Moreover, memory function may be disturbed in this way despite the relative

Table 29-3

FREQUENCY OF NEUROLOGIC SIGNS IN UNCOMPLICATED AGING (IN PERCENT)

SIGN	AGE (YEARS)			
	65–69	70–74	75–79	>80
Glabella sign (inability to inhibit blink)	10	15	27	37
Snout reflex	3	8	7	26
Limited upgaze	6	15	27	29
Limited downgaze	8	15	26	34
Abnormal visual tracking	8	18	22	32
Paratonic rigidity	6	10	12	21
Unable to recall 3 words	24	28	25	55
Unable to spell <i>world</i> backward	10	12	18	21

Source: Data from Jenkyn et al.

retention of other intellectual abilities. Characteristically, there is difficulty with recall of a name or the specific date of an experience (“episodic” memory) despite a preservation of memory for the experience itself or for the many features of a person whose name is momentarily elusive (“tip-of-the-tongue syndrome”). Also characteristic is an inconsistent retrieval of the lost name or information at a later date. It has been found, however, that if older persons are allowed to learn new material very well, until no errors are made, they forget this information at a rate similar to that of younger individuals.

Kral, who first wrote informatively on this type of memory disturbance 50 years ago, referred to it as *benign senescent forgetfulness*. He pointed out that such a memory disturbance, in distinction to that of Alzheimer disease, worsens very little or not at all over a period of many years and does not interfere significantly with the person’s work performance or activities of daily living. Crook and coworkers have refined the diagnostic criteria for senescent forgetfulness and have proposed a new term—*age-associated memory impairment* (AAMI). The diagnostic criteria for AAMI include age of 50 years or older, a subjective sense of decline in memory, impaired performance on standard tests of memory function (at least one SD below the mean), and absence of any other signs of dementia. The current terminology is *minimal cognitive impairment*, but there has been increasing recognition that Kral’s original notion of a benign condition may have been incorrect and that cognitive decline in later years may be a symptom of Alzheimer disease.

In judging the degree of cognitive decline, several abbreviated tests of mental status have been developed and are of practical value (Kokmen et al, 1991; Folstein et al) in that they can be administered in the office or at the bedside in 5 to 10 min. Repetition of spoken items, such as a series of digits, orientation as to place and time, capacity to learn and to retain several items, tests of arithmetic and calculation (concentration), and specific tests for memory (particularly tests of delayed recall or forgetfulness) distinguish the performance of normal aging persons from that of patients with Alzheimer disease (Larrabee et al). With regard to performance on the Mini-Mental Status Examination (see Table 21-6; Folstein et al), a study by Crum and associates of a large urban

population indicates a median score of 19 to 20 for individuals older than age 80 years who have a fourth grade education and 27 for those with a college education (out of maximum score of 30).

The foregoing effects of age on mental abilities are extremely variable. Some 70-year-olds perform better on psychologic testing than some “normal” 20-year-olds. And a few individuals retain exceptional mental power and perform creative work until late life. Verdi, for example, composed *Otello* at the age of 73 and *Falstaff* at 79. Humboldt wrote the five volumes of his *Kosmos* between the ages of 76 and 89 years; Goethe produced the second part of *Faust* when he was more than 70 years old; Galileo, Laplace, and Sherrington continued to make scientific contributions in their eighth decades; and Picasso continued to paint in his nineties. It must be pointed out, however, that these accomplishments were essentially continuations of lines of endeavor that had been initiated in early adult life. Indeed, little that is new and original is started after the fortieth year. High intelligence, well-organized work habits, and sound judgment compensate for many of the progressive shortcomings of old age.

Personality Changes in the Aged

These are less-easily measured than cognitive functions, but certain trends are nevertheless observable and may seriously disturb the lives of aged persons and those around them. Many old people become more opinionated, repetitive, self-centered, and rigid and conservative in their thinking; the opposite qualities—undue pliancy, vacillation, and the uncritical acceptance of ideas—are observed in others. Often these changes can be recognized as exaggerations of lifelong personality traits. Elderly persons tend to become increasingly cautious; many of them seem to lack self-confidence and require a strong probability of success before undertaking certain tasks. These changes may impair their performance on psychologic testing. Kallman’s studies of senescent monozygotic twins suggest that genetic factors are more important than environmental ones in molding these traits.

One of the weaknesses of studies of the aged has been the bias in selection of patients. Many of the reported observations have been made in cohorts of individuals

residing in nursing homes. Studies of functionally intact old people of comparable age and living independently, such as those of Kokmen (1977) and of Benassi and their colleagues, reveal fewer deficits, consisting mainly of forgetfulness of names, smallness of pupils, restriction of convergence and upward conjugate gaze, diminished Achilles reflexes and vibratory sense in the feet, stooped posture, and impairments of balance, agility, and gait (as mentioned earlier and below).

Effects of Aging on Stance and Gait and Related Motor Impairments (See also Chap. 7)

These are among the most conspicuous manifestations of the aging process. Motor agility actually begins to decline in early adult life, even by the thirtieth year; it seems related to a gradual decrease in neuromuscular control as well as to changes in joints and other structures. The reality of this motor decrement is best appreciated by professional athletes who retire at age 35 or thereabout because their legs give out and cannot be restored to their maximal condition by training. They cannot run as well as younger athletes, even though the strength and coordination of their arms, when tested independently of other functions, are relatively preserved. More subtle and imperceptibly evolving changes in stance and gait are ubiquitous features of aging (see Chap. 7). Gradually the steps shorten, walking becomes slower, and there is a tendency to stoop. The older person becomes less confident and more cautious in walking and habitually touches the handrail in descending stairs, to prevent a misstep.

To be distinguished from the ubiquitous and subtle changes in gait of the "normal" older population is a more rapidly evolving and inordinate deterioration of gait that afflicts a small proportion of the aging population while they remain relatively competent in other ways. In all likelihood, this latter disorder represents an age-linked degenerative disease of the brain, as most instances of it are sooner or later accompanied by mental changes. The basis of this gait disorder is probably a combined frontal lobe–basal ganglionic degeneration, the anatomy of which has never been fully clarified, as discussed in "Frontal Lobe Disorder of Gait" in Chap. 7. However, in many of such patients we have observed, there is no disproportionate atrophy or reduction of blood flow in the frontal lobes, making the cause of the gait disorder obscure. It has also been postulated that age-related changes in the substantia nigra are the cause of the parkinsonian appearance of the gait of the aged, but it does not respond to L-dopa or to any other therapeutic measure. The main differential diagnostic consideration is *normal-pressure hydrocephalus*, correctable by a ventriculoperitoneal shunt, which accounts for the gait disorder of a sizable group of these elderly patients, as discussed in Chaps. 7 and 30. Parkinson disease is yet another potentially treatable cause of walking difficulty. Progressive supranuclear palsy is a degenerative process in which gait and stability are affected early and profoundly.

Urinary incontinence, defined as a state in which "involuntary loss of urine is a social or hygienic problem

and is objectively demonstrated," is a common occurrence in the elderly (Wells and Diokno). Doubtless this complex of motor impairments is based on the aforementioned neuronal losses in the spinal cord, cerebellum, and cerebrum.

Falls in the Elderly

Among elderly persons without apparent neurologic disease, falls constitute a major health problem. Approximately 30 percent suffer one or more falls each year; this figure rises to 40 percent among those older than age 80 years and to more than 50 percent among elderly persons living in nursing homes. According to Tinetti and colleagues, 10 to 15 percent of falls in the elderly result in fractures and other serious injuries; they are reportedly an underlying cause of about 9,500 deaths annually in the United States.

Several factors, some mentioned earlier in regard to deterioration of gait, are responsible for the inordinately high rate of falling among older persons. Impairment of visual function and particularly of vestibular function with normal aging are important contributors. In a group of 34 elderly patients who were free of neurologic disease, postural hypotension, and leg deformities, Weiner and colleagues found a moderate or severe degree of postural reflex impairment in two-thirds. The failure to make rapid postural adjustments, which is a product of aging alone, accounts for the occurrence of falls in the course of usual activities such as walking, changing position, or descending stairs. Orthostatic hypotension, often because of antihypertensive agents and the use of sedative drugs, is another important cause of falling in the elderly.

Of course, falling is an even more prominent feature of certain age-related neurologic diseases: stroke, Parkinson disease, normal-pressure hydrocephalus, and progressive supranuclear palsy, among others.

Other Restricted Motor Abnormalities in the Aged

These are too numerous to be more than catalogued. They reflect the many ways in which the motor system can deteriorate. Compulsive, repetitive movements are the most frequent: mouthing movements, stereotyped grimacing, protrusion of the tongue, side-to-side or to-and-fro tremor of the head, odd vocalizations such as sniffing, snorting, and bleating. In some respects these disorders resemble tics (quasivoluntary movements to relieve tension), but careful observation shows that they are not really voluntary. Haloperidol and other drugs of this class have an unpredictable therapeutic effect, seeming at times to benefit the patient only by the superimposition of a drug-induced rigidity and are not recommended.

Old age is thought always to carry a liability to tremulousness, and indeed, one sees this association with some frequency. The head, chin, or hands tremble and the voice quavers, yet there is not the usual slowness and poverty of movement, facial impassivity, or flexed posture that would stamp the condition as parkinsonian. Some instances of tremor are clearly familial, having appeared or worsened only late in life. However, the relation of tremulousness to aging is sometimes open to doubt. Charcot, in a review of over 2,000 elderly

inhabitants of the Salpêtrière Hospital, could find only about 30 with tremor. Some cases probably represent the exaggeration or emergence of essential tremor, but many cases cannot be explained on this basis.

Spastic or spasmodic dysphonia, a disorder of middle and late life characterized by spasm of all the throat muscles on attempted speech, is discussed in Chap. 6.

Morphologic and Physiologic Changes in the Aging Nervous System

These have never been fully established. From the third decade of life to the beginning of the tenth decade, the average decline in weight of the male brain is from 1,394 to 1,161 g, a loss of 233 g. The pace of this change, very gradual at first, accelerates during the sixth or seventh decades. The loss of brain weight, which correlates roughly with enlargement of the lateral ventricles and widening of the sulci, is presumably the result of neuronal degeneration and replacement gliosis. The counting of cerebrocortical neurons is fraught with technical difficulties, even with the use of computer-assisted automated techniques (see the critical review of neuron-counting studies by Coleman and Flood). Most studies, point to a depletion of the neuronal population in the neocortex, especially evident in the seventh, eighth, and ninth decades.

Cell loss in the limbic system (hippocampus, parahippocampal, and cingulate gyri) is of special interest in regard to memory. Ball, who measured the neuronal loss in the hippocampus, recorded a linear decrease of 27 percent between 45 and 95 years of age. Dam reported a similar degree of cell loss and replacement gliosis. These changes seem to proceed without relationship to Alzheimer neurofibrillary changes and senile plaques (Kemper). However, more recent morphologic work, summarized by Morrison and Hof, suggests that cerebral cell loss with aging is less pronounced than previously thought. Furthermore, as pointed out by Morrison, the hippocampus may have only minimal cell loss. Moreover, this is partially a result of neurogenesis in this region. Brain shrinkage is accounted for in part by the reduction in size of large neurons, not their disappearance. There is a more substantial reduction in neuronal number in the substantia nigra, locus ceruleus, and basal forebrain nuclei. It may be possible to differentiate normal aging from disease in the medial temporal lobe by distinguishing between cell loss in specific regions (see Small et al), but novel techniques are required.

Mueller and colleagues employed quantitative volumetric MRI techniques to examine a cohort of 46 nondemented elderly individuals. They found small, constant rates of loss of brain volume with aging. Moreover, the rates of volume loss in the last decades of life were no greater than in the immediately preceding decades, suggesting that large changes in brain volume in the elderly are attributable to the dementing diseases common to this age period. Rusinek and colleagues found that serial MRIs of elderly persons predict which individuals will develop disproportionate atrophy and dementia. In particular, hippocampal atrophy increases at the rate of

less than 2 percent per year in healthy elderly people, in comparison to 4 to 8 percent a year in early Alzheimer disease. This longitudinal method of study is more sensitive than cross-sectional population studies.

Among lumbosacral anterior horn cells, sensory ganglion cells, and putaminal and Purkinje cells, neuronal loss amounts to at most 25 percent between youth and old age. Not all neuronal groups are equally susceptible. For example, the locus ceruleus and substantia nigra, as already commented, lose approximately 35 percent of their neurons, whereas the vestibular nuclei and inferior olives maintain a fairly constant number of cells throughout life. A very subtle loss, decade by decade, of the major systems of nerve cells and myelinated fibers of the spinal cord was demonstrated by Morrison. This accelerates after the age of 60 (Tomlinson and Irving).

As described earlier in normal aging, there is a gradual decline in memory and in some cognitive functions. In light of the studies just summarized, it is no longer considered that these changes can be ascribed simply to neuronal loss. Rather, they are probably caused, at least in part, by alterations in synaptic connectivity within critical cortical structures.

Scheibel and coworkers have described a loss of neuronal dendrites in the aging brain, particularly the horizontal dendrites of the third and fifth layers of the neocortex. However, the Golgi method, which was used in these studies, is difficult to interpret because of artifacts. The morphometric studies of Buell and Coleman showed that the surviving neurons actually exhibit expanded dendritic trees, suggesting that even aging neurons have the capacity to react to cell loss by developing new synapses. With advancing age, there is an increasing tendency for neuritic (amyloid and neurofibrillary) plaques to appear in the brains of nondemented individuals. At first the plaques appear in the hippocampus and parahippocampus, but later they become more widespread. These are loose aggregates of amorphous argentophilic material containing amyloid. They occur in increasing numbers with advancing age; by the end of the ninth decade of life, few brains are without them. However, as shown by Tomlinson and colleagues, relatively fewer plaques are present in the brains of mentally intact old people, in contrast to the large numbers in those with Alzheimer disease. Even more impressive is the correlation of neurofibrillary tangles and Alzheimer disease. Very few such tangles are found in the brains of mentally sound individuals, and those that are found are essentially confined to the hippocampus and adjacent entorhinal cortex. By contrast, neurofibrillary tangles are far more abundant and diffusely distributed in patients with Alzheimer disease.

The view is often expressed that neuritic plaques and Alzheimer type of neurofibrillary changes simply represent an acceleration of the natural aging process in the brain. Most investigators are more inclined to the idea that the plaques and neurofibrillary changes represent an *acquired age-linked disease*, analogous in this respect to certain cerebrovascular diseases or osteoarthritis. In support of this latter view are several observations.

First, *Homo sapiens* is the only animal species in which Alzheimer neurofibrillary changes and neuritic plaques are regularly found in the aging brain. A few plaque-like structures (but no neurofibrillary changes) have been seen occasionally in old dogs and monkeys but not in mice or rats. It seems unbiologic that human aging should differ from that of all other animal species. Second, some of the most severe forms of Alzheimer disease occur in middle adult life, long before old age. Third, these histopathologic changes in variable proportion occur in a number of other diseases unrelated to aging, such as dementia pugilistica ("punch-drunk" state), Down syndrome, postencephalitic Parkinson disease, and progressive supranuclear palsy. Fourth, neurofibrillary tangles can be reproduced in the experimental animal by such toxins as aluminum, vincristine, vinblastine, and colchicine. Finally, a small proportion of Alzheimer cases are definitely familial, as described in Chap. 39.

Virtually every molecular structure within the cell is subject to age-related biochemical modifications, such as the formation of carbonyl proteins, glycation of sugars, and oxidative changes in lipids. Some of these subcellular phenomena contribute to the aging process (see Mrak et al for details), as do the accumulation of mitochondrial DNA mutations and shortened lengths of the telomeres. Among the visible biochemical alterations is an increasing accumulation of lipofuscin granules in the cytoplasm of neurons, sometimes extreme in degree. Also, there is an age-related neuronal accumulation of iron and other pigment bodies. Granulovacuolar changes are a regular finding in aging hippocampi, regardless of the mental state of the individual. The accumulation of glycogen-containing concretions (corpora amylacea) around nerve roots and diffusely in the subpial space is yet another aging effect, which has no known clinical correlate.

Cerebral atherosclerosis is, of course, a frequent finding in the elderly, but it does not parallel aging with any degree of precision, being severe in some 30- to 40-year-old individuals and practically absent in some octogenarians. In the normotensive individual, it tends to occur in scattered, discrete plaques mostly in the aorta and cervical arteries (carotid bifurcation and higher segments), proximal middle cerebral arteries, and at the vertebrobasilar junction and basilar portions of the cerebral arterial system. In the hypertensive and diabetic, it is more diffuse and extends into finer branches of the cerebral and cerebellar arteries. One or more cerebral infarcts are found in approximately 25 percent of all individuals older than 70 years of age who were carefully examined postmortem. In addition to atherosclerotic disease, the basilar arteries become somewhat larger and more tortuous and opaque in the elderly.

Cerebral blood flow has been extensively investigated in the elderly population. Most studies show that flow declines with age and that the cerebral metabolic rate declines in parallel. There is also an age-related increase in cerebrovascular resistance. Declines in flow are somewhat greater in the cortex than in white matter and greater in prefrontal regions than in other parts of the hemispheres. Obrist demonstrated a 28 percent reduction in cerebral flow by age 80. It is noteworthy, however, that

every cohort of elderly persons tested in this way contained a significant proportion in which cerebral blood flow was equivalent to that in young control subjects. In fact, in a group of 72-year-old men rigorously selected on the basis of freedom from disease, Sokoloff demonstrated that cerebral blood flow and oxygen consumption did not differ from those of normal men 22 years of age. Nevertheless, cerebral glucose metabolism was reduced in all the elderly subjects.

With advancing age there is a general tendency for the electroencephalogram (EEG) to show a slowing of the alpha rhythm, an increase in beta activity, a decline in the percentage of slow-wave sleep, and an increasing intrusion of theta rhythms, particularly over the temporal lobes, although there are large individual differences.

With respect to the neurotransmitters, it is generally agreed that the concentrations of acetylcholine, norepinephrine, and dopamine decline in the course of normal aging. Also, the concentration of gamma-aminobutyric acid (GABA) has been shown to decline with age, particularly in the frontal cortex (Spokes et al). Analyses of postmortem human and animal brains have failed to demonstrate a decline with age in the concentration of serotonin or its metabolites (McEntee and Crook). Accurate assessment of other neurotransmitters has been more difficult because of their marked lability in postmortem material. Data from experiments in rats suggest that the glutamate content of the brain and the number of *N*-methyl-D-aspartate (NMDA) receptors diminish with age, but the functional significance of this finding is unclear. Unlike the case in Alzheimer disease, normal aging is associated with only slight and inconsistent abnormalities of cholinergic innervation of the hippocampus and cortex. This is true also of the acetylcholine content and the activity of choline acetyltransferase (the synthesizing enzyme of acetylcholine) in these regions and the number of cholinergic neurons in the nucleus basalis of Meynert (substantia innominata) and other nuclei of the basal forebrain (Decker). Again, the significance of these changes is difficult to judge. They probably reflect the depletion of cells that occurs with aging. The topics of cholinergic and glutamatergic function in the aging brain have been critically reviewed by McEntee and Crook.

Aging Changes in Muscles and Nerves

With advancing age, skeletal muscles lose cells (fibers) and undergo a gradual reduction in their weight more or less parallel to that of the brain. Atrophy of muscles and diminution in peak power and endurance are clinical expressions of these changes. Many processes contribute to this age-dependent loss of lean muscle mass, described as *sarcopenia*. These include decreased physical activity; diminished appetite associated with loss of smell and elevated levels of cholecystokinin, a satiety hormone; other endocrine changes such as diminished levels of growth hormone and androgens; and (as in the brain) the accumulation of subcellular defects such as nuclear and mitochondrial DNA mutations alluded to earlier. Moreover, with aging, the slow loss of motor

neurons contributes to a component of denervation atrophy. Our own observations, with Dr. R.D. Adams, of neuropathologic material indicate that the wasting involves several processes, some principally myopathic and others relating to disuse or denervation from loss of motor neurons. In this material, denervation atrophy of the gastrocnemius muscles was found in 80 percent of individuals older than 70 years of age. The lost muscle fibers are gradually replaced by endomysial connective tissue and fat cells. The surviving fibers are generally thinner than normal (possibly because of disuse atrophy), but some enlarge, resulting in a wider-than-normal range of fiber size. Groups of fibers all at the same stage of atrophy undoubtedly relate to loss of motor innervation. The reduction in conduction velocity and decrease in amplitude of motor nerve potentials and, to a greater extent, of sensory nerves in the aged may be taken as other indices of loss of motor and sensory axons. All these changes are more marked in the legs than elsewhere. However, when Roos and colleagues examined the contractile speed and firing rates of the quadriceps muscle in young men and compared them to those of men close to 80 years old, they found little difference despite a 50 percent reduction in the maximum voluntary contraction force developed by the muscle in the older men.

It has been repeatedly observed that age is an important prognostic factor in a large number of human diseases. This effect is very evident, for example, in the markedly slower and less-complete recovery from Guillain-Barré polyneuropathy in older age groups compared with younger ones. One presumes that the structural changes of aging in peripheral nerves limit the degree of myelin regeneration and lower the threshold for failure of electrical transmission.

GERONTOLOGIC NEUROLOGY

Gerontology is defined as the study of aging and *geriatrics* as the study of the disorders of aging, both of aging itself and of the age-related diseases. Geriatric neurology has emerged as a subspecialty focused on age-related disorders of the nervous system (see the review of the field by Stanton). In comparison to pediatric neurology, these disciplines have not aroused much interest, yet many neurologic patients seen in practice are elderly, especially if one includes those with vascular diseases of the brain. Furthermore, many of their diseases are preventable or therapeutically controllable such as hypertension, atrial fibrillation, and hypercholesterolemia as causes of stroke. Some of the age-related nutritional and endocrine disorders (e.g., vitamin B deficiencies, diabetes mellitus) and many of the common restricted involuntional changes (e.g., presbyopia) can be corrected. And always, there is the need to counsel the elderly patient on matters pertaining to health and daily activities. This was appreciated even in the time of Cicero, who, in his *De Senectute*, urged the practice of moderation in exercise and giving due attention to the mind, which must be kept active or, like a lamp that is not supplied with oil, it will grow dim.

As medical science and public health measures have brought diseases of aging and other diseases under control, the number of elderly persons has increased and will continue to do so. The U.S. Census Bureau reported a 18.5% increase in persons 60 years and older (45.8 to 57.1 million) and a 9.0% increase in persons 70 years and older (25.5 to 27.8 million) between the years 2000 and 2010. As the number of elderly increases, the need to look after them will occupy an increasing amount of the energies of physicians and the resources of society at large.

PART 4

MAJOR CATEGORIES OF NEUROLOGIC DISEASE

This page intentionally left blank

Disturbances of Cerebrospinal Fluid, Including Hydrocephalus, Pseudotumor Cerebri, and Low-Pressure Syndromes

In the chapters to follow, reference is made to the ways in which changes in the cerebrospinal fluid (CSF) reflect the basic pathologic processes in a variety of inflammatory and infectious, neoplastic, demyelinating, and degenerative diseases. The CSF alterations in these circumstances raise so many important problems that we consider it worthwhile to discuss in one place the mechanisms involved in the formation, circulation, and absorption of the CSF, particularly as they pertain to alterations of intracranial pressure (ICP). Considered in this chapter are hydrocephalus, pseudotumor cerebri, and syndromes produced by reduced pressure in the CSF compartment. Further information on the management of raised ICP as it pertains to traumatic brain injury, of which the CSF is an essential part, can be found in Chap. 35. Examination of the CSF as a diagnostic aid in neurology was discussed in Chap. 2, and the primary infectious and noninfectious inflammatory reactions of the pia-arachnoid (leptomeninges) and ependyma of the ventricles are considered in Chap. 32.

A few historical points call to mind that our understanding of the physiology, chemistry, and cytology of the CSF is the result of a technical innovation that was introduced a century ago. Although the lumbar puncture was introduced by Quincke in 1891, it was not until 1912 that Mestrezat made correlations between disease processes and the cellular and chemical changes in the CSF. In 1937, Merritt and Fremont-Smith published their monograph on CSF changes in a broad variety of disease. Our knowledge of CSF cytology has accumulated since the late 1950s, when membrane filtration techniques (particularly the cellulose ester or Millipore filter) were introduced. The studies of Dandy (1919) and of Weed (1935) provided the basis of our knowledge of CSF formation, circulation, and absorption. The important studies of Pappenheimer and of Ames and their colleagues followed, and then the monographs of Fishman and of Davson and coworkers, which are important modern contributions. (See Chap. 2 for references.) Recent inceptions in analyzing the lymphocytic cells and protein fractions in the CSF have expanded on modern technology that was developed in hematology.

PHYSIOLOGY OF THE CEREBROSPINAL FLUID

The primary function of the CSF appears to be a mechanical one; it serves as a kind of water jacket for the spinal cord and brain, protecting them from potentially injurious blows to the spinal column and skull and acute changes in venous pressure. Also, it provides the brain with buoyancy. As pointed out by Fishman, the 1,500-g brain, which has a water content of approximately 80 percent, weighs only 50 g when suspended in CSF, so the brain virtually floats in its CSF. Many of the physiologic mechanisms described below are committed to maintaining the relatively constant volume-pressure relationships of the CSF. In addition, because the brain and spinal cord have no lymphatic channels, the CSF, through its "sink action," serves to remove waste products of cerebral metabolism, the main ones being CO_2 , lactate, and hydrogen ions. The composition of the CSF is maintained within narrow limits, despite major alterations in the blood; thus the other main function of CSF, along with the intercellular fluid of the brain, is to preserve a stable chemical environment for neurons, astrocytes, and myelinated fibers. There is no reason, however, to believe that the CSF is actively involved in the metabolism of the cells of the brain, and spinal cord.

In the adult, the average intracranial volume is 1,700 mL; the volume of the brain is from 1,200 to 1,400 mL, CSF volume ranges from 70 to 160 mL (mean: 104 mL), and that of blood is approximately 150 mL. In addition, the spinal subarachnoid space contains 10 to 25 mL of CSF. Thus, at most, the CSF occupies somewhat less than 10 percent of the intracranial and intraspinal spaces. The proportion of CSF in the ventricles, and cerebral cisternae and sulci in the subarachnoid spaces varies with age. These variations have been plotted in CT scans by Meese and coworkers; the distance between the caudate nuclei at the anterior horns gradually widens by approximately 1.0 to 1.5 cm, and the width of the third ventricle increases from 3 to 6 mm by age 60 years.

Formation of CSF

The introduction of the ventriculocisternal perfusion technique by Pappenheimer and colleagues made possible measurements of the rates of formation and absorption of the CSF. They established that the average rate of CSF formation is 21 to 22 mL/h (0.35 mL/min), or approximately 500 mL/d; thus the volume of CSF as a whole is renewed 4 or 5 times daily.

The choroid plexuses, located in the floor of the lateral, third, and fourth ventricles, are the main sites of CSF formation (some CSF is formed by the meninges even after the choroid plexuses are removed). The thin-walled vessels of the plexuses allow passive diffusion of substances from the blood plasma into the extracellular space surrounding choroid cells. The choroidal epithelial cells, like other secretory epithelia, contain organelles, indicating their capacity for an energy-dependent secretory function, i.e., "active transport." The blood vessels in the subependymal regions and the pia also contribute to the CSF, and some substances enter the CSF as readily from the meninges as from the choroid plexuses. Thus, electrolytes equilibrate with the CSF at all points in the ventricular and subarachnoid spaces, and the same is true of glucose. The transport of sodium, the main cation of the CSF, is accomplished by the action of a sodium-potassium-ion exchange pump at the apical surface of the choroid plexus cells, the energy for which is supplied by adenosine tri-phosphate (ATP); drugs that inhibit the ATP system therefore reduce CSF formation (Cutler and Spertell). Electrolytes enter the ventricles somewhat more readily than they enter the subarachnoid space (water does the opposite). It is also known that the penetration of certain drugs and metabolites into the CSF (and brain) is in direct relation to their lipid solubility. Ionized compounds, such as hexoses and amino acids, being relatively insoluble in lipids, enter the CSF slowly unless facilitated by a membrane transport system. This type of facilitated (carrier) diffusion is stereospecific; i.e., the carrier (a specific protein or proteolipid) binds only with a solute having a specific configuration, and conducts it across the membrane, where it is released into the CSF, and intercellular fluid.

Diffusion gradients appear to determine the entry of serum electrolytes and proteins into the CSF, and also the exchanges of CO₂. Water and sodium diffuse as readily from blood to CSF and intercellular spaces as in the reverse direction. This explains the rapid effects of intravenously injected hypotonic and hypertonic fluids. Studies using radioisotopic tracer techniques show that the various constituents of the CSF (see Table 2-2) are in dynamic equilibrium with the blood. Similarly, CSF in the ventricles and subarachnoid spaces is in equilibrium with the intercellular fluid of the brain, spinal cord, and olfactory and optic nerves. Certain structures that maintain this equilibrium are subsumed under the term *blood-brain barrier*, which is used to designate all of the interfaces between blood, brain, and CSF. The site of the barrier varies for the different plasma constituents. One is the endothelium of the choroidal and brain capillaries; another is the plasma membrane and adventitia

(Rouget cells) of these vessels; a third is the pericapillary foot processes of astrocytes. Large molecules, such as albumin, are prevented from entry by the capillary endothelium, and this is the barrier also for such molecules as are bound to albumin, e.g., aniline dyes (trypan blue), bilirubin, and many drugs. Other smaller molecules are blocked from entering the brain by the capillary plasma membrane or astrocytes.

The substances formed in the nervous system during its metabolic activity diffuse rapidly into the CSF. Thus, the CSF has, as mentioned, a "sink action," to use Davson's term, by which the products of brain metabolism are removed into the bloodstream as CSF is absorbed.

CSF Circulation

Harvey Cushing aptly termed the CSF the "third circulation," comparable to that of blood and lymph. From its principal site of formation in the choroid plexus of the lateral ventricles, CSF flows downward sequentially through the third ventricle, aqueduct, fourth ventricle, and foramina of Magendie (medially) and Luschka (laterally) at the base of the medulla, to the perimedullary and perispinal subarachnoid spaces, thence around the brainstem and rostrally to the basal and ambient cisterns, through the tentorial aperture, and finally to the lateral and superior surfaces of the cerebral hemispheres, where most of it is absorbed (Fig. 30-1). The pressure in the CSF

Figure 30-1. A. Schematic representation of the three components of the intracranial contents: the incompressible brain tissue (orange); the vascular system (dark blue channel); and the CSF (light blue). The red outer circle represents the intracranial compartment, which is fixed in size. B. With ventricular outflow obstruction. C. With obstruction at or near the points of outlet of the CSF. D. With obstruction of the venous outflow. (Redrawn with permission from Foley.)

compartment is highest in the ventricles and diminishes successively along the subarachnoid pathways. Arterial pulsations of the choroid plexuses help drive the fluid centrifugally from the ventricular system.

The spinal fluid is in contact everywhere with the extracellular fluid of the brain and spinal cord, but the extent of bulk flow of the CSF through the brain parenchyma is small under normal conditions. The periventricular tissue offer considerable resistance to the entrance of CSF and although the pressure difference between the ventricles and the subarachnoid spaces over the convexity of the hemispheres (transmantle pressure) is above zero, the open ventricular–foraminal–subarachnoid pathway directs the bulk of CSF flow in this direction. Only if this conduit is obstructed does the transmantle pressure rise, compressing the periventricular tissues and leading to ventricular enlargement, i.e., hydrocephalus, and transpendymal flow of CSF.

CSF Absorption

Absorption of CSF is mainly through the arachnoid villi. These are microscopic excrescences of arachnoid membrane that penetrate the dura and protrude into the superior sagittal sinus and other venous structures. Multiple villi are aggregated in these locations to form the pacchionian granulations or bodies, some of them large enough to indent the inner table of the calvarium. These may increase in size with aging, and large ones (3.0 to 9.5 mm in diameter) may rarely herniate through bony defects and erode, providing a portal of entry to organisms from the ear that lead to meningitis (Samuels et al).

The arachnoid villi, most numerous on both sides of the superior sagittal sinus, are also present at the base of the brain and around the spinal cord roots and have been thought to act as functional valves that permit unidirectional “bulk flow” of CSF into the vascular lumen. However, electron microscope studies show that the arachnoid villi have a continuous membranous covering. This layer is extremely thin, and CSF passes through the villi at a linearly increasing rate as CSF pressures rise above 68 mm H₂O. This passive route is not the only manner in which CSF water and other contents are transported. Tripathi and Tripathi, in serial electron micrographs, found that the mesothelial cells of the arachnoid villus continually form giant cytoplasmic vacuoles that are capable of transcellular bulk transport. Certain substances, such as penicillin and organic acids and bases, are also absorbed by cells of the choroid plexus; the bidirectional action of these cells resembles that of the tubule cells of the kidneys. Some substances have been shown in pathologic specimens to pass between the ependymal cells of the ventricles and to enter subependymal capillaries and venules.

By infusing and withdrawing CSF under controlled circumstances, the resistance to CSF absorption and its rate of replacement can be calculated. The resistance to the passage of CSF into the venous system has been termed R_0 and can be expressed in terms similar to the Ohm law ($E = IR$): the voltage (E) reflects the difference in pressure between the CSF and the venous system

($P_{\text{CSF}} - P_v$), which drives CSF into the dural sinuses, and the equivalent of electrical current, termed I_f , represents the flow rate of CSF. In the steady state, this flow rate is equal to the rate of CSF production (0.3 mL/min). R_0 , the resistance to absorption, which under normal circumstances is approximately 2.5, rises when there is a blockage in the CSF circulation. The equation for CSF pressure can therefore be expressed as $P_{\text{CSF}} - P_v = I_f \times R_0$; when rearranged, $P_{\text{CSF}} = P_v + I_f \times R_0$. Because the product of $I_f \times R_0$ is only 0.8 mm Hg, it can be appreciated that the main contribution to CSF pressure—as measured by spinal puncture—is the venous pressure, P_v . Restated, the intracranial pressure and CSF pressure, which are in equilibrium, are derived predominantly from transmitted vascular pressures and not from CSF outflow resistance. However, in pathologic conditions such as bacterial meningitis and subarachnoid hemorrhage, R_0 may rise to levels that impede CSF circulation, raise pressure.

Cerebrospinal Fluid Volume and Pressure

In the recumbent position, ICP and, consequently, CSF pressure are normally about 8 mm Hg or 110 mm H₂O (1 mm Hg equals 13.7 mm H₂O), with an upper limit of normal that is higher in children than in adults according to Huh and colleagues. As the head and trunk are progressively elevated, the weight of the column of CSF is added incrementally to the pressure in the lumbar subarachnoid space, and the intracranial CSF pressure drops correspondingly, so that it is close to zero in the standing position. As described above, the CSF pressure is in equilibrium with the capillary and prevenous vascular pressures, which are influenced mainly by circulatory changes that alter arteriolar tone. Elevations in systemic arterial pressure cause little or no increase of pressure at the capillary level because of cerebrovascular autoregulation, and hence, little increase in CSF pressure. Extremely low blood pressure (BP), in the range of a mean of 40 mm Hg, however, cannot be compensated for and correspondingly, lower the CSF pressure (which is, of course, zero when the heart stops).

In contrast to the limited effect caused by changes in arterial BP, increased venous pressure exerts an almost immediate effect on CSF pressure by increasing the volume of blood in the cerebral veins, venules, and dural sinuses. If the jugular veins are compressed, there is a rise of ICP that is transmitted to the lumbar subarachnoid space (unless there is a spinal subarachnoid block). This was the basis of the now little used Queckenstedt test, mentioned in Chap. 2. In the case of a spinal block, pressure on the abdominal wall, which affects the spinal veins below the point of subarachnoid block, will still increase the lumbar CSF pressure. The Valsalva maneuver, as well as coughing, sneezing, and straining, causes an increased intrathoracic pressure, which is transmitted to the jugular and then to the cerebral and spinal veins and directly to the CSF compartment through the intervertebral foramina. The jugular venous valves prevent unimpeded transmission of pressure to the cranial veins but this threshold can be exceeded if central and jugular venous pressures become greatly elevated. Mediastinal

tumors, by obstructing the superior vena cava, have the same effect.

The inhalation or retention of CO_2 raises the blood PCO_2 and correspondingly decreases the pH of the CSF. By a mechanism that is not fully understood, this acidification of the CSF acts as a potent cerebral vasodilator, causing an increase in cerebral blood flow and blood volume, thus leading to intracranial hypertension. Hyperventilation, which reduces PCO_2 , has the opposite effect; it increases the pH and the cerebral vascular resistance and thereby decreases CSF pressure; this maneuver of lowering the arterial CO_2 content by hyperventilation is used in the treatment of acutely raised ICP.

DISTURBANCES OF CEREBROSPINAL FLUID PRESSURE, VOLUME, AND CIRCULATION

Increased Intracranial Pressure

Physiologic Considerations

The intact cranium and vertebral canal, together with the relatively inelastic dura, form a rigid container, such that an increase in the volume of any of its contents—brain, blood, or CSF—will elevate the ICP. Furthermore, an increase in any one of these components must be at the expense of the other two, a relationship that is known as the Monro-Kellie doctrine. Small increments in brain volume do not immediately raise the ICP because of the countervailing buffering effect of displacement of CSF from the cranial cavity into the spinal canal. To a lesser extent, there is deformation of the brain and stretching of the infoldings of the relatively unyielding dura, specifically, the falx cerebri between the hemispheres and the tentorium between the hemispheres and cerebellum. Once these compensating measures have been exhausted, a mass within one dural compartment leads to displacement, or “herniation” of brain tissue from that compartment into an adjacent one. Any further increment in brain volume necessarily reduces the volume of intracranial blood contained in the veins and dural sinuses. Also, the CSF is formed more slowly in circumstances of raised ICP. These accommodative volume-pressure relationships occur concurrently and are subsumed under the term *intracranial elastance* (the change in ICP for a given change in intracranial volume, or its inverse, compliance). As the volume of brain, blood, or CSF continue to increase, the accommodative mechanisms fail and ICP rises exponentially, as in an idealized elastance curve. The normal curve begins its steep ascent at an ICP of approximately 25 mm Hg. After this point, small increments in intracranial volume result in marked elevations in ICP.

The numerical difference between ICP and mean BP within the cerebral vessels is termed *cerebral perfusion pressure* (CPP). Besides the aforementioned brain tissue shifts, which are discussed more fully in relation to their clinical signs in Chap. 17, elevation in ICP that approaches the level of mean systemic BP eventually

causes a widespread reduction in cerebral blood flow. In its most severe form, this results in global ischemia and produces brain death. Lesser degrees of raised ICP and reduced cerebral perfusion cause correspondingly less severe, but still widespread, cerebral infarction that is similar to what arises after cardiac arrest. In all circumstances, not only the severity but also the duration of reduced cerebral perfusion, are the main determinants of the degree of cerebral damage. These are theoretical models that guide practice but are often found to be imprecise in clinical circumstances.

Lundberg has been credited with recording and analyzing intraventricular pressures over long periods of time in patients with brain tumors. He found ICP to be subject to periodic spontaneous fluctuations, of which he described three types of pressure waves, designated as A, B, and C. Only the A waves have proved to be separable from arterial and respiratory pulsations and are of clinical consequence. They consist of rhythmic wave-like elevations of ICP, up to 50 mm Hg, occurring every 15 to 30 min and lasting about 1 min, or of smaller but more protracted elevations. These *plateau waves*, as they have come to be known, coincide with an increase in intracranial blood volume, presumably as a result of a temporary failure of cerebrovascular autoregulation. Rosner and Becker have observed that plateau waves are sometimes preceded by a brief period of mild systemic hypotension. In their view, this slight hypotension induces cerebral vasodilatation in order to maintain normal blood flow. Upon recovery of the BP, the response in cerebrovascular tone is delayed, thereby allowing intracranial blood volume to accumulate in the dilated vascular bed, and raising ICP in the form of a plateau wave. In support of this explanation is the observation that a brief period of induced elevation of BP paradoxically restores the normal cerebrovascular tone and leads to an abrupt cessation of a plateau wave.

The high rates of mortality and morbidity of acute cerebral mass lesions is in part related to uncontrolled elevation in ICP. In a normal adult reclining with the head and trunk elevated to 45 degrees, the ICP is in the range of 2 to 5 mm Hg. Levels above 15 mm Hg that are considered abnormal are not in themselves hazardous; in fact, adequate cerebral perfusion can be maintained at an ICP of 40 mm Hg provided BP remains normal. A higher ICP or a lower BP may combine to reduce CPP and cause diffuse ischemic damage.

Causes of Raised ICP

In clinical practice, there are several mechanisms for elevated ICP:

1. *A cerebral or extracerebral mass* such as brain tumor; cerebral infarction with edema; traumatic contusion; parenchymal, subdural, or extradural hematoma; or abscess, all of which tend to be localized and deform the adjacent brain. The brain deformation is greatest locally, being compartmentalized to a varying degree by dural partitions.
2. *Generalized brain swelling*, as occurs in ischemic-anoxic states, acute hepatic failure, hypertensive

encephalopathy, hypercarbia, and the Reye hepatocerebral syndrome. In these disorders, the increase in pressure can reduce cerebral perfusion, but tissue shifts are minimal because the mass effect is uniformly distributed throughout the cranial contents.

3. An *increase in venous pressure* because of cerebral venous sinus thrombosis, heart failure, or obstruction of the superior mediastinal or jugular veins.
4. *Obstruction to the flow and absorption of CSF.* If the obstruction is within the ventricles or in the subarachnoid space at the base of the brain, *hydrocephalus* results. Extensive meningeal disease from any number of causes (infectious, carcinomatous, granulomatous, hemorrhagic) is another mechanism of blockage to CSF flow. If the block is confined to the absorptive sites adjacent to the cerebral convexities and superior sagittal sinus, the ventricles remain normal in size or enlarge only slightly, because the pressure over the convexities approximates the pressure within the lateral ventricles (see further on).
5. Any *process that expands the volume of CSF* (meningitis, subarachnoid hemorrhage) or increases CSF production (choroid plexus tumor). In this situation, there may be a pressure gradient between the cerebral and spinal compartments, resulting in hydrocephalus.

Clinical Features of Raised ICP (See also Chap. 17)

The clinical manifestations of increased ICP in children and adults are headache, nausea and vomiting, drowsiness, ocular palsies, and papilledema. Papilledema may result in periodic visual obscurations; if it is protracted, optic atrophy and blindness may follow (see Chap. 13 for further discussion of papilledema and optic nerve atrophy). The practice of monitoring ICP with a pressure device inserted into the cranial cavity has permitted approximate correlations to be made between clinical signs and the levels of ICP. However, the main neurologic signs of a large intracranial mass, pupillary dilatation, abducens palsies, drowsiness, and the Cushing response, as discussed below and in Chaps. 17 and 35, are caused by displacement of brain tissue, and therefore do not bear a strict relationship to ICP.

As a rule, patients with normal BP retain normal mental alertness with ICP of 25 to 40 mm Hg unless there is concurrent shift of brain tissue. Stated another way, coma generally cannot be attributed to elevated ICP alone. Only when ICP exceeds 40 to 50 mm Hg does cerebral blood flow diminish to a degree that results in loss of consciousness. Any further elevations are followed imminently by global ischemia and brain death. From our own observations, the brain shift and herniation that causes the pupil to dilate on the side of a mass lesion generally occurs at an ICP of 28 to 34 mm Hg. (Again, this is not a direct effect of the elevated ICP.) There are instances in which the dissociation between ICP and clinical signs is striking, for example, a mass in the medial temporal lobe that is contiguous to the third nerve will compress the nerve at a time when pressure is little raised, and slowly growing lesions, which raise ICP slowly and allow for compensation cause few clinical signs. Likewise, unilateral

or bilateral abducens palsies do not have a uniform relationship to the degree of elevation of ICP. Rather, abducens palsies are most frequent when raised ICP is a result of diffusely distributed brain swelling, hydrocephalus, meningitic processes, or pseudotumor states.

The consequences of increased ICP take on special features in *infants and small children*, whose cranial sutures have not closed. The head enlarges and the eyes may bulge. Then the clinical problem involves differentiation from other types of enlargement of the head with or without hydrocephalus, such as constitutional macrocrania or an enlarged brain (megalencephaly; or hereditary metabolic diseases such as Krabbe disease, Alexander disease, Tay-Sachs disease, Canavan spongy degeneration of the brain), and from subdural hematoma or hygroma, neonatal ventricular hemorrhage, and various cysts and tumors.

Monitoring Intracranial Pressure

There is evidence, mainly from retrospective cohorts of patients with traumatic brain injury, that the outcome in patients with intracranial mass lesions is better if the ICP is maintained at levels well below those that compromise cerebral perfusion. An ICP below 15 or 20 mm Hg is often given as a therapeutic target, as the elastance curve becomes steep beyond this level and small increments in cerebral volume may cause large elevations in pressure. However, guiding treatment by the direct measurement of ICP has not yielded uniformly beneficial results, and—after several decades of popularity—the advantage of such devices over clinical and imaging signs of increasing mass effect, is not certain. Nonetheless, in a patient who cannot be examined because of induced paralysis or sedation, or who will be subjected to a procedure that risks further elevating ICP, monitoring seems sensible.

The problem in demonstrating an advantage to monitoring may partly be a matter of the level of ICP at which treatment is instituted and the proper selection of patients for treatment. Contributing to the decision to institute monitoring are the prospects of ameliorating the underlying lesion, the patient's age, and associated medical disease(s). Our practice has been to measure ICP with an indwelling fiberoptic monitor or intraventricular catheter in otherwise salvageable patients who are stuporous or comatose, and in whom a traumatic or other intracranial mass has caused either a shift of intracranial structures or severe generalized brain swelling. Published guidelines suggest that monitoring should be undertaken in patients with severe traumatic brain injury if they are over 40 years of age, and have a Glasgow Coma Score below 9 (see Chap 35). The monitor is generally placed on the same side as a mass lesion. Whether recent studies, such as the one by Chesnut and colleagues comparing monitoring to clinical and imaging in directing therapy, negate these guidelines is also uncertain.

The emergency management of raised ICP is considered in greater detail in Chaps. 34 and 35 where the subject is discussed in relation to stroke and cerebral trauma. A comprehensive review can be found in the monograph on intensive care (Ropper) listed in the references.

Hydrocephalus

This is a condition of ventricular enlargement as a result of an obstruction to the normal flow of CSF. The sites of obstruction may be at the third ventricle, aqueduct of Sylvius, at the medullary foramina (Luschka and Magendie), or in the basal or convexity subarachnoid spaces. Because of the obstruction, CSF accumulates within the ventricles under increasing pressure, enlarging the ventricles, and expanding the hemispheres. As stated earlier, in the infant or young child, the head increases in size because the expanding cerebral hemispheres separate the sutures of the cranial bones.

Regarding terminology, the term *hydrocephalus* (literally, "water brain") is frequently but incorrectly applied to any enlargement of the ventricles, even if consequent to cerebral atrophy, i.e., *hydrocephalus ex vacuo*, or to ventricular enlargement because of failure of development of the brain, a state known as *colpocephaly*. Reference to these conditions as hydrocephalic is so common that it is unlikely to change; the use of "tension hydrocephalus," although not widely adopted, separates enlargement caused by pressure from passive enlargement of the ventricles.

In 1914, Dandy and Blackfan introduced the also somewhat inaccurate but now well-established terms *communicating* and *noncommunicating (obstructive) hydrocephalus*. The concept of communicating hydrocephalus was based on the observations that dye injected into a lateral ventricle would diffuse readily downward into the lumbar subarachnoid space and that air injected into the lumbar subarachnoid space would pass into the ventricular system; in other words, the ventricles were in communication with the spinal subarachnoid space. If the lumbar spinal fluid remained colorless after the injection of dye, the hydrocephalus was assumed to be obstructive, or noncommunicating. In actuality, the distinction between these two types is not fundamental, because all forms of true hydrocephalus are obstructive at some level, and the obstruction is virtually never complete.

Pathogenesis of Hydrocephalus

There are several sites of predilection of obstruction to the flow of CSF. One foramen of Monro may be blocked by a tumor or by horizontal displacement of central brain structures from a large cerebral mass. This obstruction may cause expansion of the lateral ventricle or a portion of it. Tumors within the third ventricle (e.g., colloid cyst) block the egress of CSF from both foramina of Monro, leading to dilatation of both lateral ventricles. The aqueduct of Sylvius, narrow to begin with, may be occluded by a number of developmental or acquired lesions (genetically determined atresia or forking, perinatally acquired gliosis, ependymitis, hemorrhage, tumor), and lead to dilatation of the third and both lateral ventricles. If the obstruction is in the fourth ventricle, the dilatation includes the aqueduct. Other sites of obstruction of the CSF in the ventricular pathways are at the foramina of Luschka and Magendie (e.g., congenital failure of opening of the foramina, Dandy-Walker syndrome). More common is a blockage to flow of CSF in the subarachnoid

space around the brainstem caused by inflammatory or fibrosing meningitis. This form of obstruction results in enlargement of the entire ventricular system, including the fourth ventricle. A useful adage, attributed to Ayer, is that the ventricle closest to the obstruction enlarges the most; meaning, for example, that occlusion of the basal CSF pathways causes a disproportionate enlargement of the fourth ventricle, and a mass within the fourth ventricle leads to a greater dilatation of the third than of the lateral ventricles.

Another potential site of obstruction is in the subarachnoid spaces over the cerebral convexities. A matter of considerable practical as well as theoretical interest is whether a meningeal obstruction at the site of the arachnoid villi, or a blockage of the venous sinuses into which the CSF is absorbed, can result in hydrocephalus. Russell, in her extensive neuropathologic material and review of the world's literature, could not find a well-documented example of either of these suggested etiologies, and the same is true of the pathologic material collected by our colleague R.D. Adams. Moreover, experiments in animals in which all the draining veins had been occluded, tension hydrocephalus with enlarging lateral ventricles was produced in only a few cases. Yet Gilles and Davidson have stated that hydrocephalus in children may be the result of a congenital absence, or deficient number of arachnoid villi, and Rosman and Shands have reported an instance that they attributed to increased intracranial venous pressure. Our hesitation in accepting such examples stems from the difficulty that the pathologist has in judging the patency of the basilar subarachnoid space. This is much more reliably visualized by radiologic than by neuropathologic means. Theoretically, as mentioned earlier, if the obstruction is high, near (or in) the superior sagittal sinus, the CSF should accumulate under pressure outside as well as inside the brain, and the ventricles should not enlarge at all or only slightly, and only after a prolonged period.

The rarely encountered radiologic picture of enlarged subarachnoid spaces over and between the cerebral hemispheres, coupled with modest enlargement of the lateral ventricles has been referred to as *external hydrocephalus*. Although such a condition does exist, many of the cases so designated have proved to be examples of subdural hygromas or arachnoid cysts. The condition is now seen somewhat more regularly after surgical hemispherectomy if the bone is not replaced.

Processes such as subarachnoid hemorrhage, or cerebral hemorrhage or brain abscess that rupture into the ventricles and rapidly expand the volume of CSF produce the most dramatic forms of *acute hydrocephalus*. The obstruction of the CSF pathways may also be found within the ventricular system or at the basal meninges. The corresponding clinical syndrome is described below.

An increase in the rate of formation or decrease in the rate of absorption would be expected to cause an accumulation of CSF and increased ICP. The only reported examples of overproduction of CSF are papillomas of the choroid plexus, but even in this circumstance, there is usually an associated ventricular obstruction, either of the third or fourth ventricle or of one lateral ventricle.

Characteristically in these cases, there is both a generalized dilatation of the ventricular system and basal cisterns (possibly because of increased CSF volume), and an asymmetrical enlargement of the lateral ventricles caused by obstruction of one foramen of Monro.

Syndromes of Hydrocephalus

This process gives rise to various syndromes depending on the age of the patient and the rapidity of evolution. One type occurs very early in life, before fusion of the cranial sutures and causes enlargement of the head. If the cranial sutures have fused, the head remains normal in size and the ventricular enlargement may remain asymptomatic or cause gait, urinary and cognitive difficulties. A special form of the latter is arrested or compensated hydrocephalus of late adult life that is one of the causes of *normal-pressure hydrocephalus* that is addressed in Chap. 7 and extensively below.

Congenital or Infantile Hydrocephalus The cranial bones fuse by the end of the third year; for the head to enlarge, the tension hydrocephalus must develop before this time. It may begin in utero, but usually happens in the first few months of life. Even up to 5 years of age (and very rarely beyond this time), a marked increase of ICP, particularly if it evolves rapidly, may separate the newly formed sutures (diastasis). Tension hydrocephalus, even of mild degree, also molds the shape of the skull in early life, and in radiographs, the inner table is unevenly thinned, an appearance referred to as “beaten silver”, or as convolutional or digital markings. The frontal skull regions are unusually prominent (bossed) and the skull tends to be brachiocephalic, except in the Dandy-Walker syndrome where, because of bossing of the occiput from enlargement of the posterior fossa, the head is dolichocephalic. With marked enlargement of the skull, the face looks relatively small and pinched, and the skin over the cranial bones is tight and thin, revealing prominent distended veins.

The usual causes of this disorder are (1) intraventricular matrix hemorrhages in premature infants, (2) fetal and neonatal infections, (3) type II Chiari malformation, (4) aqueductal atresia and stenosis, and (5) the Dandy-Walker syndrome.

In congenital hydrocephalus, the head usually enlarges rapidly and soon surpasses the ninety-seventh percentile. The anterior and posterior fontanels are tense even when the patient is in the upright position. The infant is fretful, feeds poorly, and may vomit frequently. With continued enlargement of the brain, torpor sets in and the infant appears languid, uninterested in his surroundings, and unable to sustain activity. Later it is noticed that the upper eyelids are retracted, and the eyes tend to turn down; there is paralysis of upward gaze, and the sclerae above the irises are visible. This is the “setting-sun sign” that has been incorrectly attributed to downward pressure of the frontal lobes on the roofs of the orbits. The fact that it disappears on shunting the lateral and third ventricles indicates that it is caused by hydrocephalic pressure on the mesencephalic tegmentum. Gradually, if left untreated, the infant adopts a posture of flexed arms and flexed or extended

legs. Signs of corticospinal tract damage are usually elicitable. Movements are feeble, and sometimes the arms are tremulous. There is no papilledema, but later the optic discs become pale and vision is reduced.

If the hydrocephalus becomes arrested, the infant or child is usually developmentally delayed in motor function but often surprisingly verbal. The head may be so large that the child cannot hold it up and must remain in bed. If the head is only moderately enlarged, the child may be able to sit but not stand, or stand but not walk. If ambulatory, the child is clumsy. Acute exacerbations of hydrocephalus or a febrile illness may cause vomiting, stupor, or coma.

The special features of congenital hydrocephalus associated with the Chiari malformation, aqueductal atresia and stenosis, and the Dandy-Walker syndrome are discussed in Chap. 38. Also mentioned here is a rare condition termed “bobble head” syndrome that is caused by a suprachiasmatic arachnoid cyst or by third ventricular enlargement, as discussed in Chap. 31. These lesions cause the child’s head to move forward and backward or side-to-side constantly or intermittently at about 2 to 3 Hz. There is no direct connection to another rhythmic head movement, spasmus nutans (listed in some books as “mutans”), or to seesaw nystagmus described in Chap. 14, but the location of the causative lesions, in and adjacent to the third ventricle, is similar in all of them.

Occult Childhood Hydrocephalus Here, the ventricular enlargement becomes evident only after the cranial sutures have closed (Fig. 30-2). The causes of obstruction to the flow of CSF are diverse, and although some are clearly congenital, symptoms may be delayed as late

Figure 30-2. MRI of adult tension hydrocephalus from a congenital stenosis of the cerebral aqueduct. There is transependymal movement of water that appears as a T2 signal rimming the lateral ventricles. The third ventricle, but not the fourth, was enlarged.

as adolescence, or early adult life, or even later. In some instances, the condition gives rise to *normal-pressure hydrocephalus*, as discussed below and in Chap. 7. The clinical features of occult hydrocephalus and the course of the illness are quite variable. We have seen a few cases in adults in whom the gait disturbance from congenital aqueductal stenosis appeared abruptly enough to give the impression of a cerebellar or frontal stroke. For unexplained reasons, the symptoms of previously occult hydrocephalus may also appear abruptly after minor cranial trauma. A suck reflex and grasp reflexes of the hands and feet are variably present; plantar reflexes are sometimes extensor. Last, there may be urinary urgency leading to sphincteric incontinence, often without the patient's awareness.

Chapter 31 discusses occult hydrocephalus caused by intracranial tumor growth.

Acute Hydrocephalus Surprisingly, little has been written about this syndrome despite its frequency in clinical practice. It is seen most often following subarachnoid hemorrhage from a ruptured aneurysm, less often with bleeding from an arteriovenous malformation or from deep intracerebral hemorrhage that dissects into the ventricles; it may also occur as the result of obstruction of the CSF pathways in the fourth ventricle by a tumor or cerebellar–brainstem hemorrhage, or within the basal cisterns by neoplastic infiltration of the meninges, although this last process tends to evolve more subacutely. The patient complains of a headache of varying severity and often of visual obscuration, may vomit, and then becomes drowsy or stuporous over a period of minutes or hours. Bilateral Babinski signs are the rule, and in the advanced stages, which are associated with coma, there is increased tone in the lower limbs and extensor posturing. Early in the process, the pupils are normal in size and the eyes may rove horizontally; as the ventricles continue to enlarge, the pupils become miotic, the eyes then cease roving and assume an aligned position, or there may be bilateral abducens palsies and limitation of upward gaze. The speed with which hydrocephalus develops determines whether there is accompanying papilledema.

If this condition is left untreated, the pupils eventually dilate symmetrically, the eyes no longer respond to oculocephalic maneuvers, and the limbs become flaccid. Or, there is an unanticipated cardiac or respiratory arrest, even at an early stage of evolution of the hydrocephalus; this complication is seen particularly in children with masses, particularly at the foramen magnum, and may be presaged by brain compression at the level of the perimesencephalic cisterns, detectable by imaging studies.

Treatment is by drainage of CSF, usually effected by a ventricular catheter or, if there is undoubted communication between all the CSF compartments, by lumbar puncture. The latter may pose some risk if spinal fluid is withdrawn rapidly or there is a sizeable leak of fluid through the spinal dura at the site of the puncture, thereby creating a pressure gradient between the cerebral and spinal regions.

Neuropathologic Effects of Hydrocephalus

Ventricular expansion tends to be maximal in the frontal horns, explaining the hydrocephalic impairment of

frontal lobe functions and of basal ganglionic–frontal motor and gait activity in most forms of hydrocephalus. The central white matter yields to pressure, while the cortical gray matter, thalami, basal ganglia, and brainstem structures remain relatively unaffected. There is an increase in the content of interstitial fluid in the tissue adjacent to the lateral ventricles (transependymal flow), readily detected by MRI (see Fig. 30-2). Myelinated fibers and axons are injured, but not to the extent that one might expect from the degree of compression; minor degrees of astrocytic gliosis and loss of oligodendrocytes in the affected tissue are present to a decreasing extent away from the ventricles and represent a chronic hydrocephalic atrophy of the brain. The ventricles are characteristically denuded of ependyma, and the choroid plexuses are flattened and fibrotic. The lumens of cerebral capillaries in biopsy preparations are said to be narrowed—a finding that is difficult to evaluate.

NORMAL-PRESSURE HYDROCEPHALUS

In meningeal and ependymal diseases, hydrocephalus may develop and reach a stable state. It is then said to be “compensated” in the sense that formation of CSF equilibrates with absorption. Once equilibrium is attained, the ICP gradually falls, though it still maintains a gradient from ventricle to basal cistern to cerebral subarachnoid space. A stage is reached where the CSF pressure reaches a high normal level of 150 to 200 mm H₂O, but the patient nonetheless eventually manifests the cerebral effects of the hydrocephalic state. The name given to this condition by Adams, Fisher, and Hakim was *normal-pressure hydrocephalus* (NPH).

A *triad of clinical findings* is characteristic of NPH: a slowly progressive gait disorder is usually the earliest feature, followed by impairment of mental function and later, sphincteric incontinence. The reader should be alerted to the fact that the fully developed triad is not usually present in the early stages of the process. Grasp reflexes in the feet and falling attacks may also occur, but there are no Babinski signs. Headaches are infrequently a complaint, and there is no papilledema.

The *gait disturbance* that accompanies NPH may be of several different types, as discussed in Chap. 7. These are difficult to classify and only vaguely simulate the patterns observed in Parkinson disease or cerebellar ataxia, but certain features predominate. Most often, there is unsteadiness and impairment of balance and shortening of the step length, with the greatest difficulty being encountered on stairs and curbs (Fisher). Weakness and tiredness of the legs are frequent complaints, although examination discloses no paresis or ataxia. An impression of Parkinson disease may be conveyed, with short steps and slightly stooped, forward-leaning posture, but there is typically no shuffling early on, nor is there festination, rigidity, slowness of alternating movement, or tremor. Some patients present with unexplained falls, often helplessly backward, but on casual inspection the gait may betray little abnormality except a minimal reduction in step length and overall slowness. When the condition

remains untreated, the steps become shorter, with more frequent shuffling and falls; eventually standing and sitting and even turning over in bed become impossible. Fisher referred to this advanced state as “hydrocephalic astasia-abasia.”

The mental changes in the cases we have encountered have been, broadly speaking, “frontal” in character and embodied mainly apathy, dullness in thinking and actions, and slight inattention. Memory trouble is eventually a component of the overall problem and has been predominant in some cases, for which reason the diagnosis of Alzheimer disease is sometimes considered before the discovery of hydrocephalus, but as a rule, the gait derangement of NPH is fairly obvious by the time memory function is substantially impaired. There is usually a degree of affective indifference, but the patient reports little in the way of emotionality. Patients who display gait difficulty with prominent and progressive verbal, graphical, and calculation difficulties are more likely to have a degenerative or cerebrovascular disease. In those cases, the difficulty with walking and stability is ostensibly a result of frontal lobe disease, either degenerative or infarctive, as discussed in Chap. 7. Unfortunately, beyond the above-noted defects that are elicitable by routine testing, we have not found neuropsychologic tests of great value in the diagnosis of NPH.

Urinary symptoms appear relatively later in the illness. Initially, they consist of urinary urgency and frequency. Later, the urgency is associated with incontinence, and ultimately there is “frontal lobe incontinence,” in which the patient is indifferent to his lapses of continence, and bowel control becomes similarly disordered.

The cause of the syndrome of NPH in most cases cannot be established and on weak grounds, an asymptomatic fibrosing meningitis is presumed to have been present. An uncertain proportion of cases can be traced to congenital aqueductal stenosis that has allowed normal brain function into adulthood and, for unknown reasons, decompensates; a few of our patients have become symptomatic after mild head trauma. This is probably the most common imputed cause of the syndrome but again, on uncertain grounds. An identical syndrome may follow subarachnoid hemorrhage from ruptured aneurysm, resolved acute meningitis or a chronic meningitis (tubercular, fungal, syphilitic, or other), Paget disease of the base of the skull, mucopolysaccharidosis of the meninges, and achondroplasia.

That the mechanical effect of ventricular enlargement on the adjacent brain is responsible for the syndrome is supported by Fisher’s observations that a reduction in ventricular size caused by extrinsic compression from subdural collections has been associated with clinical improvement. One presumes that the main clinical features are due to dysfunction of the frontal lobes and their connections with the striatum, from mechanical pressure or distortion but this is conjecture.

Diagnosis of NPH

Verification of the diagnosis of NPH, and the selection of patients for ventriculoatrial or ventriculoperitoneal shunt has presented difficulties. The CT scan, as shown in Fig. 30-3, displays enlarged ventricles without convolutional atrophy. This disproportionate enlargement of the ventricular system in comparison to the degree

Figure 30-3. CT of a patient with normal-pressure hydrocephalus. There is enlargement of all the ventricles, particularly of the frontal horns of the lateral ventricles (*left*), which is roughly disproportionate to the cortical atrophy (*right*). The frontal horn span is over 40 mm. Various formulas have been devised to quantitate the imaging features, but they are difficult to apply.

of cortical atrophy is judged by the CT and MRI appearance, but there is no broadly agreed upon method for its determination. Various unwieldy formulas have been designed to assess this ratio. As a group, patients who have a sustained response to drainage of CSF by shunting, as described below, have had the first two elements of the clinical triad (fewer than half of our successfully treated patients have reached the point of incontinence) and their lateral ventricular span at the level of the anterior horns has been in excess of approximately 40 mm (a true dimension calculated from CT or MRI scans). MRI may show some degree of transependymal egress of water surrounding the ventricles, but this is not usually the case, and this sign is sometimes difficult to differentiate from the periventricular white matter change that is ubiquitous in the elderly. There may be an indication of inadequate pulsatile flow of CSF through the aqueduct as appreciated on T-2-weighted MRI.

A lumbar puncture is often performed for diagnostic purposes and the pressure measured carefully but here too, there is no uniformly agreed upon approach. In most cases of NPH, the CSF pressure is above 150 mm H₂O with the patient fully relaxed, but the disorder has occurred, at least as judged by improvement with shunting, with lower pressures, in a few instances as low as 120 mm H₂O. Drainage of large amounts of CSF (20 to 30 mL or more) by lumbar puncture often results in clinical improvement in stance and gait for a few days, usually with a delay of hours or a day so the patient and family must be depended upon to report these changes and these reports are prone to excessive optimism. Objective improvement in gait after spinal drainage, measured by reduced time to walk a predetermined distance, is one way to select patients for shunt operations when the clinical picture is not entirely clear, but the even this test is not infallible. Several small series suggest that a negative test does not preclude benefit from shunting (see, e.g., Walchenbach et al). However, in these same series, improvement after removal of CSF has had a high predictive value for success of shunting.

When there has been doubt as to the effects of lumbar puncture, one appropriate course is to admit the patient to the hospital, and insert a lumbar drain for up to 3 d, removing approximately 50 mL of CSF daily in order to observe the response in gait and mentation. It is worthwhile to quantify the speed and facility of gait two or three times before the lumbar puncture or drainage and to perform this testing at periodic intervals for several days after the procedure in order to be certain that improvement is genuine. Even more persuasive is a definite improvement followed days later by worsening of gait.

Monitoring of CSF pressure over a day or more may show intermittent rises of pressure, possibly corresponding to the A waves of Lundberg, but this undertaking is not generally practical and is now done by only a few centers. According to Katzman and Hussey, the infusion of normal saline into the lumbar subarachnoid space at a rate of 0.76 mL/min in NPH provokes a rise in pressure to greater than 300 mm H₂O that is not observed in normal individuals. Theoretically, this test or any of its derivatives, such as the one proposed by Børgesen

and Gjerris, should reflect the adequacy of CSF absorption, but they too, have yielded unpredictable results. Radionuclide cisternography had been used in the past to demonstrate persistence of CSF labeling in the ventricles, but it is no longer considered a compelling test for NPH.

Treatment of NPH in Adults

The development of ventricular shunt tubing with one-way valves opened the way to successful treatment of hydrocephalus. CSF is diverted directly into the peritoneal cavity (ventriculoperitoneal shunt), of less often, a ventriculatrial or ventriculopleural shunt is used. The valve can be selected for a desired fixed opening pressure, or a variable valve can be inserted and adjustments can be made by an external magnetic device. Gratifying success can be obtained, often a complete or nearly complete restoration of mental function and gait after several weeks or months, by the placement of a shunt.

The most consistent improvement has been attained in the minority of patients in whom a cause could be established (subarachnoid hemorrhage, chronic meningitis, or tumor of the third ventricle). As already noted, other predictors of success are considerable enlargement of the ventricles in comparison to the degree of cortical atrophy, CSF pressures above 150 mm H₂O, and improvement after spinal puncture, but none of these is entirely dependable.

Deviations from the characteristic syndrome such as the occurrence of dementia without gait disorder or the presence of apraxias, aphasias, and other focal cerebral signs are associated with poorer outcomes after shunting. Fisher, on analyzing successfully shunted cases, noted that almost without exception gait disturbance was an early and prominent symptom. Uncertainties of diagnosis increase with advancing age owing to the frequent association of degenerative dementia and vascular lesions. However, in Fisher's experience, age alone did not exclude NPH as a cause of gait disorder, and long duration of gait symptoms did not preclude a salutary outcome from shunting. In patients who are averse to the shunting procedure or who have medical conditions that make the surgery inadvisable, it is sometimes possible to produce a reasonable improvement in gait by repeating the spinal puncture and drainage of large amounts of fluid every few weeks or months.

The potential failure of shunting must be anticipated in patients whose clinical features do not conform to the typical syndrome or whose disease has advanced to the stage of long-standing incontinence or dementia. In some instances, a lack of improvement, or marked improvement followed by subacute deterioration, is explained by inadequate decompression, which justifies a revision of the shunt or downward adjustment of a variable pressure valve. Overdrainage causes headaches that may be chronic or orthostatic and may be associated with small subdural collections of fluid. These fluid collections, or hygromas, consisting of CSF and proteinaceous fluid derived from blood products, are generally innocuous and do not require drainage unless they enlarge or cause focal neurologic symptoms or, rarely, seizures.

Although shunting is relatively simple as a surgical procedure, it is associated with complications, the main

ones being a postoperative subdural hematoma (the bridging dural veins stretch and rupture but the procedure has been performed safely in patients who must take anticoagulants after shunting); infection of the valve and catheter, sometimes with ventriculitis and occasionally bacteremia; occlusion of the tip of the catheter in the ventricle; and, particularly in infants and children, the “slit ventricle syndrome” (see below). Orthostatic headaches can be overcome by raising the opening pressure of the shunt valve. Misplacement of the catheter may rarely transect tracts in the deep hemispherical white matter and cause serious neurologic deficits, mainly hemiplegia. It is our impression that this occurs more often when the catheter is inserted from the posterior rather than through the frontal or parietal regions. The incidence of catheter blockage is reduced by placing it in the anterior horn of the ventricle (usually the right side is used), where there is no choroid plexus. Meticulous aseptic technique, and the preoperative and postoperative administration of antibiotics have apparently reduced the incidence of shunt infections. Most shunts in adults are brought to termination in the peritoneum (ventriculoperitoneal shunt). Perforation of the stomach or bowel is possible. Rare complications of ventriculoatrial shunting are pulmonary hypertension and pulmonary embolism and nephritis, which are caused by low-level infection of the shunt tube with *Staphylococcus*.

Puncture of the floor of the third ventricle by endoscopic techniques (“third ventriculostomy”) has been explored as an alternative to shunting, especially in children with congenital aqueductal stenosis. Cinalli and colleagues have suggested, and we concur based on experience with a limited number of our own adult patients, that third ventriculostomy is sometimes an effective treatment of shunt failure.

Once the CSF is shunted, the ventricles diminish in size within a week or two, even when the hydrocephalus has been present for a year or more. This indicates that hydrocephalic compression of the cerebrum is at least partly reversible. Indeed, in Black’s series, the ventricles failed to return to normal in only 1 of his 11 shunted patients, and in that patient, there was no clinical improvement. Clinical improvement occurs within a few weeks, the gait disturbance being slower to reverse than the mental disorder. Symptoms of cerebral atrophy because of Alzheimer disease and related conditions are not altered by shunting, but this approach to the treatment of degenerative dementia has been periodically, and unadvisedly, resurrected, as discussed by Silverberg and associates.

Treatment of Infantile and Childhood Hydrocephalus

Here one encounters more difficulties than in the treatment of the adult disorder. The ventricular catheter may wander or become obstructed and require revision. Peritoneal pseudocysts may form (most shunts in children are ventriculoperitoneal). Another unexpected complication has been collapse of the ventricles, the so-called “slit ventricle” syndrome (the appearance of the ventricles on imaging studies is slit-like). This occurs more frequently in young children, although we have observed it in adults. These patients develop an

intracranial low-pressure syndrome with severe generalized headaches, often with nausea and vomiting, whenever they sit up or stand. Some children become ataxic, irritable, or obtunded, or may vomit repeatedly. The CSF pressure is extremely low and the volume of CSF much reduced. In babies, the cranium may fail to grow even though the brain is of normal size. In most shunted patients with slit ventricle syndrome, the ICP in the upright position is diminished to 30 mm H₂O. To correct the condition, one would imagine that replacing the shunt valve with another that opens under a higher pressure or raising the opening pressure of an adjustable valve would suffice. Indeed, this may be successful. But once the condition is established, the most effective measure has been the placement of an antisiphon device, which prevents valve flow when the patient stands. (See further on for a discussion of intracranial hypotension in adults.)

Whether to shunt all hydrocephalic infants soon after birth is a controversial issue. In several series of cases that have been treated in this way, the number surviving with normal mental function has been small (see review of Leech and Brumback). The report of Dennis and associates is representative. They examined 78 shunted hydrocephalic children and found that 56 (72 percent) had full-scale IQs between 70 and 100; in 22 patients, the IQ was between 100 and 115; in 3 patients, it was below 70, and in 3 others, it was above 115. Mental functions improved unevenly and performance scores lagged behind verbal ones at all levels.

The use of the carbonic anhydrase inhibitor acetazolamide or other diuretics to inhibit CSF formation in children with hydrocephalus has not been successful in the hands of our colleagues, but several authors believe that by giving 250 to 500 mg of acetazolamide orally daily, shunting can be avoided in both adult normal-pressure, and infantile hydrocephalus (Aimard et al; Shinnar et al).

Parkinsonism and Midbrain Syndromes With Hydrocephalus and Shunting

Usually in the context of adult hydrocephalus due to aqueductal stenosis, a rare but distinct parkinsonian syndrome occurs that may be responsive to levodopa (Zeidler). It is particularly prone to occur if there is shunted hydrocephalus and has also been a craniotomy without replacement of the bone. The syndrome usually indicates failure of the shunt. MRI sometimes shows periaqueductal and dorsal midbrain edema, including in the region of the substantia nigra (Fig. 30-4); the mechanism of these changes is not clear. Positron emission tomography performed with ¹⁸F-DOPA has given evidence of reduced uptake in the caudate and putamen, suggesting a functional failure of the nigrostriatal dopamine system (Racette). Shunt malfunction in children also may be heralded by upward gaze palsy (“setting-sun sign”) or even a dorsal midbrain (Parinaud) syndrome, including abnormal papillary reaction, upper lid retraction, paralysis of convergence, skew deviation, and convergence-retraction nystagmus. Shunting or shunt revision usually leads to reversal of both syndromes, but there may be a delay of days or weeks, and it is often difficult to find the ideal pressure setting for the valve.

Figure 30-4. Fluid-attenuated inversion recovery (FLAIR) MRI sequence in a woman with hydrocephalus, shunt failure, and L-dopa-responsive parkinsonism. There is signal change in the dorsal midbrain and periaqueductal region.

INCREASED INTRACRANIAL PRESSURE DUE TO CEREBRAL VENOUS OBSTRUCTION

Occlusion of the major dural venous sinuses (superior longitudinal and lateral) results in increased ICP. This is not surprising in view of the direct effect of venous obstruction on CSF pressure. One such form, caused by lateral sinus thrombosis, was referred to by Symonds as “otitic hydrocephalus,” a name that he later conceded was inaccurate insofar as the ventricles are not enlarged in this circumstance. Venous congestion that complicates heart failure and superior mediastinal obstruction also raise the CSF pressure, again without enlargement of the ventricles. This may happen as well with large, high-flow arteriovenous malformations of the brain. The effects of cerebral venous occlusion are considered further in the discussion of pseudotumor cerebri (below) and in Chap. 34 in the context of thrombosis of the cerebral venous sinuses. The role of compression of the large venous channels in cases of raised ICP from a mass has not been fully explored, but it may explain some of the intractable aspects of these cases.

PSEUDOTUMOR CEREBRI

This term was coined by Nonne in 1914 and has remained a useful means of designating a syndrome of headache,

papilledema (unilateral or bilateral), minimal or absent focal neurologic signs, and normal CSF composition, all occurring in the absence of enlarged ventricles, or an intracranial mass on CT scanning, or MRI. Being a syndrome and not a disease, pseudotumor cerebri has a number of causes or pathogenetic associations. However, the most common form of the syndrome has no firmly established cause, i.e., it is idiopathic, and is generally referred to as *idiopathic intracranial hypertension*.

This syndrome was first described in 1897 by Quincke, who called it “serous meningitis.” It is particularly frequent in overweight adolescent girls and young women, attaining an incidence of 19 to 21 per 100,000 in this group, as compared with 1 to 2 per 100,000 in the general population (Radhakrishnan et al). The features of increased ICP develop over a period of weeks or months. Relatively unremitting but fluctuating headache, described as dull or a feeling of pressure, is the cardinal symptom; it can be mainly occipital, generalized, or somewhat asymmetrical. Other, less-frequent complaints are blurred vision, a vague dizziness, minimal horizontal diplopia, transient visual obscurations that often coincide with the peak intensity of the headache, shoulder and neck pains, or a trifling numbness of the face on one side. Rarely, the presenting feature may be a nasal CSF leak, as pointed out by Clarke and colleagues. Self-audible bruits have been reported by some patients; this has been attributed to turbulence created by differences in pressure between the cranial and jugular veins.

The patient is then discovered to have flagrant papilledema (see Figs. 13-9 and 13-10), immediately raising the specter of a brain tumor. Rarely, papilledema is only minimally developed or absent or, conversely, papilledema alone, without headache, is the only manifestation of the disease. The risk of visual loss, and the severity of headache make the formerly used term *benign intracranial hypertension* less appropriate.

The CSF pressure is found to be elevated by lumbar puncture, usually in the range of 250 to 450 mm H₂O, but it is not clear whether the brain itself is swollen or, as is more likely, the increased pressure is the result of a change in the pressure within the CSF and venous compartments. When the CSF pressure is monitored for many hours, there are fluctuations taking the form of irregularly occurring plateau waves of increased pressure lasting 20 to 30 min, and then falling abruptly near to normal (Johnston and Paterson).

Aside from papilledema, there is remarkably little to be found on neurologic examination, perhaps slight unilateral or bilateral abducens palsy, fine nystagmus on far lateral gaze, or minor sensory change on the face or trunk. Visual field testing usually shows minor peripheral constriction with enlargement of the blind spots. As the process continues, more severe constriction of the fields, with greater nasal or inferior nasal loss, is found, often invident to the patient. These issues are elaborated below. Enlargement of the blind spot is the result of displacement of the retina from the edges of the swollen disc. Central acuity is spared initially and the patient, in advanced cases, is left with an island of preserved central vision. These patients are at particular risk of visual

loss. A study of 66 men with pseudotumor (9 percent of a larger cohort) by Bruce and colleagues suggested that there is a higher risk of vision loss than in women. Profound disc edema, significant early visual loss and perhaps being of African-American descent are other risks for visual loss.

Exceptionally, particularly in children, an otherwise typical Bell's palsy may occur (Chutorian et al). Mentation and alertness are preserved, and the patient seems surprisingly well aside from the headaches, which infrequently become severe enough to limit daily activity.

Examinations by CT and MRI show the ventricles to be normal in size or small. The sella may be enlarged and filled with CSF ("empty sella," Chap. 31), the posterior globes may be compressed and the perioptic subarachnoid spaces, expanded. Variable attenuation of the transverse sinuses has also been pointed out (see Friedman and colleagues). These are helpful but not indispensable features of the syndrome. There is no MRI evidence of change in the density of the brain, but edema may be seen in the optic nerves.

As remarked above, most affected patients are overweight young women of short stature, often with menstrual irregularities, but the condition also occurs in children or adolescents, in whom there is no clear sex predominance, and in men (Digre and Corbett). We have had experience with several familial instances, e.g., affecting mother and daughter. In obese women without the pseudotumor syndrome, CSF pressure usually does not differ from that of normal individuals (Corbett and Mehta).

Several endocrine and menstrual abnormalities (particularly amenorrhea), as well as the use of oral contraceptives, have been postulated as causative factors, but none has been substantiated. Cases have been reported during pregnancy, both those who have symptoms for the first time during pregnancy and a larger group with ongoing pseudotumor who become pregnant. Despite the theoretical appeal of relating the endocrine and other changes of pregnancy to the increased ICP, no suitable connection has been found, and there is no evidence that premature delivery or termination of the pregnancy ameliorates the pseudotumor. Nonetheless, our obstetric colleagues have often recommended delivery when safe for the fetus if the mother's vision is threatened. Most of the standard medical treatments detailed below have been used with some benefit during pregnancy, as in the series reported by Huna-Baron and Kupersmith.

Pathophysiology

The mechanism of increased CSF pressure in the idiopathic form of the disorder has remained elusive, but some recent experience suggests that, in at least some cases, there is a functional obstruction to outflow in the venous sinuses. Karahalios and colleagues and others have found the cerebral venous pressure to be consistently elevated in pseudotumor cerebri; in half of their patients, there was a venous outflow obstruction demonstrated by venography, often with a pressure gradient across the site. These authors have proposed that venous hypertension increases the resistance to CSF absorption and is the proximate mechanism underlying pseudotumor.

Similarly, Farb and colleagues, using sophisticated MRI venography, found venous stenosis in 27 of 29 patients with pseudotumor (and in 4 of 59 control subjects). In both studies and in others like them, the nature of the obstruction was not clear, but the fact that in some series, it was bilateral and focal suggests that the stenosis was not simply the passive result of raised ICP. This issue is not yet resolved, as noted below.

A related finding in some cases, pointed out to us some time ago by Fishman, is one of partial obstruction of the lateral sinuses by enlarged pachionian granulations (seen during the venous phase of conventional angiography). It is here that the evidence has been most provocative. Intervention by stenting of a venous sinus at the sites of apparent obstruction has resulted in clinical improvement, and a reduction in CSF pressure. For example, 5 of 12 patients treated by Higgins and colleagues became asymptomatic, but this was a population selected by the demonstration of a focal pressure gradient in the lateral sinus during venography. Karahalios and colleagues had similar success in several patients. What is not clear is how prevalent these partial venous obstructions are and what precisely is their nature (if not simply enlarged granulations). In some series, the abnormality has been found in 10 to 25 percent of patients who lack any features of pseudotumor (Leach et al). We have seen an obese patient of short stature who presented with typical pseudotumor cerebri, but who was found to have, in addition, anticardiolipin antibodies that resulted in thrombosis of the right transverse sinus; lysis of the clot led to resolution of the pseudotumor syndrome.

In an attempt to settle the role of the venous stenosis, King and colleagues measured intracranial venous pressure while withdrawing spinal fluid from the cervical subarachnoid space in patients with idiopathic pseudotumor cerebri. Their observation that the venous pressure drops immediately upon the reduction in CSF pressure supports the notion that the increased venous pressure is secondary (furthermore, they describe patients with pseudotumor and normal venous pressures in the sagittal and transverse sinuses). The unsatisfactory nature of all the currently offered theories of causation of pseudotumor cerebri are reviewed by Walker, but at the moment our reading of the literature suggests that venous stenosis from granulations or from some as yet undefined functional change, does account for a proportion of what had previously been considered to be idiopathic cases. How the venous changes relate to obesity and sex is also unclear. Perhaps some individuals have a congenital configuration of the venous sinuses that is exaggerated with obesity and elevated systemic venous pressures.

Some additional comments about the physiologic changes in CSF flow and pressure in relation to alternative mechanisms of pseudotumor may be informative. Using the method of constant infusion manometrics, Mann and coworkers demonstrated an increased resistance to CSF outflow, in their view, caused by an impaired absorptive function of the arachnoid villi. Other authors have attributed intracranial venous hypertension to raised intraabdominal and cardiac filling pressures, the mechanical result of obesity (Sugerman et al, 1995). On inconclusive

evidence, benign intracranial hypertension was in the past attributed to an increase in brain volume secondary to an excess of extracellular fluid or blood volume within the cranium (Sahs and Joynt, Raichle et al). An interesting related finding has been an elevated level of vasopressin in the CSF but not in the blood (Seckl and Lightman). In the goat, this peptide causes a rise in ICP and a reduction in CSF absorption, raising the possibility that the pseudotumor state is caused by an aberration of the transit of water in the cerebrum. Finally, Jacobson and colleagues have made the observation that serum vitamin A levels (in the form of retinol) are 50 percent higher than expected, in patients with pseudotumor—a difference that is not explained by obesity. Because the levels were considerably lower than in cases of hypervitaminosis A with symptomatic forms pseudotumor (see below), the meaning of these findings is uncertain.

Symptomatic Causes of Pseudotumor Cerebri (See Table 30-1)

The main considerations in cases of generalized elevation of ICP and papilledema in the absence of an intracranial mass are, foremost, covert occlusion of the dural venous sinuses and then, a list of less-common conditions, including gliomatosis cerebri, occult arteriovenous malformation, and carcinomatous, infectious, or granulomatous

meningitis. Although occlusion of the dural venous sinuses and their large draining veins is sometimes equated with pseudotumor, these cases are not, of course, idiopathic. When papilledema occurs in the context of a persistent headache, particularly if the cranial pain is centered near the vertex or medial parietal areas or if there are seizures, venous occlusion is likely. Venous sinus thrombosis can be detected in most instances by careful attention to the appearance of the superior sagittal and transverse sinuses on the T1-weighted MRI or on the contrast-enhanced CT scan, as discussed in Chap. 34 under “Thrombosis of Cerebral Veins and Venous Sinuses.” Isolated cortical vein thrombosis on the cerebral convexity does not cause pseudotumor (but does induce seizures).

A large cerebral arteriovenous malformation (AVM), by causing an increase both of venous pressure and cerebral blood volume, can give rise to a pseudotumor syndrome. In a few of our cases, these changes in the physiology of the cerebral circulation were made evident by the appearance of early venous flow on the angiogram or by thrombosis of the superior sagittal sinus.

Several systemic diseases that are associated with raised CSF protein concentration have given rise to a pseudotumor syndrome, including the Guillain-Barré syndrome, systemic lupus, and spinal tumors, particularly oligodendroglioma. Elevated spinal fluid pressure has been attributed to a blockage of CSF absorption by the proteinaceous fluid in Guillain-Barré syndrome, but this mechanism has never been validated and fails to explain those few instances in which pseudotumor syndromes has been associated with a near-normal protein content of the CSF. This explanation is even less compelling if one recalls that the protein concentration of the fluid in the cerebral spaces is considerably lower than in the spinal ones. Also, as we have pointed out, when calculated correctly, neither the resistance to CSF absorption nor the colloid osmotic effect attributable to an increased protein content in the spinal fluid is adequate to explain the pressure elevation (Ropper and Marmorou). The mechanism of this type of pseudotumor syndrome is presently unknown.

In addition to mechanical factors, a number of toxic and metabolic disturbances may give rise to a pseudotumor syndrome. In children, as chronic corticosteroid therapy is withdrawn, there may be a period of headache, papilledema, and elevated ICP with little or no enlargement of the lateral ventricles. Lead toxicity in children may be marked by brain swelling and papilledema. Excessive doses of tetracycline (particularly outdated medication) and vitamin A (particularly in the form of isotretinoin, an oral vitamin A derivative used in the treatment of severe acne) also have been shown to cause intracranial hypertension in children and adolescents. Ingestion of large quantities of bear liver by hunters is another curious source of intoxication with vitamin A underlying pseudotumor. Isolated instances of hypo- or hyperadrenalism, myxedema, and hypoparathyroidism have been associated with increased CSF pressure and papilledema, and occasionally the administration of estrogens, phenothiazines, lithium, the antiarrhythmic drug amiodarone, and quinolone antibiotics has the same effect, for reasons not known.

Table 30-1

CAUSES AND ASSOCIATIONS OF PSEUDOTUMOR CEREBRI

- I. Idiopathic intracranial hypertension
- II. Cerebral venous hypertension (diagnosis by imaging of cerebral vasculature)
 - A. Occlusion of superior sagittal or transverse venous sinus:
 1. Hypercoagulable states (cancer, birth control pills, dehydration, antiphospholipid antibody)
 2. Traumatic
 3. Postsurgical
 4. Infectious (mainly of transverse venous sinus due to mastoiditis)
 - B. Increased blood volume due to high-flow arteriovenous malformation, dural fistulas, and other vascular anomalies
- III. Meningeal diseases (diagnosis by examination of CSF)
 - A. Carcinomatous and lymphomatous meningitis
 - B. Chronic infectious and granulomatous meningitis (fungal, tuberculous, spirochetal, sarcoidosis)
- IV. Gliomatosis cerebri
- V. Toxic
 - A. Hypervitaminosis A (especially isotretinoin, used for the treatment of acne)
 - B. Lead intoxication
 - C. Tetracycline, minocycline, doxycycline
 - D. Infrequent idiosyncratic effect of various drugs (amiodarone, quinolone and sulfa antibiotics, estrogen, phenothiazines, lithium)
- VI. Metabolic disturbances
 - A. Administration or withdrawal of corticosteroids
 - B. Hyper- and hypoadrenalism
 - C. Myxedema
 - D. Hypoparathyroidism
- VII. Greatly elevated protein concentration in the CSF
 - A. Guillain-Barré syndrome
 - B. Spinal oligodendroglioma
 - C. Systemic lupus erythematosus

The first step in differential diagnosis is to exclude an underlying tumor or the nontumorous causes of raised ICP, mainly dural venous occlusion, and meningeal inflammation. This can be accomplished by CT and MRI, although it should be borne in mind that certain chronic meningeal reactions (e.g., those caused by sarcoidosis or to tuberculous or carcinomatous meningitis), which give rise to headache and papilledema, may sometimes elude detection by these imaging procedures. In these cases, however, lumbar puncture will disclose the diagnosis. It should be emphasized that *the diagnosis of idiopathic pseudotumor cerebri should not be accepted when the CSF content is abnormal.*

Visual Loss in Pseudotumor

Careful evaluations of the visual fields and of acuity is required soon after the diagnosis of idiopathic pseudotumor is established. Repeated examination of visual function, preferably in collaboration with an ophthalmologist, is essential in detecting early and potentially reversible visual loss. At the same time, it must be acknowledged that measurements of visual acuity (and of confrontation fields) are relatively insensitive means of detecting early visual loss and that abnormalities in these tests indicate that damage to the optic nerve head has already occurred. Quantitative perimetry, using the kinetic Goldmann technique, has been more informative than other methods. The neurologist probably advised to refer the patient for perimetry as an adjunctive test. Fundus photographs are also a reasonable means of assessing the course of papilledema. A reduction in previously normal acuity to less than 20/20 corrected, enlargement of the blind spot, or the appearance of sector field defects, usually inferonasal, are indications for prompt treatment of raised ICP.

If intracranial hypertension and papilledema are left untreated or fail to respond to the measures outlined below, there is danger of permanent visual loss from compressive damage to the optic nerve fibers and compression of the central retinal veins. Corbett and associates, who described a group of 57 patients followed for 5 to 41 years, found severe visual impairment in 14, and Wall and George, using refined perimetric methods, reported an even higher incidence of visual loss. Moreover, children with pseudotumor share the same visual risks as adults (Lessell and Rosman). Sometimes, vision is lost abruptly, either without warning or following one or more episodes of monocular or binocular visual obscurations.

Treatment

Most patients with idiopathic intracranial hypertension will be found initially to have no, or minor visual changes aside from the papilledema; the headache and lumbar puncture pressure then guide treatment. Besides symptomatic relief of headaches, the progression of visual loss is the main concern. At least one-fourth of patients have recovered within 6 months after treatment by repeated lumbar punctures and drainage of sufficient CSF to maintain the pressure at normal or near-normal levels (less than 200 mm H₂O). The lumbar punctures have been

performed daily or on alternate days at first, and then at longer intervals, according to the level of pressure. While cumbersome and sometimes impractical, evidently, this is sometimes sufficient to restore the balance between CSF formation and absorption for at least several months. At the same time, weight loss has been encouraged and the best results have been reported when weight reduction was successful (see further on regarding weight loss).

Acetazolamide and Osmotic Agents This approach has been considered the first step in treatment for patients who are not losing visual acuity rapidly. Large doses of acetazolamide in the range of 1 to 5 g/d, are required and the expected side effects of paresthesias and nausea may not be tolerated. Sustained use of the drug has a risk of kidney stones. Oral hyperosmotic agents—such as glycerol (15 to 60 mg four to six times daily), or furosemide 20 to 80 mg bid—to reduce CSF formation all have their advocates, but they generally have only a short-term impact on vision and headaches.

Weight Reduction This is always advised if the patient is markedly overweight but is difficult to accomplish. In two pathologically obese patients, we have resorted to bariatric surgical approaches, which had a beneficial effect on the pseudotumor but left the patient for a time with the gastrointestinal disturbances that commonly complicate these procedures. Sugerman and associates (1999) studied 24 obese women with pseudotumor who had operations and found the results to be satisfactory over several years. Two of our patients developed a sensory polyneuropathy after surgery. The use of bariatric procedures is currently undergoing reevaluation for obesity in general, but in the circumstances of pseudotumor with visual loss, it is a reasonable alternative. The effect of weight loss in less overweight individuals is uncertain.

Lumbar-Peritoneal Shunting In patients whose headaches are unresponsive to the usual therapeutic measures—mainly acetazolamide and weight reduction—a treatment method that may have considerable temporary success is a lumbar-peritoneal shunt. Only a few of our patients have undergone this surgical procedure. It has been relatively safe and effective, but because of a tendency for the shunt to become obstructed or to be dislodged in obese patients, sometimes causing back or sciatic pain, the procedure has less appeal than in the past. Burgett et al, who treated 30 patients in this manner, reported success in reducing headache in almost all and in improving vision in 70 percent. Despite its shortcomings, this procedure may be preferable to the optic nerve fenestration described below. We have not had to resort to cranial subtemporal decompression, a procedure that was formerly used when vision was threatened.

Corticosteroids Most authorities eschew the use of corticosteroids and had objected strenuously to their inclusion as a treatment for pseudotumor in previous editions of this book. Nonetheless, with the administration of prednisone (40 to 60 mg/d) we have occasionally observed a gradual recession of papilledema and a lowering of CSF pressure, but such responses were not consistent or sustained and it has been difficult to decide whether this represented the effect of treatment or the

natural course of the disease. Greer, who has reported on 110 patients, 11 of whom were treated with these agents, decided that they were of no value. Moreover, in patients whose papilledema seems to recede under the influence of corticosteroids, there is always a danger that it will recur when the drug is tapered. Considering the potential for undesirable side effects of corticosteroids, we have used them very sparingly and only for brief periods while preparing the patient for more definitive treatment.

Fenestration of the Optic Nerve Sheath For patients who are losing vision, unilateral fenestration of the optic nerve sheath is a procedure favored by some ophthalmologists. According to Corbett and colleagues, this procedure—which consists of partial unroofing of the orbit and the creation of an intraorbital window opening in the dural–arachnoid sheaths surrounding the optic nerve—effectively preserved or restored vision in 80 to 90 percent of patients. Even when the procedure is performed on only one side, its effect on vision is often bilateral and about two-thirds of patients have some relief of headache as well, although this has been transient in most of our patients.

However, the operation carries a moderately high risk of orbital vascular obstruction and unilateral visual loss, as happened in two of our patients. The causes of visual loss after this operation by various reports have included central retinal artery or vein occlusion, choroidal infarction, optic nerve trauma, hemorrhage into the nerve sheath, and infection. Over the past decades, enthusiasm for the procedure had diminished after publication of several series in which there was visual loss in 2 to 11 percent of patients. Some of these data come from studies of sheath fenestration for ischemic optic neuropathy, a condition not comparable to the disc swelling of pseudotumor. Follow-up studies have indicated that the reduction in ICP was limited to 1 year or less. As a result of recent reexamination of the complications of this procedure, there is renewed interest for the procedure over lumbar peritoneal shunting.

Relief of Venous Obstruction In a number of patients, the CSF pressure remains elevated and the papilledema becomes chronic despite one of the above-described treatments. It is the management of this group that is the most difficult and controversial. A careful search should then be made for anatomic and hematologic causes that might underlie cerebral venous dural sinus disease. Sometimes it is useful to treat venous occlusion using interventional vascular techniques. In cases of venous thrombosis antiphospholipid antibody syndrome, sickle cell disease, hormonally induced clotting, and related disorders, medical measures may be tried first, but intravascular thrombolysis remains an option.

The more complex decision to apply stenting to the partial occlusion of the transverse sinus by generous pachionian granulations should probably be guided by the same principles, i.e., failure of medical treatment to adequately control CSF pressure, or relieve the threat to vision. In a series of 10 patients with intractably raised CSF pressure and morphologic obstruction in the venous sinuses, Donnet and colleagues were able to provide

complete relief by stenting in 6 patients and partial relief in 2 patients, with follow-up ranging from 6 to 36 months. In a summary of published cases and series of patients with pseudotumor cerebri treated by endovascular stenting of venous sinus stenosis, Aroc and colleagues concluded that approximately 80 percent were relieved of their main symptoms, and a similar proportion showed resolution, or improvement in papilledema. This is a selected group of patients.

In summary, the clinician is left with only incomplete guidance as to the course of treatment of pseudotumor cerebri. In cases with no visual impairment and with moderate headaches, we have favored aggressive weight reduction, acetazolamide, and repeated lumbar punctures. For more severe cases, we perform careful vascular imaging and correction of venous sinus occlusions as noted above. Failing this, we have advised lumbar drainage to the peritoneum. If vision is imminently threatened, optic sheath fenestration is probably the best course.

We have been impressed with the persistence of a complex migraine- or tension-like headache in some patients whose CSF pressure has been adequately reduced by repeated lumbar punctures, shunting, or optic nerve fenestration. After it has been confirmed that the pressure is not elevated, these headaches may be treated in a manner similar to the usual types of chronic headaches, as outlined in Chap. 10, especially with topiramate, which has the potential benefit of facilitating weight reduction. A recent review of the subject of surgical treatment, extensively referenced, has been given by Brazis. He was unable to conclude that any one approach was superior.

PNEUMOCEPHALUS AND PNEUMOCRANIUM

These disorders, in which air enters the ventricular system or the subarachnoid spaces, are discussed in relation to cranial injury, and the postoperative state (see Chap. 35). In the case of pneumocranium, the collection of air may act as a mass that compresses adjacent brain tissue, and requires relief by aspiration.

INTRACRANIAL HYPOTENSION (See also “Low-Pressure and Spinal Puncture Headache” in Chap. 10)

After lumbar puncture, this syndrome phenomenon is usually attributable to a lowering of ICP by leakage of CSF through the needle track into the paravertebral muscles. The headache may last for days or, rarely, weeks. Most characteristic is the relation of the cranial pain to upright posture, and its relief within moments after assuming the recumbent position. Actually, the syndrome includes more than headache. There may be pain at the base of the skull posteriorly and in the back of the neck and upper

thoracic spine, mild stiffness of the neck and shoulders, and nausea and vomiting. At times, the signs of meningeal irritation are so prominent as to raise the question of postlumbar puncture meningitis, although lack of fever usually excludes this possibility. In addition to a low or unmeasurable CSF pressure if another spinal tap is performed (the CSF pressure is found to be in the range of 0 to 60 mm H₂O), there are occasionally a few to a dozen white cells in the CSF, which may further raise concern of meningitis. In the infant or young child, stiffness of the neck may be accompanied by irritability, unwillingness to move, and refusal of food. If the headache is protracted, recumbency still reduces it, but a feeling of dull pressure may remain, which the patient continues to report as pain. Many patients also report that shaking the head produces a cephalic pain. Occasionally, there will be unilateral or bilateral sixth nerve palsy or a self-audible bruit from turbulence in the intracranial venous system. Hearing loss is a far less common complication (see Chap. 2). A rare syndrome that has been attributed to sagging of the frontal lobes in low CSF pressure situations has been described by Wicklund and coworkers. Patients are apathetic and disinhibited and have prominent daytime somnolence.

It has been recognized that low CSF pressure is associated on the MRI with variable dural enhancement by gadolinium (Fig. 30-5) and, when the syndrome is protracted and severe, there may be small subdural effusions

Figure 30-5. MRI after gadolinium infusion (T1 sequence) showing the widespread dural enhancement that is typical of low CSF pressure after lumbar puncture, spontaneous CSF leakage, or shunt overdrainage. Similar changes may be found in the spinal dura.

(see below). In older patients taking warfarin, a subdural hematoma may be found.

The use of a 22- to 24-gauge needle and the performance of a single clean (atraumatic) tap seemingly reduce the likelihood of a postlumbar puncture headache, as discussed in Chap. 2. A period of enforced recumbency, although widely practiced as a means of preventing headache, probably does not lessen its incidence (Carbaat and van Crevel). The ingestion of large volumes of fluids, the infusion of 1,000 to 2,000 mL of 5 percent glucose, and various forms of caffeine (see further on) are usually recommended, but are of uncertain benefit.

The most dependable treatment is a “blood patch” (spinal epidural injection of approximately 20 mL of the patient’s own blood). At least 75 percent of patients are thus relieved of the headache according to Safa-Tisseront and colleagues; they report that after a second injection, improvement occurs in 97 percent. Many patients have transient back or radicular pain (sciatica) following the blood patch. Curiously, the headache is often relieved almost immediately, even if the blood is injected at some distance from the original puncture (although the procedure is usually done at the same level as the previous spinal tap). Moreover, the volume of blood injected, usually about 20 mL, is not related to the chances of success. The mechanism of this rapid improvement, therefore, may not simply be the plugging of a dural leak. A number of patients fail to benefit or have only transient effects; it is then unclear whether repeating the procedure is helpful. The administration of caffeine–ergotamine preparations or intravenous caffeine may also have a salutary, although temporary, effect on the orthostatic headache. The addition of analgesic medication is required if the patient must get up to care for himself or to travel. In protracted cases, patience is called for, as most headaches will resolve in 2 weeks or less.

As to mechanism, the pain is presumed to be from tugging on cerebral veins or assuming the upright position. Panullo and colleagues also showed that there is a downward displacement of the upper brainstem and posterior fossa contents when the patient assumes the upright position; but, as pointed out in Chap. 17, only rarely are there associated signs of brain herniation, the exceptions being some of the unusual cases discussed below. Miyazawa and colleagues have proposed that hypovolemia of the CSF, rather than lowered pressure, is the cause of downward displacement of the brain and dilatation of cerebral and spinal epidural veins. They propose that the buoyancy provided by the spinal fluid is lost in these cases.

The same problem of low pressure as that which follows lumbar puncture can occur after straining, a non-hurtful fall, or for no known reason. The cardinal feature is orthostatic headache and only rarely are there other neurologic complaints, such as diplopia from sixth-nerve palsy or a self-audible bruit. In these cases, the CSF pressure is low (60 mm H₂O or less) or not measurable; the fluid may contain a few mononuclear cells but is most often normal. A few cases have presented with stupor as a result of downward transtentorial displacement of the diencephalic region (Pleasure et al) or an upper cervical

myelopathy caused by downward deformation and displacement of the spinal cord (Miyazaki et al).

Some surveys suggest that patients with structural disorders of connective tissue are at greater risk for spontaneous CSF leaks than others. The Marfan and Ehlers-Danlos syndrome as well as autosomal dominant polycystic kidney disease are risk factors as summarized by Schievink.

In many such patients with ostensibly idiopathic low CSF pressure syndromes, there has been a tear in the delicate arachnoid surrounding a nerve root, with continuous leakage of CSF. The site of the leak is difficult to ascertain except when it occurs into the paranasal sinuses (causing CSF rhinorrhea). In a series of 11 patients with spontaneous intracranial hypotension, a putative leak was found by radionuclide cisternography or CT myelography (the preferred procedure) in the cervical region or at the cervicothoracic junction in 5 patients, in the thoracic region in 5, and the lumbar region in 1 (Schievink et al). In the patients who underwent surgical repair, a leaking meningeal diverticulum (Tarlov cyst) was found and could be ligated. This seems to be the most common structural cause. A blood patch, as described above, may be useful and should be attempted before resorting to surgical repair of the cyst. Recumbency for a few days thereafter permits the pressure to build up, and there has been no recurrence in all but a few of the cases that we have encountered. Others, however, have reported repeated episodes of orthostatic headache. Rarely, a case of intracranial hypotension becomes chronic; the headache is then no longer responsive to recumbency. Mokri and colleagues (1998) have also made the point that orthostatic headache and diffuse pachymeningeal enhancement on MRI may occur in the presence of normal CSF pressures.

One of the most remarkable syndromes associated with low CSF pressure is that following spinal surgery that utilizes suction drainage of the lumbar wound. The patient may fail to awaken from anesthesia or show signs such as pupillary asymmetry or a seizure. Imaging studies show features usually associated with global brain hypoxia-ischemia including signal changes in the basal ganglia, thalamus, and deep cerebellar nuclei. This syndrome apparently occurs if there has been a dural spinal leak and a high volume of CSF drainage by the suction device (Parpaley et al). The mechanism is not clear, but cerebral venous congestion has been implicated.

As noted, a helpful diagnostic sign of low CSF pressure is prominent dural enhancement with gadolinium on the MRI (see Fig. 30-5), a phenomenon attributed by Fishman and Dillon to dural venous dilatation; this finding may extend to the pachymeninges of the posterior fossa and the cervical spine. According to Mokri and colleagues (1995), biopsy of the dura and underlying meninges in these cases shows fibroblastic proliferation and neovascularity with an amorphous subdural fluid that is hard to interpret. There may be additional subdural effusions and mass effect, either on the cerebral convexities, temporal lobes, optic chiasm, or cerebellar tonsils. Using ultrasonography, Chen and colleagues have described an enlarged superior ophthalmic vein and increased blood

flow velocity in this vessel, both of which normalized after successful treatment. The pituitary gland is usually hyperemic as well.

In the most severe cases of low-CSF pressure syndrome, downward sagging of the entire cerebrum with stupor, as described in Chap. 17, or stretching of the vein of Galen and consequent impairment of venous drainage may cause life-threatening swelling of diencephalic and mesencephalic structures (see Savoiardo et al and Schievink).

The use of a one-way shunt valve in hydrocephalus may be complicated by a syndrome of low CSF pressure. Reference has already been made to this syndrome, and to the slit ventricles in children who have been treated for hydrocephalus, and to midbrain syndromes from brain displacement (see Fig. 30-4). Usually the valve setting is too low, and readjustment to maintain a higher pressure is corrective.

Also appropriate to mention here are CSF leaks that occur after cranial, nasal, or spinal surgery. These are suspected in the postoperative period, although the precise origin of the leak may be difficult to determine, but they give rise to some of the most intractable low-pressure syndromes and must be investigated by radiologic and nuclide studies. In our experience, several such leaks have been intermittent, adding to the difficulty in diagnosis.

The treatment of spontaneous intracranial hypotension is similar to that mentioned earlier under the treatment of postlumbar puncture headache. Kantor and Silberstein pointed out that some patients who fail to respond to conservative management with bed rest, abdominal binders, hydration, caffeine, theophylline, and corticosteroids, and who have also failed with lumbar epidural blood patch, will respond to a cervical epidural blood patch. This should be administered by those who are skilled in their use and are aware of the risk of compression of the spinal cord.

SPECIAL MENINGEAL AND EPENDYMAL DISORDERS

The effects of bacterial invasion of the pia-arachnoid, cerebrospinal subarachnoid space, ventricles, and ependyma are described in Chap. 32 and summarized in Table 32-1. The point being made here is that these structures may also be involved in a number of noninfective processes, some of obscure origin.

Because the ventricular and subarachnoid spaces are in continuity, one would expect that a noxious agent entering any one part would extend throughout the CSF pathway. Such is not always the case. The lower spinal roots or spinal cord alone may be implicated in "spinal arachnoiditis." A similar process may affect the optic nerves and chiasm exclusively ("opticochiasmatic arachnoiditis," see below). A predominant localization to these basal or cervical structures may be apparent even in cases of diffuse cerebrospinal meningeal reactions, perhaps because of an uneven concentration of the noxious

agent. The mechanisms by which these meningeal reactions affect parenchymal structures (brain, cord, and nerve roots) are not fully understood. The most obvious sequela is an obstruction to the flow of CSF in hydrocephalus; here, simple fibrotic narrowing of the CSF circulatory pathway is causative. Progressive constriction of nerve roots and spinal cord, literally a strangulation of these structures, is another plausible mechanism, but it is difficult to separate vascular factors from mechanical ones. Because any toxic agent introduced into the subarachnoid space has free access via Virchow-Robin spaces and thereby to the superficial parts of the brain and spinal cord, direct parenchymal injury may follow. Perivascular reactions of subpial vessels, as in infectious processes, would be a plausible mechanism of injury to optic nerves and spinal cord, where long stretches of myelinated fibers abut the pia.

Regional Arachnoiditis

Arachnoiditis limited to the lumbosacral roots has followed ruptured discs, myelograms, and spinal surgery. Usually, there is sciatica and chronic pain in the back and lower extremities, but sensorimotor and reflex changes in the legs are variable. The MRI shows irregularly enhancing roots and arachnoidal thickening; myelography discloses loculated pockets of imaging media. This condition is discussed further in Chap. 11.

Another form of spinal arachnoiditis, in which both the spinal cord and roots are entrapped in thickened pia-arachnoid, sometimes with arachnoid-dural adhesions, is a rare but well-known and often idiopathic entity. An account of this condition is included with the spinal cord diseases (see Chap. 44). The etiologic factors have been singularly elusive, although in the past it followed the instillation of iophendylate (Pantopaque) for myelography and corticosteroids (for pain or multiple sclerosis) and other irritative agents, particularly chemically contaminated spinal anesthetics. Our colleagues saw more than 40 cases of the latter type, now rare, dating from the time when vials of anesthetic were stored in detergent sterilizing solutions. Instillation of the anesthetic agent was followed immediately by back pain and a rapidly progressive lumbosacral root syndrome (areflexic paralysis, anesthesia of the legs, and paralysis of sphincters). Several cases have, in our recent experience, followed prolonged spinal anesthesia with the patient in a decubitus position, usually for orthopedic procedures, but the resulting myelopathy or cauda equina radiculopathy was difficult to separate from a direct toxic effect of the anesthetic. The CSF protein rises rapidly in cases that were precipitated by injection of substances into the subarachnoid space, but pleocytosis is minimal. In other instances, protracted back pain lasting days to weeks is the only effect in the post anesthetic period but is followed, after months or years, by a progressive myelopathy. This takes the form of some combination of spinal arachnoiditis with ataxic paraparesis and sensory disturbance, hydrocephalus, or opticochiasmatic arachnoiditis. The point to be made is that there is always some risk attached to the subarachnoid instillation of any foreign agent.

Opticochiasmatic Arachnoiditis

This condition was well known to neurologists during the period when neurosyphilis was a common disease. It occurs after years of chronic syphilitic meningitis, sometimes in conjunction with tabes dorsalis or meningo-myelitis. However, there were always nonsyphilitic cases, the cause of which was never determined. A constriction of visual fields, usually bilateral and asymmetrical (rarely scotomas), developed insidiously and progressed. Pathologically, the optic nerves were found to be enmeshed in thickened, opaque pia-arachnoid. The optic nerves are atrophic in appearance. Idiopathic cases are likely to be confused with multiple sclerosis.

Pachymeningitis

This term refers to a chronic, inflammatory thickening of the dura. The term is somewhat confusing insofar as the pia and arachnoid may be equally involved in the inflammatory thickening and all three membranes are bound together by dense fibrous adhesions. This type of meningeal reaction, which is now uncommon, was first described by Charcot and Joffroy. It occurred mainly in the cervical region (hence the name *pachymeningitis cervicalis hypertrophica*) and was attributed to syphilis. Indeed, in some instances there was a gummatous thickening of the dura. Involvement of cervical roots and compression of the spinal cord gave rise to variable degrees of paraparesis in association with root pain, paresthesia, sensory loss, and amyotrophy of the upper limbs. In the modern era, rheumatoid arthritis (Fig. 30-6), sarcoidosis, and

Figure 30-6. MRI with gadolinium infusion showing diffuse rheumatoid pachymeningitis in an older man with minimal systemic disease. He had severe headaches, hydrocephalus, and mental dullness.

chronic local infection (fungal, tuberculous) have been the main causes, but many cases remain unexplained. Idiopathic hypertrophic pachymeningitis continue to be reported; a summary of published cases and two personally studied ones is given by Dumont and colleagues and by Jimenez-Caballero and coworkers.

A condition associated with plasma cells proliferation that contain IgG-4 receptors has been reported to involve the pachymeninges. The process has a similar appearance to rheumatoid granulomatous infiltration and it is responsive to corticosteroids. In addition to evident thickening and gadolinium enhancement of the dura on imaging studies, the characteristic features are an elevation of the IgG fraction in the serum and in CSF and infiltration of meningeal tissue by uniform plasma cells that exhibit IgG-4 markers (Plasma cells are not prominent in the CSF in this condition; they are found in other states such as *Listeria meningitis* and neurosyphilis.). This process has been known to occur in other organs such as the salivary glands, lung and kidney; it tends to occur in men in their fifth or sixth decade according to the case series of pathologic samples reported by Lindstrom and colleagues.

The subdural space and dura can be involved by extension of a pathologic process from the arachnoid, especially in infants and children, in whom subdural hygromas regularly follow meningitis. The fibrous connective tissue of which the dura is composed may also undergo pronounced thickening in the course of a mucopolysaccharidosis, especially in cases where fibroblasts are implicated. The basal pia-arachnoid may be involved, leading to obstructive hydrocephalus. Older medical writings often made reference to syphilitic cranial pachymeningitis, which later proved to be the thickened membranes of subdural hematomas. The neovascular response and fibrosis of the dura and meninges that result from low CSF pressures and give the same appearance as pachymeningitis on enhanced CT scans and MRI were discussed earlier in the chapter.

Superficial Siderosis of the Meninges

Superficial siderosis is clearly the consequence of repeated contamination of the meninges by blood (McDougal and Adams; Fishman). An oozing vascular

malformation or tumor has been the usual cause in our experience, although there have been instances in which the source of the blood could not be found; in these a past history of head trauma is common. The red blood corpuscles are phagocytosed, with the formation of hemosiderin, and gradually both iron pigment and ferritin are released into the CSF. As a result, the surface of the cerebellum, spinal cord, hippocampi, and olfactory bulbs are stained orange-brown. Iron pigments and ferritin, which are toxic, gradually diffuse through the pia into superficial parts of the cerebellum, eighth cranial nerve, and spinal cord, destroying nerve cells and exciting a glial reaction. In microscopic sections stained for iron, the histiocyte–microglial cells contain iron and ferritin, and particles of iron can be seen studding nerve and glial cells for a distance of several millimeters beneath the pia.

The clinical syndrome of siderosis of the meninges consists essentially of a progressive ataxia and nerve deafness; sometimes a spastic paraparesis is added and, rarely, mental impairment, probably from hydrocephalus. The hemosiderin and iron-stained meninges are readily visualized by MRI, as iron is strongly paramagnetic. All the iron-impregnated tissues are hypointense in T2-weighted images. Koeppen and associates attributed the vulnerability of the acoustic nerves to their extended meningeal exposure before acquiring a fibroblastic perineurium and epineurium. There is no treatment other than finding the source of the meningeal blood and preventing further hemorrhage and treating hydrocephalus if it is present. Kumar has provided a useful review of the problem of superficial siderosis. Curiously, the systemic disease hemochromatosis, does not affect the brain or meninges.

Oculoleptomeningeal Amyloidosis

Transthyretin amyloidosis can present as an infiltration of the leptomeninges by amyloidosis. The clinical syndrome includes dementia, seizures, stroke-like episodes, subarachnoid hemorrhage, ataxia, myelopathy, deafness, radiculopathy, and ocular amyloidosis, usually affecting the vitreous. The leptomeninges enhance with gadolinium on MRI; the CSF has elevated protein but is otherwise nondescript. There is no proven therapy, but liver transplantation could theoretically be effective.

Intracranial Neoplasms and Paraneoplastic Disorders

Tumors of the central nervous system (CNS) constitute a bleak but vitally important chapter of neurologic medicine. Their importance derives from their great variety; the numerous neurologic symptoms caused by their size, location, and invasive qualities; the destruction and displacement of tissues in which they are situated; the elevation of intracranial pressure they cause; and, most of all, their lethality. Slowly, this dismal state of affairs is changing as a result of advances in anesthesiology, stereotactic and microneurosurgical techniques, focused radiation therapy, and the use of new chemotherapeutic agents.

For clinicians, the several generalizations should be a matter of general knowledge about brain tumors. *First*, many types of tumor, both primary and secondary, occur in the cranial cavity and spinal canal but certain ones are much more frequent than others and are prone to occur in particular age groups. Secondary metastatic deposits are more common than primary brain tumors in adults and the opposite is true in children. Furthermore, certain cancers (breast, lung, melanoma, renal cell cancer) display a tendency to metastasize to nervous tissue and many others do not do so. *Second*, some primary intracranial and spinal tumors, such as craniopharyngioma, meningioma, and schwannoma, have a disposition to grow in particular parts of the cranial cavity, thereby producing characteristic neurologic syndromes. *Third*, the presence of a state of immunosuppression such as AIDS or cancer chemotherapy, special inherited disorders such as neurofibromatosis, and exposure to radiation each predispose to the development of tumors of the nervous system. *Fourth*, the growth rates and invasiveness of tumors vary; some, like glioblastoma, are highly malignant, invasive, and rapidly progressive and others, like meningioma, are most often benign, slowly progressive, and compressive. These different qualities have substantial clinical implications, frequently providing the explanation of slowly or rapidly evolving clinical states as well as potential surgical cure and prognosis.

Finally, a special class of disorders result from the production of autoantibodies that are elaborated by systemic, nonneural, tumors and target cerebral and spinal neurons. These remote effects, referred to as *paraneoplastic*, often constitute the initial or only clinical manifestation of the underlying neoplasm.

A comprehensive reference on brain tumors is the text edited by Kaye and Laws.

Incidence of CNS Tumors and Their Types

Currently, in each year there are an estimated 600,000 deaths from cancer in the United States. Of these, the number of patients who died of primary tumors of the brain seems comparatively small (approximately 20,000, half of them malignant gliomas), but in roughly another 130,000 patients the brain is affected at the time of death by metastases. Thus, in approximately 25 percent of all the patients with cancer, the brain or its coverings are involved by neoplasm at some time in the course of the illness. Among causes of death from intracranial disease in adults, tumor is exceeded in frequency only by stroke, whereas in children primary brain tumors constitute the most common solid tumor and represent 22 percent of all childhood neoplasms, second in frequency only to leukemia. Viewed from another perspective, in the United States, the yearly incidence of all tumors that involve the brain is 46 per 100,000, and of primary brain tumors, 15 per 100,000.

It is difficult to obtain accurate statistics as to the types of intracranial tumors, for most of them have been obtained from university hospitals with specialized cancer and neurosurgical centers. From the figures of Posner and Chernik, one can infer that secondary tumors of the brain greatly outnumber primary ones; yet in the large series reported in the past (those of Cushing [1932], Olivecrona, Zülch, and Zimmerman), only 4 to 8 percent were of this type. In the autopsy statistics of municipal hospitals, where one would expect a more natural selection of cases, the figures for metastatic tumors vary widely, from 20 to 42 percent (Rubinstein, 1972). Even these estimates probably underestimate the incidence, particularly of metastatic disease. With these qualifications, the figures in Table 31-1 may be taken as representative.

Most primary brain tumors are of presumed glia cell origin—i.e., gliomas—a category that includes astrocytomas (which occur in several grades of malignancy), oligodendrogliomas, ependymomas (which may have characteristics of both glia and of epithelium), and a number of rarer types. Other brain tumors arise from ectodermal structures related to the brain (meningioma), from lymphocytes (CNS lymphoma), or from precursor neuronal elements (neuroblastoma, medulloblastoma),

Table 31-1

TYPES OF INTRACRANIAL TUMORS IN THE COMBINED SERIES OF ZÜLCH, CUSHING, AND OLIVECRONA, EXPRESSED IN PERCENTAGE OF TOTAL (APPROXIMATELY 15,000 CASES)

TUMOR	PERCENT OF TOTAL
Gliomas ^a	
Glioblastoma multiforme	20
Astrocytoma	10
Ependymoma	6
Medulloblastoma	4
Oligodendroglioma	5
Meningioma	15
Pituitary adenoma	7
Neurinoma (schwannoma)	7
Metastatic carcinoma	6
Craniopharyngioma, dermoid, epidermoid, teratoma	4
Angiomas	4
Sarcomas	4
Unclassified (mostly gliomas)	5
Miscellaneous (pinealoma, chordoma, granuloma, lymphoma) ^b	3
Total	100

^aIn children, the proportions differ: astrocytoma, 48 percent; medulloblastoma, 44 percent; ependymoma, 8 percent. Seventy percent of gliomas in children are infratentorial; in adults, 70 percent are supratentorial. Craniopharyngioma also occurs mainly in younger age groups.

^bThe incidence of lymphoma was negligible when these series were collected, but it has increased markedly since then (see text).

germ cells (germinoma, craniopharyngioma, teratoma), or endocrine elements (pituitary adenoma). Table 31-2 provides a detailed tabulation compiled by the Central Brain Tumor Registry. Notable in all series, and emphasized in this table, is the higher frequency of certain tumors during childhood.

The main change since the first edition of this book in 1977 is the increase in incidence of primary CNS lymphomas. At that time, the incidence of this tumor, formerly called reticulum cell sarcoma, was negligible. In the last 25 years, the number in our hospitals has more than tripled; in specialized centers such as the Memorial Sloan-Kettering Cancer Center, the increase has been even more dramatic (DeAngelis). It now represents over 3 percent of all brain tumors. This increase is only partly attributable to the rise in number of immunosuppressed individuals, particularly of those with AIDS, as the tumor appears to be increasing in incidence even in those with normal immune function.

Classification and Grading of Nervous System Tumors

Classifications and grading systems of intracranial tumors abound and are often confusing to the general

Table 31-2

AGE-SPECIFIC FREQUENCY OF TUMOR TYPES WITH AGE

TUMOR	CHILDHOOD, PERCENT	ADULT, PERCENT	OLDER ADULT, PERCENT
Neuroepithelial tumors (glial origin)	78.1	44.6	41.9
Pilocytic astrocytoma	19.8	0.7	0
Glioblastoma	3.8	23.2	29.3
Malignant glioma	8.9	1.5	3.1
Diffuse astrocytoma	1.5	0.8	0.6
Anaplastic astrocytoma	2.5	4.4	2.7
Other astrocytoma	9.2	4.1	3.8
Oligodendroglioma	2.3	3.4	0.7
Anaplastic oligodendroglioma	0.8	1.5	0.4
Ependymomas	6.4	0.5	0.4
Mixed glioma	0.8	1.1	0.2
Embryonal/primitive/medulloblastoma	16.0	0.5	0
Meningeal tumors	4.3	29.9	39.6
Meningioma	3.1	28.4	39.1
Hemangioblastoma	0.8	1.2	0.4
Lymphoma	0.5	2.4	2.7
Sellar tumors	6.4	8.7	3.9
Pituitary adenoma	0.8	8.0	3.8
Craniopharyngioma	3.6	0.6	0
Cranial and spinal nerve tumors	2.0	11.3	3.4
Germ cell tumors	4.3	0	0
Local extension from regional tumors	0.5	0.2	0
Unclassified	3.8	2.8	8.5
Total	100.0	100.0	100.0

Source: Adapted from the Central Brain Tumor Registry for the United States, 1995-1999; <http://www.cbtrus.org>.

neurologist. Most classifications have been based on the presumed cell of origin of the neoplasm, while grading systems are meant to be an estimate of the rate of growth and clinical behavior, but the two are often concordant. The most recent World Health Organization (WHO) classification (the fourth revision, 2007) represents the current view of tumor specialists but the entire list is unwieldy for most clinicians. Table 31-3 shows the main items and a discussion of this system can be found in the article by Louis and colleagues (2007). In the past, the numerical grading system of Daumas-Duport and coworkers (also known as the St. Anne-Mayo system) and the three-tiered system of Ringertz (which correlates most closely with clinical survival) were widely used

Table 31-3

MAIN CATEGORIES OF THE WHO BRAINTUMOR CLASSIFICATION

I. Astrocytic tumors	Other CNS Neoplasms
A. Noninvasive: Pilocytic and subependymal giant cell astrocytomas and pleomorphic xanthoastrocytoma (grade I)	I. Tumors of the sellar region
B. Diffuse astrocytoma (grade II)	A. Pituitary adenoma
C. Anaplastic astrocytoma (grade III)	B. Pituitary carcinoma
D. Glioblastoma multiforme (grade IV)	C. Craniopharyngioma
II. Oligodendroglial tumors	II. Hematopoietic tumors
A. Oligodendroglioma (grade II)	A. Primary malignant lymphomas
B. Anaplastic (malignant) oligodendroglioma (grade III)	B. Plasmacytoma
III. Ependymal cell tumors	C. Granulocytic sarcoma
A. Ependymoma (grade II)	III. Germ cell tumors
B. Anaplastic ependymoma (grade III)	A. Germinoma
C. Myxopapillary ependymoma	B. Embryonal carcinoma
D. Subependymoma (grade I)	C. Yolk sac tumor (endodermal sinus tumor)
IV. Mixed gliomas	D. Choriocarcinoma
A. Mixed oligoastrocytoma (grade II)	E. Teratoma
B. Anaplastic (malignant) oligoastrocytoma (grade III)	F. Mixed germ cell tumors
C. Others (e.g., ependymoastrocytoma)	IV. Tumors of the meninges
V. Neuroepithelial tumors of uncertain origin	A. Meningioma
A. Polar spongioblastoma (grade IV)	B. Atypical meningioma
B. Astroblastoma (grade IV)	C. Anaplastic (malignant) meningioma
VI. Tumors of the choroid plexus	V. Nonmeningothelial tumors of the meninges
VII. Neuronal and mixed neuronal-glia tumors	A. Benign mesenchymal including lipoma
A. Gangliocytoma	B. Malignant mesenchymal including hemangiopericytoma
B. Dysplastic gangliocytoma of cerebellum (Lhermitte-Duclos)	C. Primary melanocytic lesions
C. Ganglioma	D. Hemopoietic neoplasms—malignant lymphoma
D. Anaplastic (malignant) ganglioglioma	E. Tumors of uncertain histogenesis
E. Desmoplastic infantile ganglioglioma	1. Hemangioblastoma (capillary hemangioblastoma)
F. Central neurocytoma	VI. Tumors of cranial and spinal nerves
G. Olfactory neuroblastoma (esthesioneuroblastoma)	A. Schwannoma (neurinoma, neurilemoma)
VIII. Pineal parenchyma tumors	B. Neurofibroma
A. Pineocytoma	C. Malignant peripheral nerve sheath tumor (malignant schwannoma)
B. Pineoblastoma	VII. Local extensions from regional tumors
C. Mixed pineocytoma/pineoblastoma	A. Paraganglioma (chemodectoma)
IX. Tumors with neuroblastic or glioblastic elements (embryonal tumors)	B. Chordoma
A. Primitive neuroectodermal tumors with multipotent differentiation	C. Chondroma
1. Medulloblastoma	D. Chondrosarcoma
2. Cerebral primitive neuroectodermal tumor	E. Carcinoma
B. Neuroblastoma	VIII. Metastatic tumors
C. Retinoblastoma	IX. Cysts and tumor-like lesions
D. Ependymblastoma	A. Rathke cleft cyst
	B. Epidermoid
	C. Dermoid
	D. Colloid cyst of the third ventricle
	E. Hypothalamic neuronal hamartoma

MAIN CATEGORIES OF THE WHO BRAINTUMOR CLASSIFICATION (CONTINUED)

GRADE	I	II	III	IV
Astrocytic tumors				
Subependymal giant cell astrocytoma	•			
Pilocytic astrocytoma	•			
Pilomyxoid astrocytoma		•		
Diffuse astrocytoma		•		
Pleomorphic xanthoastrocytoma		•		
Anaplastic astrocytoma			•	
Glioblastoma				•
Giant cell glioblastoma				•
Gliosarcoma				•
Oligodendroglial tumors				
Oligodendroglioma		•		
Anaplastic oligodendroglioma			•	
Oligoastrocytic tumors				
Oligoastrocytoma		•		
Anaplastic oligoastrocytoma			•	
Ependymal tumors				
Subependymoma	•			
Myxopapillary ependymoma	•			
Ependymoma		•		
Anaplastic ependymoma			•	
Choroid plexus tumors				
Choroid plexus papilloma	•			
Atypical choroid plexus papilloma		•		
Choroid plexus carcinoma			•	
Other neuroepithelial tumors				
Angiocentric glioma	•			
Choroid glioma of the third ventricle		•		
Neuronal and mixed neuronalglial tumors				
Gangliocytoma	•			
Ganglioglioma	•			
Anaplastic ganglioglioma			•	
Desmoplastic infantile astrocytoma and ganglioglioma	•			
Dysembryoplastic neuroepithelial tumor	•			
Central neurocytoma		•		
Extraventricular neurocytoma		•		
Cerebellar liponeurocytoma		•		
Paraganglioma of the spinal cord	•			
Papillary glioneuronal tumor	•			
Rosette-forming glioneuronal tumor of the fourth ventricle	•			
Pineal tumors				
Pineocytoma	•			
Pineal parenchymal tumor of intermediate differentiation		•	•	
Pineoblastoma				•
Papillary tumor of the pineal region		•	•	

Table 31-3

MAIN CATEGORIES OF THE WHO BRAIN TUMOR CLASSIFICATION

GRADE	I	II	III	IV
Embryonal tumors				
Medulloblastoma				•
CNS primitive neuroectodermal tumor (PNET)				•
Atypical teratoid/rhabdoid tumor				•
Tumors of the cranial and paraspinal nerves				
Schwannoma	•			
Neurofibroma	•			
Perineurioma	•	•	•	
Malignant peripheral nerve sheath tumor (MPNST)		•	•	•
Meningeal tumors				
Meningioma	•			
Atypical meningioma		•		
Anaplastic/malignant meningioma			•	
Hemangiopericytoma		•		
Anaplastic hemangiopericytoma			•	
Hemangioblastoma	•			
Tumors of the sellar region				
Craniopharyngioma	•			
Granular cell tumor of the neurohypophysis	•			
Pituicytoma	•			
Spindle cell oncocyoma of the adenohypophysis	•			

and are cited in the literature. The various classification systems notwithstanding, it is clear that there are practical and prognostic consequences to subclassifying tumors by additional molecular methods that are predictive of outcome and of treatment response (see further on).

The *astrocytic tumors*, the most common forms of glioma, have been subdivided into diffuse well-differentiated astrocytoma (grade II), anaplastic astrocytoma (grade III), and glioblastoma (glioblastoma multiforme, or "GBM," grade IV). These grades represent a spectrum in terms of growth potential (degree of nuclear atypia, cellularity, mitoses, and vascular proliferation) and prognosis. The glioblastomas are largely defined by the features of necrosis and anaplasia of nonneural elements such as vascular proliferation and are set apart from anaplastic astrocytomas on the basis not only of their histology but also by a later age of onset than astrocytoma and a more rapid course. The grade I classification for astrocytomas is reserved for the relatively benign group that includes pilocytic astrocytomas (well-differentiated tumors mostly of children and young adults); the pleomorphic xanthoastrocytoma (with lipid-filled cells), and the subependymal giant cell astrocytoma (associated with tuberous sclerosis). They have been set apart because of their different growth patterns, pathologic features, and better prognosis.

The *ependymomas* are subdivided into cellular, myxopapillary, clear cell, and mixed types; the anaplastic ependymoma and the subependymoma are given separate status. The pathologic criteria of malignant astrocytoma do not apply to *oligodendroglioma*, for reasons elaborated further on. They are subdivided into tumors of pure

oligodendroglial composition and those with mixed astrocytes and oligodendroglia.

Meningiomas are classified on the basis of their cytoarchitecture and genetic origin into 4 categories: (1) the common meningothelial or syncytial type, (2) the fibroblastic and (3) angioblastic variants, and (4) the malignant type. Tumors of the pineal gland, which were not included in earlier classifications, comprise germ cell tumors, the rare pineocytomas, and pineoblastomas. The *medulloblastoma* has been reclassified with other tumors of presumed neuroectodermal origin, namely neuroblastoma, retinoblastoma, neuroepithelioma, and ependymblastoma. Tumors derived from the choroid plexus are divided into two classes, both rare: papillomas and carcinomas.

Given separate status also are the intracranial midline germ cell tumors, such as germinoma, teratoma, choriocarcinoma, and endodermal sinus carcinoma. A miscellaneous group comprises CNS lymphoma, hemangioblastoma, chordoma, hemangiopericytoma, spongioblastoma, and ganglioneuroma.

Tumors of cranial and peripheral nerves differentiate into three main types: schwannomas, neurofibromas, and neurofibrosarcomas. Most are sporadic but the neurofibromas assume special importance in neurofibromatosis.

Biology of Nervous System Tumors

In considering this subject, one of the first problems is with the definition of neoplasia. It is well known that a number of lesions may simulate brain tumors in their clinical manifestations and histologic appearance but are really hamartomas and not true tumors. A hamartoma is

a “tumor-like formation that has its basis in maldevelopment” (Russell) and undergoes little change during the life of the host. The difficulty one encounters in distinguishing it from a true neoplasm, whose constituent cells multiply without restraint, is well illustrated by tuberous sclerosis and von Recklinghausen neurofibromatosis, where hamartomas and neoplasms are both found. Similarly, in a number of mass lesions—such as certain cerebellar astrocytomas, bipolar astrocytomas of the pons and optic nerves, von Hippel-Lindau cerebellar cysts, and pineal teratomas—a clear distinction between neoplasms and hamartomas is often not possible.

Many studies of the *pathogenesis of brain tumors* have gradually shed light on their origin. Johannes Müller (1838), in his atlas *Structure and Function of Neoplasms*, first enunciated the appealing idea that tumors might originate in embryonic cells left in the brain during development. This idea was elaborated upon by Cohnheim (1878), who postulated that the source of tumors was an anomaly of the embryonic anlage. Ribbert, in 1904, extended this hypothesis by postulating that the potential for differentiation of these stem cells would favor blastomatous growth.

For many years, thinking about the pathogenesis of primary CNS tumors was dominated by the *histogenetic theory* of Bailey and Cushing, which was based on the assumed embryology of nerve and glia cells. Although it is not a popular notion today, Bailey and Cushing attached the suffix *blastoma* to indicate all tumors composed of primitive-looking cells, such as glioblastoma and medulloblastoma. One prominent theory was that most tumors arise from neoplastic transformation of mature adult cells (*dedifferentiation*). A normal astrocyte, oligodendrocyte, microgliaocyte, or ependymocyte is transformed into a neoplastic cell and, as it multiplies, the daughter cells become variably anaplastic, more so as the degree of malignancy increases. (*Anaplasia* refers to the more primitive undifferentiated state of the constituent cells.)

In fact, the cells of origin of the major types of brain tumors have not been unequivocally identified or, in many cases, they appear to arise from pluripotential stem cells that reside in the brain, a concept not known in Bailey’s time. If this is indeed the case, it may be that the apparent dedifferentiation of tumor cells is an artifact of their histologic appearance and not a fundamental property.

The factor of age plays a central role in the biology of brain tumors. Medulloblastomas, polar spongioblastomas, optic nerve gliomas, and pinealomas occur mainly before the age of 20 years, and meningiomas and glioblastomas are most frequent in the sixth decade of life. A number of mutations, only some inherited, also figure greatly in the genesis of certain tumors, particularly retinoblastomas, neurofibromas, and hemangioblastomas. The gliomas associated with neurofibromatosis and tuberous sclerosis and the cerebellar hemangioblastomas of von Hippel-Lindau are the best examples of a genetic determinant. The rare familial disorders of multiple endocrine neoplasia and multiple hamartomas are associated with an increased incidence of anterior pituitary tumors and meningiomas, respectively. Glioblastomas and

cerebral astrocytomas have also been reported occasionally in more than one member of a family but the study of such families has not disclosed the operation of an identifiable genetic factor.

Although there is only indirect evidence for an association between viruses and certain primary tumors of the nervous system, epidemiologic and experimental data—drawn from studies of the human papillomavirus and the hepatitis B, Epstein-Barr, and human T-lymphotropic viruses—indicate that they may be involved or act as risk factors in certain human cancers. The genes of Epstein-Barr virus (EBV), for example, are incorporated into the DNA of many cerebral lymphomas. In transgenic mice, certain viruses are capable of inducing olfactory neuroblastomas and neurofibromas. Each of these viruses possesses a small number of genes that are incorporated in a cellular component of the nervous system (usually a dividing cell such as an astrocyte, oligodendrocyte, ependymocyte, endothelial cell, or lymphocyte). The virus is believed to act to force the cell from its normal activity into an unrestrained replicative cycle. Because of this capacity to transform the cellular genome, the virus product is called an *oncogene*; such oncogenes are capable of immortalizing, so to speak, the stimulated cell to form a tumor. Oncogenes are also found in normal cells and may contain mutations or are capable of being activated by cellular and environmental (epigenetic) events as noted later.

Molecular and Genetic Features of Brain Tumors The above concepts have been expanded greatly by the identification of certain genetic aberrations that arise in tumor cells of the nervous system. What has emerged from these studies is the view that the biogenesis and progression of brain tumors are a consequence of defects in the control of the cell cycle. Some molecular defects predispose to tumor genesis; others underlie subsequent progression and accelerated malignant transformation and yet others may confer sensitivity or resistance to chemotherapeutic agents. This model presupposes the acquisition of multiple genetic defects over time since, with the exception of special inherited conditions such as neurofibromatosis, ataxia telangiectasia, and a few others, these are not germ line mutations but are acquired as somatic events in the course of tumor evolution.

In cases that have an inherited and transmissible germ line defect there may be additional events that also cause somatic genetic mutations. Typically, inherited mutations affect only one of two copies of a tumor suppressor gene that, by itself, does not cause cancer. However, if the second copy of the gene acquires a mutation (e.g., from a chemical toxin or irradiation) the tumor suppression function of the gene is lost and neoplastic transformation of the cell becomes likely. These ideas are consistent with the observation that many of the gene defects that predispose to cancer are dominantly inherited. More recently, single nucleotide polymorphisms have been identified that in combination predispose to certain childhood tumors such as neuroblastoma, or to the more aggressive forms of various tumors.

The above model is illustrated by consideration of the astrocytoma. Among the first detectable changes are mutations acquired in the act of neoplastic cell division

that inactivate the tumor suppressor gene *p53* on chromosome 17p; over 50 percent of astrocytomas have deletions within this gene. Other early changes include overexpression of genes that control growth factors or their receptors as noted below. After the tumor develops, progression to a more malignant grade of astrocytoma or to a glioblastoma may be triggered by defects in the *p16*-retinoblastoma gene signaling pathway, loss of chromosome 10 (seen in approximately 90 percent of high-grade gliomas), or overexpression of the epidermal growth factor gene. In fact, it is striking that analysis of the patterns of these defects in some tumors correlates with the staging and aggressive characteristics of these tumors. The events that lead to their accumulation are not clear, as noted below. Also, mutations in the genes that code for isocitrate dehydrogenase (IDH1 and 2) are common in gliomas and oligodendrogliomas and their presence relates to less tumor progression.

Knowledge of the molecular signatures of certain tumors may have considerable clinical value. For example, oligodendrogliomas that have combined deletions in chromosomes 1p and 19q respond well to chemotherapy and this property increases survival (Reifenberger and Louis; Louis et al, 2002). The childhood tumors of neuroectodermal origin would seem to be particularly attractive as models to explore genetic alterations and indeed, various changes such as the amplification of the *MYCN* oncogene has been associated with an aggressive clinical course and poor outcome in neuroblastoma and medulloblastoma.

Much of the modern genetic understanding of brain tumors is derived from the technical gene microarrays. The patterns of these multiple gene analyses are able to distinguish some types of medulloblastomas from the similar-appearing, primitive neuroectodermal tumors; the medulloblastomas express classes of genes that are characteristic of cerebellar granule cells, suggesting they arise from these cells. Also, gene expression signatures confer useful prognostic information in a more general way than noted above for oligodendroglioma. For example, medulloblastomas that express genes indicative of cerebellar differentiation are associated with longer survival than those expressing genes related to cell division (Pomeroy et al).

As alluded to earlier, in approximately 50 percent of gliomas there is an overexpression or a mutant form of epidermal growth factor receptor (EGFR) and of platelet-derived transforming growth factor receptor (PDGFR), suggesting a role for these in the progression of certain tumor types. Other trophic factors are overexpressed in yet other brain neoplasms and perhaps contribute to their morphology and growth pattern; for example, vascular endothelial growth factor (VEGF) is found in extremely high concentrations in meningiomas, which are highly vascular by nature. These findings, taken together, suggest an autocrine stimulation of growth by these factors and an interaction with some of the aforementioned gene defects. However, having emphasized molecular and chromosomal changes, it is not yet clear that any of them is truly causative or if they simply reflect an aberrant genetic process that accompanies the evolution of tumor growth and progression.

Finally, epigenetic events related to the attachment of histones to various tumor genes alter transcription in ways that may be relevant to growth and treatment effects. The best studied of these is the methylation status of the promoter of *MGMT*, a methyltransferase that alters sensitivity of the glioma to chemotherapy (see further on).

On the basis of this molecular information, views of the pathogenesis of neoplasia are being cast along new lines. Some of the specifics of these new data are presented in the following discussions of particular tumor types. A more extensive review can be found in the article by Osborne and colleagues, and the text by Kaye and Laws.

Pathophysiology of Brain Tumors

The production of symptoms by tumor growth is governed by certain principles of mechanics and physiology, some of which were discussed in Chaps. 17 and 30. There it was pointed out that the cranial cavity has a restricted volume, and the three elements contained therein—the brain (about 1,200 to 1,400 mL), cerebrospinal fluid (CSF; 70 to 140 mL), and blood (150 mL)—are relatively but not entirely incompressible, particularly the brain substance, and each is subject to displacement by a localized mass lesion. According to the Monro-Kellie doctrine, the total bulk of the three elements is at all times constant, and any increase in the volume of one of them must be at the expense of the others, as discussed in Chap. 30. A tumor growing in one part of the brain therefore compresses the surrounding brain tissue and displaces CSF and blood; once the limit of this accommodation is reached, the intracranial pressure (ICP) rises. The elevation of ICP and perioptic pressure impairs axonal transport in the optic nerve and the venous drainage from the optic nerve head and retina, manifesting in papilledema.

Only some brain tumors cause papilledema and many others—often quite as large—do not. Thus one may question whether the Monro-Kellie doctrine and its simple implied relationships of intracranial volume and CSF pressure fully account for the development of raised ICP and papilledema with brain tumors. This discrepancy is in part because in a slow process, such as tumor growth, brain tissue is to some degree compressible, as one might suspect from the large indentations of brain produced by massive meningiomas.

The slow growth of most tumors permits accommodation of the brain to changes in cerebral blood flow and ICP. Only in the advanced stages of tumor growth do the compensatory mechanisms fail and CSF pressure and ICP rise, with consequences described in Chap. 30. Once pressure is raised in a particular compartment of the cranium, the tumor begins to displace tissue at first locally and at a distance from the tumor, resulting in a number of *false localizing* signs, including coma, described in Chap. 17. Indeed, the transtentorial herniations, the paradoxical corticospinal signs of Kernohan and Woltman, sixth- and third-nerve palsies, occipital lobe infarcts, mid-brain hemorrhages, and secondary hydrocephalus were

all originally described in tumor cases (see further on, under "Brain Displacements and Herniations").

Brain Edema

Brain edema is such a prominent feature of cerebral neoplasm that this is a suitable place to summarize what is known about it. With tumor growth, the venules in the cerebral tissue adjacent to the tumor are compressed, with resulting elevation of capillary pressure, particularly in the cerebral white matter where edema is most prominent.

It has been recognized that conditions leading to peripheral edema, such as hypoalbuminemia and increased systemic venous pressure, do not have a similar effect on the brain. By contrast, lesions that alter the blood-brain barrier cause rapid swelling of brain tissue. Klatzo specified two categories of edema: *vasogenic* and *cytotoxic*. Fishman added a third, which he called *interstitial* edema. An example of the latter is the edema that occurs with obstructive hydrocephalus, especially when the ependymal lining is disrupted and CSF seeps into the periventricular tissues in the spaces between cells and myelin. Most neuropathologists use the term *interstitial* to refer to any increase in the extravascular intercellular compartment of the brain; this would include both vasogenic and interstitial edema.

Vasogenic edema is the type seen in the vicinity of tumor growths and other localized processes as well

as in more diffuse injury to the blood vessels (e.g., lead encephalopathy, malignant hypertension). It is practically limited to the white matter and is evidenced by decreased attenuation on CT and by hyperintensity on T2-weighted MRI and elevated diffusivity (reduced anisotropy) on diffusion-weighted MRI. Presumably, there is increased permeability of the capillary endothelial cells so that plasma proteins exude into the extracellular spaces (Fig. 31-1A). This heightened permeability has been attributed to a defect in the tight endothelial cell junctions, but current evidence indicates that active vesicular transport of water across the endothelial cells is a more important factor.

Microvascular transudative factors, such as proteases released by tumor cells, also contribute to vasogenic edema by loosening the blood-brain barrier and allowing passage of blood proteins. The small protein fragments that are generated by this protease activity may exert osmotic effects as they spread through the white matter of the brain. This is the postulated basis of the regional swelling, or *localized cerebral edema* that surrounds the tumor. Experimentally, the increase in permeability has been shown to vary inversely with the molecular weight of various markers; e.g., inulin (molecular weight: 5,000) enters the intercellular space more readily than albumin (molecular weight: 70,000).

The vulnerability of white matter to vasogenic edema is not well understood; probably its loose structural organization offers less resistance to fluid under

Figure 31-1. A. Schematic representation of the astrocytes and endothelial cells of the capillary wall in the normal state (above) and in vasogenic edema (below). Heightened permeability in vasogenic edema is partly the result of a defect in tight endothelial junctions, but mainly a result of active vesicular transport across endothelial cells. B. Cellular (cytotoxic) edema, showing swelling of the endothelial, glial, and neuronal cells at the expense of the extracellular fluid space of the brain. (Reproduced by permission from Fishman.)

pressure than the gray matter. There may also be special morphologic characteristics of white matter capillaries. The accumulation of plasma filtrate, with its high protein content, in the extracellular spaces and between the layers of myelin sheaths would be expected to alter the ionic balance of nerve fibers, impairing their function but this has never been demonstrated satisfactorily.

By contrast, in *cytotoxic edema*, all the cellular elements (neurons, glia, and endothelial cells) swell with fluid and there is a corresponding reduction in the extracellular fluid space. Because a shift of water occurs from the extracellular to the intracellular compartment, there is relatively little mass effect, the opposite of what occurs with the vascular leak of vasogenic edema. This cellular edema occurs typically with hypoxic-ischemic injury but it may also complicate acute hyposmolality of the plasma, acute hepatic encephalopathy, inappropriate secretion of antidiuretic hormone, and the osmotic disequilibrium syndrome of hemodialysis (see discussion of hyponatremia and "dialysis disequilibrium syndrome" in Chap. 40). The effect of oxygen deprivation is the cause of failure of the adenosine triphosphate (ATP)-dependent sodium pump within cells; sodium accumulates in the cells, and water follows (Fig. 31-1B). The term *cellular edema* may be preferable to *cytotoxic edema* because it emphasizes intracellular ionic movement and not the implication of a toxic factor.

Like vasogenic edema, cytotoxic edema results in decreased attenuation in CT and hyperintensity on T2-weighted MRI. However, it is coupled with reduced diffusivity (increased anisotropy) rather than elevated diffusivity on diffusion-weighted MRI. In the case of cerebral infarction, an initial phase of cytotoxic edema precedes the onset of vasogenic edema, manifest as early reduced diffusivity followed by later elevated diffusivity on diffusion-weighted MRI.

Interstitial (hydrocephalic) edema, as defined by Fishman, is a recognizable condition but is probably of less clinical significance than cytotoxic or cellular edema. In tension hydrocephalus, the edema can extend for up to 2 to 3 mm from the ventricular wall. However, MRI suggests that the periventricular edema is more extensive than what is observed pathologically. There are also experimental data to show that a transependymal or periventricular route is utilized for absorption of CSF in hydrocephalus (Rosenberg et al).

Treatment of Brain Edema and Raised ICP (See "Management of Raised Intracranial Pressure" in Chap. 35)

The treatment of brain edema and elevated ICP is governed by the underlying disease (excision of a tumor, treatment of intracranial infection, placement of a shunt, etc.). Here we consider the therapeutic measures that can be directed against the edema itself and the raised ICP as they apply to brain tumor.

The use of high-potency glucocorticosteroids has a beneficial effect on the vasogenic edema associated with tumors, both primary and metastatic, sometimes beginning within hours. Probably these steroids act directly on the endothelial cells, reducing their permeability. Steroids also shrink normal brain tissue, thus reducing overall

intracranial pressure. Drugs such as dexamethasone also reduce the vasogenic edema associated with brain abscess and head injury, but their usefulness in these cases and in large cerebral infarctions, contusions, and hemorrhage is less clear; in fact, most attempts to demonstrate benefit in all conditions but brain tumors have proven negative. The swelling surrounding necrotic tissue is reduced; however, there is no evidence that cytotoxic or cellular edema responds to administration of glucocorticoids.

For patients with brain tumor, it is common practice initially to use doses of dexamethasone of approximately 4 mg q6h, or the equivalent dose of methylprednisolone. Although a few patients require a rigid schedule, a dose with meals and at bedtime usually suffices to suppress headache and focal tumor signs. In patients with large tumors and marked secondary edema, further benefit is sometimes achieved by the administration of extremely high doses of dexamethasone, to a total of 100 mg/d or more for a brief time. An initial dose may be given intravenously. Always to be kept in mind are the potentially serious side effects of sustained steroid administration, even at standard dose levels. Rare complications, such as aseptic necrosis of the hip, are sometimes idiosyncratic; consequently, the schedule should be organized around the desired clinical effect. It is also recognized that these drugs interfere with the metabolism of certain anticonvulsants commonly used in brain tumor patients.

In patients who have brain edema and who require intravenous fluids, one avoids solutions containing water ("free water") not matched by equivalent amounts of sodium. Normal saline (314 mOsm/L) is preferable, and lactated Ringer solution (osmolality 289 mOsm/L) is acceptable, but dextrose solutions alone, in any concentration (except D5/NS), are avoided because of their hyposmolar concentration.

The parenteral administration of hypertonic solutions, to which the brain is only partially permeable (mannitol, hypertonic saline, urea, glycerol), by shifting water from brain to plasma, is an effective means of rapidly reducing brain volume and lowering ICP as discussed more extensively in Chap. 35 in relation to trauma as we have summarized elsewhere in a review (Ropper). These agents are useful in urgent circumstances but have a diminishing effect over days. Edema, however, is actually little affected by shrinkage of the remaining normal brain provides most of the internal decompression.

Mannitol is the most widely used osmotic agent; a 25 percent solution is administered parenterally in a dose of 0.5 to 1.0 g/kg body weight over a period of 2 to 10 min. Hypertonic saline solutions (3, 7, or 23 percent) are equally effective. Repeated use on a regular schedule can lead to a reduction in headache and stabilization of some of the deleterious effects of a tumor. Diuretic drugs, notably acetazolamide and furosemide, may be helpful in special instances (interstitial edema, pseudotumor cerebri) by virtue of creating a hyperosmolar state and by reducing the formation of CSF. However, their effects are usually mild and transient.

Highly permeable solutes such as glucose do little to reduce brain volume, as they do not create an osmolar gradient that shifts water from the brain to the vasculature.

Furthermore, with repeated administration of hyperosmolar solutions such as mannitol or with diuretics, the brain gradually increases its osmolality—the result of added intracellular solute; thus these agents are not suitable for long-term use. The notion that hyperosmolar agents might exaggerate tissue shifts by shrinking normal brain tissue has not been substantiated. The net effect of hyperosmolar therapy is reflected roughly by the degree of hyperosmolality and hyponatremia that is attained.

Controlled hyperventilation is another method of rapidly reducing brain volume by producing respiratory alkalosis and cerebral vasoconstriction; it is used mainly in cases of brain trauma with high ICP (see Chap. 35), during intracranial surgery, and in the management of patients who have become acutely comatose from the mass effect of a tumor, but its effect is brief.

Brain Displacements and Herniations

(See also Chap. 17)

An understanding of the effects of elevated intracranial pressure, localized vasogenic edema, and displacements of tissue and herniations are absolutely essential to understanding the clinical behavior of intracranial tumors and mass lesions of any type. Often the symptoms of intracranial tumors are related more to these effects than to invasion or destruction of neurologic structures by the tumor. The several “false localizing” signs (coma, unilateral or bilateral abducens palsy, pupillary changes, ipsilateral or bilateral corticospinal tract signs, etc.) are also attributable to these mechanical changes and tissue displacements. The main aspects of this problem, particularly the coma-producing mechanisms, were considered in Chap. 17. The pressure from a mass within any one dural compartment causes shifts or herniations of brain tissue to an adjacent compartment where the pressure is lower. The three well-known herniations are *subfalcial*, *transtentorial*, and *cerebellar–foramen magnum* (see Fig. 17-1), and there are several less familiar ones (*upward cerebellar–tentorial*, *diencephalic–sella turcica*, and *orbital frontal–middle cranial fossa [transalar]*). Herniation of swollen brain through an acquired defect in the calvarium, in relation to craniocerebral trauma or surgical craniotomy, is yet another (transcalvarial) type.

Subfalcial herniation, in which the cingulate gyrus is pushed under the falx, occurs frequently, but little is known of its clinical manifestations except that there may be occlusion of an anterior cerebral artery and resultant frontal lobe infarction. The *cerebellar–foramen magnum herniation* or *pressure cone* described by Cushing in 1917 consists of downward displacement of the inferomedial parts of the cerebellar hemispheres (mainly the ventral paraflocculi or tonsillae) through the foramen magnum, dorsolateral to the cervical cord. The clinical manifestations are less well delineated than those of the temporal lobe–tentorial herniation. Cushing considered the typical signs of cerebellar herniation to be episodic tonic extension and arching of the neck and back and extension and internal rotation of the limbs, with respiratory disturbances, cardiac irregularity (bradycardia or tachycardia), and loss of consciousness.

Other signs with subacutely evolving masses in the posterior fossa include pain in the neck, stiff neck, head

tilt, and paresthesias in the shoulders, dysphagia, and loss of tendon reflexes in the arms. Head tilt, stiff neck, arching of the neck, and paresthesias over the shoulders are attributable to the herniation of the cerebellar tonsils into the foramen magnum, and tonic extensor spasms of the limbs and body (so-called cerebellar fits) and coma are caused by the compressive effects of the cerebellar mass on medullary structures or of hydrocephalus on upper brainstem structures. In any case, *respiratory arrest* is the feared and often fatal effect of medullary compression by a “cerebellar pressure cone.” It may occur suddenly, without the aforementioned additional signs. With cerebellar mass lesions there may also be *upward herniation* of the cerebellum through the incisura of the tentorium. The clinical effects have not been clearly determined, but Cuneo and colleagues have attributed decerebrate posturing and pupillary changes—initially both pupils are miotic but still reactive, progressing to anisocoria and enlargement—to this type of brain displacement.

CLINICAL AND PATHOLOGIC CHARACTERISTICS OF BRAIN TUMORS

It should be stated at the outset that tumors of the brain often exist with hardly any symptoms. A slight bewilderment, slowness in comprehension, or loss of capacity for sustained mental activity may be the only deviations from normal, and signs of focal cerebral disease are wholly lacking. In some patients, on the other hand, there is early indication of cerebral disease in the form of a progressive hemiparesis, a seizure occurring in a previously well person, or some other dramatic symptom. In a third group, the existence of a brain tumor can be assumed because of the presence of increased intracranial pressure with or without localizing signs of the tumor. In yet another group, the symptoms are so definite as to make it likely that not only is there an intracranial neoplasm but that it is of a certain type and is located in a particular region. These localized growths create certain syndromes seldom caused by any other disease.

In the further exposition of this subject, intracranial tumors are considered in relation to these common modes of clinical presentation:

1. Patients who present with focal cerebral signs and general impairment of cerebral function, headaches, or seizures
2. Patients who present with evidence of increased intracranial pressure
3. Patients who present with specific intracranial tumor syndromes

Patients Presenting with General Impairment of Cerebral Function, Headaches, and Seizures

Altered mental function, headache, dizziness, and seizures are the usual manifestations in this group of patients. Until the advent of modern imaging procedures,

these were the patients who presented the greatest difficulty in diagnosis and about whom decisions were often made with a great degree of uncertainty. Their initial symptoms are vague, and not until some time has elapsed will signs of focal brain disease appear; when they do, they are not always of accurate localizing value.

Changes in Mental Function

A lack of persistent application to everyday tasks, undue irritability, emotional lability, mental inertia, faulty insight, forgetfulness, reduced range of mental activity (judged by inquiring about the patient's introspections and manifested in his conversation), indifference to common social practices, lack of initiative and spontaneity—all of which may be misattributed to anxiety or depression—make up the cognitive and behavioral abnormalities seen in this clinical circumstance. Inordinate drowsiness or apathy may be prominent. We have sought a convenient term for this complex of symptoms, which is perhaps the most common type of mental disturbance encountered with neurologic disease, but none seems entirely appropriate. There is both a reduction in the amount of thought and action and a slowing of reaction time. MacCabe referred to this condition as "mental asthenia," which has the merit of distinguishing it from depression.

Much of this change in behavior is accepted by the patient with forbearance; if any complaint is made, it is of being weak, tired, or dizzy (nonvertiginous). Within a few weeks or months, these symptoms become more prominent. When the patient is questioned, a long pause precedes each reply (abulia); at times the patient may not respond at all. Or, at the moment the examiner decides that the patient has not heard the question and prepares to repeat it, an appropriate answer is given, usually in few words. Moreover, the responses are often more intelligent than one would expect, considering the patient's torpid mental state. Many of these features will be recognized as components of a frontal lobe syndrome, but the tumor is often situated elsewhere, or is diffusely infiltrative. There are, in addition, patients who are overtly confused or demented. If the condition remains untreated, dullness and somnolence increase gradually and, finally, as increased intracranial pressure supervenes, the patient progresses to stupor or coma.

Headaches (See also "Headaches of Brain Tumor" in Chap. 10)

These are an early symptom in fewer than 25 percent of patients with brain tumor and are variable in nature. In some, the pain is slight, dull, and episodic; in others, it is severe and either dull or sharp but also intermittent. If there are any characteristic features of the headache, they would be its nocturnal occurrence or presence on first awakening and perhaps its deep, nonpulsatile quality. However, these are not specific attributes, as migraine and hypertensive vascular headaches may also begin in the early morning hours or upon awakening. But if vomiting occurs at the peak of the head pain, tumor is more likely, as noted later. Occipitotemporal headache with vomiting is indicative of a tumor in or near the cerebellum

and foramen magnum and is one typical presentation in children.

Patients with brain tumors do not always complain of head pain even when it is present, but they may betray its existence by placing their hands to their heads and looking distressed. When headache appears in the course of the psychomotor asthenia syndrome, it serves to clarify the diagnosis, but not nearly as much as does the occurrence of a seizure.

The mechanism of the headache is not fully understood and there may be more than one pathophysiology. In the majority of instances, the CSF pressure is normal during the first weeks when the headache is present, and one can attribute it only to local swelling of tissues and to distortion of blood vessels in the dura overlying the tumor. Later, the headache may be related to increases in intracranial pressure, thus the early morning occurrence after recumbency and vomiting, as discussed in Chap. 10. Tumors above the tentorium cause headache on the side of the tumor and in its vicinity, in the orbitofrontal, temporal, or parietal region; tumors in the posterior fossa usually cause ipsilateral retroauricular or occipital headache. With elevated intracranial pressure, bifrontal or bioccipital headache is the rule regardless of the location of the tumor.

Vomiting and Dizziness

Vomiting appears in a relatively small number of patients with a tumor syndrome and usually accompanies the headache when the latter is severe. It is more frequent with tumors of the posterior fossa. The most persistent vomiting (lasting several weeks) that we have observed has been in patients with low brainstem gliomas, fourth ventricular ependymomas, and subtentorial meningiomas. Some patients may vomit unexpectedly and forcibly without preceding nausea ("projectile vomiting"), a sign that is fairly specific to tumor in children, but others suffer nausea and severe discomfort. Usually the vomiting is not related to the ingestion of food, and, often, it occurs before breakfast.

No less frequent is the complaint of *dizziness*. As a rule it is not described with accuracy and consists of an unnatural sensation in the head, coupled with feelings of strangeness and insecurity when the position of the head is altered. Positional vertigo can be a symptom of a tumor in the posterior fossa affecting vestibular structures, but has many other more common and benign causes (see Chap. 15).

Seizures

The occurrence of focal or generalized seizures is the other major manifestation of brain tumor besides slowing of mental functions and signs of focal brain damage. Convulsions have been observed in 20 to 50 percent of all patients with cerebral tumors. *A first seizure during adulthood is always suggestive of brain tumor and, in the authors' experience, has been the most common initial manifestation of primary and metastatic neoplasm.* The localizing significance of seizure patterns was discussed in Chap. 16. Seizures caused by brain tumor most often have a focal onset and may secondarily generalize. There may

be one seizure or many, and they may follow the other symptoms or precede them by weeks or months or—exceptionally, in patients with low-grade astrocytoma, oligodendroglioma, or meningioma—by several years. Status epilepticus as an early event from brain tumor is rare but has occurred in a few of our patients. As a rule, the seizures respond to standard antiepileptic medications and may improve after surgery for tumor resection.

Patients Presenting with Regional or Localizing Symptoms and Signs (Glioblastoma Multiforme, Astrocytoma, Oligodendroglioma, Ependymoma, Metastatic Carcinoma, Meningioma, and Primary Lymphoma)

Sooner or later, focal cerebral signs will be discovered in most patients with brain tumors. Most often the focal signs are at first slight and subtle, but some patients present with such signs. In the modern era of ubiquitous imaging for all manner of cerebral complaints, CT or MRI often will have disclosed the presence of a tumor before either focal cerebral signs or the signs of increased intracranial pressure have become evident.

The cerebral tumors that are most likely to produce the syndromes of asthenia, headache, seizures, or focal signs are the ones listed above in the heading. The clinical aspects of these diseases, which happen to be the most common brain tumors in adults, are discussed in the sections below.

Glioblastoma Multiforme and Anaplastic Astrocytoma

These high-grade gliomas account for approximately 20 percent of all intracranial tumors and for more than 80 percent of gliomas of the cerebral hemispheres in adults. Although predominantly cerebral in location, they may also arise in the brainstem, cerebellum, or spinal cord. The peak incidence is in middle adult life (mean age for the occurrence of glioblastoma is approximately 60 years, and 46 years for anaplastic astrocytoma), but no age group is exempt. The incidence is higher in men (ratio of approximately 1.6:1). Almost all of the high-grade gliomas occur sporadically, without a familial predilection.

The glioblastoma, known since the time of Virchow, was definitively recognized as a glioma by Bailey and Cushing and given a place in their histogenetic classification. They are now listed as grade IV glial tumors in the WHO classification. Most arise in the deep white matter as a heterogenous mass and quickly infiltrate the brain extensively, sometimes attaining enormous size before attracting medical attention.

The tumor may extend to the meningeal surface or the ventricular wall, which probably accounts for the increase in CSF protein (more than 100 mg/dL in many cases), as well as for an occasional pleocytosis of 10 to 100 cells or more, mostly lymphocytes. The CSF is usually normal, however. Malignant cells, carried in the CSF, rarely may form distant foci on spinal roots or cause a widespread meningeal gliomatosis. Extraneural metastases, involving bone and lymph nodes, are very rare; usually they occur only after a craniotomy has been

performed. Approximately 50 percent of glioblastomas occupy more than one lobe of a hemisphere; between 3 and 6 percent show multicentric foci of growth and thereby simulate metastatic cancer. A legitimate question is whether these tumors can have a multicentric origin or spread via CSF pathways. We have the impression that the first configuration does exist.

The tumor has a variegated appearance, being a mottled gray, red, orange, or brown, depending on the degree of necrosis and presence of hemorrhage, recent or old. The imaging appearance is usually that of an inhomogeneous mass, often with a center that is hypointense and nonenhancing. An irregular rim of enhancement surrounds the core lesion, and is surrounded by nonenhancing edematous brain tissue, consisting of a combination of infiltrating tumor cells and vasogenic edema (Fig. 31-2). It is not uncommon to see small nodular enhancing lesions adjacent to, but distinct from, the primary lesion. Part of one lateral ventricle is often distorted, and both lateral and third ventricles may be displaced.

The characteristic histologic findings of glioblastoma are hypercellularity with pleomorphism of cells and nuclear atypia; identifiable astrocytes with fibrils in combination with primitive forms in many cases; tumor giant cells and cells in mitosis; hyperplasia of endothelial cells of small vessels; and necrosis, hemorrhage, and thrombosis of vessels. This variegated appearance distinguishes glioblastoma from the anaplastic astrocytomas, which show frequent mitoses and atypical cytogenic features but no grossly necrotic or hemorrhagic areas. It is the necrotic and sometimes cystic areas that appear hypointense on imaging studies. An MRI study by Ulmer and colleagues showed that 70 percent of patients show evidence of a small region of infarction immediately surrounding the tumor in the postoperative period;

Figure 31-2. Glioblastoma multiforme. Contrast-enhanced T1-weighted MRI illustrates a large irregularly enhancing tumor with internal necrosis deep within the left cerebral hemisphere.

most of the affected areas also demonstrate these cystic encephalomalacic areas. The vasculature and fibroblasts can undergo a sarcomatous transformation giving the tumor a mixed appearance that is termed *gliosarcoma*.

Originally, glioblastoma was thought to be derived from and composed of primitive embryonal cells, or, in the late decades of the twentieth century, to arise through anaplasia of maturing astrocytes. However, these views have been called into question because models of malignant transformation of neural stem cells or of glial progenitor cells explain many of the characteristics and behavior of gliomas. The location, cellular and genetic heterogeneity, and manner of growth and spread of these tumors are consistent with an origin in a primitive cell. Sanai and colleagues have summarized the case for stem cell origin, but this notion is not universally accepted and potential deficiencies in this theory are noted by Reid and coworkers. The genetic or epigenetic events that putatively lead to a malignant evolution of these progenitor cells are not known. Ironically, this is a reversion to the idea of the early last century that posited an embryonal origin of glioma.

The histologic grade may vary from site to site within a tumor and it is common for sites of low-grade astrocytoma and glioblastoma to coexist; in some high-grade tumors there are even sites of well-differentiated astrocytoma. This relates to a problem that arises in interpreting single small biopsy samples taken for diagnosis. It is a fair statement that the most aggressive component (e.g., glioblast elements) determines the tumor's behavior.

To some extent, this behavior is also related to the genetic changes described earlier under "Molecular and Genetic Features of Brain Tumors." Amplification of the *EGFR* gene is characteristic in older patients with tumors that begin entirely as glioblastomas, whereas acquired mutations of the *p53* gene tend to occur in younger individuals whose tumors progress from an astrocytoma to a glioblastoma. More recently, the progression of astrocytomas and oligodendrogliomas to more malignant forms has been related to the enzyme isocitrate dehydrogenase, encoded by the genes *IDH1* and *IDH2*. Patients with mutations in these genes had better outcomes and slower tumor progression as presented by Yan and colleagues. The change in *EGFR*, a receptor tyrosine kinase that is implicated in the growth of a number of solid tumors, and other acquired mutations and epigenetic alterations, such as in the *MGMT* promoter gene discussed further on, are proving to be predictors of responsiveness to chemotherapeutic agents and of prognosis, as noted later in the chapter. Other tumors display underexpression of the tumor suppressor gene *PTEN*. It is likely that genetic analyses of tumor material from individual patients will become an increasingly important part of therapeutic decisions.

The natural history of untreated glioblastoma is well characterized. Fewer than 20 percent of patients survive for 1 year after the onset of symptoms and only about 10 percent live beyond 2 years (Shapiro). Age is an important prognostic factor; fewer than 10 percent of patients older than age 60 years survive for 18 months, in comparison to two-thirds of patients younger than age 40 years. Survival with anaplastic astrocytoma is somewhat better, typically 3 to 5 years. Cerebral edema and increased

intracranial pressure are usually the causes of death. Survival rates with treatment are discussed below.

The diagnosis must be confirmed by a stereotactic biopsy or by a craniotomy that aims to remove as much tumor as is feasible at the same time.

Treatment At operation, usually only part of the tumor can be removed; its multicentricity and diffusely infiltrative character defy the scalpel. Partial resection of the tumor ("debulking"), however, seems to prolong survival as noted below. Neurosurgeons have developed a number of cortical electrophysiologic mapping and imaging techniques to facilitate maximal resection without injuring adjacent brain tissue.

Except for palliation, little can be done to alter the course of glioblastoma. For a brief period, corticosteroids, usually dexamethasone in doses of 4 to 10 mg q6–12h, are helpful if there are symptoms of mass effect, such as headache or drowsiness; local signs and surrounding edema tend to improve as well. Antiepileptic medications are not required unless there have been seizures. Although some neurologists and neurosurgeons still administer them in order to preempt a convulsion, several series have found antiepileptic medications to be unnecessary for this purpose. Serious skin reactions (erythema multiforme and Stevens-Johnson syndrome) may occur in patients receiving phenytoin at the same time as cranial radiation (Delattre et al). A maximally feasible resection, the debulking described above, is combined with radiation and chemotherapy. Cranial irradiation to a total dose of 6,000 cGy increases survival by 5 months on average (see below). This is true even in the elderly who have had only a biopsy without resection according to a trial conducted by Keime-Guibert and colleagues.

It had been considered for several decades that the addition of chemotherapeutic nitrosourea agents such as carmustine (BCNU) or lomustine (CCNU) increase survival slightly. Cisplatin and carboplatin have provided similar small marginal improvements in survival beyond that obtained by debulking and radiation therapy. Several randomized trials, however, have failed to show substantial benefit of chemotherapy but the Glioma Meta-analysis Trialists (GMT) Group had concluded in 2002 that there was a clear but quite small benefit of chemotherapy.

The methylating agent temozolomide, given in the form of an orally administered prodrug, has lower toxicity and has been shown in several trials to produce slightly superior results to the aforementioned agents. In a large trial conducted by Stupp and colleagues, the median survival was 14.6 months with radiation and temozolomide, compared to 12.1 months with radiation alone, but 2-year survival was more than doubled from 10 to 27 percent. The drug is administered daily (75 mg/m²) concurrently with radiotherapy and, after a hiatus of 4 weeks, given for 5 d every 28 d for 6 cycles. Its main complications are thrombocytopenia or leukopenia in 5 to 10 percent of patients, and rare cases of *Pneumocystis carinii* pneumonia. Furthermore, high levels of a methyltransferase protein (*MGMT*) in some glioblastomas lead to resistance to chemotherapy. Hegi and colleagues found a relationship between the epigenetic silencing of the promoter of this gene ("methylation status") and the response to temozolomide. In fact, almost

all the marginal benefit of the drug in their study could be attributed to improved survival in this group who displayed a methylated gene. However, there is still activity of temozolomide in nonmethylated tumors and is used in almost all cases. Additionally, there may be an interaction between MGMT methylation and mutations in other genes such as *IDH1* (Wick et al).

Tyrosine kinase inhibitors (erlotinib, gefitinib) have been developed in response to the upregulation of EGFR mentioned earlier. In a preliminary but provocative study, Mellinghoff and coworkers found that a deletion mutation of the gene for this protein and expression of the tumor suppression protein PTEN predicted responsiveness of recurrent gliomas to treatment with EGFR kinase inhibitors. This represents one example in a growing field of prediction of treatment response in relation to tumor genetics.

Brachytherapy (implantation of iodine-125 or iridium-193 beads or needles) and high-dose focused radiation (stereotactic radiosurgery) have so far not significantly altered survival times but continue to be studied.

The treatment of recurrent glioblastoma or anaplastic astrocytoma after surgery and radiation, almost inevitable occurrences, is controversial and must be guided by the location and pattern of tumor growth and the patient's age and relative state of health. Almost all glioblastomas recur within 2 cm of their original site and 10 percent develop additional lesions at distant locations. Reoperation is sometimes undertaken for local recurrences. The most aggressive approach—a second surgery and chemotherapy—can prove effective and has been generally used in patients younger than age 40 years whose original operation was many months earlier. If the PCV regimen discussed earlier has not already been used, some neurooncologists resort to that combination or the newer and better-tolerated alkylating agent temozolomide (which may be used if the PCV regimen was administered previously). These chemotherapeutic drugs may prolong the symptom-free interval but have little effect on survival. A promising approach for recurrent malignant gliomas is the use of drugs that target the tumor's vasculature. Antiangiogenic agents such as bevacizumab, a VEGF inhibitor, sometimes given in combination with chemotherapy, may delay progression and greatly reduce cerebral edema, therefore diminishing the requirement for corticosteroids, but also do not prolong survival. A recent but preliminary provocative observation from retrospective series has been that patients with glioblastoma receiving valganciclovir, ostensibly for concurrent CMV infections, had better survival than those who did not receive the drug (Söderberg-Nauclér and colleagues).

With aggressive surgical removal and radiotherapy, as described above, median survival for patients with glioblastoma is 12 months, compared to 7 to 9 months without such treatment.

Low- and Intermediate-Grade Astrocytoma

The lower-grade astrocytomas (grade II in the WHO classification), which constitute between 25 and 30 percent of cerebral gliomas, may occur anywhere in the brain or spinal cord. The median survival in cases of anaplastic astrocytoma is considerably longer than for glioblastoma,

2 to 5 years, often longer. Favored sites of occurrence are the cerebrum, cerebellum, hypothalamus, optic nerve and chiasm, and pons. In general, the location of the tumor appears to be influenced by the age of the patient. Astrocytomas of the cerebral hemispheres arise mainly in adults in their third and fourth decades or earlier; astrocytomas in other parts of the nervous system, particularly the posterior fossa and optic nerves, are more frequent in children and adolescents. These tumors are classified further according to their histologic characteristics: protoplasmic or fibrillary; gemistocytic (enlarged cells distended with hyaline and eosinophilic material); pilocytic (elongated, bipolar cells); and mixed astrocytoma-oligodendroglioma types. The most common type is composed of well-differentiated fibrillary astrocytes. The tumor cells contain glial fibrillary acidic protein (GFAP), which is a useful diagnostic marker in biopsy specimens. Some cerebral astrocytomas present as mixed astrocytomas and glioblastomas. The most common low-grade fibrillary type (grade II) is distinguished from the more benign WHO grade I pilocytic tumor and the rare pleomorphic xanthoastrocytoma. These distinctions correlate to a degree with the biologic behavior of the astrocytomas and therefore have prognostic importance.

Cerebral astrocytoma is a slowly growing tumor of infiltrative character with a tendency in some cases to form large cavities or pseudocysts. Other tumors of this category are noncavitating and appear grayish white, firm, and relatively avascular, almost indistinguishable from normal white matter, with which they merge imperceptibly. Fine granules of calcium may be deposited in parts of the tumor, but calcium in a slow-growing intracerebral tumor is more characteristic of an oligodendroglioma. The CSF is acellular; the only abnormalities in some cases are the increased pressure and protein content. The tumor may distort the lateral and third ventricles and displace adjacent cerebral vessels (Fig. 31-3). It may not be possible on clinical or imaging grounds to distinguish low-grade gliomas from a number of rare tumors in childhood such as the dysembryoplastic neuroepithelioma (DNET) discussed further on.

In about two-thirds of patients with astrocytoma, the first symptom is a focal or generalized seizure, and between 60 and 75 percent of patients have recurrent seizures in the course of their illness. Other subtle cerebral symptoms follow after months, sometimes after years. Headaches and signs of increased intracranial pressure are relatively late occurrences.

MRI may be helpful in distinguishing the more frequent fibrillary type of tumor under discussion from pilocytic astrocytomas. Pilocytic types are sharply demarcated, with smooth borders and little edema. On T1-weighted MRI, they are isointense or hypointense; on T2 sequences, hyperintense, and there tends to be marked enhancement of the nodular solid portion of the tumor after gadolinium infusion. Cyst formation and small amounts of calcification are common, especially in cerebellar tumors. The fibrillary tumors have a less-stereotyped appearance, generally taking the form of a more homogenous T1 hypointense and T2 hyperintense infiltrating mass with less well-defined borders and little or no contrast enhancement.

Figure 31-3. Astrocytoma of the left frontal lobe; the T2-weighted MRI shows an infiltrating tumor with minimal mass effect and mild edema. The degree of contrast enhancement is variable but most often less than glioblastoma.

Figure 31-4. Cystic astrocytoma of the right cerebellum. MRI demonstrates the large cystic component of the tumor (*smaller arrow*) which appears hypointense compared to the solid tissue component (*larger arrow*). (Reproduced by permission from Bisese JH: *Cranial MRI*. New York, McGraw-Hill, 1991.)

In children, astrocytic tumors usually arise in the cerebellum (Fig. 31-4) and declare themselves by some combination of gait unsteadiness, unilateral ataxia, and increased intracranial pressure (headaches, vomiting).

Treatment One of the more interesting developments in the treatment of low-grade tumors has been the comparison made by Jakola and colleagues between the practices in two Norwegian centers, one which practiced an aggressive approach of removing accessible tumors when they are discovered, and another, of observing the patient by sequential imaging to determine if the tumor has transformed into a more aggressive mode. While a small, and not a randomized trial, surgical excision resulted in longer survival.

Excision of part of a cerebral astrocytoma can improve survival in a good functional state for many years. The cystic astrocytoma of the cerebellum is relatively benign in its overall behavior. In such cases, resection of the tumor nodule is of singular importance in delaying or preventing a recurrence. In recent series, the rate of survival 5 years after successful surgery has been greater than 90 percent (Pencalet et al). The outcome is less assured when the tumor also involves the brainstem and cannot be safely resected.

The natural history of the low-grade gliomas is to grow slowly and eventually undergo malignant transformation. The duration of progression before this transformation occurs and the latency to recurrence with modern treatment may extend for many years. A survey of the outcome of these low-grade supratentorial tumors showed that 10-year survival after operation was from 11 to 40 percent provided that 5,300 cGy was given postoperatively (Shaw et al). This, of course, is quite in contrast to the figures for glioblastoma.

In younger patients, particularly if the neurologic examination is normal or nearly so, radiation can be delayed and the course of the tumor evaluated by serial imaging. A number of studies have come to the conclusion that delaying radiation in younger patients may avoid the consequences of dementia and hypopituitarism (Peterson and DeAngelis), but others have suggested that the tumor itself and antiepileptic drugs cause more difficulty than high-dose radiation. An extensive randomized trial of early radiotherapy in adults demonstrated that median progression-free survival was extended to 5.3 years by early treatment in comparison to 3.4 years for observation only and radiation treatment that was initiated when signs of progression occurred, but that overall survival was unaffected, averaging just over 7 years in both groups (van den Bent et al).

Lacking any clear benefit on survival, it seems to us that radiation may be withheld initially. An increase in seizures or worsening neurologic signs then presses one to turn to radiation or further surgery. Repeated operations prolong life in some patients. Although chemotherapy has as yet no established place in the treatment of low-grade pure astrocytomas, tumors with an oligodendroglial component respond well to combination chemotherapy used for the treatment of anaplastic oligodendroglioma, as described later.

The special features of astrocytomas of the pons, hypothalamus, optic nerves, and chiasm, which produce highly

characteristic clinical syndromes and do not behave like a cerebral mass, are discussed further on in this chapter.

Gliomatosis Cerebri

In this variant of high-grade glioma there is a diffuse infiltration of neoplastic glial cells, involving much of one or both cerebral hemispheres with sparing of neuronal elements but without a discrete tumor mass. Whether this type of "gliomatosis" represents neoplastic transformation of multicentric origin or direct spread from one or more small neoplastic foci is not known. For these and other reasons, the tumor is impossible to classify (or to grade) using the conventional brain tumor schemes, though the genetic and molecular alterations found in high-grade gliomas, as described earlier, are seen in some cases of gliomatosis cerebri as well.

Many small series of gliomatosis cerebri have been reported since Nevin introduced the term in 1938, but no truly distinctive clinical picture has emerged (Dunn and Kernohan). Impairment of intellect, headache, seizures, and papilledema are the major manifestations and do not set these cases apart on a clinical basis from the malignant astrocytoma, in which the tumor may also be more widespread than the macroscopic picture suggests. If there is a syndrome that can be associated early on with gliomatosis, in our experience it has been a nondescript frontal lobe behavioral syndrome sometimes mistaken for depression or a subacute dementia, or pseudobulbar palsy may be the first manifestation. The prognosis is variable but generally poor, measured in months to a few years from the time of diagnosis.

CT and MRI reveal small ventricles and one or more large confluent areas of signal change (Fig. 31-5). Imaging

Figure 31-5. Gliomatosis cerebri invading both hemispheres. T2-weighted MRI shows a large confluent area of involvement in the frontal lobes with effacement of overlying cortical sulci. There was slight enhancement along the margins of the lesions after gadolinium infusion. The patient was mentally slow but had no other neurologic signs.

studies characteristically show the tumor crossing and thickening the corpus callosum. Contrast enhancement is scant, differentiating the tumor from cerebral lymphoma, which otherwise may have a similar appearance. As the tumor advances, enhancing nodules may appear, suggesting the emergence of foci of high-grade glioma.

Treatment These tumors are too infrequent for categorical assessments of therapy, but the overall response to all antitumor treatments has been disappointing and the prognosis, as mentioned, is poor, survival usually being measured in months. Corticosteroids have little clinical effect, probably because of a paucity of vasogenic edema. Most trials suggest a benefit to radiation treatment, but the absolute prolongation of life has been only several weeks (Leibel et al). The addition of chemotherapy may confer a marginal further benefit when survival at 1 year is considered. Small series of patients treated with temozolomide suggest it may be a promising agent for this tumor but it will be difficult to conduct a randomized trial given its rarity. When a large region is infiltrated, particularly in the temporal lobe, surgical debulking may prolong life, but otherwise surgery is futile except to obtain a diagnosis.

Oligodendroglioma

This tumor was first identified by Bailey and Cushing in 1926 and described more fully by Bailey and Bucy in 1929. It is derived from oligodendrocytes or their precursor cells and may occur at any age, most often in the third and fourth decades, with an earlier peak at 6 to 12 years. It is relatively infrequent, constituting approximately 5 to 7 percent of all intracranial gliomas. From the time of its original descriptions, it was recognized as being more benign than the malignant astrocytoma. The incidence in men is twice that in women. In some cases the tumor may be recognized at surgery by its pink-gray color and multilobular form, its relative avascularity and firmness (slightly tougher than surrounding brain), and its tendency to encapsulate and form calcium and small cysts. Most oligodendrogliomas, however, are grossly indistinguishable from other gliomas, and a proportion—up to half in some series—are mixed *oligoastrocytomas*, suggesting that the precursor cell is pluripotential.

The neoplastic oligodendrocyte has a small round nucleus and a halo of unstained cytoplasm ("fried egg" appearance). The cell processes are few and stubby, visualized only with silver carbonate stains. Some of the oligodendrocytes have intense immunoreactivity to GFAP, similar to normal myelin-forming oligodendrocytes. Microscopic calcifications are observed frequently, both within the tumor and in immediately adjacent brain tissue.

The most common sites of this tumor are the frontal and temporal lobes (40 to 70 percent), often deep in the white matter, with one or more streaks of calcium but little or no surrounding edema. It is rarely found in other parts of the nervous system. By extending to the pial surface or ependymal wall, the tumor may metastasize distantly in ventricular and subarachnoid spaces, accounting for 11 percent of the series of gliomas with meningeal dissemination reported by Polmeteer and Kernohan (less frequent than medulloblastoma and glioblastoma; see also

Yung et al). The tumor does not lend itself easily to any of the grading scales, but a distinction is made between low grade (grade II) and a malignant type with degeneration, evidenced by greater cellularity and by numerous and abnormal mitoses; necrosis may occur in small regions of the tumor in about one-third of cases. In the oligoastrocytomas, either cell type may be anaplastic.

The typical oligodendroglioma grows slowly. As with astrocytomas, the first symptom in more than half of patients is a focal or generalized seizure; seizures often persist for many years before other symptoms develop. Approximately 15 percent of patients have early symptoms and signs of increased intracranial pressure; an even smaller number have focal cerebral signs (hemiparesis). Much less frequent are unilateral extrapyramidal rigidity, cerebellar ataxia, Parinaud syndrome, intratumoral hemorrhage, and meningeal oligodendrogliosis (cranial-spinal nerve palsies, hydrocephalus, lymphocytes, and tumor cells in CSF).

The appearance on imaging studies is variable, but the most typical is a hypodense (on CT) or T2 hyperintense (on MRI) heterogeneous mass near the cortical surface with relatively well-defined borders (Fig. 31-6). Intratumoral calcification can be seen in more than half the cases and is a helpful diagnostic sign, but in the context of seizures, this finding also raises the possibility of an arteriovenous malformation or a low-grade astrocytoma. Approximately half of oligodendrogliomas demonstrate some contrast enhancement, and leptomeningeal enhancement adjacent to the tumor can be seen but is rare.

In recent years, a remarkable degree of progress has been made in understanding the genetic aberrations that

occur as acquired somatic mutation within these tumors and the relationship of these changes to the prognosis and response to therapy. Specifically, loss of certain alleles on chromosome 1p has been predictive of a high degree of responsiveness to the below-described PCV chemotherapy regimen, and a similar loss on chromosome 19q has been associated with longer survival.

Treatment Surgical excision followed by radiation therapy has been the conventional treatment for oligodendroglioma. However, because of uncertainty as to the histologic classification of many of the reported cases, it is not clear whether radiation therapy is attended by longer survival. Well-differentiated oligodendrogliomas should probably not receive radiation if seizures are well controlled and there are no neurologic deficits. As mentioned earlier, in the discovery by Cairncross and MacDonald of considerable importance is that many oligodendrogliomas, especially anaplastic ones, respond impressively to chemotherapeutic agents. This has been studied with the PCV regimen (procarbazine, cyclophosphamide, and vincristine) given in approximately 6 cycles, but also applies to the better-tolerated temozolomide, which has become the preferred treatment.

The identification by Cairncross and others of genetic markers has been of great interest. For example, of 50 patients who had loss of regions on 1p, median survival was over 10 years. These findings have been variably adopted into general clinical practice and it is likely that refinements in this approach will be forthcoming (see Louis et al [2007] and Reifenberger and Louis for discussion). Mutations in IDH1 also appear to confer survival benefit. Mixed oligodendrogliomas and astrocytomas should generally be treated like astrocytomas, but temozolomide probably suffice to treat both components. An adequate direct comparison between temozolomide and PCV is awaited.

Ependymoma (See also "Ependymoma and Papilloma of the Fourth Ventricle" further on)

This tumor proves to be more complex and variable than other gliomas. Correctly diagnosed by Virchow as early as 1863, its origin from ependymal cells was first suggested by Mallory, who found the typical blepharoplasts (small, darkly staining cytoplasmic dots that are the basal bodies of the cilia as seen by electron microscopy). Two types were recognized by Bailey and Cushing: one was the ependymoma, and the other, with more malignant and invasive properties, the ependymoblastoma, now recognized as an anaplastic ependymoma. Approximately 6 percent of all intracranial gliomas are ependymomas, the percentage being slightly higher in children (8 percent). Approximately 40 percent of the infratentorial ependymomas occur in the first decade of life, a few as early as the first year. The supratentorial ones are more evenly distributed among all age groups, but in general the age incidence is lower than that of other malignant gliomas.

There is also a myxopapillomatous type of ependymoma, localized exclusively in the filum terminale of the spinal cord as discussed further on in the chapter. The latter gives rise to a special syndrome that variably combines symptoms and signs of the conus medullaris and

Figure 31-6. A partially cystic oligodendroglioma of the right frontotemporal region. There was no abnormal contrast enhancement.

the cauda equina such as sciatica or femoral pain, bladder difficulty, saddle anesthesia, and spastic leg weakness.

Ependymomas are derived from ependymal cells, i.e., the cells lining the ventricles of the brain and the central canal of the spinal cord; this is the most common glioma of the spinal cord. These cells have both glial and epithelial characteristics. As one might expect, the tumors grow either into the ventricle or adjacent brain tissue. The most common cerebral site is the fourth ventricle; less often they occur in the lateral or third ventricles. Grossly, those in the fourth ventricle are grayish pink, firm, cauliflower-like growths; those in the cerebrum, arising from the wall of the lateral ventricle, may be large (several centimeters in diameter), reddish gray, and softer and more clearly demarcated from adjacent tissue than astrocytomas, but they are not encapsulated. The tumor cells tend to form rosettes with central lumens or, more often, circular arrangements around blood vessels (pseudorosettes). Some ependymomas, called epithelial, are densely cellular; others form papillae. Some of the well-differentiated fourth ventricular tumors are probably derived from subependymal astrocytes (see later in this chapter and also Fig. 31-12).

Anaplastic ependymomas are identified by their high mitotic activity and endothelial proliferation, nuclear atypia, and necrosis. However, correlations between histopathologic features and clinical outcomes have not been well defined.

The *symptomatology* depends on the location of the neoplasm. The clinical manifestations of fourth ventricular tumors are described further on in this chapter; the point to be made here is the frequent occurrence of hydrocephalus and signs of raised intracranial pressure (manifest in children by lethargy, nausea, vomiting, and papilledema). Cerebral ependymomas otherwise resemble the other gliomas in their clinical expression in that seizures occur in approximately one-third of the cases.

The imaging characteristics are rather different from those of other tumors. With CT one observes a well-demarcated heterogeneous hyperdense mass with fairly uniform contrast enhancement. Calcification and some degree of cystic change are common in supratentorial tumors, but less so in infratentorial ones. There are mixed signal characteristics on MRI, generally hypointense on T1 sequences and hyperintense on T2. *An intraventricular location supports the diagnosis of ependymoma*, but meningioma and a number of other tumors may be found in this location. In keeping with the variability of anaplasia, the interval between the first symptom and the diagnosis ranges from 4 weeks in the most malignant types, to 7 to 8 years.

Treatment and Outcome In a follow-up study of 101 cases in Norway, where ependymomas made up 1.2 percent of all primary intracranial tumors (and 32 percent of intraspinal tumors), the postoperative survival was poor. Within a year, 47 percent of the patients had died, although 13 percent were alive after 10 years. Doubtless the prognosis depends on the degree of anaplasia (Mørk and Løken), the location of the tumor, and whether it is operable but the lack of certainty of these dicta have been alluded to earlier. Surgical removal is supplemented by radiation therapy, particularly to address the high rate of

seeding of the ventricles and spinal axis. In the treatment of anaplastic ependymomas, antineoplastic drugs are often used in combination with radiation therapy.

Meningioma (See also "Meningioma of the Sphenoid Ridge" further on)

This is a tumor, first illustrated by Matthew Baillie in his *Morbid Anatomy* (1787) and first identified properly by Bright, in 1831, originating from the dura mater or arachnoid. It was analyzed from every point of view by Harvey Cushing and was the subject of one of his most important monographs (Cushing, 1962).

Meningiomas represent approximately 15 percent of all primary intracranial tumors; they are more common in women than in men (2:1) and have their highest incidence in the sixth and seventh decades of life. Some are familial. There is evidence that persons who have undergone radiation therapy to the scalp or cranium are vulnerable to the development of meningiomas and that the tumors appear at an earlier age in such individuals (Rubinstein et al). Radiofrequency energy exposure from portable cellular devices has failed to be linked to elevated incidence of meningiomas (or gliomas), however due to some inconclusive data, and mainly social pressure, the International Agency for Research on Cancer has classified radiofrequency electromagnetic fields as "possibly carcinogenic." There are also a number of reports of a meningioma developing at the site of previous trauma, such as a cranial fracture line, but the association is uncertain.

The most frequent acquired genetic defects of meningiomas are truncating (inactivating) mutations in the neurofibromatosis 2 gene (merlin) on chromosome 22q. These are present in the great majority of certain meningiomas (e.g., fibroblastic and transitional types), but not others. Merlin deletions probably also play a role in those instances in which there is a loss of the long arm of chromosome 22. In meningiomas of both the sporadic and neurofibromatosis type 2 (NF2)-associated types, other somatic genetic defects are found, including deletions on chromosomes 1p, 6q, 9p, 10q, 14q, and 18q. Meningiomas also elaborate a variety of soluble proteins, some of which (VEGF) are angiogenic and probably relate to both the highly vascularized nature of these tumors and their prominent surrounding edema (see Lamszus for further details). Some meningiomas contain estrogen and progesterone receptors. The implications of these findings are not yet clear, but may relate to the increased incidence of the tumor in women, its tendency to enlarge during pregnancy, and an association with breast cancer.

The precise origin of meningiomas is still not settled. According to Rubinstein, they may arise from dural fibroblasts, but it was the opinion of our colleague R.D. Adams that, they are more clearly derived from arachnoidal (meningothelial) cells, in particular from those forming the arachnoid villi. Because the clusters of arachnoidal cells penetrate the dura in largest number in the vicinity of venous sinuses, these are the sites of predilection for the tumor. Grossly, the tumor is firm, gray, and sharply circumscribed, taking the shape of the space in which it grows; thus, some tumors are flat and plaque-like,

others round and lobulated. They may indent the brain and acquire a pia-arachnoid covering as part of their capsule, but they are clearly demarcated from the brain tissue (extraaxial) except in the unusual circumstance of a malignant invasive meningioma. Infrequently, they arise from arachnoidal cells within the choroid plexus, forming an intraventricular meningioma.

The cells of meningiomas are relatively uniform, with round or elongated nuclei, visible cytoplasmic membrane, and a characteristic tendency to encircle one another, forming whorls and *psammoma bodies* (laminated calcific concretions). A notable electron microscopic characteristic is the formation of very complex interdigitations between cells and the presence of desmosomes (Kepes). Cushing and Eisenhardt and, more recently, the World Health Organization (Lopes et al) have divided meningiomas into many subtypes depending on their mesenchymal variations, the character of the stroma, and their relative vascularity, but the value of such classifications is debatable. Currently neuropathologists recognize a meningothelial (syncytial) form as being the most common. It is readily distinguished from other similar but nonmeningothelial tumors such as hemangiopericytomas, fibrosarcomas, and chondrosarcomas.

Meningiomas occur at sites of dural folds, most commonly the frontoparietal parasagittal convexities, falx, tentorium cerebelli, sphenoid wings, olfactory groove, and tuberculum sellae. Ninety percent of meningiomas are supratentorial, and the majority of infratentorial meningiomas occur at the cerebellopontine angle. Some meningiomas—such as those of the olfactory groove, sphenoid wing, and tuberculum sellae—express themselves by highly distinctive syndromes that are almost diagnostic; these are described further on in this chapter. Rarely, the tumors are multiple. Inasmuch as the meningioma extends from the dural surface, it commonly incites hyperostosis of adjacent bone and can, in more

malignant cases, invade and erode the cranial bones or excite an osteoblastic reaction, giving rise to an exostosis on the external surface of the skull. Most of the following remarks apply to meningiomas of the parasagittal, sylvian, and other surface areas of the cerebrum.

Small meningiomas, less than 2.0 cm in diameter, are often found at autopsy in middle-aged and elderly persons without having caused symptoms. Only when they exceed a certain size and indent the brain or cause a seizure do they alter function. The size that must be reached before symptoms appear varies with the size of the space in which the tumor grows and the surrounding anatomic arrangements. Focal seizures are an early sign of meningiomas that overlie the cerebrum. The parasagittal frontoparietal meningioma may cause a slowly progressive spastic weakness or numbness of one leg and later of both legs, and incontinence in the late stages. The larger sylvian tumors are manifest by a variety of motor, sensory, and aphasic disturbances in accord with their location, and by seizures.

Before brain imaging became widely available, a meningioma often gave rise to neurologic signs for many years before the diagnosis was established, attesting to its slow rate of growth. Even now some tumors reach enormous size, to the point of causing papilledema, before the patient comes to medical attention. Many are detected on CT in individuals with unrelated neurologic diseases. The diagnosis of meningioma is greatly facilitated by their ready visualization with contrast-enhanced CT and MRI (Figs. 31-7 and 31-8), which reveal their tendency to calcify as well as their prominent vascularity. These changes are reflected by homogeneous contrast enhancement and by “tumor blush” on angiography. Typically the tumor takes the form of a smoothly contoured mass sometimes lobulated, with one edge abutting the inner surface of the skull, along the dura. On CT performed without contrast they are isointense or slightly hyperintense; calcification

Figure 31-7. A. Parafalcine meningioma; coronal image, MRI with gadolinium. Note the rightward displacement of an anterior cerebral artery (hypointense flow void) trapped between the right lateral margin of the mass and the right medial frontal lobe. B. Small and asymptomatic left olfactory groove meningioma, MRI with gadolinium.

Figure 31-8. Gadolinium-enhanced MRI of meningioma. Large subfrontal extraaxial mass with central calcification and surrounding vasogenic edema. Homogeneous avid enhancement is characteristic of the tumor.

at the outer surface or heterogeneously throughout the mass is common. The amount of edema surrounding the tumor is highly variable and may relate to the extent of local brain symptoms. The CSF protein is usually elevated.

Treatment Surgical excision should afford long-term or permanent cure in most symptomatic and accessible tumors. Recurrence is likely if removal is incomplete, as is often the case, but for some the growth rate is so slow that there may be a latency of many years or decades. A few tumors show malignant qualities; i.e., a high mitotic index, nuclear atypia, marked nuclear and cellular pleomorphism, and invasiveness of brain. Their regrowth is then rapid if they are not completely excised. Tumors that lie beneath the hypothalamus, along the medial part of the sphenoid bone and parasellar region, or anterior to the brainstem are the most difficult to remove surgically. By invading adjacent bone, they may become impossible to remove totally. Carefully planned radiation therapy, including various forms of stereotactic treatment, is beneficial in cases that are inoperable and when the tumor is incompletely removed or shows malignant characteristics.

Smaller tumors at the base of the skull can be obliterated or reduced in size by focused radiation, probably with comparable or less risk than posed by surgery (see discussion by Chang and Alder). Conventional chemotherapy and hormonal therapy are probably ineffective, but the latter has been a subject of interest. Investigations are being undertaken with antiangiogenic antibodies for recurrent tumors.

Primary Central Nervous System Lymphoma

This tumor has assumed increasing significance in the last few decades because of its increased incidence in patients with AIDS and other immunosuppressed states.

There is a preponderance of men, with the peak incidence in the fifth through seventh decades of life, or in the third and fourth decades in patients with AIDS.

For many years, the cell of origin of this tumor was attributed to the reticulum cell, a histiocytic component of the germinal center of lymph nodes that produces the reticulum stroma of the nodes, and the tumor was termed "reticulum cell sarcoma." The meningeal histiocyte and microglia are the equivalent cells in the brain to the reticulum cell and considered then the origin of the tumor. Later, it was recognized that the malignant cells were lymphocytes and lymphoblasts, leading to its reclassification as a lymphoma (diffuse large cell type). It has been appreciated, on the basis of immunocytochemical studies, that the tumor cells are B lymphocytes. There is a fine reticulum reaction between the reticulum cells derived from fibroblasts and microglia or histiocytes. The disproportionate emphasis on this reticular stroma was in part the result of staining methods that brought it into relief with the lymphocytes. The B lymphocyte or lymphoblast is the tumor cell, whereas the fine reticulum and "microglia" are secondary interstitial reactions.

In contrast, T-cell lymphomas of the nervous system are rare but do occur in both immunocompetent and immunosuppressed patients. Because the brain is devoid of lymphatic tissue, it is uncertain how this tumor arises; one theory holds that it represents a systemic lymphoma with a particular propensity to metastasize to the nervous system. This seems unlikely to the authors; systemic lymphomas of the usual kind rarely metastasize, as discussed further on, under "Involvement of the Nervous System in Systemic Lymphoma."

Primary CNS lymphoma may arise in any part of the cerebrum, cerebellum, or brainstem, with 60 percent being in the cerebral hemispheres; they may be solitary or multifocal. A periventricular localization is common. Vitreous, uveal, and retinal (ocular) involvement occurs in 10 to 20 percent of cases; here vitreous biopsy may be diagnostic, but it is not often performed. (Two-thirds of patients with ocular lymphoma will have cerebral involvement within a year.) Lai and colleagues have presented evidence that, in advanced cases that were autopsied, microscopic deposits of tumor found their way to many regions of the brain and not solely in areas indicated by nodular enhancement on MRI. Whether this indicates a widespread or multifocal origin of brain lymphoma is not clear.

The pia and arachnoid may be infiltrated, and a purely meningeal form of B-cell lymphoma that involves peripheral and cranial nerves is also known. Most such cases of what has been termed *neurolymphomatosis* present with painful, predominantly motor polyradiculopathies. One such patient of ours had a flaccid paraparesis and back and sciatic pain; MRI showed tumor infiltrating the cauda equina nerve roots and contiguous meninges.

The tumor forms a pinkish gray, soft, ill-defined, infiltrative mass in the brain, difficult at times to distinguish from an astrocytoma. Perivascular and meningeal spread results in shedding of cells into the CSF, accounting perhaps for the multifocal appearance of the tumor in many cases. The neoplasm is highly cellular and grows around and into blood vessels ("angiocentric" pattern)

but elicits no tendency to necrosis. The nuclei are oval or bean-shaped with scant cytoplasm, and mitotic figures are numerous. B-cell markers applied to fixed tissue define the lymphoblastic cell population as monoclonal and identify the tumor cell type. The stainability of reticulum and microglial cells also serves to distinguish this tumor microscopically. There is no tumor tissue outside the brain.

Several of our cases of meningeal and cranial nerve lymphoma with similar histologic characteristics to primary CNS lymphoma were complications of chronic lymphatic leukemia, a type of so-called Richter transformation.

Primary lymphoma involving the cerebral hemispheres initially pursues a clinical course somewhat similar to that of the gliomas but with a vastly different response to treatment. Behavioral and personality changes, confusion, dizziness, and focal cerebral signs predominate over headache and other signs of increased intracranial pressure as presenting manifestations. Seizures may occur but are less common, in our experience, than they are as the introductory feature of gliomas. Most cases occur in adult life, but some have been observed in children, in whom the tumor may simulate the cerebellar symptomatology of medulloblastoma.

The finding on CT and MRI of one or several dense (hypercellular), homogeneous, enhancing, infiltrating, nonnecrotic, nonhemorrhagic, periventricular masses is characteristic (Fig. 31-9). However, rim enhancement also occurs, and any part of the brain may be involved. The radiologic appearance in the immunosuppressed patient is less predictable and may be difficult to distinguish from that of toxoplasmosis or another process with which lymphoma may coexist.

In some cases, a multitude of deep cerebral white matter lesions, some radially oriented and thereby simulating multiple sclerosis, are seen. Tumor enhancement with contrast agents tends to be more prominent and homogeneous than with the acute lesions of multiple sclerosis. A similar multinodular appearance occurs with intravascular lymphoma discussed in a later section.

Characteristic of primary CNS lymphoma is the disappearance on imaging of the lesions or complete but transient resolution of contrast enhancement in response

to corticosteroids. Lymphocytic and mononuclear pleocytosis of CSF is more frequent than with gliomas and metastatic tumors. The immunohistochemical demonstration in CSF of monoclonal lymphocytes or an elevated beta microglobulin points to leptomeningeal spread of the tumor (Li et al), but frequently the diagnosis is not possible from CSF cytologic examination.

Patients with AIDS and less-common immunodeficiency states, such as the Wiskott-Aldrich syndrome and ataxia-telangiectasia, and those who are receiving immunosuppressive drugs for long periods, as for example, in renal transplantation, are particularly liable to develop this type of lymphoma. Many of the tumors in immunosuppressed patients contain the EBV genome, suggesting a pathogenetic role for the virus (Bashir et al); however, the EBV genome has also been found in the tumors of a few immunocompetent patients (Hochberg and Miller). Sometimes this tumor appears as a complication of an obscure medical condition such as salivary and lacrimal gland enlargement (Mikulicz syndrome) or Sjögren syndrome.

Stereotactic needle biopsy is the preferred method of establishing the histologic diagnosis in sporadic cases. In immunosuppressed patients, the differential diagnosis of a solitary brain nodule that is suspected to be lymphoma is aided by the response, or lack thereof, to treatment for toxoplasmosis, the main alternative diagnosis (see "Toxoplasmosis" in Chap. 32). Reduction in the size of the lesion with antimicrobial drugs makes biopsy unnecessary.

Treatment Because the tumors are deep and often multicentric, surgical resection is ineffective except in rare instances. Treatment with cranial irradiation and corticosteroids often produces a partial or, transiently, a complete response, but the tumor recurs in greater than 90 percent of patients. Until recently, the median survival of patients treated in this way has been 10 to 18 months and less in those with AIDS and in individuals who are otherwise immunocompromised. In immunocompetent patients, the addition of intrathecal methotrexate and intravenous cytosine arabinoside has increased median survival to more than 3 years (DeAngelis), and apparent cure is not unknown. However, this combined treatment is associated with a high risk of a leukoencephalopathy (see further on and Fig. 31-25) and causes considerable systemic side effects.

Glass and colleagues (1994) recommended a treatment regimen consisting of several cycles of intravenous methotrexate (3.5 g/m^2) and citrovorum, administered at 2- to 3-week intervals and at times continued indefinitely if the treatment is tolerated. More recently, methotrexate plus either cytarabine or a combination of rituximab and temozolomide has been favored. Cranial irradiation is not typically part of the initial treatment. Ocular lymphoma is eradicated only by radiation therapy. Corticosteroids are added at any point to control neurologic symptoms. The median survival time with this approach in the non-AIDS patient is in the range of 3.5 years with intravenous methotrexate alone and 4 years or more if radiation is given subsequently. Some patients are alive at 10 years.

Intracranial Metastatic Carcinoma

These are far more common than are primary brain tumors. Among secondary intracranial tumors, only metastatic

Figure 31-9. Cerebral lymphoma. *Left:* Axial T2-FLAIR MRI showing hyperintensity in the right peritrial white matter, without mass effect. *Right:* Contrast-enhanced MRI reveals two foci of nodular enhancement.

carcinoma occurs with high frequency. Occasionally one encounters a rhabdomyosarcoma, Ewing tumor, carcinoid, and others that have metastasized, but these have such low incidence that cerebral metastases seldom become a matter of diagnostic concern. The interesting pathobiology of metastatic carcinoma—the complex biologic mechanisms that govern the detachment of tumor cells from the primary growth, their transport to distant tissues, and their implantation on the capillary endothelium of the particular organ in which they will eventually grow is of research interest. Suffice it to say that tumor cell adhesion molecules, the vasculature, and a number of other cellular events participate in the implantation of what is essentially a neoplastic embolus.

Autopsy studies disclose intracranial metastases in approximately 25 percent of patients who die of cancer (Posner, 1978). Approximately 80 percent are in the cerebral hemispheres and 20 percent in posterior fossa structures, corresponding roughly to the relative size and weights of these portions of the brain and their blood flow. Cancers of the pelvis and colon are exceptional in this respect, having a somewhat higher tendency than this to spread to the posterior fossa. Intracranial metastases assume three main patterns—those to the skull and dura, those to the brain itself, and those spreading diffusely through the craniospinal meninges (meningeal carcinomatosis). As common as intracranial metastases are, metastases to the vertebral column, which eventually cause compression of the spinal cord and nerve roots. This separate problem is discussed in Chap. 44. Metastatic deposits in the spinal cord itself are infrequent but are seen from time to time; they are more common, however, than another cancer-associated spinal cord lesion, paraneoplastic necrotic myelopathy (see further on).

Metastases to the skull and dura occur with any tumor that metastasizes to bone, but they are particularly common with carcinoma of the breast and prostate and in the special case of multiple myeloma. Secondary deposits usually occur without metastases to the brain itself and reach the skull either via the systemic circulation (as in carcinoma of the breast) or via the Batson vertebral venous plexus—a valveless system of veins that runs the length of the vertebral column from the pelvic veins to the large venous sinuses of the skull, bypassing the systemic circulation (the route presumably taken by carcinoma of the prostate). Metastatic tumors of the convexity of the skull are usually asymptomatic but those at the base may implicate the cranial nerve roots or the pituitary gland. Bony metastases are readily recognized on radionuclide bone and CT scans and most are evident in plain films. Occasionally, a carcinoma metastasizes to the subdural surface dura and compresses the brain, comparable to a subdural hematoma. Many metastases in the skull and dura, perhaps most, are asymptomatic.

Apart from the above, most carcinomas reach the brain by hematogenous spread. Almost one-third of metastases to the brain originate in the lung and half this number in the breast; melanoma is the third most frequent source in most series, and the gastrointestinal tract (particularly the colon and rectum) and kidney are the next most common, in part reflecting the prevalence of

each of these tumors but also because of a tropism for the nervous system, as noted below. Carcinomas of the gallbladder, liver, thyroid, testicle, uterus, ovary, pancreas, etc., account for the remainder. Tumors originating in the prostate, esophagus, oropharynx, and skin (except for melanoma) only rarely metastasize to the substance of the brain. From a different perspective, certain neoplasms are particularly prone to metastasize to the brain—75 percent of melanomas do so, 55 percent of testicular tumors, and 35 percent of bronchial carcinomas, of which 40 percent are small cell tumors according to Posner and Chernik. They describe a solitary metastasis in 47 percent of cases, a somewhat higher figure than that observed in our practice and reported by others (see Henson and Ulrich). The metastatic tumors most likely to be single come from kidney, breast, thyroid, and adenocarcinoma of the lung. Small cell carcinomas and melanomas more often tend to be multiple, but exceptions abound.

Generally, the cerebral metastasis forms a circumscribed mass, usually solid but sometimes in the form of a ring (i.e., cystic), that excites little glial reaction but much regional vasogenic edema. Edema alone is often evident on imaging studies until the administration of contrast exposes small tumor nodules (Fig. 31-10).

Metastases from melanoma and chorioepithelioma are often hemorrhagic, but some from the lung, thyroid, and kidney exhibit this characteristic as well. In a number of these cases, one-quarter in some series, the first manifestation of the metastasis is an intratumoral hemorrhage. The relative frequency of lung cancer makes it the most common metastatic tumor to bleed, even though only a small proportion does so.

The usual clinical picture of *metastatic carcinoma of the brain* is much like that of glioma. Seizures, headache, focal weakness, mental and behavioral abnormalities, ataxia, aphasia, and signs of increased intracranial pressure—all inexorably progressive over a few weeks or months—are the common clinical manifestations. In addition, a number of unusual syndromes may occur. One that presents particular difficulty in diagnosis is a diffuse cerebral disturbance with headache, nervousness, depressed mood, trembling, confusion, and forgetfulness, resembling a relatively rapid dementia from degenerative disease. *Cerebellar metastasis*, with headache, dizziness, and ataxia (the latter being brought out only by having the patient walk) is another condition that may be difficult to diagnose. Brainstem metastases, most often originating in the lung, are rare but distinctive, giving rise to diplopia, imbalance, and facial palsy, as in the characteristic case described by Weiss and Richardson.

The onset of symptoms from brain metastases is infrequently abrupt or even “stroke-like” rather than insidious. Some cases of sudden onset can be explained by bleeding into the tumor and others perhaps by tumor embolism that occludes a cerebral vessel. In most cases, the explanation for this temporal profile is not known. Also, non-bacterial thrombotic (marantic) endocarditis with cerebral embolism must be suspected when a stroke-like event occurs in a cancer patient. It is not unusual for one or other of these neurologic manifestations to precede the discovery of a pancreatic, bowel, gastric, breast, or lung carcinoma.

Figure 31-10. Contrast-enhanced MRI (left) showing multiple metastases from renal cell carcinoma. Note the extensive hypointense edema surrounding each lesion. The right image is a gradient echo MRI in which blood products appear hypointense. This sequence can aid in detection of small or nonenhancing hemorrhagic metastases, such as the lesion in the left occipital lobe.

When any of the several clinical syndromes caused by metastatic tumor is fully developed, diagnosis is relatively easy. If only headache and vomiting are present, a common problem is to attribute them to migraine or tension headache. One should invoke such explanations only if the patient has the standard symptoms of one of these conditions. CT, with and without contrast, will detect practically all sizable (1 cm) metastases though MRI is more sensitive especially for cerebellar and subcentimeter lesions, and will expose associated leptomeningeal disease. *Multiple nodular deposits of tumor in the brain on imaging studies most clearly distinguish metastatic cancer from other tumors* but this pattern may also occur with brain abscesses, brain lymphoma, and glioblastoma.

Solitary metastatic disease must be distinguished from a primary tumor of the brain and from infective abscess. Multiple brain metastases must not be confused with the neurologic syndromes that sometimes accompany carcinoma but are not caused by the invasion or compression of the nervous system by tumor. The latter, referred to as *paraneoplastic disorders*, include sensory neuronopathies and the Lambert-Eaton myasthenic syndrome (usually with carcinoma of the lung), cerebellar degeneration (ovarian and other carcinomas and Hodgkin disease), necrotizing myelopathy (rare), limbic encephalitis, and the opsoclonus-myoclonus syndrome. These paraneoplastic syndromes are discussed further on, under "Remote Effects of Neoplasia on the Nervous System (Paraneoplastic Disorders)."

In addition to the aforementioned conditions, there are many patients with cancer who exhibit symptoms of an altered mental state without evidence of metastases or a recognizable paraneoplastic disorder. These symptoms usually have their basis in systemic metabolic disturbances (hypercalcemia in particular), drugs, and psychologic

reactions, some of which have yet to be clearly delineated. Problems of this type were noted in a high percentage of cancer patients seen in consultation at the Memorial Sloan-Kettering Cancer Center (Clouston et al) and are seen almost daily on the wards of our hospital. Once chemotherapy or brain radiation has been administered, the secondary effects of these treatments further cloud the picture.

Treatment The treatment of secondary (metastatic) tumors of the nervous system is undergoing a change. Current programs utilize various combinations of corticosteroids, brain irradiation, surgical intervention, and chemotherapy. Corticosteroids produce prompt improvement, probably on the basis of a reduction in the edema surrounding the lesion(s), but sustained use is restricted by side effects and eventual loss of efficacy. Most patients also temporarily benefit from the use of whole-brain irradiation, usually administered over a 2-week period, in 10 doses of 300 cGy each. High-dose focused radiotherapy is a suitable alternative for single or several cerebral metastases.

One randomized trial comparing stereotactic radiotherapy alone, or combined with whole-brain radiation for 1 to 4 metastases, found no difference in survival but there was a reduction in the frequency of recurrence at other sites in the brain when whole-brain treatment was added (Aoyama et al). Several other studies have suggested that control of local symptoms related to a metastasis is better with focused radiotherapy. However, with the exception of a single lesion from small cell lung cancer, there does not seem to be an advantage to either approach. If focused treatment has been used, whole-brain radiation can still be instituted at the time of a recurrence. Whether there is evidence to justify the routine implementation of this approach is not clear,

especially as overall measures of the quality of life are not generally improved. An arbitrary limit of stereotactic treatment of four metastases arose as the field evolved but it appears that the results are similar with even greater numbers.

The issue of prophylactic radiation of the entire cranium in the case of certain tumors is more controversial. The best current information is from a trial by Slotman and colleagues and an older one by Aupérin and coworkers in patients with chemotherapy-responsive small cell lung cancer. Prophylactic radiation prolonged survival by 1.5 months and reduced the later emergence of metastasis to the brain.

In patients with a single parenchymatous metastasis (shown to be solitary by gadolinium-enhanced MRI), surgical extirpation may be undertaken provided that growth of the primary tumor and its systemic metastases is under good control and the metastasis is accessible to the surgeon and not located in a strategic motor or language area of the brain; usually excision is followed by radiation therapy to the entire brain. Patchell and coworkers have shown that survival and the interval between treatment and recurrence are longer and that the quality of life is better in patients treated in this way than in comparable patients treated with whole-brain radiation alone. Single or dual metastases from renal cell cancer, melanoma, and adenocarcinoma of the gastrointestinal tract lend themselves best to surgical removal, sometimes repeatedly.

There is increasing evidence that some metastatic brain tumors are sensitive to chemotherapeutic agents, especially if the primary tumor is similarly responsive. Intrathecal and intraventricular chemotherapy are not thought to be of value in the treatment of parenchymal metastases. Immunotherapy has not yet been widely employed.

Prophylactic antiepileptic drugs are generally not employed as they do not appear to prevent a first seizure, as mentioned earlier. Several studies, some well controlled, corroborate this as discussed in Chap. 16.

Despite all of these measures, survival is only slightly prolonged by treatment. The average period of survival in cases of brain metastases, even with therapy, is about 6 months, but it varies widely and is dominated by the extent of other systemic metastases. Between 15 and 30 percent of patients live for a year and 5 to 10 percent for 2 years; with certain radiosensitive tumors (lymphoma, testicular carcinoma, choriocarcinoma, some breast cancers), however, survival can be much longer. Patients with bone metastases tend to live longer than those with brain and meningeal metastases.

Carcinomatous Meningitis

Widespread dissemination of tumor cells throughout the meninges and ventricles, a special form of metastatic cancer, is the pattern in approximately 5 percent of cases of adenocarcinoma of breast, lung, and gastrointestinal tract, melanoma, childhood leukemia, and systemic lymphoma. This is among the most deceptive of neurologic diagnoses. With certain carcinomas, notably gastric, it may be the first manifestation of a neoplastic illness,

although more often the primary tumor has been present and is under treatment.

Headache and backache, often with sciatica, are common but not invariable. Polyradiculopathies (particularly of the cauda equina), multiple cranial nerve palsies, and a confusional state have been the principal manifestations, and many cases are restricted to one of these features. Only a small number have an uncomplicated meningeal syndrome of headache, nausea, and meningismus, but these features develop within weeks in many cases. Delirium, stupor, and coma follow. Focal neurologic signs and seizures may be associated, and somewhat fewer than half the patients develop hydrocephalus. The combination of a cranial neuropathy, such as unilateral facial weakness, hearing loss (always suggestive of lymphoma), or ocular motor palsy, with bilateral asymmetrical limb weakness is particularly characteristic. The evolution in all these syndromes is generally subacute over weeks with a more rapid phase as the illness progresses.

The diagnosis can be established in most cases by identifying tumor cells in the CSF using cytology and flow cytometry techniques. More than one examination, using generous quantities of CSF, may be needed. Increased pressure in the subarachnoid space, elevation of CSF protein and low glucose levels, and lymphocytic pleocytosis (up to 100 cells but typically much fewer) are other common findings. Nevertheless, in a few patients, the CSF remains persistently normal. Measurement of certain biochemical markers of cancer in the CSF—such as lactate dehydrogenase, β -glucuronidase, β_2 -microglobulin, and carcinoembryonic antigen (CEA)—offers another means of making the diagnosis and following the response to therapy. These markers are most likely to be abnormal in hematologic malignancies but may also be altered in some cases of intracranial infection and parenchymal metastases (Kaplan et al). In a few of the cases of meningeal carcinomatosis, there are also parenchymal brain metastases.

Also known is a rare primary malignant melanoma of the meninges that acts in a similar way to carcinomatous meningitis but has the striking feature of bloody CSF (1,000 to 10,000 red blood cells per mm^3). The origin of the neoplasm is from native melanotic cells in the meninges. The prognosis is as bleak as it is for metastatic carcinomatous meningitis as discussed by Liubinas et al.

Treatment and Outcome of Carcinomatous Meningitis This consists of radiation therapy to the symptomatic areas (cranium, posterior fossa, or spine) followed in selected cases by the intraventricular administration of methotrexate, but these measures rarely stabilize neurologic symptoms for more than a few weeks. The methotrexate is administered into the lateral ventricle via an Ommaya reservoir (12 mg diluted in preservative-free saline) or into the lumbar subarachnoid space through a lumbar puncture needle (12 to 15 mg). Several regimens have been devised, including daily instillation for 3 to 4 days followed by radiation, or methotrexate doses on days 1, 4, 8, 11, and 15. Involvement of the cranial nerves or an encephalopathy caused by widespread infiltration of the cranial meninges has been treated with whole-brain radiation, 3,000 cGy, given in fractions of 300 cGy per day for 10 days. Spinal root infiltration responds to

spinal radiation, and regional treatments are helpful temporarily for local seeding of the lumbar roots.

The median duration of survival after diagnosis of meningeal carcinomatosis was 6 months in the large series reported by Wasserstrom and colleagues, but only 43 days in the series of Sorenson and coworkers. An encephalopathy caused by widespread tumor infiltration is a highly concerning and usually preterminal sign. The leukoencephalopathy that follows the combined use of intrathecal methotrexate and radiation therapy is described later. The best response to treatment occurs in patients with lymphoma and breast and small cell lung cancers; cases of meningeal infiltration by other lung cancers, melanoma, and adenocarcinoma do most poorly.

Involvement of the Nervous System in Leukemia

Almost one-third of all leukemic patients have evidence of diffuse infiltration of the leptomeninges and cranial and spinal nerve roots at autopsy (Barcos et al). The incidence is greater in acute than in chronic leukemia and greater in lymphocytic than in myelocytic leukemia; it is also far more frequent in children than in adults. The highest incidence is in children with acute lymphocytic (lymphoblastic) leukemia who relapse after treatment with combination chemotherapy (60 to 70 percent at time of death). The clinical and CSF picture of meningeal leukemia is much the same as that of meningeal carcinomatosis discussed earlier, with the qualification that leukemic cells are more likely to be found by cytologic examination of the spinal fluid. The treatment of the two disorders is also similar.

The studies of Price and Johnson demonstrated that CNS leukemia is primarily a pial disease. The earliest evidence of leukemia is detected in the walls of pial veins, with or without cells lying freely in the CSF. The leukemic infiltrate in our pathologic material has extended to the deep perivascular spaces, where the pial-gliar membrane often confines it; at this stage the CSF consistently contains leukemic cells. Depending on the severity of meningeal involvement, transgression of the pial-gliar membrane eventually occurs, with varying degrees of superficial parenchymal infiltration by collections of leukemic cells. Hemorrhages of varying sizes are another common complication and are sometimes lethal. Chloroma, a solid green-colored mass of myelogenous leukemic cells, may infiltrate the dura or, less often, the brain, but it is distinctly uncommon.

Cranial radiation, combined with methotrexate given intrathecally or intravenously, has been effective in the prevention and treatment of meningeal involvement in childhood leukemia. However, in a significant number of patients this combination gives rise to a distinctive *necrotizing leukoencephalopathy* within several days to months after the last administration of methotrexate and several months after completion of radiotherapy (Robain et al). The leukoencephalopathy occurs most frequently and is most severe when all three modalities of treatment, i.e., cranial irradiation and intrathecal and intravenous methotrexate, are used. The initial symptoms—consisting of apathy, drowsiness, depression of consciousness, and

behavioral disorders—evolve over a few weeks to include cerebellar ataxia, spasticity, pseudobulbar palsy, extrapyramidal motor abnormalities, and akinetic mutism. Large hypodense areas of varying size appear on CT but—unlike the case with tumor metastases—there is no contrast enhancement. On MRI these lesions appear T2 hyperintense, but compared with pure radiation necrosis (see further on), they have poorly demarcated borders and like on CT, do not enhance. In some patients the condition stabilizes or improves, with corresponding radiographic resolution of the lesions. More often the patient is left with severe persistent sequelae; in most, death occurs within several weeks or months of onset but a few survive for years. Radiation injury seems to be the most important factor, coupled with the age of the patient (most are younger than 5 years old). In an attempt to reduce the cognitive sequela of cranial radiation in children with leukemia, Pui and coworkers conducted a study and found that it could be safely omitted if all other aspects of therapy have been optimized.

Involvement of the Nervous System in Systemic Lymphoma

Extradural compression of the spinal cord or cauda equina is the most common neurologic complication of all types of lymphoma, the result of extension from vertebrae or paravertebral lymph nodes. Treatment is with radiation to the affected portion of the neuraxis or, if a tissue diagnosis is lacking, surgical decompression. Systemic lymphoma rarely metastasizes to the brain. In a review of more than 100 autopsies at the Mallory Institute of Pathology, our colleague R.D. Adams observed only a half-dozen instances where patients with lymphomas had deposits of tumor cells in the brain and in none of these cases were they from multiple myeloma (Sparling et al). In the series of Levitt and associates, comprising 592 patients with non-Hodgkin lymphoma, there were only 8 with intracerebral metastases.

Much more common is meningeal dissemination of non-Hodgkin lymphoma (the earlier mentioned *neurolymphomatosis*), the clinical and CSF pictures being similar to those of meningeal leukemia and carcinomatosis described earlier. In the rare cases of meningeal involvement with Hodgkin lymphoma, there may be an eosinophilic pleocytosis. Leptomeningeal dissemination occurs almost exclusively in high-grade lymphomas with diffuse (rather than nodular) changes in the lymph nodes. Cranial nerve palsies are common, with a predilection for the eighth nerve; the cauda equina is involved eventually in most cases. The optimal treatment has not yet been ascertained. Radiotherapy and systemic and intraventricular chemotherapy have all met with some degree of success in small series.

Intravascular Lymphoma and Related Disorders (Malignant Angioendotheliomatosis, Angiotropic or Angioblastic Lymphoma, Lymphomatoid Granulomatosis, Castleman Disease)

These conditions are presented here with other forms of lymphoma, although their clinical behavior is as much in

keeping with a vasculitic or prelymphomatous process. Although considered rare, we encounter several new cases yearly in our service. The nomenclature is confusing and the original term, *lymphomatoid granulomatosis* (also known as Castleman disease), is not equivalent to the more recently elucidated process of intravascular lymphoma; it is more accurate to consider the former a prelymphomatous process. As described by Liebow and colleagues, lymphomatoid granulomatosis is a systemic disease with prominent nodular pulmonary lesions, dermal, and lymph node changes and, in approximately 30 percent of cases, involvement of the CNS. In a small proportion, the changes are confined to the nervous system. According to Katzenstein and associates, a systemic malignant lymphoma develops in 12 percent of such patients, but others have noted this transformation in a considerably higher number. The genomic sequences of EBV, HHV-6, or HHV-8 have been found in most of these lesions.

The *angioblastic or intravascular lymphoma*, on the other hand, is regarded as a multifocal neoplasm of large anaplastic monoclonal lymphocytes that infiltrate the walls of blood vessels and surrounding areas (Sheibani et al) or grow intravascularly and cause occlusion of small and moderate-sized vessels, hence the several alternative designations for the same process. The disease can be distinguished from primary CNS lymphoma, which is also typically "angiocentric," meaning centered around vessels, but does not selectively invade and occlude vascular structures. In the brain and spinal cord there are lesions of various sizes that represent the combined effects of occlusion of small vessels and concentric infiltration of the adjacent tissue by neoplastic cells. In half of the cases, meningeal vessels are involved and in a few, the peripheral nerves, or more particularly the endoneurial vessels within spinal roots, have been involved by the neoplasm, and we have seen two cases with a flaccid paraplegia on this basis.

Although the lymphoid origin of the intravascular anaplastic cells is clear, not all are T cells as was at one time believed; an equal number are B cells. As in some cases of primary CNS lymphoma, portions of the genome of EBV have been isolated from the malignant B cells in a few cases. It has been proposed that the disorder in some cases represents an EBV-induced proliferation of B cells with a prominent inflammatory T-cell reaction (Guinee et al).

Because of the inconsistent location and size of the nervous system lesions there is no uniform syndrome, but intravascular lymphoma should be suspected in patients with a subacute encephalopathy and indications of focal brain and spinal cord or nerve root lesions. Headache is a prominent early component in some cases. One of our patients had intermittent seizures 3 months before confusion and progressive encephalopathy. The variety of clinical presentations is emphasized in the reviews of cases by Beristain and Azzarelli and the article by Glass and associates (1993). All had focal cerebral signs, 7 had dementia, 5 had seizures, and 2 had myelopathy. Some of our own patients, as mentioned above, have also had a flaccid paraplegia as a result of infiltration of the cauda roots; this peripheral involvement has been commented on by other authors. Only a few patients will have nodular or multiple infiltrative pulmonary lesions, skin lesions, or

adenopathy; almost all of our cases were restricted to the brain and spinal cord, but other reports suggest systemic disease in a high proportion, including infiltration of the adrenal glands.

MRI shows multiple nodular or variegated abnormalities on T2-weighted images throughout the white matter of the brain; most lesions are enhanced by gadolinium, and some demonstrate restricted diffusion resulting from microvascular occlusion and infarction. In one of the cases we studied there were numerous hemorrhagic lesions. Definitive diagnosis is possible only through a biopsy of radiographically involved lung or nervous tissue that includes tissue with numerous intrinsic blood vessels. A helpful diagnostic feature may be the presence of antibodies to nuclear cytoplasmic antigens (c-ANCA), in some cases, as they are in a number of other vasculitic and granulomatous processes. A small number of our patients have also had adrenal or renal enlargement, as mentioned earlier, presumably because of infiltration of the vessels of these organs by the neoplasm. The spinal fluid has a variable lymphocytic pleocytosis and protein elevation, but malignant cells are not found. The sedimentation rate and serum lactate dehydrogenase (LDH) are said to be elevated in most patients, but this has not been consistently so in our experience.

Similar to demyelinating and lymphomatous lesions, these abnormalities may recede temporarily in response to treatment with corticosteroids and there is corresponding clinical improvement. The course tends to be fluctuating over months, although one of our patients died within weeks despite treatment. In a few cases, whole-brain irradiation has been successful in prolonging survival, but the outlook in most instances is poor.

An uncertain number of these patients have AIDS, although we have not encountered this combination. The illness must be distinguished from multiple sclerosis, primary CNS lymphoma, gliomatosis cerebri, and a process that simulates it closely, sarcoidosis (which produces brain and lung lesions) as well as from the cerebral vasculitides and Behçet disease, but intravascular lymphoma is more rapidly progressive than most of these conditions.

Sarcomas of the Brain

These are malignant tumors composed of cells derived from connective tissue elements (fibroblasts, rhabdomyocytes, lipocytes, osteoblasts, smooth muscle cells). They take their names from their histogenetic derivation—namely, fibrosarcoma, rhabdomyosarcoma, osteogenic sarcoma, and chondrosarcoma—and sometimes from the tissue of which the cells are a part, such as adventitial sarcomas and hemangiopericytoma.

All these tumors are rare. They constitute from 1 to 3 percent of intracranial tumors, depending on how wide a range of neoplasms one chooses to include in this group (see below). Occasionally one or more cerebral deposits of these types of tumors will occur as a metastasis from a sarcoma in another organ. Almost all others are primary in the cranial cavity and exhibit as one of their unique properties a tendency to metastasize to nonneural tissues—a decidedly rare occurrence with primary glial tumors. It is a disturbing fact that a few sarcomas have developed 5 to

10 years after cranial irradiation or, in one instance among 3,000 patients of which we are aware, after proton beam irradiation of the brain. Fibrosarcomas have occurred after radiation of pituitary adenomas and osteogenic sarcoma after other types of radiation, all localized to bone or meninges. Our experience with hemangiopericytoma has included two intracranial lesions that simulated meningiomas and two others that arose in the high cervical spinal cord and caused subacute quadriplegia initially misdiagnosed as a polyneuropathy.

A number of other cerebral tumors, described in the literature as sarcomas, are probably tumors of other types. The rapidly growing, highly malignant "monstrocellular sarcoma" of Zülch or "giant cell fibrosarcoma" of Kernohan and Uihlein, so named for their multinucleated giant cells, were reinterpreted by Rubinstein (1972) as a form of giant cell glioblastoma or mixed glioblastoma and fibrosarcoma. The "hemangiopericytoma of the leptomeninges," also classified by Kernohan and Uihlein as a form of cerebral sarcoma, is considered by Rubinstein (1972) to be a variant of the angioblastic meningioma.

Patients who Present Primarily with Signs of Increased Intracranial Pressure (Medulloblastoma, Ependymoma of the Fourth Ventricle, Hemangioblastoma of the Cerebellum, Pinealoma, Colloid Cyst of the Third Ventricle and Rarer Related Tumors)

Upon first presentation, a number of patients show the characteristic symptoms and signs of increased intracranial pressure: periodic bifrontal and bioccipital headaches that awaken the patient during the night or are present upon awakening, projectile vomiting, mental torpor, unsteady gait, sphincteric incontinence, and papilledema. Most of these symptoms and the increased ICP are the result of hydrocephalus.

The diagnostic problem is resolved by CT or MRI, which should be obtained in all patients with symptoms of increased intracranial pressure with or without focal signs. In addition to the tumors listed in the heading above, other tumors that may present in this way are central neurocytoma, craniopharyngioma, and a high spinal cord tumor. In addition, with some of the gliomas discussed in the preceding section, increased intracranial pressure may occasionally precede the first focal cerebral signs.

Medulloblastoma, Neuroblastoma, and Retinoblastoma

Medulloblastoma Medulloblastoma is an invasive and rapidly growing tumor, mainly of childhood, that arises in the posterior part of the cerebellar vermis and neuroepithelial roof of the fourth ventricle in children. It accounts for 20 percent of childhood brain tumors. Rarely, it presents elsewhere in the cerebellum or other parts of the brain in adults (Peterson and Walker).

The origin of this tumor remained in doubt for a long time and is still not entirely settled, but some recent insights are notable. Bailey and Cushing introduced the name *medulloblastoma*, although medulloblasts have never been identified in the fetal or adult human brain; nevertheless

the term has been retained for no reason other than its familiarity. The current view of the tumor is that it originates from pluripotential stem cells (that can differentiate into neuronal or glial elements) that have been prevented from maturing to their normal growth-arrested state. For this reason, newer classifications include it among the primitive neuroectodermal tumors (PNETs).

The tumor may differentiate uni- or pluripotentially, varying from case to case, and accounting for the recognized histologic variants, ranging from the undifferentiated medulloblastoma to medulloblastoma with glial, neuronal, or even myoblastic components. Rosette formation, highly characteristic of the below-described neuroblastoma is seen in half of medulloblastomas. Certain molecular genetic similarities relate the medulloblastoma to retinoblastomas and pineal cell tumors, and, rarely, to autosomal dominant diseases such as neurofibromatosis type 1. Chromosomal studies of medulloblastomas reveal a deletion on the distal part of chromosome 17 distal to the *p53* region. Schmidek has proposed that this accounts for the neoplastic transformation of cerebellar stem cells at various stages of their differentiation into tumor cells. It is also notable that medulloblastomas are encountered in Gorlin syndrome, caused by mutations in the gene encoding "patched," the receptor for sonic hedgehog ligand, and in Turcot syndrome, as a consequence of mutations in DNA repair genes (Louis et al). Gene expression profiling has given preliminary evidence that amplification or overexpression of the transcription factor MYCN (*N-MYC*) is associated with a poorer prognosis (as it is in neuroblastoma). Aberrations in the copy number of chromosomes 6q and 17q also appear to have predictive value for the behavior of the tumor. Maris has reviewed the complex genetic aspects of the tumor and has introduced the possibility that a combination of common variants may be a risk factor for its development. Another line of research has implicated the JC virus, the same agent that causes progressive multifocal leukoencephalopathy (Chap. 33). Genomic sequences from this virus have been found in 72 percent of tumors in some series (Khalili et al), and an experimental transgenic model in which the JC protein is expressed is characterized by a cerebellar tumor that resembles the medulloblastoma.

The majority of the patients are children 4 to 8 years of age, and males outnumber females 3:2 or 3:1 in most reported series. As a rule, symptoms have been present for 1 to 5 months before the diagnosis is made. The clinical picture is fairly distinctive and derives from secondary hydrocephalus and raised intracranial pressure as a result of blockage of the fourth ventricle. Typically, the child becomes listless, vomits repeatedly, and has a morning headache. The first diagnosis that suggests itself may be gastrointestinal disease or abdominal migraine. Soon, however, a stumbling gait, frequent falls, and diplopia as well as strabismus lead to a neurologic examination and the discovery of papilledema or sixth nerve palsies. However, when the tumor is located in the lateral cerebellum or in the cerebrum, as it usually is in adults, signs of raised intracranial pressure may be delayed. Dizziness (positional) and nystagmus are then frequent. A small proportion of children have a slight sensory loss on one

side of the face and a mild facial weakness. Head tilt, the occiput being tilted back and away from the side of the tumor, indicates a developing cerebellar-foraminal herniation. Rarely, signs of spinal root and subarachnoid metastases precede cerebellar signs.

Extraneural metastases (cervical lymph nodes, lung, liver, and particularly bone) may occur, but usually only after craniotomy, which may allow tumor cells to reach scalp lymphatics. In rare instances the tumor cells may be spontaneously blood-borne and become metastatic to lung or liver. Decerebrate attacks ("cerebellar fits") appear in the late stages of the disease.

The radiologic appearance is also distinctive: high signal intensity on both T1- and T2-weighted MRIs, heterogeneous enhancement, and, of course, the typical location adjacent to and extending into the fourth ventricle. The tumor frequently fills the fourth ventricle and infiltrates its floor (Fig. 31-11). Seeding of the tumor may occur on the ependymal and meningeal surfaces of the cisterna magna and around the spinal cord. The tumor is solid, gray-pink in color, and fairly well demarcated from the adjacent brain tissue. It is very cellular, and the cells are small and closely packed with hyperchromatic nuclei, little cytoplasm, many mitoses, and a tendency to form clusters and pseudorosettes. The interstitial tissue is sparse.

Figure 31-11. Medulloblastoma. MRI in the sagittal (*above*) and axial (*below*) planes, illustrating involvement of the cerebellar vermis and neoplastic obliteration of the fourth ventricle.

Treatment Maximal resection of the tumor is recommended. The addition of chemotherapy and radiotherapy of the entire neuraxis improves the rate and length of disease-free survival even for those children with the most extensive tumors at the time of diagnosis (Packer). The combination of surgery, radiation of the entire neuraxis, and chemotherapy permits a 5-year survival in more than 80 percent of cases.

Fear of radiation-induced cognitive deficits in the young children most often affected by this tumor has led to exploration of postoperative chemotherapy without radiation. Rutkowski and colleagues have reported some promising results, especially in those who had gross total tumor resection, but a large number nonetheless acquired a leukoencephalopathy that was said to be asymptomatic. The presence of desmoplastic features (i.e., connective tissue formations) is associated with a better prognosis independent of the type or treatment. Children who have residual tumor, and more so those with metastases, have a much poorer prognosis. Any of the features of brainstem invasion, spinal subarachnoid metastases, incomplete removal, and very early age of onset (younger than 3 years) greatly reduce the period of survival. Acquired genetic alterations in the tumor cells that have prognostic influence have been summarized earlier. A novel inhibitor of the abnormal hedgehog pathway in medulloblastoma cells had a marked effect in one adult patient (Rudin et al).

Neuroblastoma This, the most common solid tumor of childhood, is a different entity from medulloblastoma but of nearly identical histologic appearance, arising in the adrenal medulla and sometimes metastasizing widely. Usually it remains extradural even if it invades the cranial and spinal cavities. The main neurologic interest is a syndrome of *polymyoclonus with opsoclonus and ataxia* that occurs as a paraneoplastic complication as discussed further on. A rare form of neuroblastic medulloblastoma in adults tends to be more benign (Rubinstein, 1985).

In keeping with the genetic determinants of prognosis in this broad class of tumors, a loss of heterozygosity of certain sites on chromosomes 1 and 11 has been associated with somewhat poorer outcomes by Attiyeh and colleagues. MYCN amplification or overexpression is a poor prognostic factor, as it is in medulloblastoma. Various acquired chromosomal deletions and gains may also have predictive importance. More provocative are findings that suggest the emergence of an aggressive tumor based on polymorphisms in chromosome 6p. Maris has provided a review of the interesting genetic aspects of the tumor.

Several staging systems have evolved for neuroblastoma and The Children's Oncology Group has produced a risk-based system that includes the status of chromosomal changes (17q, 1p, 11q), but these approaches are under frequent revision.

Treatment is predicated on clinical staging, with the lowest risk category allowing observation because some lesions regress spontaneously. Those patients who are at intermediate risk are treated with chemotherapy and high-risk children have surgical resection and receive intensive chemotherapy, radiation, and in selected cases, hematopoietic stem cell transplantation. The two better-risk strata

have survival rates exceeding 90 percent, but the highest risk group has a 30 percent survival rate.

Retinoblastoma Another closely related tumor is *retinoblastoma*. This proves to be one of the most frequent extracranial malignant tumors of infancy and childhood. Eighty percent develop before the fifth year of life. It is a small cell tumor with neurofibrils and, like neuroblastoma, has a tendency to form rosettes. The tumor develops within the eye and the blindness that it induces may be overlooked in an infant or small child. It is easily seen ophthalmoscopically, because it arises from cells of the developing retina. An abnormal protein encoded by a growth-suppressor or antioncogenic gene (*Rb*), mentioned earlier in relation to the genetics of brain tumors, has been identified. It is postulated that an inherited mutation affects one allele of the normal gene, and only if this is accompanied by a mutation that eliminates the function of the second allele will the tumor develop. Early recognition and radiation or surgery effect cure.

Ependymoma and Papilloma of the Fourth Ventricle

Ependymomas, as pointed out earlier in this chapter, arise from the lining cells in the walls of the ventricles. Approximately 70 percent of them originate in the fourth ventricle, according to Fokes and Earle (Fig. 31-12). Postmortem, some of these tumors, if small, are found protruding into the fourth ventricle, never having produced local symptoms. Whereas the supratentorial ependymoma occurs at all ages, fourth ventricular ependymomas appear mostly in childhood. In the large series of Fokes and Earle (83 cases), 33 developed in the first decade of life, 6 in the second decade, and 44 after the age of 20 years. Males have been affected almost twice as often as females.

Cerebral ependymomas usually arise from the floor of the fourth ventricle and extend through the foramina of Luschka and Magendie. They may later invade the medulla. These tumors produce a clinical syndrome much like that of the medulloblastoma except for their more protracted course and lack of early cerebellar signs. The histologic features of this tumor were described earlier in this chapter. The degree of anaplastic change varies and has prognostic significance. The most anaplastic form is the *ependymoblastoma*, a highly aggressive tumor that falls within the spectrum of primitive neuroectodermal tumors (see later).

Symptoms may be present for 1 or 2 years before diagnosis and operation. About two-thirds of the patients come to notice because of increased intracranial pressure; in the remainder, vomiting, difficulty in swallowing, paresthesia of the extremities, abdominal pain, vertigo, and neck flexion or head tilt are prominent manifestations. Some patients with impending cerebellar–tonsillar herniation are disinclined to sit and have vertical downbeating nystagmus. Surgical removal offers the only hope of survival. The addition of radiation therapy and sometimes ventriculoperitoneal shunting of CSF may prolong life. Myxopapillary ependymomas of the spinal cord and filum are discussed with the spinal cord tumors.

Papillomas of the choroid plexus are about one-fifth as frequent as ependymomas. They arise mainly in the lateral and fourth ventricles, occasionally in the third. Two authoritative studies (Laurence et al; Matson and Crofton) give the ratios of lateral/third/fourth ventricular locations as 50:10:40. The tumor, which takes the form of a giant choroid plexus, has as its cellular element the cuboidal epithelium of the plexus, which is closely related embryologically to the ependyma. An oncogene

Figure 31-12. Ependymoma of the fourth ventricle. A. Coronal T2 MRI shows an ependymoma growing out of the fourth ventricle. B. Axial T2 FLAIR MRI shows that the mass completely obliterates the fourth ventricle.

T (tumor) antigen of the SV40 virus is possibly involved in tumor induction (see Schmidek). Essentially, these are tumors of childhood. Fully 50 percent cause symptoms in the first year of life and 75 percent in the first decade. In the younger patient, hydrocephalus is usually the presenting syndrome, sometimes aggravated acutely by hemorrhage; there may be papilledema, an unusual finding in a hydrocephalic infant with enlarging head. Headaches, lethargy, stupor, spastic weakness of the legs, unsteadiness of gait, and diplopia are more frequent in the older child. Tumors that arise from the choroid plexus and project into the lateral recess of the fourth ventricle may present with a syndrome of the cerebellopontine angle (see further on). One consequence of the tumor (rather uncertain or inconsistent) may be increased CSF formation, which contributes to the hydrocephalus. Some of the tumors acquire more malignant attributes (mitoses, atypia of nuclei) and invade surrounding brain. They have the appearance of a carcinoma and may be mistaken for an epithelial metastasis from an extracranial site.

Treatment by surgical excision is usually curative, but palliative ventricular shunting may be needed first if the patient's condition does not permit surgery. The prognosis of the rare choroid plexus carcinomas is poor.

Primitive Neuroectodermal Tumor

This term was introduced by Hart and Earle in 1973 to describe tumors that have the histologic features of medulloblastoma but occur supratentorially. Various poorly differentiated or embryonal tumors of infancy and childhood were in the past included in this group: medulloblastoma, neuroblastoma, retinoblastoma, ependymoblastoma, and pineoblastoma (described further on). Subsequent authors have broadened the category of PNETs to include all CNS neoplasms of neuroectodermal origin. With the advent of immunohistochemical techniques, many of these poorly differentiated neoplasms of infancy came to be recognized as small cell gliomas (Friede et al); others, after ultrastructural study, could be

classified as other types of primitive neoplasms. To some pathologists, the term *primitive neuroectodermal tumors* has appeal but has added little to our understanding of their undifferentiated embryonal origin. In practical terms, the prognosis and treatment of all these tumors are much the same, regardless of what they are called (see Duffner et al). Certain patterns of gene expression are used to distinguish this group of tumors from histologically similar medulloblastomas.

Hemangioblastoma of the Cerebellum

This tumor is referred to most often in connection with von Hippel-Lindau disease. Dizziness, ataxia of gait or of the limbs on one side, symptoms and signs of increased ICP from compression of the fourth ventricle, and in some instances an associated retinal angioma or hepatic and pancreatic cysts (disclosed by CT or MRI) constitute the syndrome. There is a tendency later for the development of malignant renal or adrenal tumors. Many patients have polycythemia as a result of elaboration of an erythropoietic factor by the tumor.

The age of onset is usually between 15 and 50 years. Blacks, whites, and Asians are equally affected. Dominant inheritance of von Hippel-Lindau disease is well known. Seizinger and coworkers, in cases associated with renal cell carcinoma and pheochromocytoma, localized a defect in a tumor suppressor gene (termed *VHL*; see Chap. 38).

The diagnosis can be deduced from the appearance on CT or MRI of a cerebellar cyst containing an enhancing nodular lesion on its wall. Often the associated retinal hemangioma will be disclosed by the same imaging procedure. The angiographic picture is also characteristic: a cluster of small vessels forming a mass 1.0 to 2.0 cm in diameter (Fig. 31-13). Craniotomy with opening of the cerebellar cyst and excision of the mural hemangioblastomatous nodule is usually curative, but there is a high rate of recurrence if the entire tumor, including the nodule, is not completely removed. In the series of Boughey and colleagues, the lesion was successfully excised in 80 percent

Figure 31-13. Hemangioblastoma. Contrast-enhanced MRI in the axial plane (*left*) shows the vascular tumor in the left cerebellar hemisphere. Selective left vertebral angiogram (*right*) defines a hypervascular nodule with dilated draining veins.

of patients; 15 percent of patients, who had only partial resection of an isolated cerebellar lesion, developed recurrent tumors. More recently, several groups have used endovascular embolization of the vascular nodule prior to surgery, but it is not clear if this reduces the incidence of recurrence. Treatment with focused radiation is also being undertaken, particularly for multifocal or surgically inaccessible lesions, and several modern case series using either stereotactic radiosurgery, or external or proton beam radiation indicate results that may be comparable to conventional treatment.

Hemangioblastomas of the spinal cord are frequently associated with a syringomyelic lesion (greater than 70 percent of cases); such lesions may be multiple and are located mainly in the posterior columns. A retinal hemangioblastoma may be the initial finding and leads to blindness if not treated by laser. New lesions continue to be formed over a period of years while the patient is under observation. The children of a parent with a hemangioblastoma of the cerebellum should be examined regularly for an ocular lesion and renal cell carcinoma.

Pineal Tumors

There has been much uncertainty as to the proper classification of pineal tumors. Originally they were all thought to be composed of pineal cells; hence they were classified as true *pinealomas*, a term suggested by Krabbe. Globus and Silbert believed that these originated from embryonic pineal cells but Russell later pointed out that some tumors in the pineal region are really atypical teratomas resembling the seminoma of the testicle. Four types of pineal tumors are now recognized: *germinoma*, nongerminomatous germ cell tumors, *pinealoma* (pineocytoma, atypical pineocytoma, and pineoblastoma), and a *glioma* originating in astroglial cells of the pineal body. Some would include teratomas in this group.

The germinoma is a firm, discrete mass that usually reaches 3 to 4 cm in greatest diameter. It compresses the superior colliculi and sometimes the superior surface of the cerebellum and narrows the aqueduct of Sylvius. Often it extends anteriorly into the third ventricle and may then compress the hypothalamus. A germinoma may also arise in the *suprasellar area*. Microscopically, these tumors are composed of large, spherical epithelial cells separated by a network of reticular connective tissue and containing many lymphocytes.

Of the four groups of pineal tumors, approximately 50 percent are germinomas. Pinealomas, pineoblastomas, and gliomas are infrequent. Children, adolescents, and young adults—males more than females—are affected. Only rarely does one see a patient with a pineal tumor that has developed after the thirtieth year of life.

The *pineocytoma*, *atypical pineocytoma*, and *pineoblastoma* reproduce the normal structure of the pineal gland. These tumors enlarge the gland, are locally invasive, and may extend into the third ventricle and seed along the neuraxis. Cytologically, the pineocytoma is a moderately cellular tumor with none of the histologic attributes of anaplasia. The tumor cells tend to form circular arrangements, so-called pineocytomatous rosettes. Pinealocytes may be impregnated by silver carbonate methods, and

some contain the retinal S antigen of photoreceptor cells. Pineoblastomas are highly cellular and composed of small, undifferentiated cells bearing some resemblance to medulloblasts. The *teratoma* and *dermoid* and epidermoid cysts of the pineal body have no special features—some are quite benign. The gliomas have the usual morphologic characteristics of an astrocytoma of varying degrees of malignancy. In some cases, the clinical syndrome of the several types of pineal tumors consists solely of symptoms and signs of increased intracranial pressure. Beyond this, the most characteristic localizing signs are an inability to look upward and slightly dilated pupils that react on accommodation but not to light (Parinaud syndrome). Sometimes ataxia of the limbs, choreic movements, or spastic weakness appears in the later stages of the illness. It is uncertain whether the ocular and motor signs are caused by neoplastic compression of the brachia conjunctivae and other tegmental structures of the upper midbrain or to hydrocephalus (dilatation of the posterior part of the third ventricle). Probably both mechanisms are operative. Precocious puberty occurs in males who harbor a germinoma. Although the pineal gland is the source of melatonin, sleep is not affected to an important degree in patients with these tumors, as discussed in “The Pineal Gland and Melatonin” in Chap. 27. Measurement of CSF or serum melatonin is useful mainly in the detection of tumor recurrence after surgical extirpation. In patients with a germ cell tumor, the CSF or serum may show elevations of β -human chorionic gonadotropin or alpha-fetoprotein. The diagnosis is made by neuroimaging (Fig. 31-14). The CSF may contain tumor cells and lymphocytes but may also be entirely normal.

Treatment These lesions were formerly judged to be inoperable. However, the use of the operating microscope now makes it possible to excise them by a supracerebellar or transtentorial approach. Operation for purposes of excision and histologic diagnosis is advised because each type of pineal tumor must be managed differently. Moreover, one may occasionally find an arachnoidal cyst that needs only excision. The germ cell tumors should be removed insofar as possible and the ventricular region radiated for germinomas, and the whole neuraxis is treated in the case of nongerminomatous lesions. The use of chemotherapy in addition to or instead of cranial irradiation is still being evaluated. Several of our patients have survived more than 5 years after the removal of a pineal glioma.

Neuroepithelial Tumors (DNET), Germinomas, Gangliocytomas, Mixed Neuronal-Glial Tumors, and Lhermitte-Duclos Disease

Malignant germ cell tumors occurring in locations other than the pineal body are usually found in the suprasellar space and rarely in the roof of the third. Germinoma is the most common of this rare group of neoplasms, which also includes choriocarcinoma, embryonal cell carcinoma, endodermal sinus tumors, and malignant teratomas. Certain biochemical markers of these tumors are of interest and of clinical utility, because they may be detected in samples of the blood and CSF. The beta subunit of human chorionic gonadotropin (hCG) is elaborated by choriocarcinoma and alpha-fetoprotein, and by endodermal sinus tumors and

Figure 31-14. Pineal tumor. T2-weighted MRI in the sagittal plane (*above*) demonstrates a tumor that compresses the tectum and the cerebral aqueduct. Axial T2 FLAIR MRI (*below*) shows the tumor and evidence of hydrocephalus and transependymal flow of CSF from the lateral ventricles, resulting from aqueductal compression.

immature teratomas. Typical germinomas have shown little elevation of either. Most often these markers indicate the presence of complex mixed germ cell tumors.

Gangliogliomas and mixed neuronal–glial tumors are special tumor types, more frequent in the young and of variable but usually low-grade malignancy. They are composed both of differentiated glial cells, usually astrocytes, and of neurons in various degrees of differentiation. The latter, which may resemble glial cells, can be identified by Nissl stains, silver stains, and immunochemical reactions for cytoskeletal proteins. Inflammation is common in the parenchyma and adjacent to these tumors; this has led to the erroneous diagnosis of a nonneoplastic inflammatory condition if only limited biopsy samples are taken.

Some of these developmental tumors are difficult to separate from hamartomas or from the tubers of tuberous sclerosis. In the case of hamartomas, it may be difficult to determine if the tumor or the associated developmental abnormality is the cause of seizures. Some of these tumors take the form of large, slowly growing cystic lesions.

The best characterized, albeit rare, type in this group is the *gangliocytoma*, a tumor that occurs in the adrenal gland, retroperitoneal and thoracic sympathetic chain, internal auditory canal, and in the spinal cord. One form is the dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease). This is a slowly evolving lesion that forms a mass in the cerebellum; it is composed of granule, Purkinje, and glia cells. Reproduced therein, in a disorganized fashion, is the architecture of the cerebellum with no clear plane from normally structured cerebellar tissue. The importance of distinguishing this disease from other cerebellar tumors is its lack of growth potential and favorable prognosis. It should, however, be excised if symptomatic. The appearance on imaging is highly characteristic; a cerebellar hemisphere is occupied with an indistinct mass of “tiger stripe” appearance as a result of alternating layers of dysmorphic cerebellar cells (Fig. 31-15). Interest in this entity derives from its association with a germ line mutation in the *PTEN* gene that relates the disease to other gangliocytomas and to Cowden syndrome of multiple skin hamartomas and cancers of the gynecologic, breast, and thyroid glands (and which may include Lhermitte-Duclos as a component). Mice with the *PTEN* gene knocked-out have abnormal synaptic structure and dysplasia of the cerebellar granule cells.

Other forms of gangliogliomas include the *desmoplastic infantile ganglioglioma*, some of the *xanthoastrocytomas*, and the *dysembryoplastic neuroepithelioma tumor* (DNET).

Figure 31-15. Lhermitte-Duclos disease. T2-weighted MRI showing the characteristic “tiger stripe” appearance of this hamartomatous tumor in the right cerebellar hemisphere.

Figure 31-16. Contrast-enhanced MRI of a cystic and nodular dysembryoplastic neuroepithelial tumor (DNET) of the left temporal lobe in an adult who had a single seizure. The nodule had an inflammatory component and the seizures ceased with resection.

This last of these tumors, DNET, is worthy of comment as it often causes seizures that may be difficult to control in children. We have encountered them mostly in young adults after a single seizure or as an incidental finding on MRI. Although the tumors may be located in any part of the brain, there is a proclivity for the superficial (juxtacortical or intracortical) lateral or medial temporal lobe. The radiologic appearance is usually of a nodule or small cyst, or more specific to this entity, a cluster of several adjacent small cystic lesions, generally not enhancing and hyperintense on T2-weighted MRI (Fig. 31-16). The lesion is very slow growing and, if appropriately situated,

may remodel the bone of the orbital roof or calvarium. The tumors originate from dysplastic cells in the germinal matrix that become arrested during migration toward the cortex; they are often associated with an adjacent region of cortical heterotopia. The histologic appearance varies but has as its main element a collection of neuroepithelial cells and clusters of oligodendrocytes with multinodular architecture that create mucinous cysts in some cases. When the lesion is single and has a nonspecific radiologic appearance, a biopsy or resection is required to differentiate it from a low-grade glioma or oligodendroglioma. Biopsy alone may be misleading in showing only the adjacent inflammation, at times prominent enough to appear almost granulomatous. Resection is curative and often eliminates the seizures but it is not clear what the best course of action is for asymptomatic lesions.

Another tumor that may be considered in this group is the subependymal giant cell astrocytoma that is found in up to 20 percent of patients with tuberous sclerosis. These are very slowly growing tumors that arise mostly near the foramen of Munro. Repeated resection is sometimes required to treat hydrocephalus. Krueger and colleagues have reported that everolimus, an inhibitor of the mTOR complex, which is disrupted in this phakomatosis, reduces the size of the tumor and ameliorates seizures. The remaining tumors mentioned earlier are rare and affect children mostly; therefore, they are not discussed further here. Good descriptions are to be found in the monographs of Russell, of Rubinstein (1972), of Levine (both articles from 1993), and of Schmidek, and in the article by Zentner and coworkers.

Colloid (Paraphysal) Cyst and Other Tumors of the Third Ventricle

The most important of these is the colloid tumor, which is derived from ependymal cells of a vestigial third ventricular structure known as the *paraphysis*. The cysts formed

Figure 31-17. Colloid cyst of the third ventricle. MRI in the axial and sagittal planes. Hydrocephalus due to obstruction at the foramen of Monro can occur, but is not apparent here.

in this structure are always situated in the anterior portion of the third ventricle between the interventricular foramina and are attached to the roof of the ventricle (Fig. 31-17). They vary from 1 to 4 cm in diameter, are oval or round with a smooth external surface, and are filled with a gelatinous material containing a variety of mucopolysaccharides. The wall is composed of a layer of epithelial cells, some ciliated, surrounded by a capsule of fibrous connective tissue. Although congenital, the cysts practically never declare themselves clinically until adult life, when they block CSF outflow through the foramen of Monro and produce an obstructive hydrocephalus.

Suspicion of this tumor is occasioned by intermittent, severe bifrontal-bioccipital headaches, sometimes modified by posture ("ball valve" obstruction) or with crises of headache and obtundation, incontinence, unsteadiness of gait, bilateral paresthesias, dim vision, and weakness of the legs, with sudden falls but no loss of consciousness ("drop attacks"). Stooping may result in an increase or onset of headache and loss of balance. However, this intermittent obstructive syndrome has been infrequent in our experience. More often the patient has no headache and presents with the symptoms comparable to those of normal-pressure hydrocephalus or, as frequently, the tumor is found incidentally on CT or MRI. On CT and MRI, the lesion density depends on the hydration state of the mucopolysaccharides. These lesions do not restrict diffusion or enhance with contrast. Subtle behavioral changes are common and a few patients, as emphasized by Lobosky and colleagues, experience mild confusion and changes in personality that may reach the extreme of psychotic behavior. In our experience, chronic headache or gait difficulty is usually present by that time.

The treatment for many years has been surgical excision, which always carries some risk, but satisfactory results have also been obtained by ventriculoperitoneal shunting of the CSF, leaving the benign growth untouched. Decompression of the cyst by aspiration under stereotactic control has also become an increasingly popular procedure.

Other tumors found in the third ventricle and giving rise mainly to obstructive symptoms are craniopharyngiomas (see later), papillomas of the choroid plexus, and ependymomas (discussed earlier).

Arachnoid Cyst

This CSF-filled lesion, which is probably congenital, presents clinically at all ages but may become evident only in adult life, when it gives rise to symptoms of increased intracranial pressure and sometimes to focal cerebral or cerebellar signs, simulating intracranial neoplasm. Seizures may occur but are not characteristic. In infants and young children, macrocrania and extensive unilateral transillumination are characteristic features. Usually these cysts overlie the sylvian fissure or temporal pole; occasionally they are interhemispheric under the frontal lobes or lie in the pineal region or under the cerebellum. They may attain a large size, to the point of enlarging the middle cranial fossa and remodeling and elevating the lesser wing of the sphenoid, but they do not communicate with the ventricles. Rarely, one of these cysts may

cover the entire surface of both cerebral hemispheres and create a so-called external hydrocephalus.

The cysts are readily recognized (often accidentally) on unenhanced CT or MRI, showing a circumscribed tissue defect filled with fluid that has the density of CSF (Gandy and Heier). If these cysts are completely asymptomatic, they should be left alone; if symptomatic, additional MRI studies are indicated, so as not to overlook a chronic subdural hematoma, which is often associated and may not be visualized on the unenhanced CT. Suprasellar arachnoid cysts are discussed further on, under "Empty Sella Syndrome."

The treatment of enlarging and symptomatic cysts is marsupialization or, less preferably, by shunting from the cyst to the subarachnoid space.

Skull Base and Other Regional Intracranial Tumor Syndromes (Vestibular Schwannoma, Other Tumors of the Cerebellopontine Angle, Craniopharyngioma, Pituitary, Meningioma of the Sphenoid Ridge and Olfactory Groove, Glioma of the Optic Nerve, Pontine Glioma, Chordoma Chondrosarcoma, Glomus Jugulare and Carotid Body Tumors, Nasopharyngeal Carcinoma)

In this group of tumors, symptoms and signs of general cerebral impairment and increased pressure occur late or not at all. Instead, special syndromes referable to particular intracranial loci arise and progress slowly. One arrives at the correct diagnosis by localizing the lesion accurately from the neurologic findings and by reasoning that the etiology must be neoplastic because of an afebrile and steadily progressive nature. Investigation by CT, MRI, and other special studies will usually confirm the clinical impression.

The tumors that most often produce these unique intracranial syndromes are the ones listed above as well as a number of other erosive tumors at the base of the skull. The aforementioned medulloblastoma, hemangioblastoma, and ependymoma of the fourth ventricle may have a similar regional clinical signature.

Vestibular Schwannoma (Acoustic Neuroma)

This tumor was first described as a pathologic entity by Sandifort in 1777, diagnosed clinically by Oppenheim in 1890, and recognized as a surgically treatable disease in the early 1900s. Cushing's monograph (1917) was a milestone, and the papers of House and Hitselberger and of Ojemann and colleagues provide valuable descriptions of diagnostic tests and surgical treatment in the era before modern imaging.

Approximately 3,000 new cases of acoustic neuroma are diagnosed each year in the United States (incidence rate of 1 per 100,000 per year). The tumor occurs occasionally as part of von Recklinghausen neurofibromatosis, in which case it takes one of two forms. In classic von Recklinghausen disease (peripheral or type 1 neurofibromatosis), a schwannoma may sporadically involve the eighth nerve, usually in adult life, but it may involve

Figure 31-18. Bilateral vestibular schwannomas in neurofibromatosis type 2. T1-weighted MRI in the axial plane before (*left*) and after (*right*) contrast administration.

any other cranial (particularly trigeminal) or spinal nerve root. Rarely, if ever, do *bilateral acoustic neuromas* occur in this form of the disease. However, bilateral acoustic neuromas are the hallmark of the genetically distinct neurofibromatosis type 2 (NF2), in which they practically always occur before the age of 21 and show a strong (autosomal dominant) heredity (Fig. 31-18). Schwannomas are distinguished from neurofibromas (composed of both Schwann cells and fibroblasts) found in peripheral nerves of type 1 von Recklinghausen disease. A small percentage of neurofibromas become malignant, a phenomenon that is highly unusual in schwannomas.

In this context, a rare form of familial schwannomatosis should be mentioned, characterized by multiple schwannomas without vestibular tumors, which maps genetically to chromosome 22 but is distinct from NF2. The primary gene defect in this familial schwannomatosis has not been defined (MacCollin et al), although

mutations in the *SMARCB1* gene on chromosome 22 locus have been identified in some patients.

The typical vestibular schwannoma in adults presents as a solitary tumor. Being a schwannoma, it originates in nerve. The examination of small tumors reveals that they practically always arise from the vestibular rather than the cochlear division of the eighth nerve, just within the internal auditory canal (Fig. 31-19). As the eighth nerve schwannoma grows, it extends into the posterior fossa to occupy the angle between the cerebellum and pons (cerebellopontine angle). In this lateral position, it is so situated as to compress the seventh, fifth, and less often the ninth and tenth cranial nerves, which are implicated in various combinations. Later it displaces and compresses the pons and lateral medulla and obstructs the CSF circulation; very rarely, it is a source of subarachnoid hemorrhage.

Certain biologic and clinical data assume clinical importance. The highest incidence is in the fifth and sixth

Figure 31-19. A. MRI of a small vestibular schwannoma emanating from the left porus acusticus, showing typical homogenous gadolinium enhancement. B. A larger atypical vestibular schwannoma with rim enhancement, causing compression of the left middle cerebellar peduncle.

decades of life, and the sexes are equally affected. Familial occurrence is a mark, usually, of von Recklinghausen disease. The earliest symptom reported by the 46 patients in the decades-old but instructive series of Ojemann and coworkers was loss of hearing (33 of 46 patients); headache (4 patients); disturbed sense of balance (3 patients); unsteadiness of gait (3 patients); and facial pain, tinnitus, and facial weakness, each in a single case. Some patients sought medical advice soon after the appearance of the initial symptom, some later, after other symptoms had occurred. One-third of the patients were troubled by vertigo associated with nausea, vomiting, and pressure in the ear. The vertiginous symptoms differed from those of Ménière disease in that discrete attacks separated by periods of normalcy were rare. The vertigo coincided more or less with hearing loss and tinnitus (most often a unilateral high-pitched ringing, sometimes a machinery-like roaring or hissing sound, like that of a steam kettle). Some of our patients ignored their deafness for many months or years; often the first indication of the tumor in such patients is a shift to the unaccustomed ear (usually right to left) in the use of the telephone. Others neglected these symptoms to a point where they presented with impaired mentation, imbalance, and sphincteric incontinence because of brainstem compression and secondary hydrocephalus.

The neurologic findings at the time of examination in the series mentioned above were as follows: eighth nerve involvement (auditory and vestibular; 45 of 46 patients), facial weakness including disturbance of taste (26 patients), sensory loss over the face (26 patients), gait abnormality (19 patients), and unilateral ataxia of the limbs (9 patients). Inequality of reflexes and eleventh- and twelfth-nerve palsies were present in only a few patients. Signs of increased intracranial pressure appear late and have been present in fewer than 25 percent of our patients. These findings are comparable to those reported by House and Hitselberger and by Harner and Laws. With the shift in recent years to fairly routine investigation of unilateral hearing loss by cerebral imaging, it is common to find these tumors at a far earlier stage, if as an incidental finding on cerebral imaging, well before the tumor becomes symptomatic.

The contrast-enhanced CT will detect practically all vestibular schwannomas that are larger than 2.0 cm in diameter and project further than 1.5 cm into the cerebellopontine angle. Much smaller intracanalicular tumors (i.e., restricted to within the internal acoustic canal) can be detected reliably by MRI with gadolinium (see Fig. 31-19). Specialized thin-slice MRI sequences such as steady-state free precession can accurately define anatomic relationships between the tumor and adjacent cranial nerves and vessels with high resolution.

Audiologic and vestibular evaluation includes the various tests described in Chap. 15, the brainstem auditory evoked response probably being the most sensitive to the presence of acoustic schwannoma. In combination, they permit localization of the deafness and vestibular disturbance to the cochlear and vestibular nerves rather than to their end organs. The CSF protein is raised in two-thirds of the patients (greater than 100 mg/dL in one-third);

a clinically inevent acoustic schwannoma is one of the causes of an unexpectedly elevated CSF protein when a lumbar puncture is performed for other reasons.

Treatment The preferred treatment in most symptomatic cases has been surgical excision. Neurosurgeons who have had a lot of experience with these tumors favor a microsurgical suboccipital transmeatal approach (Martuza and Ojemann). The facial nerve can usually be preserved by intraoperative monitoring of brainstem auditory responses and facial nerve electromyography (EMG); in experienced hands, hearing can be preserved in approximately one-third of patients with tumors smaller than 2.5 cm in diameter. If no attempt is to be made to save hearing, small tumors can be removed safely by the translabyrinthine approach.

An alternative to surgery is focused radiation, which controls the growth of many of the smaller tumors. In a large series of patients treated with radiosurgery, facial motor and sensory functions were preserved in 75 percent of cases and, after 28 months of observation, no new neurologic deficits were detected (Kondziolka et al). This approach is favored in older patients with few symptoms but is being adopted increasingly for others. The rates of hearing loss and facial numbness and weakness are comparable or lower than with surgery, but the follow-up period in most series is less than 5 years (Flickinger et al). Focused radiation with the gamma Knife or proton beam also appears to be preferable to surgery in cases of recurrent tumor. The antiangiogenic agent, bevacizumab, in preliminary reports has reduced the size of these tumors in patients with NF2 (Plotkin et al).

There is no consensus on the management of an incidentally identified tumor but it is reasonable to follow these with audiograms and serial imaging. Some sources suggest that half of lesion smaller than 2 cm in diameter will not progress, or do so slowly enough that hearing and balance are not impaired. However, lesions larger than this size are associated with more surgical complications and make sparing of hearing less likely.

Other Tumors of the Cerebellopontine Angle

Neurinoma or schwannoma of the trigeminal (gasserian) ganglion or neighboring cranial nerves and *meningioma of the cerebellopontine angle* may, in some instances, be indistinguishable from a vestibular schwannoma. Fifth cranial nerve tumors should always be considered if deafness, tinnitus, and lack of response to caloric stimulation ("dead labyrinth") are not the initial symptoms of a cerebellopontine angle syndrome. A true *cholesteatoma (epidermoid cyst)* is a relatively rare tumor that is most often located in the cerebellopontine angle where it may simulate an acoustic neuroma but usually causes more severe facial weakness. Spillage of the contents of the cyst may produce intense chemical meningitis. Other disorders that enter into the differential diagnosis are glomus jugulare tumor (see later), metastatic cancer, neoplastic meningitis (especially lymphomatous), syphilitic meningitis, arachnoid cyst, and epidural plasmacytoma of the petrous bone. All these disorders may produce a cerebellopontine angle syndrome consisting of imbalance and unilateral hearing

loss, but they are more likely to cause multiple lower cranial neuropathies and their temporal course differs from that of vestibular schwannoma. Occasionally, a tumor that originates in the pons or in the fourth ventricle (ependymoma, astrocytoma, papilloma, medulloblastoma) or a nasopharyngeal carcinoma may present as a cerebellopontine angle syndrome.

Craniopharyngioma (Suprasellar Epidermoid Cyst, Rathke Pouch or Hypophyseal Duct Tumor, Adamantinoma)

This is a histologically benign epithelioid tumor, generally assumed to originate from cell rests (remnants of the Rathke pouch [or adenohypophyseal diverticulum]) at the junction of the infundibular stem and pituitary gland. By the time the tumor has attained a diameter of 3 to 4 cm, it is almost always cystic and partly calcified. Usually it lies above the sella turcica, compressing and elevating the optic chiasm and extending up into the third ventricle. Less often it is subdiaphragmatic, i.e., within the sella, where it compresses the pituitary body and erodes one part of the wall of the sella or a clinoid process; seldom it balloons the sella like a pituitary adenoma. Large tumors may obstruct the flow of CSF.

The tumor is oval, round, or lobulated and has a smooth surface. The wall of the cyst and the solid parts of the tumor consist of cords and whorls of epithelial cells (often with intercellular bridges and keratohyalin) separated by a loose network of stellate cells. If there are bridges between tumor cells, which have an epithelial origin, the tumor is classed as an *adamantinoma*. The cyst contains dark albuminous fluid, cholesterol crystals, and calcium deposits; the calcium can be seen in plain films or CT of the suprasellar region in 70 to 80 percent of cases. The sella beneath the tumor tends to be flattened and enlarged. The majority of the patients are children, but the tumor is not infrequent in adults, and we have encountered patients up to 60 years of age.

The presenting syndrome may be one of increased intracranial pressure, but more often it takes the form of a combined pituitary-hypothalamic-chiasmal derangement. The symptoms are often subtle and long standing. In children, visual loss and diabetes insipidus are the most frequent findings, followed in a few cases by adiposity, delayed physical and mental development, headaches, and vomiting. The visual disorder takes the form of dim vision, chiasmal field defects, optic atrophy, or papilledema, as emphasized long ago by Kennedy and Smith. In adults, waning libido, amenorrhea, slight spastic weakness of one or both legs, headache without papilledema, failing vision, and mental dullness and confusion are the usual manifestations. One of the most remarkable cases in our experience was a middle-aged nurse who became distractible and ineffective at work and was thought for many months to be simply depressed. Often it is observed that drowsiness, ocular palsies, diabetes insipidus, and disturbance of temperature regulation (indicating hypothalamic involvement) occur later. Spontaneous rupture of the cystic lesion can incite severe aseptic meningitis, at times with depressed

glucose in the CSF, a syndrome similar to that caused by rupture of the earlier described cholesteatoma.

In the *differential diagnosis* of the several craniopharyngioma syndromes, a careful clinical analysis is often more informative than laboratory procedures. Among the latter, MRI is likely to give the most useful information. Often, because of the cholesterol content, the tumor gives an increased signal on T1-weighted images. Usually, the cyst itself is isointense, like CSF, but occasionally it may give a decreased T2 signal.

Treatment Modern microsurgical techniques, reinforced by corticosteroid therapy before and after surgery and careful control of temperature and water balance postoperatively, permit successful excision of all or part of the tumor in the majority of cases. Although smaller tumors can be removed by a transsphenoidal approach, attempts at total removal require craniotomy and remain a challenge because of frequent adherence of the mass to surrounding structures (Fahlsbusch et al), as well as the potential for postoperative chemical meningitis from cyst contents. Partial removal practically ensures recurrence of the tumor, usually within 3 years, and the surgical risks of reoperation are considerable (10 percent mortality in large series). In 21 of our 35 patients, only partial removal was possible; of these, 8 died, most in the first postoperative year. Stereotactic aspiration is sometimes a useful palliative procedure, as are focused radiation therapy and ventricular shunting in patients with solid, nonresectable tumors. Endocrine replacement is necessary for an indefinite time. We have several times seen a syndrome of prolonged but reversible delirium after tumor resection.

Glomus Jugulare Tumor

This tumor is relatively rare but of interest to neurologists nonetheless. It is a purplish red, highly vascular tumor composed of large epithelioid cells, arranged in an alveolar pattern and possessing an abundant capillary network. The tumor is thought to be derived from minute clusters of nonchromaffin paraganglioma cells (glomus bodies) found mainly in the adventitia of the dome of the jugular bulb (*glomus jugulare*) immediately below the floor of the middle ear, as well as in multiple other sites in and around the temporal bone. These clusters of cells are part of the chemoreceptor system that also includes the carotid, vagal, ciliary, and aortic bodies.

The fully developed syndrome consists of partial deafness, facial palsy, dysphagia, and unilateral atrophy of the tongue combined with a vascular polyp in the external auditory meatus and a palpable mass below and anterior to the mastoid eminence, occasionally with a bruit that may be audible to the patient ("self-audible bruit"). Other neurologic manifestations are phrenic nerve palsy, numbness of the face, a Horner syndrome, cerebellar ataxia, and temporal lobe epilepsy. As with vestibular schwannoma, the availability of MRI has led to the earlier discovery of these tumors.

The jugular foramen is eroded and CSF protein may be elevated. Women are affected more than men, and the peak incidence is during middle adult life. The tumor

grows slowly over a period of many years, sometimes 10 to 20 or more. Treatment in the past has consisted of radical mastoidectomy and removal of as much tumor as possible, followed by radiation. The combined intracranial and extracranial two-stage operation has resulted in the cure of many cases (Gardner et al). Embolization prior to resection is now also employed. A detailed account of this tumor can be found in the article by Kramer.

Carotid Body Tumor (Paraganglioma)

This is a generally benign but potentially malignant tumor originating in a small aggregate of paraganglioma cells of neuroectodermal type. The normal carotid body is small (4 mm in greatest diameter and 10 mg in weight) and is located at the bifurcation of the common carotid artery. The cells are of uniform size, have an abundant cytoplasm, are rich in substance P, and are sensitive to changes in PO_2 , PCO_2 , and pH (i.e., they are chemoreceptors, not to be confused with baroreceptors). The tumors that arise from these cells are identical in appearance to tumors of other chemoreceptor organs such as the glomus jugulare neoplasm described in the preceding section (paragangliomas). Interestingly, they are many times more frequent in individuals living at high altitudes.

The usual presentation is of a painless mass at the side of the neck below the angle of the jaw; thus it must be differentiated from the branchial cleft cyst, mixed tumor of the salivary gland, and carcinomas and aneurysms in this region. As the tumor grows (at an estimated rate of 2.0 cm in diameter every 5 years) it may implicate the sympathetic, glossopharyngeal, vagus, spinal accessory, and hypoglossal nerves (syndrome of the retropharyngeal space; see Chap. 47). Hearing loss, tinnitus, and vertigo are present in some cases. Tumors of the carotid body have been a source of transient ischemic attacks in 5 to 15 percent of the 600 or more reported cases. One of the most interesting presentations has been with sleep apnea, particularly with bilateral tumors (see later); respiratory depression as well as lability of blood pressure are common postoperative problems. Malignant transformation occurs in 5 percent of cases.

A similar *paraganglioma of the vagus nerve* has been reported; it occurs typically in the jugular or nodose ganglion but may arise anywhere along the course of the nerve. These tumors may also undergo malignant transformation in about 5 percent of cases, metastasize, or invade the base of the skull.

Carotid body tumor has been seen in combination with von Recklinghausen neurofibromatosis type 1 (NF1) and in von Hippel-Lindau disease. Familial cases are known, especially with bilateral carotid body tumors (about 5 percent of these tumors are bilateral). The treatment is surgical excision with or without prior intravascular embolization; radiation therapy has not been advised.

Pituitary Adenoma (See also "Pituitary Insufficiency" in Chap. 27)

Tumors arising in the anterior pituitary are of considerable interest to neurologists because they often cause visual and other symptoms related to involvement of

structures bordering upon the sella turcica, before an endocrine disorder becomes apparent. Pituitary tumors are age-linked; they become increasingly numerous with each decade. By the eightieth year, small adenomas are found in more than 20 percent of pituitary glands. In some cases, an apparent stimulus to adenoma formation is endocrine end-organ failure, as occurs, for example, with ovarian atrophy that induces a basophilic adenoma. Only a small proportion (6 to 8 percent) enlarge the sella, i.e., most are "microadenomas," as discussed below.

On the basis of conventional hematoxylin-eosin-staining methods, cells of the normal pituitary gland were for many years classified as chromophobe, acidophil, and basophil, these types being present in a ratio of 5:4:1. Adenomas of the pituitary are most often composed of chromophobe cells (4 to 20 times as common as acidophil cell adenomas); the incidence of basophil cell adenomas is uncertain. Histologic study is now based on immunoperoxidase-staining techniques that define the nature of the hormones within the pituitary cells—both of the normal gland and of pituitary adenomas. These methods have shown that either a chromophobe or an acidophil cell may produce prolactin, growth hormone (GH), and thyroid-stimulating hormone (TSH), whereas the basophil cells produce adrenocorticotropic hormone (ACTH), β -lipotropin, luteinizing hormone (LH), and follicle-stimulating hormone (FSH).

The development of sensitive methods for the measurement of pituitary hormones in the serum has made possible the detection of adenomas at an early stage of their development and the designation of several types of pituitary adenomas on the basis of the endocrine disturbance. Hormonal tests for the detection of pituitary adenomas, preferably carried out in an endocrine clinic, are listed in Table 31-4. Between 60

Table 31-4

HORMONAL TESTS FOR DETECTION OF PITUITARY ADENOMAS

HORMONE	TEST
Prolactin	Serum prolactin level, chlorpromazine- or TRH-provocative tests, L-dopa suppression
Somatotropin (GH)	Serum GH level, glucagon, L-dopa, glucose-GH suppression, somatostatin C
Adrenocorticotropic	Serum cortisol, urinary steroids, metyrapone test, dexamethasone suppression
Gonadotropin	Serum FSH, LH, estradiol, testosterone, GnRH stimulation
Thyrotropin	TSH, T_4 , TRH
Vasopressin	Urine and serum osmolality after water restriction for deficiency of hormone; without water restriction for excess of hormone

FSH, follicle-stimulating hormone; GH, growth hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; T_4 , thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

and 70 percent of tumors in both men and women are prolactin secreting. About 10 to 15 percent secrete growth hormone, and a smaller number secrete ACTH. Tumors that secrete gonadotropins and TSH are quite rare. These tumors may be monohormonal or plurihormonal and approximately one-third are composed of nonfunctional (null) cells.

Pituitary tumors usually arise as discrete nodules in the anterior part of the gland (adenohypophysis). They are reddish gray, soft (almost gelatinous), and often partly cystic, with a rim of calcium in some instances. The adenomatous cells are arranged diffusely or in various patterns, with little stroma and few blood vessels; less frequently the architecture is sinusoidal or papillary in type. Variability of nuclear structure, hyperchromatism, cellular pleomorphism, and mitotic figures are interpreted as signs of malignancy, which is exceedingly rare. Tumors less than 1 cm in diameter are referred to as *microadenomas* and are at first confined to the sella. As the tumor grows, it first compresses the pituitary gland; then, as it extends upward and out of the sella, it compresses the optic chiasm; later, with continued growth, it may extend into the cavernous sinus, third ventricle, temporal lobes, or posterior fossa. Recognition of an adenoma when it is still confined to the sella is of considerable practical importance, since total removal of the tumor by transsphenoidal excision or some form of stereotactic radiosurgery is possible at this stage with prevention of further damage to normal glandular structure and the optic chiasm. Penetration of the diaphragm sellae by the tumor and invasion of the surrounding structures make treatment more difficult.

Pituitary adenomas come to medical attention because of endocrine or visual abnormalities. Headaches are reported by nearly half of patients with macroadenomas but are not clearly part of the syndrome. The visual disorder usually proves to be a *complete or partial bitemporal hemianopia*, which has developed gradually and may not be evident to the patient (see the description of the chiasmatic syndromes in "Neurologic Causes of Reduced Vision" in Chap. 13). Early on, the upper parts of the visual fields may be affected predominantly, since those fibers run along the inferior optic nerve and chiasm. A small number of patients will be almost blind in one eye and have a temporal hemianopia in the other. Bitemporal central hemianopic scotomata are a less-frequent finding. A postfixed (situated relatively posteriorly) chiasm may be compressed in such a way that there is an interruption of some of the nasal retinal fibers, which, as they decussate, project into the base of the opposite optic nerve (Wilbrand knee); the controversy regarding the validity of this projection in humans is mentioned in Chap. 13. This results in a central scotoma on one or both sides (junctional syndrome) in addition to the classic temporal field defect (see Fig. 13-2).

If the visual disorder is longstanding, the optic nerve heads are atrophic. In 5 to 10 percent of cases, the pituitary adenoma extends into the cavernous sinus, causing some combination of ocular motor palsies as well as potential compression of the cavernous segment of the internal carotid artery. Other neurologic abnormali-

ties, rare to be sure, are seizures from indentation of the medial temporal lobe, CSF rhinorrhea from erosion of the sella, and diabetes insipidus, hypothermia, and somnolence from hypothalamic compression.

With regard to differential diagnosis, *bitemporal hemianopia with a normal-size sella* indicates that the causative lesion is probably a saccular aneurysm of the circle of Willis or a meningioma of the tuberculum sellae; multiple sclerosis may simulate this pattern and eventration of a greatly hydrocephalic third ventricle is an uncertain cause (see Chap. 13). The idiopathic syndrome of an "empty sella" also can cause bitemporal hemianopia and is discussed further on.

The major endocrine syndromes associated with pituitary adenomas are described briefly in the following pages. Their functional classification can be found in the monograph edited by Kovacs and Asa. A detailed discussion of the diagnosis and management of hormone-secreting pituitary adenomas is given in the reviews of Klibanski and Zervas and of Pappas and colleagues; recommended also is an article that details the neurologic features of pituitary tumors by Anderson and colleagues. Worthy of emphasis is the catastrophic syndrome of pituitary apoplexy discussed further on.

Amenorrhea-Galactorrhea Syndrome As a rule, this syndrome becomes manifest during the childbearing years. The history usually discloses that menarche had occurred at the appropriate age; primary amenorrhea is rare. A common history is that the patient took birth control pills, only to find, when she stopped, that the menstrual cycle did not reestablish itself. On examination, there may be no abnormalities other than galactorrhea. Serum prolactin concentrations are increased (usually in excess of 100 ng/mL). In general, the longer the duration of amenorrhea and the higher the serum prolactin level, the larger the tumor (prolactinoma). The elevated prolactin levels distinguish this disorder from idiopathic galactorrhea, in which the serum prolactin concentration is normal.

Males with prolactin-secreting tumors rarely have galactorrhea and usually present with a larger tumor and complaints such as headache, impotence, and visual abnormalities. In normal persons, the serum prolactin rises markedly in response to the administration of chlorpromazine or thyrotropin-releasing hormone (TRH); patients with a prolactin-secreting tumor fail to show such a response. With large tumors that compress normal pituitary tissue, thyroid and adrenal function will also be impaired. It should be emphasized that large, nonfunctioning pituitary adenomas also cause modest hyperprolactinemia by distorting the pituitary stalk and reducing dopamine delivery to prolactin-producing cells.

Acromegaly This disorder consists of acral growth and prognathism in combination with visceromegaly, headache, and several endocrine disorders (hypermetabolism, diabetes mellitus). The highly characteristic facial and bodily appearance, well known to all physicians, is caused by an overproduction of GH after puberty; prior to puberty, an oversecretion of GH leads to gigantism. In a small number of acromegalic patients, there is an

excess secretion of both GH and prolactin, derived apparently from two distinct populations of tumor cells. The diagnosis of this disorder, which is often long delayed, is made on the basis of the characteristic clinical changes, the finding of elevated serum GH values (0.10 ng/mL), and the failure of the serum GH concentration to rise in response to the administration of glucose or TRH. The new growth hormone-receptor antagonist pegvisomant was introduced to reduce many of the manifestations of acromegaly (see the review by Melmed).

Cushing Disease Described in 1932 by Cushing, this condition is only about one-fourth as frequent as acromegaly. A distinction is made between *Cushing disease* and *Cushing syndrome*, as indicated in Chap. 27. The former term is reserved for cases that are caused by the excessive secretion of pituitary ACTH, which, in turn, causes adrenal hyperplasia; the usual basis is a pituitary adenoma. *Cushing syndrome* refers to the effects of cortisol excess from any one of several sources—excessive administration of steroids (the most common cause), adenoma of the adrenal cortex, ACTH-producing bronchial carcinoma, and, very rarely, other carcinomas that produce ACTH. The clinical effects are the same in all of these disorders and include truncal obesity, hypertension, proximal muscle weakness, amenorrhea, hirsutism, abdominal striae, hyperglycemia, osteoporosis, and in some cases a characteristic mental disorder (see “Cushing Disease and Corticosteroid Psychoses” in Chap. 58).

Although Cushing originally referred to the disease as pituitary basophilism and attributed it to a basophil adenoma, the pathologic change may consist only of hyperplasia of basophilic cells or of a nonbasophilic microadenoma. Seldom is the sella turcica enlarged: Consequently, visual symptoms or signs as a result of involvement of the optic chiasm or nerves and extension to the cavernous sinus are rare. The diagnosis of Cushing disease is made by demonstrating increased concentration of plasma and urinary cortisol; these levels are not suppressed by the administration of relatively

small doses of dexamethasone (0.5 mg qid), but they are suppressed by high doses (8 mg daily). A low level of ACTH and a high level of cortisol in the blood, increased free cortisol in the urine, and nonsuppression of adrenal function after administration of high doses of dexamethasone are evidence of an adrenal source of the Cushing syndrome—usually a tumor and less often a micronodular hyperplasia of the adrenal gland.

Diagnosis of Pituitary Adenoma This is virtually certain when a chiasmal syndrome is combined with an endocrine syndrome of either hypopituitary or hyperpituitary type. Laboratory data that are confirmatory of an endocrine disorder, as described above, and sometimes a ballooned sella turcica on plain films of the skull are occasionally found. Patients who are suspected of having a pituitary adenoma should be examined by MRI with gadolinium; this procedure will visualize pituitary adenomas as small as 3 mm in diameter and show the relationship of the tumor to the optic chiasm (Fig. 31-20). This also provides the means of following the tumor’s response to therapy. It should be kept in mind that pituitary tissue normally enhances on CT and MRI, revealing small tumors as relatively hypoenhancing nodules.

Tumors and lesions other than pituitary adenomas may sometimes expand the sella. Enlargement may be the result of an intrasellar craniopharyngioma, meningioma, carotid aneurysm, or cyst of the pituitary gland. Intrasellar epithelium-lined cysts are rare lesions. They originate from the apex of the Rathke pouch, which may persist as a cleft between the anterior and posterior lobes of the hypophysis. Rarer still are intrasellar cysts that have no epithelial lining and contain thick, dark brown fluid, the product of intermittent hemorrhages. Both types of intrasellar cysts may compress the pituitary gland and mimic the endocrine-suppressive effects of pituitary adenomas. Neoplasms originating in the nasopharynx or sinuses may invade the sella and pituitary gland, and sarcoid lesions at the base of the brain may do the same. Also, the pituitary gland and the infundibulum

Figure 31-20. Pituitary macroadenoma. Coronal T1 MRI before (left) and after (right) contrast administration. A homogeneously enhancing mass originating in the sella protrudes into the suprasellar cistern and displaces the optic chiasm and inferior hypothalamus. The lesion also extends into the left greater than right cavernous sinuses.

(and the chiasm) may be the site of metastases, most of them from the lung and breast (Morita et al); they give rise to diabetes insipidus, pituitary insufficiency, or orbital pain, and rarely may be the first indication of a systemic tumor.

Empty Sella Syndrome More common than the aforementioned conditions is a *nontumorous enlargement of the sella* ("empty sella"). This results from a defect in the dural diaphragm, which may occur without obvious cause or with states of raised intracranial pressure, such as pseudotumor cerebri (see Chap. 30) or hydrocephalus, or may follow surgical excision of a pituitary adenoma or meningioma of the tuberculum sellae or pituitary apoplexy (see later). The arachnoid covering the diaphragm sellae will bulge downward through the dural defect, and the sella then enlarges gradually, presumably because of the pressure and pulsations of the CSF acting on its walls. In the process, the pituitary gland becomes flattened, sometimes to an extreme degree; however, the functions of the gland are usually unimpaired. Flattening of the pituitary gland precedes bony expansion of the sella in many cases. Erosion or dishiscence of the sellar floor does not occur and the appearance of these changes implicates another type of lesion. Downward herniation of the optic chiasm occurs occasionally and may cause visual disturbances simulating those of a pituitary adenoma (Kaufman et al). As mentioned earlier, a bitemporal hemianopia with a normal-sized sella is usually caused by a primary suprasellar lesion (saccular aneurysm of the distal carotid artery, meningioma, or craniopharyngioma).

Treatment This varies with the type and size of the pituitary tumor, the status of the endocrine and visual systems, and the age and childbearing plans of the patient. The administration of the dopamine agonist *bromocriptine* (which inhibits prolactin) in a beginning dosage of 0.5 to 1.25 mg daily (taken with food) may be the only therapy needed for small or even large prolactinomas, and is a useful adjunct in the treatment of the amenorrhea-galactorrhea syndrome. The dose should be slowly increased by 2.5 mg or less every several days until a therapeutic response is obtained. Under the influence of bromocriptine, the tumor decreases in size within days, the prolactin level falls, and the visual field defect improves.

Some cases of acromegaly also respond to the administration of bromocriptine but even better to *octreotide*, an analogue of somatostatin. The initial dose of octreotide is 200 mg/d, increased in divided doses to 1,600 mg by increments of 200 mg weekly. In Lamberts' series of acromegaly patients, the growth hormone levels returned to normal and tumor size was reduced in 12 of 15 cases. Treatment with bromocriptine and octreotide must be continuous to prevent relapse. Newer slow-release somatostatin analogues and long-acting dopamine agonists such as cabergoline have been developed for use in patients who do not respond to the conventional agents (Colao and Lombardi).

If the patient is intolerant of medication (or, in the case of acromegaly, to octreotide and newer drugs), the treatment is surgical, using a transsphenoidal microsurgical approach, with an attempt at total removal of the tumor and preservation of normal pituitary function.

Unfortunately, approximately 15 percent of GH-secreting tumors and prolactinomas will recur at 1 year. For this reason, incomplete removal or recurrence of the tumor (or tumors that are unresponsive to hormonal therapy) should be followed by radiation therapy.

Alternative primary treatment for intrasellar tumors is forms of stereotactic radiosurgery, *provided that vision is not being threatened and there is no other urgent need for surgery*. These forms of radiation can be focused precisely on the tumor and will destroy it. Kjellberg and colleagues and Chapman, using proton beam radiation, in the past treated more than 1,100 pituitary adenomas without a fatality and with few complications (Kliman et al). A single brief exposure was all that was necessary. An endocrine deficit will follow in most instances and must be corrected by hormone replacement therapy. Several equivalent methods (gamma knife, Cyberknife) are more accessible and have become widely used. The advantage of these radiotherapeutic methods is that tumor recurrence is rare. A disadvantage is that the radiation effect is obtained only after several months. Estrada and colleagues have also reported that external beam-radiation therapy may be employed after unsuccessful transsphenoidal surgery for Cushing disease. After approximately 3.5 years following radiation, 83 percent of their patients showed no signs of tumor growth. There are a few reports, however, of a decline in memory ability after radiation treatment of all types.

Large extrasellar extensions of a pituitary growth must be removed by craniotomy, usually with a transfrontal approach, followed by radiation therapy. Visual field defects often remain, but some improvement in vision can be anticipated.

Pituitary Apoplexy This syndrome, described originally by Brougham, Heusner, and Adams, occurs as a result of infarction of an adenoma that has outgrown its blood supply. It is characterized by the acute onset of severe headache that may be retro-orbital, frontal, bitemporal, or generalized ophthalmoplegia; bilateral visual loss; and in severe cases, drowsiness or coma, with either subarachnoid hemorrhage or pleocytosis and elevated protein in the CSF. The CT or MRI shows infarction of tumor, often with hemorrhage in and above an enlarged sella. Pituitary apoplexy may threaten life unless the acute Addisonian state is treated by hydrocortisone. Blindness is the other dreaded complication. If there is no improvement after 24 to 48 h, or if vision is markedly affected, transsphenoidal decompression of the sella is indicated. Factors that may precipitate the necrosis or hemorrhage of a pituitary tumor are anticoagulation, pituitary function testing, radiation, bromocriptine treatment, and head trauma; most cases, however, occur spontaneously. Some pituitary adenomas have been cured by this accident.

Ischemic necrosis of the pituitary, without the presence of a tumor followed by hypopituitarism, occurs under a variety of circumstances, the most common being in the partum or postpartum period (Sheehan syndrome).

Meningioma of the Sphenoid Ridge

This tumor, mentioned earlier in the chapter, is situated over the lesser wing of the sphenoid bone. As it grows, it may expand medially to involve structures in the wall of

the cavernous sinus, anteriorly into the orbit, or laterally into the temporal bone. Fully 75 percent of such tumors occur in women, and the average age at onset is 50 years. Most prominent among the symptoms are a slowly developing unilateral exophthalmos, slight bulging of the bone in the temporal region, and radiologic evidence of thickening or erosion of the lesser wing of the sphenoid bone. Variants of the clinical syndrome include anosmia; oculomotor palsies; painful ophthalmoplegia (sphenoidal fissure and Tolosa-Hunt syndromes; see Table 47-2); blindness and optic atrophy in one eye, sometimes with papilledema of the other eye (Foster Kennedy syndrome); mental changes; seizures (“uncinate fits”); and increased intracranial pressure. Rarely, a skull bruit can be heard over a highly vascular tumor. Sarcomas arising from skull bones, metastatic carcinoma, orbitoethmoidal osteoma, benign giant cell bone cyst, tumors of the optic nerve, and angiomas of the orbit must be considered in the differential diagnosis. Neuroimaging with contrast provides the definitive diagnosis. The tumor is resectable without further injury to the optic nerve if the bone has not been invaded.

Meningioma of the Olfactory Groove

This tumor originates in arachnoidal cells along the cribriform plate. The diagnosis depends on the finding of ipsilateral or bilateral anosmia or ipsilateral or bilateral blindness—often with optic atrophy and mental changes. The tumors may reach enormous size before coming to the attention of the physician but as many are small and found incidentally with cerebral imaging (see Fig. 31-7B). If the anosmia is unilateral, it is rarely if ever reported by the patient. The unilateral visual disturbance may consist of a slowly developing central scotoma. Abulia, confusion, forgetfulness, and inappropriate jocularity (*witzelsucht*) are the usual psychic disturbances from compression of the inferior frontal lobes (see Chap. 22). The patient may be indifferent to or joke about his blindness. Usually there are radiographic changes along the cribriform plate. MRI with gadolinium is diagnostic. Except for the largest and most invasive tumors, surgical removal is possible.

Meningioma of the Tuberculum Sella

Cushing was the first to delineate the syndrome caused by this tumor. All of his 23 patients were female. The presenting symptoms were visual failure—a slowly advancing bitemporal hemianopia with a sella of normal size. Often the field defects are asymmetrical, indicating a combined chiasmal–optic nerve involvement. Usually there are no hypothalamic or pituitary deficits. If the tumor is not too large, complete excision is possible. If removal is incomplete or the tumor recurs or undergoes malignant changes, radiation therapy of one type or another is indicated. The outlook is then guarded; several of our patients succumbed within a few years.

Glioma of the Brainstem

Astrocytomas of the brainstem are relatively slow-growing tumors that infiltrate tracts and nuclei. They produce a variable clinical picture depending on their location in the medulla, pons, or midbrain. Most often, this tumor

begins in childhood (peak age of onset is 7 years), and 80 percent appear before the twenty-first year. Symptoms have usually been present for 3 to 5 months before coming to medical notice. In most patients the initial manifestation is a palsy of one or more cranial nerves, usually the sixth and seventh on one side, followed by long tract signs—hemiparesis, unilateral ataxia, ataxia of gait, paraparesis, and hemisensory and gaze disorders in addition to pseudobulbar dysarthria and palsy. In the remaining patients the symptoms occur in the reverse order—i.e., long tract signs precede the cranial nerve abnormalities. Patients in the latter group survive longer than those whose illness begins with cranial nerve palsies. Headache, vomiting, and papilledema may occur, usually late in the illness. The course is slowly progressive over several years unless some part of the tumor becomes more malignant (anaplastic astrocytoma or glioblastoma multiforme) or, as rarely happens, spreads to the meninges (meningeal gliomatosis), in which instance the illness may terminate fatally within months.

The main problem in diagnosis is to differentiate this disease from a pontine form of multiple sclerosis, a vascular malformation of the pons (usually a cavernous hemangioma), or brainstem encephalitis, and to distinguish the focal from the diffuse type of glioma (see below). The most helpful procedure in diagnosis and prognosis is contrast-enhanced MRI (Fig. 31-21).

A study of 87 patients by Barkovich and coworkers emphasized the importance of distinguishing between diffusely infiltrating and focal nodular tumors. In the more common diffuse type, there is mass effect with hypointense signal on T1-weighted MRI and heterogeneously increased T2 signal, which reflects edema and tumor infiltration. These diffusely infiltrating tumors, usually showing an asymmetrical enlargement of the pons, have a poorer prognosis than the focal or nodular tumors, which tend to occur in the dorsal brainstem and

Figure 31-21. Pontine glioma. Contrast-enhanced T1 MRI demonstrates a mass with prominent irregular peripheral gadolinium enhancement. The patient was a 3-year-old male with progressive cranial nerve and long tract deficits.

often protrude in an exophytic manner. In a few instances of diffuse brainstem glioma, surgical exploration is necessary to establish the diagnosis (inspection and possibly biopsy). However, the histologic characteristics of a minute biopsy specimen of the tumor are not particularly helpful in determining prognosis or treatment and the general practice is to avoid surgery unless the tumor exhibits unusual clinical behavior or does not conform to the typical MRI appearance of the diffuse type.

Treatment The treatment of the diffuse infiltrative type is radiation, and if increased intracranial pressure develops as a result of hydrocephalus, ventricular shunting of CSF becomes necessary. Adjuvant chemotherapy has not been helpful. A series of 16 patients treated by Pollack and colleagues emphasizes that the focal and exophytic brainstem tumors are almost all low-grade astrocytomas; these tumors, in contrast to the more diffuse type, usually respond well to partial resection and permit long-term survival because they recur only slowly and do not undergo malignant transformation. Gangliocytomas or mixed astrogangliocytomas are rare imitators of nodular glioma in the brainstem. The rarer cystic glioma of the brainstem (see Fig. 31-19), a pilocytic tumor like its counterpart in the cerebellum, is treated by resection of the mural nodule and, as mentioned earlier, has an excellent prognosis. Landolfi and colleagues emphasized the longer survival in adults with pontine glioma (median 54 months) as compared to children. Most of the patients with pontine tumors with which we are familiar proved to have malignant gliomas.

Glioma of the Optic Nerves and Chiasm

This tumor, like the brainstem glioma, occurs most frequently during childhood and adolescence. In 85 percent of cases, it appears before the age of 15 years (average 3.5 years), and it is twice as frequent in girls as in boys (Cogan). The initial symptoms are dimness of vision with constricted fields, followed by bilateral field defects of homonymous, heteronymous, and sometimes bitemporal type and progressing to blindness and optic atrophy with or without papilledema. Ocular proptosis from the orbital mass is the other main feature. Hypothalamic signs (adiposity, polyuria, somnolence, and genital atrophy) occur occasionally as a result of proximal tumor extension. CT, MRI, and ultrasonography will usually reveal the tumor, and radiographs will show an enlargement of the optic foramen (greater than 7.0 mm). This finding and the lack of ballooning of the sella or of suprasellar calcification will exclude pituitary adenoma, craniopharyngioma, Hand-Schüller-Christian disease, and sarcoidosis. In adolescents and young adults, the medial sphenoid, olfactory groove, and intraorbital meningiomas (optic nerve sheath meningioma) are other tumors that cause monocular blindness and proptosis. If the entire tumor is prechiasmatic (the less-common configuration), surgical extirpation can be curative. For tumors that have infiltrated the chiasm or are causing regional symptoms and hydrocephalus, partial excision followed by radiation is all that can be offered. Both gliomas and nontumorous gliotic (hamartomatous) lesions of the optic nerves may occur in von Recklinghausen disease; the latter are sometimes

impossible to distinguish from optic nerve gliomas and should be followed closely.

Chordoma

This is a soft, jelly-like, gray-pink growth that arises from remnants of the primitive notochord. It is located most often within the clivus (from dorsum sellae to foramen magnum) and in the sacrococcygeal region. It affects males more than females, usually in early or middle adult years and is one of the rare causes of syndromes involving multiple cranial nerves or the cauda equina. Approximately 40 percent of chordomas occur at each of these two ends of the neuraxis; the rest are found at any point in the vertebral bodies in between. The tumor is made up of cords or masses of large cells with granules of glycogen in their cytoplasm and often with multiple nuclei and intracellular mucoid material. Chordomas are locally invasive, especially of surrounding bone, but they do not metastasize.

The cranial neurologic syndrome caused by this tumor is remarkable in that all or any combination of cranial nerves from the second to twelfth on one or both sides may be involved. Associated signs in the series of Kendall and Lee were facial pain, conductive deafness, and cerebellar ataxia, the result of pontomedullary and cerebellar compression. A characteristic feature is neck pain radiating to the vertex of the skull on neck flexion. The tumors at the base of the skull may destroy the clivus and bulge into the nasopharynx, causing nasal obstruction and discharge and sometimes dysphagia. Extension to the cervical epidural space may result in cord compression. Thus, chordoma is one of the lesions that may present both as an intracranial and extracranial mass, the others being meningioma, neurofibroma, glomus jugulare tumor, and carcinoma of the sinuses or pharynx. CT of the skull base is useful for defining the bony margins of the tumor, and MRI can identify involved and adjacent neural and vascular structures. Midline (Wegener) granulomas, histiocytosis, Erdheim-Chester disease, and sarcoidosis also figure in the differential diagnosis. Chondrosarcoma of the clivus produces a similar syndrome.

Treatment of the chordoma is surgical excision and radiation (focused radiation). This form of treatment has effected a 5-year survival without recurrence in approximately 80 percent of patients.

Nasopharyngeal Growths That Erode the Base of the Skull (Nasopharyngeal Transitional Cell Carcinoma, Schmincke Tumor)

These are seen regularly in a general hospital; they arise from the mucous membrane of the paranasal sinuses or the nasopharynx near the eustachian tube, i.e., the fossa of Rosenmüller. In addition to symptoms of nasopharyngeal or sinus disease, which may not be prominent, facial pain and numbness, abducens, and other cranial nerve palsies may occur. Diagnosis depends on inspection and biopsy of a nasopharyngeal mass or an involved cervical lymph node and radiologic evidence of erosion of the base of the skull. Bone scans and CT are helpful in diagnosis (see Fig. 47-5). The treatment is surgical resection and radiation but chemotherapy is increasingly being included. Carcinoma of the ethmoid or sphenoid sinuses and

postradiation neuropathy, coming on years after the treatment of a nasopharyngeal tumor, may produce similar clinical pictures and are difficult to differentiate. The syndromes resulting from nasopharyngeal tumors are discussed in Chap. 47, under "Diseases of the Cranial Nerves."

Other Tumors of the Base of the Skull

In addition to meningioma, nasopharyngeal tumors, and the other tumors enumerated earlier, there are a large variety of tumors, rare to be sure, that derive from tissues at the base of the skull and paranasal sinuses, ears, and other structures and give rise to distinctive syndromes. Included in this category are osteomas, chondromas, ossifying fibromas, giant cell tumors of bone, lipomas, epidermoids, teratomas, mixed tumors of the parotid gland, and hemangiomas and cylindromas (adenoid cystic carcinomas of salivary gland origin) of the sinuses and orbit; sarcoid granulomas may produce the same effect. Most of these tumors are benign, but some have a potential for malignant change. To the group must be added the *esthesioneuroblastoma* (of the nasal cavity) with anterior fossa extension and, perhaps most common of all of these, the *systemic malignant tumors that metastasize to basal skull bones* (prostate, lung, and breast being the most common sources), or involve them as part of a multicentric neoplastic process, e.g., primary lymphoma, multiple myeloma, plasmacytoma, and lymphocytic leukemia.

Suprasellar arachnoid cysts also occur in this region. CSF flows upward from the interpeduncular cistern but is trapped above the sella by thickened arachnoid (membrane of Lilliequist). As the CSF accumulates, it forms a cyst that invaginates the third ventricle; the dome of the cyst may intermittently block the foramina of Monro and cause hydrocephalus (see Fox and Al-Mefty). Children with this condition exhibit a curious to-and-fro bobbing and nodding of the head, like a doll with a weighted head resting on a coiled spring. This has been referred to as the "bobble-head doll syndrome" by Benton and colleagues; it can be cured by emptying the cyst. Seesaw and other pendular and jerk types of nystagmus may also result from these suprasellar lesions.

Tables 31-5 and 47-1, adapted from Bingas' large neurosurgical service in Berlin, summarizes the facts about the focal syndromes of the skull base; his authoritative article and the more recent one by Morita and Piepgras, both in the *Handbook of Clinical Neurology*, are recommended references.

Modern imaging techniques now serve to clarify many of the diagnostic problems posed by these tumors. MRI is particularly helpful in delineating structures at the base of the brain and in the upper cervical region. CT is also capable of determining the absorptive values of the tumor itself and the sites of bone erosion. When the lesion is analyzed in this way, an etiologic diagnosis often becomes possible. For example, the absorptive value of lipomatous tissue is different from that of brain tissue, glioma, blood, and calcium. Bone scans (technetium and gallium) display active destructive lesions with remarkable fidelity, but in some cases, even when the tumor is seen with various studies, it may be difficult to obtain a satisfactory biopsy.

Tumors of the Foramen Magnum

Tumors in the region of the foramen magnum are of particular importance because of the need to differentiate them from diseases such as multiple sclerosis, Chiari malformation, syringomyelia, and bony abnormalities of the craniocervical junction. Failure to recognize these tumors is a consequential matter because the majority are benign and extramedullary, i.e., potentially resectable and curable. If unrecognized, they terminate fatally by causing medullary and high spinal cord compression.

Although these tumors are not common (approximately 1 percent of all intracranial and intraspinal tumors) sizable series have been collected by several clinicians (see Meyer et al for a complete bibliography). In all series, meningiomas, schwannomas, neurofibromas, and dermoid cysts are the most common types; others, all rare, are teratomas, dermoids, granulomas, cavernous hemangiomas, hemangioblastomas, hemangiopericytomas, lipomas, and epidural carcinomas.

Pain in the suboccipital or posterior cervical region, mostly on the side of the tumor, is usually the first and by far the most prominent complaint. In some instances the pain may extend into the shoulder and even the arm. The latter distribution is more frequent with tumors arising in the spinal canal and extending intracranially than the reverse. For uncertain reasons, the pain may radiate down the back, even to the lower spine. Both spine and root pain can be recognized, the latter because of involvement of either the C2 or C3 root or both.

One pattern is weakness of a shoulder and arm progressing to the ipsilateral leg and then to the opposite leg and arm ("around-the-clock" paralysis) as discussed in Chap. 3. Another configuration is triplegia that is a characteristic but not invariable sequence of events, caused by the encroachment of tumor upon the decussating corticospinal tracts at the foramen magnum. Occasionally, both upper limbs are involved alone; surprisingly, there may be atrophic weakness of the hand or forearm or even intercostal muscles with diminished tendon reflexes well below the level of the tumor, an observation made originally by Oppenheim. Involvement of sensory tracts also occurs; more often it is posterior column sensibility that is impaired on one or both sides, with patterns of progression similar to those of the motor paralysis. Sensation of intense cold in the neck and shoulders has been another unexpected complaint, and also "bands" of hyperesthesia around the neck and back of the head. Segmental brachial sensory loss has been demonstrated in a few of the cases and a Lhermitte sign (really a symptom) of electric-like sensations down the spine and limbs upon flexing the neck has been reported frequently. The cranial nerve signs most frequently conjoined and indicative of intracranial extension of a foramen magnum tumor are dysphagia, dysphonia, dysarthria, and drooping shoulder (because of vagal, hypoglossal, and spinal accessory involvement); included less often are nystagmus and episodic diplopia, sensory loss over the face and unilateral or bilateral facial weakness, and a Horner syndrome.

Table 31-5

CLINICAL SYNDROMES CAUSED BY TUMORS AT THE BASE OF THE SKULL

SITE OF LESION	EPONYM	CLINICAL SYMPTOMS	ETIOLOGY ^a
Anterior part of the base of the skull		Olfactory disturbances (uni- or bilateral anosmia), possibly psychiatric disturbances, seizures.	Tumors that invade the anterior part of the base of the skull from the frontal sinus, nasal cavity, or the ethmoid bone, osteomas. Meningiomas of the olfactory groove.
Superior orbital fissure	Rochon-Duvigneau; syndrome of the pterygopalatine fossa (Behr) and the base of the orbit (DeJean) commencing with a lesion of the maxillary and pterygoid rami and evolving into the superior orbital fissure syndrome.	Lesions of the third, fourth, sixth, and first divisions of the fifth nerves with ophthalmoplegia, pain, and sensory disturbances in the area of V ₁ ; often exophthalmos, some vegetative disturbances.	Tumors: meningiomas, osteomas, dermoid cysts, giant-cell tumors, tumors of the orbit, nasopharyngeal tumors; more rarely, optic nerve gliomas; eosinophilic granulomas, angiomas, local or neighboring infections, trauma.
Apex of the orbit	Jacod-Rollet (often combined with the syndrome of the superior orbital fissure); infraclinoid syndrome of Dandy.	Visual disturbances, central scotoma, papilledema, optic nerve atrophy; occasional exophthalmos, chemosis.	Optic nerve glioma, infraclinoid aneurysm of the internal carotid artery, trauma, orbital tumors, Paget disease.
Cavernous sinus	Foix-Jefferson; syndrome of the sphenopetrosal fissure (Bonnet and Bonnet) corresponding in part to the cavernous sinus syndrome of Raeder.	Ophthalmoplegia caused by lesions of the third, fourth, sixth, and often fifth nerves; exophthalmos; vegetative disturbances. Jefferson distinguished three syndromes: (1) the anterior-superior, corresponding to the superior orbital fissure syndrome; (2) the middle, causing ophthalmoplegia and lesions of V ₁ and V ₂ ; (3) the caudal, in addition affecting the whole trigeminal nerve.	Tumors of the sellar and parasellar area, infraclinoid aneurysms of the internal carotid artery, nasopharyngeal tumors, fistulas of the sinus cavernosus and the carotid artery (traumatic), tumors of the middle cranial fossa, e.g., chondromas, meningiomas, and neurinomas.
Apex of the petrous temporal bone	Gradenigo-Lannois	Lesions of the fifth and sixth nerves with neuralgia, sensory, and motor disturbances, diplopia.	Inflammatory processes (otitis), tumors such as cholesteatomas, chondromas, meningiomas, neurinomas of the gasserian ganglion and trigeminal root, primary and secondary sarcomas at the base of the skull.
Sphenoid and petrosal bones (petrosphenoidal syndrome)	Jacod	Ophthalmoplegia caused by loss of function of the third, fourth, and sixth nerves; amaurosis; trigeminal neuralgia possibly with sensory signs.	Tumors of the sphenoid and petrosal bones and middle cranial fossa, nasopharyngeal tumors, metastases.
Jugular foramen	Vernet	Lesions of ninth, tenth, and eleventh nerves with disturbance of deglutition; curtain phenomenon; sensory disturbances of the tongue, soft palate, pharynx, and larynx; hoarseness; weakness of the sternocleidomastoid and trapezius.	Tumors of the glomus jugulare; neurinomas of eighth, ninth, tenth, and eleventh nerves; chondromas, cholesteatomas, meningiomas, nasopharyngeal and ear tumors; infections, angiomas, rarely trauma.
Anterior occipital condyles	Collet-Sicard (Vernet-Sargnon)	Loss of twelfth nerve function (loss of normal tongue mobility) in addition to the symptoms of the jugular foramen.	Tumors of the base of the skull, ear, parotid; leukemic infiltrates; aneurysms, angiomas, and inflammations.
Retroparotid space (retropharyngeal syndrome)	Villaret	Lesions of the lower group of nerves (Collet-Sicard) and Bernard-Horner syndrome with ptosis and miosis.	Tumors of the retroparotid space (carcinomas, sarcomas), trauma, inflammations.
Half of the base of the skull	Garcin (Guillain-Alajouanine-Garcin); also described by Hartmann in 1904.	Loss of function of all twelve cranial nerves of one side; in many cases, isolated cranial nerves spared; rarely signs of raised intracranial pressure or pyramidal tract symptoms.	Nasopharyngeal tumors, primary tumors at the base of the skull, leukemic infiltrates of basal meninges, trauma, metastases.

(Continued)

Table 31-5

CLINICAL SYNDROMES CAUSED BY TUMORS AT THE BASE OF THE SKULL (CONTINUED)

SITE OF LESION	EPONYM	CLINICAL SYMPTOMS	ETIOLOGY ^a
Cerebellopontine angle		Loss of function of eighth nerve (hearing loss, vertigo, nystagmus); cerebellar disturbances; lesions of the fifth, seventh, and possibly ninth and tenth cranial nerves. Signs of raised intracranial pressure, brainstem symptoms.	Acoustic neuromas (raised protein in CSF), meningiomas, cholesteatomas, metastases, cerebellar tumors, neurinomas of the caudal group of nerves and the trigeminal nerve, vascular processes such as angiomas, basilar aneurysms.

^aMetastatic deposits may produce any of these syndromes.

Source: Adapted from Bingas. (See also Tables 47-1 and 47-2.)

The clinical course of such lesions often extends for years, with deceptive and unexplained fluctuations. The important diagnostic procedure is contrast-enhanced MRI (Fig. 31-22). With *dermoid cysts* of the upper cervical region, as in the case reported by Adams and Wegner, complete and prolonged remissions from quadriplegia may occur.

Tumors of the foramen magnum, as mentioned, should be differentiated from spinal or brainstem-cerebellar multiple sclerosis, Chiari malformation with syrinx, and bony compression. Persistent occipital neuralgia with a foramen magnum syndrome is particularly suggestive of a tumor at that site. The early occipitocervical pain must be differentiated from mundane crucial osteoarthritis. Treatment is surgical excision (Hakuba et al) followed by focused radiation if the resection is incomplete and the tumor is known to be radiosensitive.

REMOTE EFFECTS OF NEOPLASIA ON THE NERVOUS SYSTEM (PARANEOPLASTIC DISORDERS) (TABLE 31-6)

In the past 50 years a group of neurologic disorders has been delineated that occur in patients with systemic neoplasia even though the nervous system is not the site of metastases or direct invasion or compression by the tumor. These so-called paraneoplastic disorders are not specific or confined to cancer, but the conditions are linked far more frequently than could be accounted for by chance. They assume special importance because in many cases the neurologic syndrome becomes apparent before the underlying tumor is found. The great variety of clinical presentations of paraneoplastic encephalitis disease can be appreciated from early series reported by Graus and colleagues of 200 patients: sensory neuropathy, 54 percent; cerebellar ataxia, 10 percent; limbic encephalitis, 9 percent; and others, including multiple sites, in 11 percent. Some of the paraneoplastic disorders that involve nerve and muscle—namely, polyneuropathy, polymyositis, and the myasthenic-myopathic syndrome of Lambert-Eaton—are described in later chapters on these subjects. Here we present the paraneoplastic processes that involve the spinal cord, cerebellum, brainstem, and cerebral hemispheres.

Comprehensive accounts of the paraneoplastic disorders may be found in the writings of Posner (1995), Darnell and Posner, and Dalmau and Rosenfeld. Some are associated with immunoglobulin G (IgG) autoantibodies (see Table 31-5), but it should be remarked that although certain antibodies are associated with specific syndromes, they are not invariably linked to particular cancers and vice versa. Furthermore, the same

Table 31-6

THE MAIN PARANEOPLASTIC DISORDERS AND THEIR ASSOCIATED AUTOANTIBODIES^a

NEUROLOGIC DISORDER	CLINICAL FEATURES	PREDOMINANT AUTOANTIBODY	TUMOR
Cerebellar degeneration	Ataxia, subacute	Anti-Yo (anti-Purkinje cell)	Ovary, fallopian tube, lung, Hodgkin disease (anti-Tr)
Encephalomyelitis including limbic and brainstem encephalitis	Subacute confusion, brainstem signs, myelitis	Anti-Hu (ANNA 1) Anti-Ma, Anti-CRMP-5, Anti-Caspr2	Small cell lung, neuroblastoma, prostate, breast, Hodgkin, testicular (Ma)
	Psychosis, seizures, hypersympathetic state	Anti-NMDA, Anti-mGluR5	Ovarian (and other site) teratoma
Opsoclonus–myoclonus–ataxia	Ocular movement disorder, gait ataxia	Anti-Ri (ANNA 2)	Breast, fallopian tube, small cell lung
Retinal degeneration	Scotomas, blindness, disc swelling	Antirecoverin (Anti-CAR)	Small cell lung, thymoma, renal cell, melanoma
Subacute sensory neuropathy and neuronopathy	Distal or proximal sensory loss	Anti-Hu (ANNA-1)	Small cell lung, Hodgkin, other lymphomas
Lambert-Eaton myasthenic syndrome	Proximal fatiguing weakness, autonomic symptoms (dry mouth)	Anti-voltage-gated (VGCC) calcium channel	Small cell lung, Hodgkin, other lymphomas
Stiff person syndrome and neuromyotonia	Muscle spasms and rigidity	Antiampiphysin, Anti-Caspr2, Anti-GAD	Breast, lung
Chorea	Bilateral choreoathetosis	Anti-Hu, Anti-CRMP-5	Lung, Hodgkin, others
Optic neuropathy	Blindness	Anti-CRMP-5	Lung

^aIn many cases, a particular autoantibody is associated with a specific tumor type rather than with the clinical syndrome (e.g., small cell lung cancer and polyneuropathy with ANNA 1, breast cancer with anti-Purkinje cell antibody, testicular tumors with anti-Ma). Clinical syndromes similar to each of these may occur with non–small cell lung cancer and lymphoma, most often in the absence of detectable antibodies.

syndromes and antibodies occur sometimes without an evident tumor. This was emphasized in the survey by Pittock and colleagues at the Mayo Clinic, who found that one-third of sera from patients with paraneoplastic neurologic disorders had more than one antibody. They have suggested that this reflects the numerous immunogenic onconeural proteins that are expressed by tumors. Consequently, the relationships between particular antibodies and a clinical syndromes listed in Table 31-6 should be taken as approximate, or nonexclusive. Nonetheless, certain syndromes seem to occur disproportionately often with particular antibodies. Small cell cancer of the lung, adenocarcinoma of the breast and ovary, and Hodgkin disease are the tumors most often associated with these disorders, but the paraneoplastic neurologic syndromes occur in only a very small proportion of patients with these tumors.

The mechanisms by which carcinomas produce their remote effects are incompletely understood. Perhaps the most plausible theory, as intimated above, is that they have an autoimmune basis. According to this theory, antigenic molecules are shared by certain tumors and central or peripheral neurons. The immune response is then directed to the shared antigen in both the tumor and the nervous system. The evidence for such an autoimmune mechanism is most clearly exemplified by the Lambert-Eaton syndrome, in which an antibody derived from a tumor binds to voltage-gated calcium channels at neuromuscular junctions (see Chap. 49).

Furthermore, in some types of paraneoplastic disorders, there is provocative evidence that the inciting tumor has antigen on its surface and self-binding of the antibody may inhibit tumor growth. This may account for the difficulty in detecting diminutive small cell lung cancers that underlie some of the paraneoplastic syndromes. It should be noted, however, that there is no evidence that suppressing or removing the antibody leads to growth of the tumor.

Encephalomyelitis Associated with Carcinoma and “Limbic Encephalitis”

The occurrence of regional and bilateral encephalomyelitic changes in association with carcinoma has been described by several authors (Corsellis et al; Henson and Ulrich; Posner, 1995). In most of the reported cases, the encephalitic process has been associated with carcinoma of the bronchus, usually of the small cell type, but all types of neoplasms, including Hodgkin disease, have been implicated. Histologically, this group of paraneoplastic disorders is characterized by extensive loss of neurons, accompanied by microglial proliferation, small patches of necrosis, and marked perivascular cuffing by lymphocytes and monocytes. Foci of lymphocytic infiltration have been observed in the leptomeninges as well. These pathologic changes may involve the brain and spinal cord diffusely, but more often they predominate in a particular part of the nervous system, notably in

the medial temporal lobes and adjacent nuclei ("limbic encephalitis," Fig. 31-23), the brainstem, the cerebellum (see earlier), or the gray matter of the spinal cord. The symptoms will, of course, depend on the location and severity of the inflammatory changes and may overlap. Most cases are subacute, meaning specifically a progression over a few weeks or months, but often the main symptoms in mild form become apparent in a matter of days. Rare instances of remission have been reported.

The most distinctive features of *paraneoplastic limbic encephalitis* consists of a confusional-agitated state, memory defect (Korsakoff syndrome), seizures, sometimes focal, hallucinations, and dementia—singly or in various combinations and evolving subacutely (Gultekin et al); an amnestic component is almost universal and the central feature in most cases.

Vertigo, nystagmus, ataxia, nausea and vomiting, and a variety of ocular and gaze palsies reflect a different process of *paraneoplastic brainstem encephalitis*. As indicated above, these symptoms may be joined with cerebellar ataxia, and another group has an additional sensory neuropathy. We have seen instances of this condition involving only the midbrain and others involving only the medulla, the latter with unusual breathing patterns including gasping, inspiratory breathholding, and vocal-respiratory incoordination, and yet others with chorea and additional basal ganglionic features. Pathologic studies have partially clarified this form of paraneoplastic disorder. In some cases, few changes were demonstrable in the brain, even though there had been a prominent dementia during life. Contrariwise, widespread inflammatory changes may be found without clinical abnormalities having been recorded during life.

In most of these cases, MRI shows abnormal T2 hyperintensity and edema in affected regions; in severe cases, zones of focal necrosis may be seen. Odd seizures, including *epilepsia partialis continua*, have been observed with this disorder, but they must be uncommon. Sensory symptoms may be related to neuronal loss in the posterior horns, traced to the commonly associated loss of neurons in the dorsal root ganglia (sensory neuronopathy and sensory neuropathy) as mentioned earlier and discussed further on.

Most patients with small cell lung cancer and any of the types of paraneoplastic encephalomyelitis have been found to harbor circulating polyclonal IgG antibodies (*anti-Hu*, or *antineuronal antibody type 1*) that bind to the nuclei of neurons in many regions of the brain and spinal cord, dorsal root ganglion cells, and peripheral autonomic neurons. The antibodies are reactive with certain nuclear RNA-binding proteins. Cancers of the prostate and breast and neuroblastoma may rarely produce a similar antibody. The antibody titer is higher in the CSF than in the serum (as it is for anti-Yo with cerebellar degeneration), indicating production of antibody within the nervous system. Low titers of anti-Hu are found in approximately 15 percent of patients with small cell cancer who are neurologically normal, probably because these tumors have expressed only low levels of antigens that are recognized by anti-Hu. Antibodies to voltage-gated potassium channels (VGKC) have been identified in patients with limbic

encephalitis without, or less often with, cancer (Vincent et al). A number of these cases respond to plasma exchange. The anti-VGKC disorders tend to be slower in evolution and less severe than the typical paraneoplastic neurologic syndromes.

Treatment Despite a few reports of improvement with plasma exchange or intravenous gamma globulin, the results of treatment have been disappointing. However, those few patients who did improve had treatment from the onset of symptoms, and this is possibly a way of limiting the neuronal loss.

Anti-NMDA Encephalitis

A special form of paraneoplastic encephalitis presents itself as an acute or subacute psychiatric syndrome consisting of some combination of hallucinations, panic, delusions, and incoherence, coupled with seizures, memory disturbance and hypoventilation has been described by Vitaliani and colleagues in four women with ovarian teratoma. Many patients have a non-descript prodrome of malaise, fatigue, headache excessive sleepiness, or low fever. Dalmau and coworkers (2007) demonstrated that this syndrome is associated with antibodies against a component of the NMDA receptor. The teratoma in one of their patients was located in the mediastinum instead of the ovary and rare cases have occurred with small cell lung cancer, including in men. Dalmau's series of 100 patients (2008) is instructive in that they were very predominantly women in their twenties with presentations or psychiatric or memory deterioration but a large number had dyskinesias, seizures, or hypoventilation. Almost all had several or dozens of white blood cells in the CSF, a majority had oligoclonal bands and the MRI showed abnormal T2 hyperintensity in the medial temporal lobes, similar to those of the anti-Hu type of limbic encephalitis.

We have been impressed with the autonomic overactivity in the patients under our care with this syndrome. Episodes of hypertension, tachycardia and diaphoresis can be pronounced, as is excessive salivation, pupillary dilation, and other signs of sympathetic dysfunction, individually or concurrently.

Dalmau and colleagues have identified the target of the antibody as the subunit of the NMDA receptor, NR1. There is a reasonable degree of certainty that the antibody is pathogenic.

Another peculiar syndrome associated with prostate cancer, which we have encountered once, was described by Baloh and colleagues prior to the discovery of most of the currently known paraneoplastic antibodies. These patients display brainstem signs, particularly loss of horizontal gaze, and facial and pharyngeal spasms or abdominal myoclonus. Whether this process will be subsumed under one or another of the known antibody syndromes is not known but it is notable because prostate cancer otherwise rarely gives rise to paraneoplastic disease.

Treatment A premium is attached to early identification of this disorder and rapid removal of the ovary containing the teratoma or resection of another inciting tumor. Vaginal ultrasound may be necessary for the demonstration of the ovarian lesion but a more extensive

examination such as CT or PET is needed for the detection of other tumors. Improvement after tumor removal is associated with subsidence of the antibody titer over many weeks and a good outcome occurs in a majority of cases. Decisions regarding oophorectomy are difficult in view of reducing fertility in young women.

It has become apparent that a fair proportion of cases with circulating anti-NMDA antibody do not have a tumor that is detectable and immune treatments such as intravenous gamma globulin may then be used. It is reasonable to start these same immune treatments while awaiting surgery in cases that are highly symptomatic.

Paraneoplastic Sensory Neuropathy

(See also Chap. 46)

This is a distinctive syndrome that is associated in most cases with the anti-Hu antibody. It should be emphasized that a nondescript, mainly sensory neuropathy is a more common accompaniment of systemic cancer, and it may or may not be associated with the anti-Hu antibody. As discussed further in Chap. 46, a sensory polyneuropathy from chemotherapeutic agents, notably the platinum-based ones and vincristine, also needs to be distinguished from the anti-Hu neuropathy syndrome.

The sensory neuropathy and neuropathy were first described by Denny-Brown in 1948 and are notable because they served to introduce the modern-day concept of paraneoplastic neurologic disease. The initial symptoms in both processes are numbness or paresthesia, sometimes painful, in a limb or in both feet. There may be lancinating pains at the onset. Over a period of days in some cases, but more typically over weeks, the initially focal symptoms become bilateral and may spread to all limbs and their proximal portions and then to the trunk. It is this widespread and proximal distribution and the involvement of the face, scalp, and often the oral and genital mucosa that mark the process as a sensory ganglionitis and radiculitis and when subacute are highly suggestive of a paraneoplastic process.

As the illness progresses, all forms of sensation are greatly reduced, resulting in *disabling ataxia* and pseudoathetoid movements of the outstretched hands. The reflexes are lost, but not always at the outset, and strength is relatively preserved. *Autonomic dysfunction*—including constipation or ileus, sicca syndrome, pupillary areflexia, and orthostatic hypotension—is sometimes associated. Also, a virtually pure form of peripheral autonomic failure has been recorded as a paraneoplastic phenomenon (*paraneoplastic dysautonomia*). One of our patients with sensory neuropathy had gastric atony with fatal aspiration after vomiting and another died of unexpected cardiac arrhythmia. Very early in the illness, the electrophysiologic studies may be normal, but this soon gives way to a loss of all sensory potentials, sometimes with indications of a mild motor neuropathy.

The spinal fluid usually contains an elevated protein and a few lymphocytes. As with paraneoplastic encephalomyelitis, most of the cases associated with small cell lung cancer demonstrate the anti-Hu antibody. As mentioned, neuropathy and encephalomyelitis often

occur together. The sensory neuropathy–ganglionopathy that is related to Sjögren disease and an idiopathic variety do not have this antibody, making its presence a reliable marker for lung cancer in patients with sensory neuropathy. The polyneuropathy is refractory to almost all forms of treatment, or there is a transient benefit, and most patients die within months of onset, but there have been reports of brief remissions with plasma exchange and intravenous gamma globulin applied early in the illness. Resection of the lung tumor may halt progression of the neurologic illness.

Paraneoplastic Cerebellar Degeneration

For many years, this disorder was considered to be quite uncommon, but it is perhaps the most characteristic of the paraneoplastic syndromes. In reviewing this subject in 1970, Adams and Victor were able to find only 41 pathologically verified cases; in a subsequent review (Henson and Urich), only a few more cases were added. The actual incidence is much higher than these figures would indicate. At the Cleveland Metropolitan General Hospital, in a series of 1,700 consecutive autopsies in adults, there were 5 instances of cerebellar degeneration associated with neoplasm. In the experience of Henson and Urich, about half of all patients with nonfamilial, late-onset cerebellar degeneration proved sooner or later to be harboring a neoplasm. Large series of cases have been reported from the Mayo Clinic and the Memorial Sloan-Kettering Cancer Center (Hammock et al and N.E. Anderson et al, respectively). We see several such cases yearly, but have also encountered numerous instances of an identical syndrome with no cancer evident and no antibodies that are probably a result of diverse causes summarized in Chap. 5 and Table 5-1.

In approximately one-third of the cases, the underlying neoplasm has been in the lung (most often a small cell carcinoma)—a figure reflecting the high incidence of this tumor. However, the association of ovarian carcinoma and lymphoma, particularly Hodgkin disease, accounting for approximately 25 and 15 percent, respectively, is considerably higher than would be expected on the basis of the frequency of these malignancies. Carcinomas of the breast, bowel, uterus, and other viscera have accounted for most of the remaining cases (Posner, 1995).

The cerebellar symptoms have a subacute onset and steady progression over a period of weeks to months; in more than half the cases, the cerebellar signs are recognized before those of the associated neoplasm. Symmetrical ataxia of gait and limbs—affecting arms and legs more or less equally—dysarthria, and nystagmus are the usual manifestations; some have vertigo. Striking in fully developed cases has been the severity of the ataxia, matched by few other diseases. Occasionally, myoclonus and opsoclonus or a fast-frequency myoclonic tremor may be associated (“dancing eyes–dancing feet,” as noted later). In addition, there are quite often symptoms and signs not strictly cerebellar in nature, notably diplopia, vertigo, Babinski signs (common in our cases), sensorineural hearing loss, disorders of ocular motility, and alteration of affect and mentation—findings that

serve to distinguish paraneoplastic from alcoholic and other varieties of cerebellar degeneration. Lambert-Eaton syndrome is known to occur with cerebellar degeneration as paraneoplastic illnesses. These are well emphasized in the series of 47 patients collected by Anderson and colleagues and the 55 cases by Peterson et al, who tabulated these noncerebellar neurologic features.

The CSF may show a mild pleocytosis (up to 50 cells/mm³ in a few of our patients) and increased protein, or it may be entirely normal. Early in the course of the disease, CT and MRI show no abnormality, but after a few months, atrophy of the brainstem and cerebellum may appear. In a few cases, T2-weighted MRI discloses increased signal of the cerebellar white matter (Hammock et al), but this has not been uniform in our experience, and furthermore does not correlate well to the degree of Purkinje cell loss (Fig. 31-23).

Pathologically, there are diffuse degenerative changes of the cerebellar cortex and deep cerebellar nuclei. Purkinje cells are affected prominently and all parts of the cerebellar cortex are involved. Degenerative changes in the spinal cord, involving the posterior columns and spinocerebellar tracts, have been found rarely. The cerebellar neuronal degeneration is frequently associated with perivascular and meningeal clusters of inflammatory cells. Henson and Urich regard the inflammatory changes as an independent process, part of a subacute paraneoplastic encephalomyelitis (see below). This view is supported by the finding that the specific antibodies linked to cerebellar degeneration differ from those found in paraneoplastic inflammatory lesions in other parts of the nervous system.

Figure 31-23. Axial T2 FLAIR MRI from a woman with anti-voltage-gated potassium channel (VGKC) paraneoplastic limbic encephalitis associated with thyroid cancer. The hippocampus and amygdala appear abnormally T2 hyperintense.

Anti-Purkinje cell antibodies (termed “anti-Yo”) can be found in the sera of about half of patients with paraneoplastic cerebellar degeneration and in the large majority of those related to carcinoma of the breast or female genital tract, linking the clinical syndrome and this antibody closely. Antibodies against a nuclear antigen, termed anti-Hu, may also be present; they are more closely linked to the paraneoplastic encephalomyelitis discussed further on. (Hu and Yo are taken from the names of patients in whom the antibody was first found.) In the Mayo Clinic series of 32 patients with paraneoplastic cerebellar degeneration, 16 had such antibodies; all were women and most of them had breast or ovarian cancers. Anderson and colleagues report a similar proportion but point out that several anti-Purkinje antibodies besides the highly characteristic one may be found by special techniques. Death occurred in 4 to 18 months. In an equal number of cases without antibodies, half are men with lung cancer, some of whom display the anti-Hu antibody. This leaves a proportion who have no circulating antibody but who are nonetheless found to have a concealed tumor that must be sought by other ancillary tests including positron emission tomography (PET) of the entire body. In another small group, it must be conceded that no underlying tumor can be found despite extensive examinations and even at autopsy. The death rate in these cases has varied widely from 6 months to several years and depends on the behavior of the underlying tumor.

Whether the anti-Yo antibodies are merely markers of an underlying tumor or the agents of destruction of the Purkinje cells is not clear. They bind to a C-myc protein that initiates a degeneration of Purkinje cells. Regardless of the pathogenic significance of the antibodies, their presence in a patient with the typical neurologic disorder has considerable diagnostic significance. As mentioned above, they usually indicate that there is an underlying breast or ovarian cancer, which may be asymptomatic and small enough to be resected successfully. Other antibodies besides anti-Yo and anti-Hu are found on occasion, such as those against a glutamate receptor in patients with Hodgkin disease (Smitt et al). The differential diagnosis of subacute cerebellar ataxia is broad, as indicated in Table 5-1. The main considerations are a variant of Creutzfeldt-Jakob disease, postinfectious cerebellitis, and various intoxications.

Treatment Reports of aggressive plasma exchange or intravenous immunoglobulin treatment early in the course suggest some benefit, but it should not be assumed that this approach will succeed in most patients, and our own experience has been discouraging in this regard. There are also on record several cases in which there was a partial or complete remission of symptoms after removal of the primary tumor (Paone and Jeyasingham). Furthermore, in some cases associated with Hodgkin disease, there has been spontaneous improvement of the cerebellar symptoms.

Opsoclonus–Myoclonus–Ataxia Syndrome

In children, this syndrome is usually a manifestation of neuroblastoma, but it is more common and occurs in

adults in relation to breast cancer and small cell lung cancer. The unique feature of the neuroblastoma is a response of this syndrome to corticosteroids and ACTH in most children and in some adults, and resolution of the neurologic signs when the neuroblastoma is removed. A subgroup of breast cancers produce an antineuronal antibody directed against a different RNA-binding antigen from the anti-Hu antibody; thus it has been termed "anti-Ri" (*antineuronal antibody type 2*). This antibody is not found in the opsoclonus-ataxic syndrome of neuroblastoma and is present only rarely with small cell lung cancer. There have also been a limited number of positive serologic tests in children with opsoclonus, apparently without an underlying tumor. A few such patients have had a mild pleocytosis in the CSF; the MRI is usually normal. More complex syndromes have been reported with the anti-Ri antibody, manifest by rigidity and intense stimulus-sensitive myoclonus in addition to the core features of opsoclonus and ataxia.

The neuropathologic findings have not been distinctive; mild cell loss has been described in the Purkinje cell layer, inferior olives, and brainstem, with mild inflammatory changes (Luque et al).

Besides breast cancer, we have observed the opsoclonus-myoclonus syndrome in a middle-aged woman with bronchial carcinoma and in a man with gastric carcinoma. Similar cases occur with both cerebellar ataxia and an irregular tremor, which we have interpreted as myoclonic in character. These patients were found to have marked degeneration of the dentate nuclei. The prognosis in this syndrome is somewhat better than that for the other paraneoplastic diseases, but besides a trial of ACTH, there is little that can be done but search for the tumor and resect it if possible.

Carcinomatous Myelopathy and Motor Neuronopathy

In addition to subacute degeneration of spinal cord tracts that may be associated with paraneoplastic cerebellar degeneration (see earlier), there has been described a rapidly progressive form of more widespread degeneration of the spinal cord (Mancall and Rosales). The myelopathy is characterized by a rapidly ascending sensorimotor deficit that terminates fatally in a matter of weeks. There is a roughly symmetrical necrosis of both the gray and white matter of most of the cord. This necrotizing *myelopathy* is distinctly rare, being far less common than compression of the spinal cord from cancer and even less frequent than intramedullary spinal cord metastases. Flanagan and colleagues have summarized a large series of their cases and described a variety of presentations including longitudinally extensive involvement on imaging studies that simulate the pattern seen with anti-aquaporin antibodies of Devic disease as described in Chaps. 36 and 44. It can therefore be said that there is a paraneoplastic type of neuromyelitis optica. Most of their cases had a CSF pleocytosis, half had oligoclonal bands, and one of the known paraneoplastic autoantibodies was found the majority.

Better defined is *subacute motor neuronopathy* that occurs as a remote effect of bronchogenic carcinoma, Hodgkin disease, and other lymphomas as mentioned earlier in the discussion of encephalomyelitis (Schold et al). Some cases take the form of a relatively benign, purely motor weakness of the limbs, the course and severity of which are independent of the underlying neoplasm. Other cases are severe and progressive, causing respiratory failure and death, thus simulating amyotrophic lateral sclerosis (ALS); some of these will have the anti-Hu antibody (Verma et al; Forsyth et al). The basic neuropathologic change is a depletion of anterior horn cells; also seen are inflammatory changes and neuronophagia as in chronic poliomyelitis. The few autopsied cases have shown gliosis of the posterior columns, pointing to an asymptomatic affection of the primary sensory neuron, as well as a reduction in the number of Purkinje cells.

Forsyth and colleagues subdivided their cases of *paraneoplastic motor neuron syndromes* into three groups: (1) rapidly progressive amyotrophy and fasciculations with or without brisk reflexes—all of their 3 patients displayed anti-Hu antibodies, 2 with small cell lung cancer and 1 with prostate cancer; (2) a predominantly corticospinal syndrome that affected the oropharyngeal or limb musculature, without definite evidence of denervation, thus resembling primary lateral sclerosis—all were breast cancer patients and none showed antineuronal antibodies; and (3) a syndrome indistinguishable from ALS in 6 patients with breast or small cell lung cancer, Hodgkin disease, or ovarian cancer, none of whom had antineuronal antibodies. In the latter two groups one cannot be certain that the condition was not a chance occurrence of the idiopathic variety of motor neuron disease. Nevertheless, this is such a rare cause of motor neuron disease that an evaluation for tumor is not required in the typical case of ALS.

A rare paraneoplastic syndrome of spinal myoclonus with tonic spasms can occur and is assumed to be from inflammation of the spinal cord gray matter as discussed in Chaps. 6 and 44.

Other Paraneoplastic Disorders

Several more recently discovered antibodies, such as CRMP-5 (collapsin-responsive mediator protein) and anti-Ma1 and -Ma2, have been detected in cases of brainstem encephalitis including with ophthalmoplegia but there have been associations with limbic and diencephalic syndromes as well and a hypokinetic parkinsonian appearance (Dalmau et al 2004). The anti-Ma antibodies cross-react with testicular antigens and a search for a testicular tumor is undertaken (Voltz et al). Although rare, the clinical syndromes associated with the anti-Ma antibody and testicular tumors are diverse: limbic, brainstem, or hypothalamic inflammation and an ataxic-opsoclonic syndrome that is more typical of anti-Ri antibody (see earlier).

The antibody to CRMP-5 is reported in some series to be second in frequency only to anti-Hu. Lung carcinoma has been the most common source in the series of Yu and colleagues, with thymoma, renal cell, and other

neoplasms accounting for a few of the cases. The clinical features have been as diverse as for anti-Hu, including seizures, dementia, confusion, depression, as well as a variety of peripheral and cranial neuropathies and, surprisingly, the Lambert-Eaton syndrome.

An illness similar to the one caused by anti-NMDA antibodies, under the name of Ophelia syndrome, has been reported as a paraneoplastic syndrome that is due to antibodies directed against the metabotropic glutamate receptor, mGluR5 (see Lancaster et al).

Paraneoplastic Optic Neuropathy

An optic neuropathy is probably the most specific associated syndrome with the CRMP-5 antibody, as described by Cross and colleagues. There is subacute visual loss, disc swelling, and a cellular reaction in the vitreous. Most patients have features of another paraneoplastic syndrome. Several authors have remarked on the occurrence of chorea as a presenting symptom along with basal ganglionic changes on MRI. It is difficult for us to make sense of the clinical features aside from the optic neuropathy (really an optic neuritis), but they seem comparable to the perivenous inflammatory encephalitis and neuritis of the anti-Hu syndromes. Presumably this antibody accounts for some of the odd subacutely progressive syndromes previously thought to be antibody-negative; testing for this antibody might be included when an unusual paraneoplastic syndrome is suspected. The heterogeneity of antibody response to these expressed proteins may account for different clinical manifestations of the immune process but there is no certain evidence yet of their pathogenetic role.

Paraneoplastic Retinopathy

In recent years, there have been reports of retinopathy as a paraneoplastic syndrome that is distinct from the above-described optic neuropathy. Small cell carcinoma of the lung has been the most common underlying malignancy. In about half of the reported cases, retinal symptoms preceded the discovery of the tumor by several months. The lesion is in the photoreceptor cells, and antiretinal antibodies (directed against a calcium-binding protein, recoverin) have been identified in the serum. Photosensitivity, ring scotomas, and attenuation of the retinal arterioles are the main clinical features; Jacobson and coworkers suggested that they constitute a diagnostic triad.

Paraneoplastic Stiff Man Syndrome and Related Neuromuscular Disorders (See Chap. 48)

Occasionally this disorder (stiff man syndrome) occurs as a paraneoplastic disease. Lesser degrees of unexplained mild rigidity are seen from time to time, perhaps as a consequence of loss of spinal cord interneurons. In what might be called "stiff woman syndrome," Folli and associates described 3 female patients with breast cancer who developed a state of generalized motor hyperexcitability and rigidity. These patients generally have no antibodies to glutamic acid decarboxylase (GAD), as in the sporadic cases of "stiff man syndrome"; probably there are antibodies to other synaptic proteins.

The "chorée fibrillaire" of Morvan is an extraordinary disorder of continuous muscle fiber activity, insomnia, and hallucinosis that may be caused by a paraneoplastic antibody to voltage-gated potassium channels, as discussed in Chap. 48 and 50s. This same antibody, as well as acetylcholine receptor antibodies, has been associated with neuromyotonia of *Isaac syndrome*, seen in cases of lung cancer, lymphoma, and thymoma.

The *Lambert-Eaton syndrome* is perhaps the most common paraneoplastic neurologic syndrome; it is associated with antibodies directed against calcium channels, as mentioned earlier. This disorder, which may occur concurrently with other paraneoplastic syndromes such as cerebellar ataxia, is discussed in Chap. 53. Basal ganglia syndromes, chorea in particular, are associated with the anti-Hu and CRMP-5 antibodies as already noted. A myoclonus syndrome without ataxia or opsoclonus is reported from time to time in the literature and probably is a derivative of one of the better-characterized antibody diseases.

Radiation Injury of the Brain

Injury to the CNS from radiation is appropriately discussed here, since it occurs mainly in relation to therapy of brain tumors. Three syndromes of radiation damage have been delineated: acute, early delayed, and late delayed, although these syndromes often blend into one another. The acute reaction may begin during the latter part of a series of fractionated treatments or soon thereafter. There may be a seizure, a transitory worsening of the tumor symptoms, or signs of increased intracranial pressure. Although the condition has been attributed to brain edema, this is not always visible on MRI and its basis is unknown. The symptoms subside in days to weeks. Corticosteroids are usually administered, but with the exception of cases with demonstrable edema, their effect is uncertain. A novel syndrome of migraine-like headache and focal neurologic deficits, developing many years after cranial radiation, has also been described and is referred to below.

The early radiation syndrome has been more troublesome in our experience that has the very acute form. As with the acute syndrome, focal tumor symptoms may increase, and as seen on MRI (Fig. 31-25), the tumor mass enlarges, raising the possibility of further tumor growth, but again the symptoms usually reflect extensive demyelination, loss of oligodendrocytes beyond the confines of the tumor, and varying degrees of tissue necrosis. Possibly the administration of dexamethasone or a similar corticosteroid hastens resolution of this condition.

The late-delayed process is the most serious of radiation complications. Here one finds—in structures adjacent to a cerebral neoplasm, the pituitary gland, or other structures of the head and neck—necrosis of the white matter of the brain and, occasionally, of the brainstem. In some areas, the tissue undergoes softening and liquefaction, with cavitation. With lesser degrees of injury, the process is predominantly a demyelinating one, with partial preservation of axons. Later reactions are thought to be caused by diffuse vascular changes as a result of radiation energy. Endothelial cells frequently multiply and, because ionization injures dividing cells, the vessels

are most vulnerable. The result is hyaline thickening of vessels with fibrinoid necrosis and widespread microthrombosis. There is a lesser degree of damage to glial cells. Neurons are relatively resistant though they can be secondarily affected by loss of glial support as well as reduced tissue perfusion.

The symptoms of delayed injury, coming on 3 months to many years after radiation therapy, are either those of a subacutely evolving mass, difficult to separate from those of tumor growth, or of a subacute dementia. The clinical pattern varies with the site of the lesion: focal or generalized seizures, impairment of mental function, and, sometimes, increased ICP. Whole-brain radiation for metastatic tumor or acute lymphoblastic leukemia can lead to multifocal zones of necrosis and holohemispheric spongiform changes in the white matter, with diffuse cerebral atrophy and enlarged ventricles. Progressive dementia, ataxia, and urinary incontinence are the main clinical features of this state (DeAngelis et al). In its mildest form there are no radiographic changes aside from the tumor, but the patient becomes mentally dull, slightly disinhibited, and often sleepy for large parts of the day. Panhypopituitarism is another complication of whole-brain radiotherapy, particularly in children, who may also suffer growth retardation. Radiation necrosis of the spinal cord is described in Chap. 44.

In the production of radiation necrosis, the total and fractional doses of radiation and the time over which treatment is administered are obviously important factors, but the exact amounts that produce such damage cannot be stated. Accepted levels of large-field radiation are tolerated in amounts approaching 6,000 cGy, provided it is given in small daily doses (200 to 300 cGy) 5 days per week over a period of 6 weeks. Other factors, still undefined, must play a part, as similar courses of radiation treatment may damage one patient and leave another unaffected. The severe necrotizing encephalopathy that has followed the combined use of methotrexate (intrathecally but also intravenously) was discussed earlier, under "Involvement of the Nervous System in Leukemia," the condition in which it was first described and formerly was most prevalent.

CT and MRI show a contrast-enhancing lesion, and by angiography there is an avascular mass. Small calcifications may appear many years after the radiation. MRI is somewhat more sensitive in distinguishing radiation necrosis from tumor and peritumor products, but PET is the most reliable way of differentiating the two, perhaps obviating the need for biopsy (Glantz et al, 1991). Single-photon emission tomography (SPECT) can be useful for this purpose as well (Carvalho et al). CT or MRI perfusion imaging can also be used to differentiate radiation necrosis from tumor progression; cerebral blood volume is reduced in the former and most often elevated in the latter.

Treatment has consisted of the administration of corticosteroids, which may cause regression of symptoms and of edema surrounding the lesion. Very high doses may be necessary, 40 mg or more of dexamethasone (or its equivalent) daily. Rarely, surgical resection of a necrotic mass has been attempted, with uncertain results.

A difficult to classify migraine-like syndrome following cranial irradiation has been described by Partap and colleagues and by Pruitt and coworkers. This syndrome has been given the acronym *SMART*, for stroke-like migraine attacks after radiation therapy. The typical case is of a young adult who, years or decades after receiving radiation as a child for an intracranial neoplasm, develops episodes of severe headache and simultaneous symptoms such as aphasia, hemiparesis, or hemianopia, sometimes lasting days. There may be an independent headache suggestive of migraine. The CSF protein is often elevated. In some cases there is diffuse gyriform enhancement over a large region of cortex spanning several arterial territories, and focal narrowing of intracranial vessels or capillary telangiectasias can be seen as well, both interpreted by the above authors as radiation-induced change. Corticosteroids seemed helpful in some cases.

It is also known that tumors, usually sarcomas, can be induced by radiation, as mentioned earlier (Cavin et al). While well documented, this occurs rarely and only after an interval of many years. We have also seen two cases of fibrosarcoma of the brachial plexus region in the radiation field for breast tumors (Gorson et al). These lesions appeared more than 10 years after the initial treatment, and many cases of even longer latency are on record.

Tumors of the spinal cord and peripheral nerves are discussed in Chaps. 44 and 46, respectively. The various neurologic effects of chemotherapy for systemic tumors, especially polyneuropathy, are discussed in Chaps. 43 and 46. The interesting problem of the effects on the nervous system of graft-versus-host disease are taken up in Chap. 36 with other inflammatory conditions (Figs. 31-24 and 31-25).

Figure 31-24. Paraneoplastic cerebellar degeneration. Coronal T2 FLAIR MRI showing subtle diffuse abnormal T2 hyperintensity of the cerebellar cortex.

Figure 31-25. Radiation leukoencephalopathy. A patient who underwent proton beam radiation therapy for carcinoma of the mastoid area presented several years later with a seizure and was found to have extensive abnormal T2 hyperintensity in the adjacent left hemisphere (*left*), consistent with radiation necrosis. Another patient with lung cancer who was treated with prophylactic whole-brain radiation, presented several years later with gait difficulties and cognitive decline and was found to have extensive symmetric leukoencephalopathy with ex vacuo ventricular dilation.

Infections of the Nervous System (Bacterial, Fungal, Spirochetal, Parasitic) and Sarcoidosis

This chapter is concerned mainly with bacterial infections of the central nervous system (CNS), particularly bacterial meningitis, septic thrombophlebitis, brain abscess, epidural abscess, and subdural empyema. The granulomatous infections of the CNS, notably tuberculosis, syphilis and other spirochetal infections, and certain fungal infections are also discussed in some detail. In addition, consideration is given to sarcoidosis, a granulomatous disease of uncertain etiology, and to the CNS infections and infestations caused by certain rickettsias, protozoa, worms, and ticks.

A number of other important infectious diseases of the nervous system are discussed elsewhere in this book. Viral infections, because of their frequency and importance, are allotted a chapter of their own (see Chap. 33). Diseases caused by bacterial exotoxins—diphtheria, tetanus, botulism—are considered with other toxins that affect the nervous system (see Chap. 43). Leprosy, which is essentially a disease of the peripheral nerves, is described in Chap. 46, and trichinosis, mainly a disease of muscle, in Chap. 48.

BACTERIAL INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

These infections reach the intracranial structures by one of two pathways, either by hematogenous spread (emboli of bacteria or infected thrombi) or by extension from cranial structures adjacent to the brain (ears, paranasal sinuses, osteomyelitic foci in the skull, penetrating cranial or congenital sinus tracts). In a number of cases, infection is iatrogenic, being introduced in the course of cerebral or spinal surgery, the placement of a ventriculo-peritoneal shunt or, rarely, by a lumbar puncture needle. Increasingly, craniospinal infections are nosocomial, i.e., acquired in-hospital; in urban hospitals, nosocomial meningitis is now as frequent as the non-hospital-acquired variety (Durand et al).

Surprisingly little is known about the mechanisms of hematogenous spread and animal experiments involving the injection of virulent bacteria into the bloodstream have yielded somewhat contradictory results. In most instances of bacteremia or septicemia, the nervous system seems not to be infected; yet sometimes a bacteremia

caused by pneumonia or endocarditis is the only apparent predecessor to meningitis. With respect to the formation of brain abscess, cerebral tissue has a notable resistance to infection. Direct injection of virulent bacteria into the brain of an animal seldom results in abscess formation. In fact, this condition has been produced consistently only by injecting culture medium along with the bacteria or by causing necrosis of the tissue at the time bacteria are inoculated. In humans, infarction of brain tissue because of arterial occlusion (thrombosis or embolism) or venous occlusion (thrombophlebitis) appears to be a common and perhaps necessary antecedent by way of causing of a necrotic nidus.

The mechanism of meningitis and brain abscess from infection of the middle ear and paranasal sinuses is easier to understand. The cranial epidural and subdural spaces are practically never the sites of blood-borne infections, in contrast to the spinal epidural space, where such infections are either hematogenous spread but can be from contiguous osteomyelitis. Furthermore, the cranial bones and the dura mater (which essentially constitutes the inner periosteum of the skull) protect the cranial cavity against the ingress of bacteria. This protective mechanism may fail if suppuration occurs in the middle ear, mastoid cells, or frontal, ethmoid, and sphenoid sinuses. Two pathways from these sources have been demonstrated: (1) infected thrombi may form in diploic veins and spread along these vessels into the dural sinuses (into which the diploic veins flow), and from there, in retrograde fashion, along the meningeal veins into the brain, and (2) an osteomyelitic focus may erode the inner table of bone and invade of the dura, subdural space, pia-arachnoid, and even brain. Each of these pathways has been observed by the authors in some fatal cases of epidural abscess, subdural empyema, meningitis, cranial venous sinusitis and meningeal thrombophlebitis, and brain abscess. However, in many cases coming to autopsy, the pathway of infection cannot be determined.

With a hematogenous infection in the course of a bacteremia, usually a single type of virulent bacterium gains entry to the cranial cavity. In the adult the most common pathogenic organisms are pneumococcus (*Streptococcus pneumoniae*), meningococcus (*Neisseria meningitidis*), *Haemophilus influenzae* in unvaccinated children, *Listeria monocytogenes*, and staphylococcus; in the

neonate, *Escherichia coli* and group B streptococcus; in the infant and unvaccinated child, *H. influenzae*. By contrast, when septic material embolizes from infected lungs, pulmonary arteriovenous fistulas, or congenital heart lesions, or extends directly from ears or sinuses, more than one type of bacterial flora common to these sources may be transmitted. Such "mixed infections" pose difficult problems in therapy. Occasionally in these latter conditions, the demonstration of the causative organisms may be unsuccessful, even from the pus of an abscess (mainly because of inadequate culturing techniques for anaerobic organisms and the prior use of antibiotics). Infections that follow neurosurgery or the insertion of a cranial appliance are usually staphylococcal; a small number are a result of mixed flora, including anaerobic ones, or one of the enteric organisms. In determining the most likely invading organism, the age of the patient, the clinical setting of the infection (community-acquired, postsurgical, or nosocomial), the immune status of the patient, and evidence of systemic and local cranial disease all must be taken into account.

ACUTE BACTERIAL MENINGITIS (LEPTOMENINGITIS)

The Biology of Bacterial Meningitis

The immediate effect of bacteria or other microorganisms in the subarachnoid space is to cause an inflammatory reaction in the pia and arachnoid as well as in the cerebrospinal fluid (CSF). Because the subarachnoid space is continuous around the brain, spinal cord, and optic nerves, an infective agent gaining entry to any one part of the space allows it to spread rapidly to all of it, even its most remote recesses; in other words, meningitis is always cerebrospinal. Infection also reaches the ventricles, either directly from the choroid plexuses or by reflux through the foramina of Magendie and Luschka.

The first reaction to bacteria or their toxins is hyperemia of the meningeal venules and capillaries and an increased permeability of these vessels, followed shortly by exudation of protein and the migration of neutrophils into the pia and subarachnoid space. The subarachnoid exudate increases rapidly, particularly over the base of the brain; it extends into the sheaths of cranial and spinal nerves and, for a very short distance, into the perivascular spaces of the cortex. During the first few days, mature and immature neutrophils, many of them containing phagocytosed bacteria, are the predominant cells. Within a few days, lymphocytes and histiocytes increase gradually in numbers. During this time, there is exudation of fibrinogen, which is converted to fibrin after a few days. In the latter part of the second week, plasma cells appear and subsequently increase in number. At about the same time the cellular exudate becomes organized into two layers—an outer one, just beneath the arachnoid membrane, made up of neutrophils and fibrin, and an inner one, next to the pia, composed largely of lymphocytes, plasma cells, and mononuclear cells or macrophages. Although fibroblasts of the meninges begin to proliferate

early, they are not conspicuous until later, when they take part in the organization of the exudate, resulting in fibrosis of the arachnoid and loculation of pockets of exudate.

During the process of resolution, the inflammatory cells disappear in almost the reverse order as they had appeared. Neutrophils begin to disintegrate by the fourth to fifth day, and soon thereafter, with treatment, no new ones appear. Lymphocytes, plasma cells, and macrophages disappear more slowly, and a few lymphocytes and mononuclear cells may remain in small numbers for several months. The completeness of resolution depends on the stage at which the infection is arrested. If it is controlled in the very early stages, there may not be any residual change in the arachnoid; following an infection of several weeks' duration, there is a permanent fibrous overgrowth of the meninges, resulting in a thickened, cloudy, or opaque arachnoid and often in adhesions between the pia and arachnoid and even between the arachnoid and dura.

From the earliest stages of meningitis, changes are also found in the small and medium-sized subarachnoid arteries. The endothelial cells swell, multiply, and crowd into the lumen. This reaction appears within 48 to 72 h and increases in the days that follow. The adventitial connective tissue sheath becomes infiltrated by neutrophils. Foci of necrosis of the arterial wall sometimes occur. Neutrophils and lymphocytes migrate from the adventitia to the subintimal region, often forming a conspicuous layer. Later there is subintimal fibrosis. This is a striking feature of nearly all types of subacute and chronic infections of the meninges but most notably of tuberculous and syphilitic meningitis (Heubner arteritis). In the veins, swelling of the endothelial cells and infiltration of the adventitia also occur. Subintimal layering, as occurs in arterioles, is not observed, but there may be a diffuse infiltration of the entire wall of the vessel. It is in veins so affected that focal necrosis of the vessel wall and mural thrombi are most often found. Cortical thrombophlebitis of the larger veins does not usually develop before the end of the second week of the infection.

The unusual prominence of the vascular changes may be related to their anatomic peculiarities. The adventitia of the subarachnoid vessels, both of arterioles and venules, is actually formed by an investment of the arachnoid membrane, which is invariably involved by the infectious process. Thus, in a sense, the outer vessel wall is affected from the beginning by the inflammatory process—an infectious vasculitis. The much more frequent occurrence of thrombosis in veins than in arteries is probably accounted for by the thinner walls and the slower current of blood flow in the former.

Although the spinal and cranial nerves are surrounded by purulent exudate from the beginning of the infection, the perineurial sheaths become infiltrated by inflammatory cells only after several days. Exceptionally, there is infiltration of the endoneurium and degeneration of myelinated fibers, leading to the appearance of fatty macrophages and proliferation of Schwann cells and fibroblasts. More often, there is little or no damage to nerve fibers. Occasionally cellular infiltrations may be found in the optic nerves or olfactory bulbs.

The arachnoid membrane tends to serve as an effective barrier to the spread of infection into the adjacent subdural compartment, but some secondary reaction in this space may occur nevertheless (subdural effusion). This happens far more often in infants than in adults; according to Snedeker and coworkers, approximately 40 percent of infants with meningitis younger than 18 months of age develop subdural effusions. As a rule, there is no subdural pus, only a sterile yellowish exudate. In an even higher percentage of cases, small amounts of fibrinous exudate are found in microscopic sections that include the spinal dura.

In the early stages of meningitis, very little change in the substance of the brain can be detected. Neutrophils appear in the Virchow-Robin perivascular spaces but enter the brain only if there is necrosis. After several days, microglia and astrocytes increase in number, at first in the outer zone and later in all layers of the cortex. The associated nerve cell changes may be very slight. Obviously some disorder of the cortical neurons must take place from the beginning of the infection to account for the stupor, coma, and convulsions that are sometimes observed, but several days must elapse before any change can be demonstrated microscopically. It is uncertain whether these cortical changes are a result of the diffusion of toxins from the meninges, of a circulatory disturbance, or of some other factor, such as increased intracranial pressure or cortical venous thrombosis. The aforementioned changes are not because of invasion of brain substance by bacteria and should therefore be regarded as a noninfectious encephalopathy. When macrophages are exposed to endotoxins, they synthesize and release cytokines, among which are interleukin-1 and

tumor necrosis factor. These cytokines are believed to stimulate and modulate the local immune response but may also affect neurons.

There is also little change initially in the ependyma and the subependymal tissues; but in later stages of meningitis, conspicuous changes are invariably found. The most prominent finding is infiltration of the subependymal perivascular spaces and often of the adjacent brain tissue with neutrophilic leukocytes and later with lymphocytes and plasma cells. Microglia and astrocytes proliferate, the latter sometimes overgrowing and burying remnants of the ependymal lining. The bacteria may pass through the ependymal lining and set up this inflammatory reaction in part because this sequence of events is favored by a developing hydrocephalus, which stretches and breaks the ependymal lining. Collections of subependymal astrocytes then begin to protrude into the ventricle, giving rise to a granular ependymitis, which, if prominent, may narrow and obstruct the aqueduct of Sylvius. As any meningitis becomes more chronic, the pia-arachnoid exudate tends to accumulate around the base of the brain (basilar meningitis), obstructing the flow of CSF and giving rise to *hydrocephalus*. In a survey of community-acquired bacterial meningitis, hydrocephalus occurred in only 5 percent, but it was associated with poor outcome (Kasanmoentalib et al).

The reader may question this digression into matters that are more pathologic than clinical, but knowledge of the morphologic features of meningitis enables one to understand the clinical state and its sequelae. The meningeal and ependymal reactions to bacterial infection and the clinical correlates of these reactions are summarized in Table 32-1.

Table 32-1

PATHOLOGIC-CLINICAL CORRELATIONS IN ACUTE, SUBACUTE, AND CHRONIC MENINGEAL REACTIONS

- I. In acute meningeal inflammation:
 - A. *Pure pia-arachnoiditis*: headache, stiff neck, Kernig and Brudzinski signs.
 - B. *Subpial encephalopathy*: confusion, stupor, coma, and convulsions. Cerebral infarction because of cortical vein thrombosis may underlie these symptoms in some cases.
 - C. *Inflammatory or vascular involvement of cranial nerve roots*: ocular palsies, facial weakness, and deafness are the main signs. Deafness may also be caused by middle ear infection, by extension of meningeal infection to the inner ear, or by toxic effects of antimicrobial agents.
 - D. *Thrombosis of meningeal veins*: focal seizures, focal cerebral defects such as hemiparesis, aphasia (rarely prominent), most often after the first week.
 - E. *Ependymitis, choroidal plexitis*: it is doubtful if there are any recognizable clinical effects.
 - F. *Cerebellar or cerebral hemisphere herniation*: caused by swelling causing upper cervical cord compression with quadriplegia or signs of midbrain-third-nerve compression.
- II. In subacute and chronic forms of meningitis:
 - A. *Hydrocephalus*: at first caused by purulent exudate around the base of the brain, later by meningeal fibrosis, and rarely by aqueductal stenosis.
 - B. *Subdural effusion*: impaired alertness in a child, refusal to eat, vomiting, immobility, bulging fontanels, and persistence of fever despite clearing of CSF.
 - C. *Venous or arterial infarction*: unilateral or bilateral hemiplegia, decorticate or decerebrate rigidity, cortical blindness, stupor or coma with or without seizures. Deep infarcts may occur from an infectious vasculitis at the base of the brain.
- III. Late effects or sequelae:
 - A. *Meningeal fibrosis around optic nerves or around spinal cord and roots*: blindness and optic atrophy, spastic paraparesis with sensory loss in the lower segments of the body (opticochiasmatic arachnoiditis and meningomyelitis, respectively).
 - B. *Chronic meningoencephalitis with hydrocephalus*: dementia, stupor or coma, and paralysis (e.g., general paralysis of the insane). If lumbosacral posterior roots are chronically damaged, a tabetic syndrome results. Deep infarcts.
 - C. *Persistent hydrocephalus in the child*: blindness, arrest of mental activity, bilateral spastic hemiplegia.

Types of Bacterial Meningitis

Almost any bacterium gaining entrance to the body may produce meningitis but by far the most common are *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*, which account for approximately 75 percent of sporadic cases. Infection with *L. monocytogenes* is now the fourth most common type of nonsurgical bacterial meningitis in adults. The following are less frequent causes: *Staphylococcus aureus* and group A (*Streptococcus pyogenes*) and group D streptococci, usually in association with brain abscess, epidural abscess, head trauma, neurosurgical procedures, or cranial thrombophlebitis; *E. coli* and group B streptococci in newborns; *Pseudomonas* and the Enterobacteriaceae, such as *Klebsiella*, *Proteus*, which are usually a consequence of lumbar puncture, spinal anesthesia, or shunting procedures to relieve hydrocephalus. Less-common meningeal pathogens include *Salmonella*, *Shigella*, *Clostridium*, *Neisseria gonorrhoeae*, and *Acinetobacter calcoaceticus*. In endemic areas, *mycobacterial infections* (to be considered further on) are as frequent as those caused by other bacterial organisms. They now assume greater importance in developed countries as the number of immunosuppressed persons increases.

Epidemiology

Pneumococcal, influenzal (*H. influenzae*), and meningococcal forms of meningitis have a worldwide distribution, occurring mainly during the winter and early spring and, in the case of the first two, also in the fall, and predominating slightly in males. Each has a relatively constant incidence, although epidemics of meningococcal meningitis seem to occur roughly in 10-year cycles. Drug-resistant strains appear with varying frequency, and such information, gleaned from surveillance reports issued by the Centers for Disease Control and Prevention and from reports of local health agencies and hospital infection surveillance, are of great practical importance.

H. influenzae meningitis, formerly encountered mainly in infants and young children, has been nearly eliminated in this age group as a result of vaccination programs in developed countries. It continues to be common in less-developed nations and is now occurring with increasing frequency in adults. *Meningococcal meningitis* occurs most often in children and adolescents but is also encountered throughout much of adult life, with a sharp decline in incidence after the age of 50 years. *Pneumococcal meningitis* predominates in the very young and in older adults. Perhaps the greatest change in the epidemiology of bacterial meningitis, aside from the one related to *H. influenzae* vaccination, has been the increasing incidence of nosocomial infections, accounting for 40 percent of cases in large urban hospitals (Durand et al); staphylococcus and gram-negative bacilli account for a large proportion of these. Noteworthy is the report of Schuchat and colleagues, who found that in 1995, some 5 years after the introduction of the conjugate *H. influenzae* vaccine, the incidence of bacterial meningitis in the United States had been halved. The yearly incidence rate (per 100,000 population) of the responsible pathogens is approximately as follows: *S. pneumoniae*, 1.1; *N. meningitidis*, 0.6; group B

streptococcus (newborns), 0.3; *L. monocytogenes*, 0.2; and *H. influenzae*, 0.2. In an informative epidemiologic survey of bacterial meningitis in the United States from 1998 to 2007, Thigpen and colleagues found the relative order of the frequency of various organisms to be much the same and again emphasized the decrease in incidence of the disease due mainly to the *H. influenzae* vaccination program. They estimated the recent overall incidence to be 4,100 cases annually, resulting in 500 deaths. Their article is recommended for its detailed analysis of age, race, and underlying medical condition.

Pathogenesis

The most common meningeal pathogens are all normal inhabitants of the nasopharynx in a significant part of the population and depend on antiphagocytic capsular or surface antigens for survival in the tissues of the infected host. To a large extent they express their pathogenicity by extracellular proliferation. It is evident from the frequency with which the carrier state is detected that nasal colonization is not a sufficient explanation of infection of the meninges. Factors that predispose the colonized patient to invasion of the bloodstream, which is the usual route by which these bacteria reach the meninges, are obscure but include antecedent viral infections of the upper respiratory passages or, in the case of *S. pneumoniae*, infections of the lung. Once blood-borne, it is evident that pneumococci, *H. influenzae*, and meningococci possess a predilection for the meninges, although the precise factors that determine this tropism are not known. Whether the organisms enter the CSF via the choroid plexus or meningeal vessels is also unknown. It has been variously postulated that the entry of bacteria into the subarachnoid space is facilitated by disruption of the blood-CSF barrier by trauma, circulating endotoxins, or an initial viral infection of the meninges. These organisms, being commensal in most persons, create immunity, but bacteria may nonetheless penetrate the mucosa. Certain features of the organisms enhance their ability to cause infection; this is particularly true of the meningococcus (Rosenstein et al).

Avenues other than the bloodstream by which bacteria can gain access to the meninges include congenital neuroectodermal defects; craniotomy sites; diseases of the middle ear and paranasal sinuses, particularly perilymphatic fistulas; skull fractures; and, in cases of recurrent infection, dural tears from remote minor or major trauma. Occasionally, a brain abscess may rupture into the subarachnoid space or ventricles, thus infecting the meninges. The isolation of anaerobic streptococci, *Bacteroides*, *Actinomyces*, or a mixture of microorganisms from the CSF should suggest the possibility of a brain abscess with an associated meningitis.

Clinical Features

Adults and Children

The early clinical effects of acute bacterial meningitis are fever, headache, usually severe, and stiffness of the neck (resistance to passive movement on forward bending),

and less often initially, generalized convulsions and a disorder of consciousness (i.e., confusion, drowsiness, stupor, and coma). Flexion at the hip and knee in response to forward flexion of the neck (Brudzinski sign) and inability to completely extend the legs with the hips flexed (Kernig sign) have the same significance as stiff neck but are less-consistently elicitable. Basically, all of these signs are part of a flexor protective reflex (one of the "nocifensive" responses in Fulton's terms). Stiffness of the neck that is part of paratonic or extrapyramidal rigidity should not be mistaken for that of meningeal irritation. The former is more or less equal in all directions of movement, in distinction to that of meningitis, which is present only or predominantly on forward flexion. Whether it is stiffness in the initial few degrees of flexion of the neck or in the subsequent part of the movement that is more specific for meningitis has been debated; our experience has been that the latter is more sensitive but also proves to be mistaken for other disorders; thus the first may be more specific for meningitis.

Diagnosis of meningitis may be difficult when the initial manifestations consist only of fever and headache, when stiffness of the neck has not yet developed, or when there is only pain in the neck or abdomen or a febrile confusional state or delirium. Also, stiffness of the neck may not be apparent in the deeply stuporous or comatose patient or in the infant or the elderly, as indicated further on.

The symptoms comprised by the meningitic syndrome are common to the three main types of bacterial meningitis, but certain clinical features and the setting in which each of them occurs correlate more closely with one type than another.

Meningococcal meningitis should be suspected when the evolution is extremely rapid (delirium and stupor may supervene in a matter of hours), when the onset is attended by a petechial or purpuric rash or by large ecchymoses and lividity of the skin of the lower parts of the body, when there is circulatory shock, and especially during local outbreaks of meningitis. Because a petechial rash accompanies approximately 50 percent of meningococcal infections, its presence dictates immediate institution of antibiotic therapy, even though a similar rash may be observed with certain viral (echovirus serotype 9 and some other enteroviruses), as well as *S. aureus* infections, and, rarely, with other bacterial meningitides.

Pneumococcal meningitis is often preceded by an infection in the lungs, ears, sinuses, or heart valves. In addition, a pneumococcal etiology should be suspected in alcoholics, in splenectomized patients, in the very elderly, and in those with recurrent bacterial meningitis, dermal sinus tracts, sickle cell anemia ("autosplenectomized"), and basilar skull fracture. On the other hand, *H. influenzae* meningitis usually follows upper respiratory and ear infections in the uninoculated child.

Other specific bacterial etiologies are suggested by particular clinical settings. Meningitis in the presence of furunculosis or following a neurosurgical procedure directs attention to the possibility of a coagulase-positive staphylococcal infection. Ventricular shunts or drains inserted for the relief of hydrocephalus are particularly

prone to infection with coagulase-negative staphylococci and *Propionibacterium acnes* and *diphtheroids*. HIV infection, myeloproliferative or lymphoproliferative disorders, defects in cranial bones (tumor, osteomyelitis), collagen diseases, metastatic cancer, and therapy with immunosuppressive agents are clinical conditions that favor invasion by such pathogens as Enterobacteriaceae, *L. monocytogenes*, *A. calcoaceticus*, *Pseudomonas*, and occasionally by parasites.

Focal cerebral signs in the early stages of the disease, although seldom prominent, are most frequent in pneumococcal and *H. influenzae* meningitides. Some of the transitory focal cerebral signs may represent postictal phenomena (Todd paralysis); others may be related to an unusually intense focal meningitis, for example, purulent material collected in one sylvian fissure. Seizures are encountered most often with *H. influenzae* meningitis. Although seizures are most common in infants and children, it is difficult to judge the significance, because young children may convulse with fever of any cause. Persistent focal cerebral lesions or intractable seizures usually develop in the second week of the meningeal infection and are caused by an infectious vasculitis, as described earlier, usually with occlusion of surface cerebral veins and consequent infarction of cerebral tissue. Cranial nerve abnormalities are particularly frequent with pneumococcal meningitis, the result of invasion of the nerve by purulent exudate and possibly ischemic damage as the nerve traverses the subarachnoid space.

Infants and Newborns

Acute bacterial meningitis during the first month of life is said to be more frequent than in any subsequent 30-day period of life. It poses a number of special problems. Infants, of course, cannot complain of headache, stiff neck may be absent, and one has only the nonspecific signs of a systemic illness: fever, irritability, drowsiness, vomiting, convulsions, and a bulging fontanel to suggest the presence of meningeal infection. Signs of meningeal irritation do occur, but only late in the course of the illness. A high index of suspicion and liberal use of the lumbar puncture needle are the keys to early diagnosis. Lumbar puncture is ideally performed before any antibiotics are administered for other neonatal infections. An antibiotic regimen sufficient to control a septicemia may allow a meningeal infection to smolder and to flare up after antibiotic therapy for the systemic infection has been discontinued.

A number of other facts about the natural history of neonatal meningitis are noteworthy. It is more common in males than in females, in a ratio of about 3:1. Obstetric abnormalities in the third trimester (premature birth, prolonged labor, premature rupture of fetal membranes) occur frequently in mothers of infants who develop meningitis in the first weeks of life. The most significant factor in the pathogenesis of the meningitis is maternal infection (usually a urinary tract infection or puerperal fever of unknown cause). The infection in both mother and infant is most often caused by gram-negative enterobacteria, particularly *E. coli*, and group B streptococci, and less often to *Pseudomonas*, *Listeria*, *S. aureus* or *epidermidis*

(formerly *albus*), and group A streptococci. Analysis of postmortem material indicates that in most cases infection occurs at or near the time of birth, although clinical signs of meningitis may not become evident until several days or a week later.

In infants with meningitis, one should be prepared to find a unilateral or bilateral sympathetic *subdural effusion* regardless of bacterial type. Young age, rapid evolution of the illness, low polymorphonuclear cell count, and markedly elevated protein in the CSF correlate to some extent with the formation of effusions, according to Snedeker and coworkers. Also, these attributes greatly increase the likelihood of the meningitis being associated with neurologic signs. Transillumination of the skull is the simplest method of demonstrating the presence of an effusion, but CT and MRI are the definitive diagnostic tests. When aspirated, most of the effusions prove to be sterile. If recovery is delayed and neurologic signs persist, a succession of aspirations is required. Children in whom meningitis is complicated by subdural effusions are no more likely, according to authoritative sources, to have residual neurologic signs and seizures than are those without effusions.

Spinal Fluid Examination

As already indicated, *the lumbar puncture is an indispensable part of the examination of patients with the symptoms and signs of meningitis or of any patient in whom this diagnosis is suspected.* Bacteremia is not a contraindication to lumbar puncture. The dilemma concerning the risk of promoting transtentorial or cerebellar herniation by lumbar puncture, even without a cerebral mass, as indicated in Chaps. 2 and 17, has been settled in favor of performing the tap if there is a reasonable suspicion of meningitis. The highest estimates of risk come from studies such as those of Rennick, who reported a 4 percent incidence of clinical worsening among 445 children undergoing lumbar puncture for the diagnosis of acute meningitis; most other series give a lower number. It must be pointed out that a cerebellar pressure cone (tonsillar herniation) may occur in fulminant meningitis independent of lumbar puncture; therefore the risk of the procedure is probably even less than usually stated.

If there is clinical evidence of a focal lesion with increased intracranial pressure, then CT or MRI scanning of the head, looking for a mass lesion, is a prudent first step, but *in most cases this is not necessary and should not delay the administration of antibiotics.* In an attempt to determine the utility of the CT scan performed prior to a lumbar puncture, Hasbun and colleagues were able to identify several clinical characteristics that were likely to be associated with an abnormality on the scan in patients with suspected meningitis; these included a recent seizure, coma or confusion, gaze palsy, and others. The more salient finding from this study in our opinion was that only 2 percent of 235 patients had a focal mass lesion that was judged a risk for lumbar puncture; many others had CT findings of interest, including some with diffuse mass effect. This study does not entirely clarify the issue of the safety of lumbar puncture but it emphasizes that patients who lack

major neurologic findings are unlikely to have findings on the scan that will preclude lumbar puncture.

Only a sizable brain abscess or substantial brain swelling entirely interdicts a lumbar puncture in suspected bacterial meningitis. Furthermore, the fact that death results from cerebral herniation in many fatal cases of bacterial meningitis does not, of course, mean that lumbar puncture precipitated the demise. When there are signs of impending herniation or indications of a dangerous configuration on cerebral images, one may wish to draw blood cultures and institute empiric treatment rather than take the small risk of precipitation herniation with a lumbar puncture. Any coagulopathy that is deemed a risk for hemorrhagic complication of lumbar puncture should be rapidly reversed if possible.

The spinal fluid *pressure* is so consistently elevated (above 180 mm H₂O) that a normal pressure on the initial lumbar puncture in a patient with suspected bacterial meningitis suggests another diagnosis or raises the possibility that the needle is partially occluded or the spinal subarachnoid space is blocked. Pressures over approximately 350 mm H₂O suggest the presence of brain swelling and the potential for cerebellar herniation. Many neurologists favor the administration of intravenous mannitol if the pressure is this high, but this practice does not provide assurance that herniation will be avoided.

A *pleocytosis* in the spinal fluid is diagnostic. The number of leukocytes ranges from 250 to 100,000/mm³, but the usual number is from 1,000 to 10,000. Occasionally, in pneumococcal and influenzal meningitis, the CSF may contain a large number of bacteria but few, if any, neutrophils for the first few hours. Cell counts of more than 50,000/mm³ raise the possibility of a brain abscess having ruptured into a ventricle. Neutrophils predominate (85 to 95 percent of the total), but an increasing proportion of mononuclear cells is found as the infection continues for days, and especially in partially treated meningitis. In the early stages, careful cytologic examination may disclose that some of the mononuclear cells are myelocytes or young neutrophils. Later, as treatment takes effect, the proportions of lymphocytes, plasma cells, and histiocytes steadily increase.

Substantial hemorrhage or substantial numbers of red cells in the CSF are uncommon in meningitis, the exceptions being anthrax meningitis (see Lanska) as well as certain rare viral infections (Hantavirus, dengue fever, Ebola virus, etc.) and some cases of amebic meningoencephalitis.

The *protein* content is higher than 45 mg/dL in more than 90 percent of the cases; in most cases, it falls in the range of 100 to 500 mg/dL. The *glucose* content is diminished, usually to a concentration below 40 mg/dL, or less than 40 percent of the blood glucose concentration (measured concomitantly or within the previous hour), provided that the latter is less than 250 mg/dL. However, in atypical or *culture-negative* cases, other conditions associated with a reduced CSF glucose should be considered. These include hypoglycemia from any cause; sarcoidosis of the CNS; fungal or tuberculous meningitis; and some cases of subarachnoid hemorrhage, meningeal carcinomatosis, chemically induced inflammation from

craniopharyngioma or teratoma, and meningeal gliomatosis. The factors that alter CSF glucose concentration, especially at the extremes of blood glucose, are discussed in Chap. 2.

A special problem pertains to identifying patients with a meningitic syndrome and CSF pleocytosis who do not, in fact, have bacterial meningitis but likely have a viral or other cause for their syndrome. This is driven by a desire to avoid exposure to high-potency intravenous antibiotics that are expensive and potentially dangerous. To address this problem, Nigrovic and colleagues have developed a clinical prediction rule that classifies patients at very low risk for bacterial meningitis if they lack all of the following criteria: positive CSF Gram stain, CSF absolute neutrophil count of at least 1,000 cells/mL, CSF protein of at least 80 mg/dL, peripheral absolute neutrophil count of at least 10,000 cells/mL, and a history of a seizure at or after the time of presentation. This rule was validated in a multicenter retrospective cohort study that encompassed 3,295 patients. Of those who were categorized at very low risk, only 2 had bacterial meningitis. Whether this low rate justifies withholding antibiotics is, of course, a clinical judgement made at the bedside.

The *Gram stain of the spinal fluid* sediment permits identification of the causative agent in most cases of bacterial meningitis; pneumococci and *H. influenzae* are identified more readily than meningococci. Small numbers of gram-negative diplococci in leukocytes may be indistinguishable from fragmented nuclear material, which may also be gram-negative and of the same shape as bacteria. In such cases, a thin film of uncentrifuged CSF may lend itself more readily to morphologic interpretation than a smear of the sediment. The most common error in reading Gram-stained smears of CSF is the misinterpretation of precipitated dye or debris as gram-positive cocci or the confusion of pneumococci with *H. influenzae*. The latter organism may stain heavily at the poles, so that they resemble gram-positive diplococci, and older or rapidly growing pneumococci often lose their capacity to take a gram-positive stain.

Cultures of the spinal fluid, which prove to be positive in 70 to 90 percent of cases of bacterial meningitis, are best obtained by collecting the fluid in a sterile tube and immediately inoculating plates of blood, chocolate, and MacConkey agar; tubes of thioglycolate (for anaerobes); and at least one other broth. The advantage of using broth media is that large amounts of CSF can be cultured. The importance of obtaining blood cultures is mentioned below.

The problem of identifying causative organisms that cannot be cultured, particularly in patients who have received antibiotics, may be overcome by the application of special laboratory techniques. One of these is counterimmunoelectrophoresis (CIE), a sensitive test that permits the detection of bacterial antigens in the CSF in a matter of 30 to 60 min. It is particularly useful in patients with partially treated meningitis, in whom the CSF still contains bacterial antigens but no organisms on a smear or grown in culture.

Several more recently developed serologic methods, radioimmunoassay (RIA) and latex-particle agglutination

(LPA), as well as an enzyme-linked immunosorbent assay (ELISA), may be even more sensitive than CIE. An argument has been made that these procedures are not cost-effective, as—in virtually all instances in which the bacterial antigen can be detected—Gram stain also shows the organism. Our sense is that the more expensive tests are of some assistance if Gram stain is difficult to interpret and one or more doses of antibiotics render the cultures negative. Gene amplification by the polymerase chain reaction (PCR) is the most recently developed and most sensitive technique. As it has become more widely available in clinical laboratories, rapid diagnosis has been facilitated (Desforges; Naber), but the use of carefully Gram-stained preparations still needs to be encouraged.

It is of interest that chloride concentrations in the CSF are usually found to be low, possibly reflecting dehydration and low serum chloride levels. In contrast, CSF lactate dehydrogenase (LDH), although also infrequently measured, can be of diagnostic and prognostic value. A rise in total LDH activity is consistently observed in patients with bacterial meningitis; most of this is because of fractions 4 and 5, which are derived from granulocytes. Fractions 1 and 2 of LDH, which are presumably derived from brain tissue, are only slightly elevated in bacterial meningitis but rise sharply in patients who develop neurologic sequelae or later die. Various enzymes in the CSF, derived from leukocytes, meningeal cells, or plasma, may also be increased in meningitis, but the clinical significance of this observation is unknown. Levels of lactic acid in the CSF (determined by either gas chromatography or enzymatic analysis) are also elevated in both bacterial and fungal meningitides (greater than 35 mg/dL) and may be helpful in distinguishing these disorders from viral meningitides, in which lactic acid levels remain normal; however, these ancillary tests are infrequently performed.

Other Laboratory Findings

In addition to CSF cultures, *blood cultures* should be obtained if possible because they are positive in 40 to 60 percent of patients with *H. influenzae*, meningococcal, and pneumococcal meningitis, and may provide the only definite clue as to the causative agent. Routine cultures of the oropharynx are as often misleading as helpful, because pneumococci, *H. influenzae*, and meningococci are common in the throats of healthy persons. In contrast, *cultures of the nasopharynx* may aid in diagnosis, although often not in a timely way; the finding of encapsulated *H. influenzae* or groupable meningococci may provide the clue to the etiology of the meningeal infection. Conversely, the absence of such a finding prior to antibiotic treatment makes an *H. influenzae* and meningococcal etiology unlikely. The leukocyte count in the blood is generally elevated, and immature forms are usually present. Meningitis may be complicated after several days by severe hyponatremia, the result of inappropriate secretion of antidiuretic hormone (ADH).

Imaging Studies

In patients with bacterial meningitis, chest films are essential because they may disclose an area of pneumonia

or abscess. Sinus and skull films may provide clues to the presence of cranial osteomyelitis, paranasal sinusitis, mastoiditis, or cranial osteomyelitis, but these structures are better visualized on CT scans, which have supplanted conventional films in most cases. The CT scan is particularly useful in detecting lesions that erode the skull or spine and provide a route for bacterial invasion, such as tumors or sinus wall defects, as well as in demonstrating a brain abscess or subdural empyema. MRI with gadolinium enhancement may display the meningeal exudate and cortical reaction, and both types of imaging, with appropriate techniques, will demonstrate venous occlusions and adjacent infarctions. The issues pertaining to an abscess and to brain swelling in meningitis have already been noted and are discussed further on as well.

Recurrent Bacterial Meningitis

This is observed most frequently in patients who have had some type of shunting procedure for the treatment of hydrocephalus or who have an incompletely closed dural opening after cranial or spinal surgery. When the origin of the recurrence is inapparent, one should suspect a congenital neuroectodermal sinus or a fistulous connection between the nasal sinuses and the subarachnoid space. The fistula in these latter cases is more often traumatic than congenital in origin (e.g., a previous basilar skull fracture), although the interval between injury and the initial bout of meningitis may be several years. The site of trauma is in the frontal or ethmoid sinuses or the cribriform plate, and *S. pneumoniae* is the usual pathogen. Often it reflects the predominance of such strains in nasal carriers. These cases usually have a good prognosis; mortality is much lower than in ordinary cases of pneumococcal meningitis.

CSF rhinorrhea is present in most cases of posttraumatic meningitis, but it may be transient and difficult to find. Suspicion of its presence is raised by the recent onset of anosmia or by the occurrence of a watery nasal discharge that is salty to the taste and increases in volume when the head is dependent. One way of confirming the presence of a CSF leak is to measure the glucose concentration of nasal secretions; ordinarily they contain little glucose, but in CSF rhinorrhea the amount of glucose approximates that obtained by lumbar puncture (two-thirds of the serum value). A "dipstick" used for urine testing is sometimes adequate but these are regrettably decreasingly available on general hospital wards. Another bedside test for CSF rhinorrhea or otorrhea is to estimate the amount of protein in the fluid. A high protein, sufficient to make a handkerchief stiff on drying, suggests it is of nasal mucosal origin. If the fluid fails to cause a handkerchief to stiffen on drying, a spinal fluid leak is suspected. The most specific and sensitive test for CSF otorrhea and rhinorrhea is the finding of beta₂-transferrin (tau), not found in fluids other than CSF.

The site of a CSF leak can sometimes be demonstrated by injecting a dye, radioactive albumin, or water-soluble contrast material into the spinal subarachnoid space and detecting its appearance in nasal secretions or its site of exit by CT scanning. This testing is best performed after the acute infection has subsided. Persistence

of CSF rhinorrhea or a spinal CSF leak usually requires surgical repair.

Differential Diagnosis

The diagnosis of bacterial meningitis is usually not difficult in an immunocompetent individual. *Febrile patients with lethargy, headache, stiff neck, or confusion of sudden onset—even those with low-grade fever—should generally undergo lumbar puncture* if no alternative explanation for the state is evident. It is particularly important to recall the possibility of meningitis in drowsy, febrile, and septic patients in an intensive care unit when no obvious source of fever is apparent. Overwhelming sepsis itself, or the multiorgan failure that it engenders, may cause an encephalopathy; but if there is meningitis, it is imperative, in deciding on the choice of antibiotics, to identify it early. The same can be said for the confused alcoholic patient. Too often, the symptoms are ascribed to alcohol intoxication or withdrawal, or to hepatic encephalopathy, until examination of the CSF reveals meningitis. Although this approach undoubtedly results in many negative spinal fluid examinations, it is preferable to the consequence of overlooking bacterial meningitis. Viral meningitis (which is far more common than bacterial meningitis), subarachnoid hemorrhage, chemical meningitis (following lumbar puncture, spinal anesthesia, or myelography), and tuberculous, leptospiral, sarcoid, and fungal meningoencephalitis, and allergic-immune reactions enter into the differential diagnosis as well, as discussed in later sections.

A number of nonbacterial meningitides must be considered in the differential diagnosis when the meningitis recurs repeatedly and all cultures are negative. Included in this group are Epstein-Barr virus (EBV) infections; Behçet disease, which is characterized by recurrent oropharyngeal mucosal ulceration, uveitis, orchitis, and meningitis; Mollaret meningitis, which consists of recurrent episodes of fever and headache in addition to signs of meningeal irritation (in many cases caused by herpes simplex, as discussed in Chap. 33); and the Vogt-Koyanagi-Harada syndrome, in which recurrent meningitis is associated with iridocyclitis and depigmentation of the hair and skin (poliosis and vitiligo). The CSF in these recurrent types may contain large numbers of lymphocytes or polymorphonuclear leukocytes but no bacteria, and the glucose content is not reduced (see discussion of Chronic and Recurrent Meningitis Chap. 33). These recurrent syndromes rarely present in the fulminant manner of acute bacterial meningitis but sometimes they do, and the CSF formulas can be similar, including a reduction in glucose concentration. Rarely, a fulminant case of cerebral angitis or intravascular lymphoma will present with headache, fever, and confusion in conjunction with a meningeal inflammatory reaction.

The other intracranial purulent diseases and their differentiation from bacterial meningitis are considered further on in this chapter.

Treatment

Bacterial meningitis is a medical emergency. The first therapeutic measures are directed to sustaining blood

pressure and treating septic shock (volume replacement, pressor therapy). A premium is then placed on choosing an antibiotic that is known both to be bactericidal for the suspected organism and is able to enter the CSF in effective amounts. *Treatment should begin while awaiting the results of diagnostic tests* and may be altered later in accordance with the laboratory findings. Whereas penicillin formerly sufficed to treat almost all meningitides acquired outside the hospital, the initial choice of antibiotic has become increasingly complicated as resistant strains of meningitic bacteria have emerged. The selection of drugs to treat nosocomial infections also presents special difficulties.

In recent years, many reports have documented an increasing incidence of pneumococcal isolates that have a relatively high resistance to penicillin, reaching 50 percent in some European countries. Current estimates are that, in some areas of the United States, 15 percent of these isolates are penicillin-resistant to some degree (most have a relatively low level of resistance). In the 1970s, *H. influenzae* type B strains producing beta-lactamase, which are resistant to ampicillin and penicillin, were recognized. Currently, 30 percent of *H. influenzae* isolates produce the beta-lactamase enzyme, but almost all remain sensitive to third-generation cephalosporins (e.g., cefotaxime, ceftizoxime, ceftriaxone).

Recommendations for the institution of empiric treatment of meningitis have been reviewed by van de Beek and colleagues (2006) and by Tunkel and colleagues, often updated, and are summarized in modified form in Table 32-2. The choice of agents varies every few years based on epidemiology and geographic region, but these ones given here are a good approximation to current practice in developed countries.

Table 32-2

EMPIRIC THERAPY OF BACTERIAL MENINGITIS

AGE OF PATIENT	ANTIMICROBIAL THERAPY ^a
0–4 wk	Cefotaxime plus ampicillin
4–12 wk	Third-generation cephalosporin plus ampicillin (plus dexamethasone)
3 mo–18 y	Third-generation cephalosporin plus vancomycin (± ampicillin)
18–50 y	Third-generation cephalosporin plus vancomycin (± ampicillin)
>50 y	Third-generation cephalosporin plus vancomycin plus ampicillin
Immunocompromised state	Vancomycin plus ampicillin and ceftazidime
Basilar skull fracture	Third-generation cephalosporin plus vancomycin
Head trauma; neurosurgery	Vancomycin plus ceftazidime
CSF shunt	Vancomycin plus ceftazidime

^aFor all ages from 3 months onward, an alternative treatment is meropenem plus vancomycin (does not provide coverage for *Listeria*). For severe penicillin allergy, consider vancomycin and chloramphenicol (for meningococcus) and trimethoprim-sulfamethoxazole (for *Listeria*). A high failure rate has been reported with chloramphenicol in patients with drug-resistant pneumococcus.

In children and adults, third-generation cephalosporins such as ceftriaxone, combined with vancomycin is probably the best initial therapy for the three major types of community-acquired meningitides. In areas with low numbers of high-level penicillin-resistant pneumococci, it is possible to avoid adding vancomycin or rifampin. Ampicillin should be added to the regimen in cases of suspected *Listeria* meningitis, particularly in an immunocompromised patient. Intravenous drug abusers have high rates of meningitis due to *S. aureus* and should receive cefepime or ceftazidime with vancomycin. When serious allergy to penicillin and cephalosporins precludes their use, chloramphenicol may be a suitable alternative in some regions, but not for *Listeria*.

Isolation from the blood or CSF of a resistant organism requires the use of ceftriaxone with the addition of vancomycin and rifampin. *N. meningitidis*, at least in the United States, remains highly susceptible to penicillin and ampicillin. Regional variations and ongoing antibiotic-induced changes in the infecting microorganisms underscore the need for constant awareness of drug resistance in the physician's local area, especially in the case of pneumococcal infections. Throughout the course of treatment, it is necessary to have access to a laboratory that can carry out rapid and detailed drug-resistance testing.

Nosocomial Meningitis In cases of meningitis caused by coagulase-positive *S. aureus*, including those that occur after neurosurgery or major head injury, administration of vancomycin plus a third-generation cephalosporin (e.g., cefepime, ceftazidime, or meropenem) is a reasonable first approach. If *Pseudomonas* is considered possible, such as after neurosurgery, an antipseudomonal cephalosporin such as ceftazidime or cefapime should be added. Once the sensitivity of the organism has been determined, therapy may have to be altered or may be simplified by using vancomycin or nafcillin alone. These approaches have been reviewed by van de Beek and colleagues (2010). They note that the CSF cell count may be low in cases of ventricular catheter-associated meningitis. They also provide recommendations on the use of prophylactic antibiotics after a basilar skull fracture, a controversial problem that is reviewed in Chap. 35.

Table 32-3 lists the approximate dosages of the most used antibiotics, and Table 32-4 gives reasonable choices of antibiotic for the treatment of specific bacterial isolates.

Duration of Therapy Most cases of bacterial meningitis should be treated for a period of 10 to 14 days except when there is a persistent parameningeal focus of infection (otitic or sinus origin), in which cases longer treatment may be needed. Antibiotics should be administered in full doses parenterally (preferably intravenously) throughout the period of treatment. Treatment failures with certain drugs, notably ampicillin, may be attributable to oral or intramuscular administration, resulting in inadequate concentrations in the CSF. Repeated lumbar punctures are not necessary to assess the effects of therapy as long as there is progressive clinical improvement. The CSF glucose may remain low for many days after other signs of infection have subsided and should occasion concern only if bacteria are present in the fluid and the patient remains febrile and ill.

Table 32-3

RECOMMENDED DOSAGES OF ANTIMICROBIAL AGENTS FOR BACTERIAL MENINGITIS IN ADULTS WITH NORMAL RENAL AND HEPATIC FUNCTION^a

ANTIMICROBIAL AGENT	TOTAL DAILY DOSE	DOSING INTERVAL, HOURS
Amikacin ^b	15 mg/kg	8
Ampicillin	12 g	4
Cefepime	4–6 g	8–12
Cefotaxime	12 g	4–6
Ceftazidime	6 g	8
Ceftriaxone	4 g	12–24
Chloramphenicol ^c	6 g	6
Ciprofloxacin	800–1, 200 mg	12
Gentamicin ^b	5 mg/kg	8
Linezolid	1,200 mg	12
Meropenem ^d	3–6 g	8
Nafcillin	9–12 g	4
Oxacillin	9–12 g	4
Penicillin G	24 million units	4
Quinupristin-dalfopristin	22.5 mg/kg	8
Rifampin ^e	600 mg	24
Tobramycin ^b	5 mg/kg	8
Trimethoprim-sulfamethoxazole ^f	20 mg/kg	6–12
Vancomycin ^g	2–4 g	6–12

^aUnless indicated, therapy is administered intravenously.

^bAminoglycosides are not used as sole treatment for meningitis. Peak and trough serum concentrations should be monitored.

^cHigher dose recommended for pneumococcal meningitis.

^dRisk of seizures with meropenem.

^eOral administration.

^fDosage based on trimethoprim component.

^gCSF concentrations may have to be monitored in severely ill patients.

Newer drugs are available for methicillin-resistant staphylococcal infections but are not well studied for staphylococcal meningitis: linezolid, quinupristin-dalfopristin, and daptomycin.

Persistence of fever or the late appearance of drowsiness, hemiparesis, or seizures should raise the suspicion of subdural effusion, mastoiditis, venous sinus thrombosis, cortical vein or jugular phlebitis, or brain abscess; all require that therapy be continued for a longer period. Bacteriologic relapse after treatment is discontinued requires reinstitution of therapy and exploration for a persistent parameningeal focus of infection, such as in the spinal column.

Corticosteroids Controlled studies several decades ago were unable to demonstrate beneficial effects of corticosteroids in the treatment of bacterial meningitis. More recent studies have given another perspective of the therapeutic value of dexamethasone in children and adults with meningitis. In children, although mortality was not affected in the main study conducted by Lebel and colleagues, fever subsided more rapidly and the incidence of sensorineural deafness and other neurologic sequelae was reduced, particularly in those children with *H. influenzae* meningitis. On these grounds, it has been recommended that the treatment of childhood meningitis include dexamethasone in high doses (0.15 mg/kg qid for 4 days), instituted as soon as possible.

Despite similarly conflicting results from earlier studies of corticosteroids in adults, the trial by deGans and van de Beck has demonstrated a reduction in mortality and improved overall outcome if dexamethasone 10 mg is given just before the first dose of antibiotics and then repeated q6h for 4 days. The improvement was largely in patients who were infected with pneumococcus. Seizures and coma were reduced in incidence as a result of the administration of corticosteroids, but neurologic sequelae, such as hearing loss, were not affected. Based on a number of smaller studies, some authorities in the field of bacterial meningitis have endorsed the administration of dexamethasone in the doses mentioned above, but only if they can be started before antibiotics, and only in those with presumed pneumococcal infection (see Tunkel and Scheld). They also advise against the use of the drug if there is septic shock. In developing countries, especially those with high rates of AIDS, the benefits of adjuvant dexamethasone have not been clear. Improved survival was limited to those who ultimately had bacteria isolated from the CSF, in contrast to those with suspected meningitis but negative cultures.

Nonetheless, the incidence of deafness was reduced (Nguyen et al; Scarborough et al). The use of corticosteroids is therefore suggested in cases with overwhelming infection at any age (very high CSF pressure or signs of herniation, high CSF bacterial count with minimal pleocytosis, and signs of acute adrenal insufficiency, i.e., the Waterhouse-Friderichsen syndrome). It is not always possible to determine with certainty at the first presentation those cases that will be culture positive but one is referred back to the prediction “rules” validated by Nigrovic and colleagues.

Other Forms of Therapy There is no evidence that repeated drainage of CSF is therapeutically effective. In fact, increased CSF pressure in the acute phase of bacterial meningitis is largely a consequence of cerebral edema, in which case the lumbar puncture may predispose to cerebellar herniation. As already mentioned, a second lumbar puncture to gauge the effectiveness of treatment is generally not necessary, but it may be of value if the patient is worsening without explanation. Mannitol and urea have been employed with apparent success in some cases of severe brain swelling with unusually high initial CSF pressures (400 mm H₂O). Acting as osmotic diuretics, these agents enter cerebral tissue slowly, and their net effect is to decrease brain water. However, neither mannitol nor urea has been studied in controlled fashion in the management of meningitis. An adequate but not excessive amount of intravenous normal saline (and avoiding fluids with free water) should be given. Particular care should be taken with children to avoid hyponatremia and water intoxication—potential causes of brain swelling.

Antiepileptic drugs need not be administered routinely but should be given if a seizure has occurred or there is evidence of cortical vein thrombosis.

Prophylaxis Household contacts of patients with meningococcal meningitis should be protected with antibiotic treatment. The risk of secondary cases is small for adolescents and adults, but ranges from 2 to 4 percent for those younger than 5 years of age and is probably higher

Table 32-4

SPECIFIC ANTIMICROBIAL THERAPY FOR ACUTE MENINGITIS

MICROORGANISM	STANDARD THERAPY	ALTERNATIVE THERAPIES
<i>Haemophilus influenzae</i>		
Beta-lactamase–negative	Ampicillin	Third-generation cephalosporin ^a ; chloramphenicol
Beta-lactamase–positive	Third-generation cephalosporin ^a	Chloramphenicol; cefepime
<i>Neisseria meningitidis</i>	Penicillin G or third-generation cephalosporin ^a	Chloramphenicol
<i>Streptococcus pneumoniae</i>		
Penicillin MIC <0.1 µg/mL (sensitive)	Penicillin G or ampicillin	Third-generation cephalosporin ^a ; chloramphenicol; vancomycin plus rifampin
Penicillin MIC 0.1–1.0 µg/mL (intermediate sensitivity)	Third-generation cephalosporin ^a	Vancomycin; meropenem
Penicillin MIC ≥2.0 µg/mL (highly resistant)	Vancomycin plus third-generation cephalosporin	Meropenem
Enterobacteriaceae	Third-generation cephalosporin ^a	Meropenem; fluoroquinolone; trimethoprim-sulfamethoxazole, or cefepime
<i>Pseudomonas aeruginosa</i>	Ceftazidime or cefepime ^b	Meropenem; fluoroquinolone ^b ; piperacillin
<i>Listeria monocytogenes</i>	Ampicillin or penicillin G ^b	Trimethoprim-sulfamethoxazole
<i>Streptococcus agalactiae</i>	Ampicillin or penicillin G ^b	Third-generation cephalosporin ^a ; Vancomycin
<i>Staphylococcus aureus</i>		
Methicillin-sensitive	Nafcillin or oxacillin plus third-generation cephalosporin	Vancomycin
Methicillin-resistant ^d	Vancomycin ^c plus third-generation cephalosporin	Linezolid, quinupristin-dalfopristin, tigecycline
<i>Staphylococcus epidermidis</i>	Vancomycin ^c	Linezolid, tigecycline

MIC, minimal inhibitory concentration.

^aCefotaxime or ceftriaxone.

^bAddition of an aminoglycoside should be considered.

^cAddition of rifampin should be considered.

^dLinezolid, quinupristin-dalfopristin, and daptomycin are newer alternatives for methicillin-resistant *Staphylococcus*, but few cases have been studied.

in the elderly. A single dose of ciprofloxacin is effective. An alternative is a daily oral dose of rifampin—600 mg q12h in adults and 10 mg/kg q12h in children—for 2 days. If 2 weeks or more have elapsed since the index case was found, no prophylaxis is needed.

As mentioned, immunization against *H. influenzae* is steadily reducing the incidence of meningitis from this organism. Also, many institutions housing young adults, such as colleges and the military, have instituted programs of immunization against *N. meningitidis*.

Prognosis and Sequelae of Meningitis

Untreated, bacterial meningitis is usually fatal. The overall mortality rate of uncomplicated but treated *H. influenzae* and meningococcal meningitis has remained at approximately 5 percent for many years; in pneumococcal meningitis, the rate is considerably higher (approximately 15 percent), perhaps related to the older and sicker population that is affected. Fulminant meningococcemia, with or without meningitis, also has a high mortality rate because of the shock associated with adrenocortical hemorrhages (Waterhouse-Friderichsen syndrome). A disproportionate number of deaths from meningitis occur in infants and in the aged. The mortality rate is highest in neonates, from 40 to 75 percent in several reported series, and at least half of those who recover show serious neurologic sequelae. In adults, the presence

of bacteremia, coma, seizures, and a variety of concomitant diseases—including alcoholism, diabetes mellitus, multiple myeloma, and head trauma—all worsen the prognosis. The triad of pneumococcal meningitis, pneumonia, and endocarditis (Osler triad) has a particularly high fatality rate.

Surprisingly often, it is impossible to explain the death of a patient with meningitis or at least to trace it to a single specific mechanism. The effects of overwhelming infection, with bacteremia and hypotension, or brain swelling and cerebellar herniation, are clearly implicated in some patients during the initial 48 h. These events may occur in bacterial meningitis of any etiology; however, they are far more frequent in meningococcal and pneumococcal infection. Some of the deaths occurring later in the course of the illness are attributable to respiratory failure, often consequent to aspiration pneumonia.

It has been stated that relatively few adult patients who recover from meningococcal meningitis show residual neurologic defects, whereas such defects are encountered in at least 25 percent of children with *H. influenzae* meningitis and up to 30 percent of child and adult patients with pneumococcal meningitis. Kastenbauer and Pfister, reporting on adults with pneumococcal meningitis, have emphasized that the mortality remains quite high and that cerebral venous or arterial thrombosis occurred in almost a third of cases, as discussed further on. They also had two patients with an associated myelitis. We have

seen several instances of upper cervical cord and lower medullary infarction in bacterial meningitis; quadriplegia and respiratory failure were the result of compression from descent of the cerebellar tonsils (Ropper and Kanis). As already discussed, the role of lumbar puncture in promoting this complication of cerebellar herniation has not been clarified.

Among infants who survive *H. influenzae* meningitis, Ferry and coworkers, in a prospective study of 50 cases, found that about half were normal, whereas 9 percent had behavioral problems and about 30 percent had neurologic deficits (seizures or impairment of hearing, language, mentation, and motor function). In a report of a series of 185 children recovering from bacterial meningitis, Pomeroy and associates found that 69 were not normal neurologically at the end of a month; however, at the end of a year, only 18 were left with a hearing deficit, 13 with late afebrile seizures, and 8 with multiple deficits. The presence of a persistent neurologic deficit was the only independent predictor of later seizures. Dodge and colleagues in past decades found that 31 percent of children with pneumococcal meningitis were left with persistent sensorineural hearing loss; for meningococcal and *H. influenzae* meningitis, the figures were 10.5 and 6 percent, respectively. These events are seemingly less frequent now, specifically in developed countries, but still reflect the seriousness of these sequelae in less advantaged regions of the world.

Cranial nerve palsies other than deafness, if they occur, tend to disappear after a few weeks or months. Deafness in these infections is a result of suppurative cochlear destruction or, less often now, of the ototoxic effects of aminoglycoside antibiotics. Bacteria reach the cochlea mainly via the cochlear aqueduct, which connects the subarachnoid space to the scala tympani. This occurs quite early in the course of infection, hearing loss being evident within a day of onset of the meningitis; in about half or most of such cases, the acute deafness resolves. Hydrocephalus is an infrequent complication that may become manifest months after treatment and then requires shunting if gait or mentation is affected. It may be difficult to determine on clinical grounds whether a residual state of imbalance is the result of hydrocephalus or of eighth nerve damage. The acute complications of bacterial meningitis, the intermediate and late neurologic sequelae, and the pathologic basis of these effects are summarized in Table 32-1.

ENCEPHALITIS DUE TO BACTERIAL INFECTIONS

Quite apart from acute and subacute bacterial endocarditis, which may give rise to cerebral embolism and characteristic inflammatory reactions in the brain (see further on), there are several systemic bacterial infections that are complicated by a special type of encephalitis or meningoencephalitis. Three common ones are *Mycoplasma pneumoniae* infections, *L. monocytogenes meningoencephalitis*, and *Legionnaire disease*. Probably Lyme borreliosis should

be included in this category but it is more chronic and is described further on in this chapter with the spirochetal infections. The rickettsial encephalitides (particularly Q fever), which mimic bacterial meningoencephalitis, are also addressed later in the chapter. Catscratch disease is another rare cause of bacterial meningoencephalitis. Meningoencephalitis caused by brucellosis occurs very rarely in the United States. Whipple disease, discussed later, which appears to be a focal invasion of the brain by an unusual intracellular bacterium, is an oddity but also belongs in this category.

Mycoplasma pneumoniae

This organism, which causes 10 to 20 percent of all pneumonias, is associated with a number of neurologic syndromes. Guillain-Barré polyneuritis, cranial neuritis, acute myositis, aseptic meningitis, transverse myelitis, global encephalitis, seizures, cerebellitis, acute disseminated (postinfectious) encephalomyelitis, and acute hemorrhagic leukoencephalitis (Hurst disease) have all been reported in association with mycoplasmal pneumonias or with serologic evidence of a recent infection (Westenfelder et al; Fisher et al; Rothstein and Kenny). We have observed several patients with striking cerebral, cerebellar, brainstem, or spinal syndromes incurred during or soon after a mycoplasmal pneumonia or tracheobronchitis. In addition to the cerebellitis, which is clinically similar to the illness that follows varicella, unusual encephalitic syndromes of choreoathetosis, seizures, delirium, hemiparesis, and acute brain swelling (Reye syndrome) have each been reported in a few cases. The incidence of these complications has been estimated as 1 in 1,000 mycoplasmal infections, but it may approach 5 percent when more careful surveillance is carried out during epidemics. A severe prodromal headache has occurred in most of our cases. At the time of onset of the neurologic symptoms, there may be scant signs of pneumonia, and in some patients, only an upper respiratory syndrome occurs.

The mechanism of cerebral damage that complicates mycoplasmal infections has not been established, but recent evidence suggests that the organism is present in the CNS during the acute illness. To our knowledge, the organism has been cultured from the brain in only one fatal case, but PCR techniques have detected fragments of mycoplasmal DNA in the spinal fluid from several patients (Narita et al). In other instances, the nature of the neurologic complications and their temporal relationship to the mycoplasmal infection clearly suggest that secondary autoimmune factors are operative, i.e., that these are instances of postinfectious encephalomyelitis (a type of acute disseminated encephalomyelitis described in Chap. 36). This is almost certainly the mechanism of postmycoplasmal Guillain-Barré syndrome. Most of the patients with the infectious variety have recovered with few or no sequelae, but rare fatalities are reported.

The CSF usually contains small numbers of lymphocytes and other mononuclear cells and an increased protein content. The diagnosis can be established by culture of the organism from the respiratory tract (which

is difficult), by rising serum titers of complement-fixing immunoglobulin IgG and IgM antibodies and cold agglutinin antibodies in the blood and CSF, or by DNA detection techniques from the CSF.

Treatment Macrolide antibiotics such as azithromycin and clarithromycin but also erythromycin and tetracycline derivatives reduce morbidity, mainly by eradicating the pulmonary infection, but the effects of antibiotics on the nervous system complications are not known.

Listeria monocytogenes

Meningoencephalitis from this organism is most likely to occur in immunosuppressed and debilitated individuals and is a well-known and occasionally fatal cause of meningitis in the newborn. Meningitis is the usual neurologic manifestation, but there are numerous recorded instances of isolated focal bacterial infectious encephalitis, rarely with a normal CSF, most cases showing a pleocytosis that may be initially polymorphonuclear. Between 1929, when the organism was discovered, and 1962, when Gray and Killinger collected all the reported cases, it was noted that 35 percent of patients had either meningitis or meningoencephalitis as the primary manifestation.

The infection may take the form of a brainstem encephalitis, or "rhombencephalitis," specifically with several days of headache, fever, nausea, and vomiting followed by asymmetrical cranial-nerve palsies, signs of cerebellar dysfunction, hemiparesis, quadriparesis, or sensory loss. Respiratory failure has been reported. Of 62 cases of *Listeria* brainstem encephalitis reported by Armstrong and Fung, 8 percent were in immunosuppressed patients, meningeal signs were present in only half the patients, and the spinal fluid often showed misleadingly mild abnormalities. CSF cultures yielded *Listeria* in only 40 percent of cases (blood cultures were even more often normal). Consistent with our experience, the early CT scan was often normal; MRI, however, has revealed abnormal signals in the parenchyma of the brainstem.

The monocytosis, which gives the organism its name, refers to the reaction in the peripheral blood in rabbits but these cells have not been prominent in the blood or CSF of patients. One patient described by Lechtenberg and coworkers had a proven brain abscess; other patients have had multiple small abscesses (Uldry et al) but it is not clear if this is a uniform feature of the illness that explains the rhombencephalitis. Judging from the clinical signs in some cases, the infection appears to affect both the brainstem parenchyma and the extraaxial portion of the lower cranial nerves.

Treatment The treatment is ampicillin (2 g intravenously q4h) in combination with gentamicin (5 mg/kg intravenously in 3 divided doses daily). If the condition of the host is compromised, the outcome is often fatal, but most of our patients without serious medical disease have made a full and prompt recovery with treatment.

Melioidosis

In India and Southeast Asia, particularly Cambodia and Thailand, a brainstem, cerebellar, and meningitic

illness, similar to that caused by *Listeria*, results instead from melioidosis (*Burkholderia pseudomallei*). It should be suspected in returning travelers from that region but the disease is, of course, well known to physicians in areas endemic for the organism. Diabetics are particularly prone to this infection. The CSF shows one to several dozen white blood cells and raised protein but glucose may be normal. There is usually an associated pulmonary infection but this may be minor and the degree of temperature elevation varies. The diagnosis can be made by the culture of the organism from any body site, CSF, pharynx, blood, urine or sputum, as it is not a normal commensal bacterium but both blood agar and special Ashdown's medium containing gentamicin are required. There is a commercial serologic test but there are high background rates of positivity in endemic regions.

Treatment This is in two phases, an intensive eradication component with high intravenous doses of ceftazidime (or several equivalent regimens) for 10 to 14 days, followed by an eradication phase that is necessary to prevent relapse, using co-trimoxazole alone or accompanied by doxycycline.

Legionella

This potentially fatal respiratory disease caused by the gram-negative bacillus *Legionella pneumophila*, first came to medical notice in July 1976, when a large number of members of the American Legion fell ill at their annual convention in Philadelphia. The fatality rate was high. In addition to the obvious pulmonary infection, manifestations referable to the CNS and other organs were observed regularly. Lees and Tyrrell described patients with severe and diffuse cerebral involvement, and Baker and associates and Shetty and colleagues described others with cerebellar and brainstem syndromes. The clinical details have varied. One constellation consisted of headache, obtundation, acute confusion or delirium with high fever, and evidence of pulmonary distress; another took the form of tremor, nystagmus, cerebellar ataxia, extraocular muscle and gaze palsies, and dysarthria.

Other neurologic abnormalities have been observed, such as inappropriate ADH secretion, or a syndrome of more diffuse encephalomyelitis or transverse myelitis, similar to that observed with *Mycoplasma* infections. The CSF is usually normal and CT scans of the brain are negative, a circumstance that makes diagnosis difficult. The neuropathologic abnormalities have not been studied. Suspicion of the disease, based on exposure or on the presence of an atypical pneumonia, should prompt urine antigen and culture of blood and CSF. Serologic tests are available but require paired sera and have little impact on clinical decision making. In most patients the signs of CNS disorder resolve rapidly and completely, although residual impairment of memory and a cerebellar ataxia have been recorded. To date, the *Legionella* bacillus has not been isolated from the brain or spinal fluid.

Treatment Treatment in adults has consisted of one of levofloxacin, moxifloxacin, or azithromycin; rifampin is sometimes used. In the past, erythromycin, 0.5 to 1.0 g was used intravenously q6h for a 7 to 10 days.

Catscratch Fever (*Bartonella henselae*)

Reports of over 100 cases of encephalitis from *catscratch disease* have appeared in the medical literature and several have occurred on our services over the years, for which reason we do not consider it rare. The causative organism is a gram-negative bacillus now called *Bartonella henselae* (formerly *Rochalimaea henselae*). The illness begins as unilateral axillary or cervical adenopathy occurring after a seemingly innocuous scratch (rarely a bite) from an infected cat. The cases with which we are familiar began with an encephalopathy and high fever (higher temperature than with most of the other organisms that are capable of causing a bacterial encephalitis), followed by seizures or status epilepticus. The organism has also been implicated in causing a focal cerebral vasculitis in AIDS patients as well as neuroretinitis in both immunocompromised and immunocompetent patients. Demonstration of elevated complement-fixing titers and detection of the organism by PCR or by silver staining from an excised lymph node are diagnostic. A single high antibody titer is probably inadequate for this purpose.

Treatment First-line treatment is with azithromycin or doxycycline, sometimes with rifampin in recalcitrant cases. Erythromycin is used less frequently. Most patients recover completely, but one of our patients and a few reported by others have died.

Anthrax

This rare form of meningoencephalitis is included here because of the current interest in *Bacillus anthracis* as a bioweapon. Lanska was able to collect from the literature 70 patients with meningeal infection, most of whom were encephalopathic. He has estimated that fewer than 5 percent of infected individuals will acquire a meningoencephalitis; in a 2001 U.S. outbreak, only 1 of 11 cases with anthrax pneumonitis developed this complication. Reflecting the main site of natural infection, the majority of cases originated in cutaneous anthrax. In addition to a typically fulminating course after a prodrome of one or several days, the exceptional feature was a hemorrhagic and inflammatory spinal fluid formula. Subarachnoid hemorrhage was prominent in autopsy material, presumably reflecting necrosis of the vessel walls as a toxic effect of *B. anthracis*.

Treatment Although natural isolates are sensitive to penicillin, bioengineered strains are resistant; therefore, combined treatment with ciprofloxacin with clindamycin, rifampin, or meropenem has been recommended initially. The benefit of specific antitoxin is uncertain once meningoencephalitis has occurred.

Recently, very similar overwhelming cases with meningitis and subarachnoid hemorrhage caused by *Bacillus cereus* have appeared in immunosuppressed patients.

Brucellosis

This worldwide disease of domesticated livestock is frequently transmitted to humans in areas where the infection is enzootic. In the United States, it is distinctly rare, with 200 cases or less being reported annually since

1980, some in abattoir workers. During the 1950s it was a fashionable explanation for chronic fatigue. In the Middle East, infection with *Brucella* is still frequent, attributable to the ingestion of raw milk. In Saudi Arabia, for example, al Deeb and coworkers reported on a series of 400 cases of brucellosis, of which 13 presented with brain involvement (acute meningoencephalitis, papilledema and increased intracranial pressure, and meningovascular manifestations). The CSF showed a lymphocytic pleocytosis and increased protein content. Blood and CSF antibody titers to the organism were greater than 1:640 and 1:128, respectively.

Treatment Prolonged treatment with doxycycline with streptomycin or gentamicin; an alternative is doxycycline plus rifampin to suppress the infection.

Whipple Disease

This is a rare but often-discussed disorder, predominantly of middle-aged men. Weight loss, fever, anemia, steatorrhea, abdominal pain and distention, arthralgia, lymphadenopathy, and hyperpigmentation are the usual systemic manifestations. Less often, infection is associated with a number of neurologic syndromes. It is caused by a gram-positive bacillus, *Tropheryma whipplei*, which resides predominantly in the gut. Biopsy of the jejunal mucosa, which discloses macrophages filled with the periodic acid-Schiff (PAS)-positive organisms, is diagnostic. PAS-positive histiocytes have also been identified in the CSF, as well as in periventricular regions, in the hypothalamic and tuberal nuclei, and diffusely scattered in the brain.

The neurologic manifestations most often take the form of a slowly progressive memory loss or dementia of subacute or early chronic evolution. Supranuclear ophthalmoplegia, ataxia, seizures, myoclonus, nystagmus, and a highly characteristic oculomasticatory movement described as myorhythmia (which looks to us like rhythmic myoclonus) have been noted less often than the dementing syndrome. The rhythmic myoclonus or spasm occurs in synchronous bursts involving several adjacent regions, mainly the eyes, jaw, and face. This movement disorder is fairly specific but insensitive for Whipple disease, occurring in only approximately 10 percent of patients. As pointed out by Matthews and colleagues, cerebellar ataxia, although obviously much less specific for Whipple disease of the brain, is more frequent, occurring in about half the documented cases. Almost always, the myorhythmias are accompanied by a supranuclear vertical gaze paresis that sometimes affects horizontal eye movements as well. Presumably, the neurologic complications are the result of infiltration of the brain by the organism, but this has not been satisfactorily established.

Approximately half of the patients have a mild pleocytosis and some of these have PAS-positive material in the CSF. A variety of brain imaging abnormalities have been recorded, none characteristic, but either enhancing focal lesions or a normal scan may be found. The diagnosis is made mainly from PAS staining of an intestinal (jejunal) biopsy, as already mentioned, supplemented by PCR testing of the bowel tissue or biopsy material from brain or lymph node. In cases of subacute progressive

limb and gait ataxia occurring in middle-aged or older men in whom no cause is uncovered by less-invasive means, it is justifiable to perform these tests (see Chap. 5). Rarely, the neurologic symptoms may occur in the absence of gastrointestinal disease (Adams et al, 1987). In the review of 84 cases of cerebral Whipple disease by Louis and colleagues, 71 percent had cognitive changes, half with psychiatric features; 31 percent had myoclonus; 18 percent had ataxia; and 20 percent had the oculomastatory and skeletal myorhythmias (Schwartz et al).

Treatment A course of induction by penicillin or ceftriaxone for 2 weeks followed by trimethoprim-sulfamethoxazole or doxycycline continued for 1 year are the currently recommended regimens. An alternative approach is 2 weeks of ceftriaxone followed by treatment with trimethoprim-sulfamethoxazole or a tetracycline for a year. Antibiotic-resistant cases and instances of relapse after antibiotic treatment are known. The review by Anderson may be consulted for details.

“Acute Toxic Encephalopathy”

We are uncertain of its status but have been shown putative cases of this disorder described by Lyon and colleagues as “acute encephalopathy of obscure origin in children,” a febrile and sometimes fatal illness that could not be ascribed to direct infection of the nervous system. During the height of a systemic bacterial or sometimes viral infection, the child sinks into coma, seizures are infrequent, the neck is supple, and the spinal fluid shows no changes or only a few cells. This is undoubtedly an illness of diverse causes, common among them being fluid overload and electrolyte imbalance, Reye syndrome (see Chap. 30) and, possibly most commonly, the immune condition of postinfectious encephalitis (see Chap. 36). Nonetheless, cases continue to be reported, such as those of Thi and colleagues, which can only be classified as a noninfectious bacterial encephalopathy or encephalitis. A relationship to the “septic encephalopathy” of adults, which has been emphasized by the group from London, Ontario, is possible but unproved. The term *acute toxic encephalopathy* still has some utility in cases of obscure cause, but a careful search for better-characterized causes of febrile coma must be undertaken. The acute necrotizing encephalopathy that has been reported, particularly in Asian children after influenza, belongs to this category and consists of a number of diseases as discussed by Mizuguchi and coworkers.

SUBDURAL EMPYEMA

Subdural empyema is an intracranial (rarely intraspinal) purulent process between the inner surface of the dura and the outer surface of the arachnoid that occurs mainly in children. The term *subdural abscess*, among others, had been applied to this condition but the proper name is *empyema*, indicating suppuration in a preformed space. Thrombosis of the underlying cortical veins and dural sinuses is a common accompaniment. Contrary to prevailing opinion, subdural empyema is not a rarity

(although it is only about one-fifth as frequent as cerebral abscess) and is increasingly the result of surgical procedures on the sinuses and cranium.

The infection usually originates in the frontal or ethmoid or, less often, the sphenoid sinuses and in the middle ear and mastoid cells. As with bacterial meningitis, in the last decade there have been an increasing number of cases that follow surgery of the sinuses and other cranial structures. In infants and children, and infrequently in adults, there may be a spread from a leptomeningitis. Infection gains entry to the subdural space by direct extension through bone and dura or by spread from septic thrombosis of the venous sinuses, particularly the superior longitudinal sinus. Rarely, the subdural infection is metastatic from infected lungs; hardly ever is it secondary to bacteremia or septicemia. Occasionally it extends from a brain abscess.

It is of interest that cases of sinus origin have predominated in adolescent and young adult men (Kaufman et al), a distinction for which there is no explanation. In such cases, streptococci (nonhemolytic and *viridans*) are the most common organisms, followed by facultative anaerobic streptococci (often *Streptococcus milleri*) or *Bacteroides*. Less often *S. aureus*, *E. coli*, *Proteus*, and *Pseudomonas* are causative. In about half the cases unrelated to surgery, no organisms can be cultured or seen on Gram stain.

Pathology

A collection of subdural pus ranging from a few milliliters to 100 to 200 mL lies over the cerebral hemisphere. Pus may spread into the interhemispheric fissure or be confined there; occasionally it is found in the posterior fossa, covering the cerebellum. The arachnoid, when cleared of exudate, is cloudy, and thrombosis of meningeal veins may be seen. The underlying cerebral hemisphere is compressed, and in fatal cases there is often an ipsilateral temporal lobe herniation. Microscopic examination discloses various degrees of organization of the exudate on the inner surface of the dura and infiltration of the underlying arachnoid with small numbers of neutrophilic leukocytes, lymphocytes, and mononuclear cells. Thrombi in cerebral veins seem to begin on the sides of the veins nearest the subdural exudate. The superficial layers of the cerebral cortex undergo ischemic necrosis, which probably accounts for focal seizures and other signs of disordered cerebral function (Kubik and Adams).

Symptomatology and Laboratory Findings

Usually the history includes reference to chronic sinusitis or mastoiditis with a recent flare-up causing local pain and increase in purulent nasal or aural discharge. In sinus cases, the pain is over the brow or between the eyes; it is associated with tenderness on pressure over these parts and sometimes with orbital swelling. General malaise, fever, and headache—at first localized, then severe and generalized and associated with vomiting are the first indications of intracranial spread. They are followed in a few days by drowsiness and increasing stupor, rapidly

progressing to coma. At about the same time, focal neurologic signs appear, the most important of which are unilateral motor seizures, hemiplegia, hemianesthesia, aphasia, and paralysis of lateral conjugate gaze. Fever and leukocytosis are always present and the neck is stiff. Cases that follow surgery may be more indolent.

The usual CSF findings are an increased pressure, pleocytosis in the range of 50 to 1,000/mm³, a predominance of polymorphonuclear cells, elevated protein content (75 to 300 mg/dL), and normal glucose values. The spinal fluid is often sterile, but on occasion an organism is cultured. If the patient is stuporous or comatose, there is a risk associated with performing a lumbar puncture, and one should proceed first with imaging procedures.

By CT scanning one can see the ear or sinus lesions or bone erosion. The meninges around the empyema enhance and the collection of pus can be visualized more dependably with MRI. Empyema that follows meningitis in children tends to localize on the undersurface of the temporal lobe and may require coronal views to be well visualized.

Several conditions must be distinguished clinically from subdural empyema: a treated subacute bacterial meningitis, cerebral thrombophlebitis, brain abscess (see further on), herpes simplex encephalitis (see Chap. 33), acute disseminated encephalomyelitis and necrotizing hemorrhagic leukoencephalitis (see Chap. 36), and septic embolism because of bacterial endocarditis (see further on in this chapter).

Treatment

Most subdural empyemas, by the time they are recognized clinically, require drainage through multiple burr holes, or through a craniotomy in cases with an interhemispheric, subtemporal, or posterior fossa location. The surgical procedure should be coupled with appropriate antibiotic therapy, generally a third-generation cephalosporin and metronidazole. Bacteriologic findings or an unusual presumed source may dictate a change to different drugs, particularly to later-generation cephalosporins. Without such massive antimicrobial therapy and surgery, some patients will die, usually within 7 to 14 days. On the other hand, patients who are treated promptly may make a surprisingly good recovery, including full or partial resolution of their focal neurologic deficits.

As with certain small brain abscesses, small subdural collections of pus that are recognized by CT scanning or MRI before stupor and coma have supervened may respond to treatment with large doses of antibiotics alone. The resolution (or lack thereof) of the empyema can be readily followed by repeated imaging of the brain (Leys et al).

CRANIAL EPIDURAL ABSCESS

This condition is usually associated with osteomyelitis in a cranial bone and originates from an infection in the ear or paranasal sinuses, or it is from a surgical procedure, particularly if the frontal sinus or mastoid

had been opened or a foreign device inserted. Rarely, the infection is metastatic or spreads outward from a dural sinus thrombophlebitis. Pus and granulation tissue accumulate on the outer surface of the dura, separating it from the cranial bone. The symptoms are those of a local inflammatory process: frontal or auricular pain, purulent discharge from sinuses or ear, and fever and local tenderness. Sometimes the neck is slightly stiff. Localizing neurologic signs are usually absent. Rarely, a focal seizure may occur, or the fifth and sixth cranial nerves may be involved with infections of the petrous part of the temporal bone. The CSF is usually clear and under normal pressure but may contain a few lymphocytes and neutrophils (20 to 100 per milliliter; fewer than in subdural empyema) and a slightly increased amount of protein. Treatment consists of antibiotics, usually vancomycin alone or with a cephalosporin, aimed at the appropriate pathogen(s)—often *S. aureus*. Later, the diseased bone in the frontal sinus or the mastoid, from which the extradural infection had arisen, may have to be removed. Results of treatment are usually good.

Spinal Epidural and Subdural Abscesses

(See Chap. 44)

These types of abscesses possess unique clinical features and constitute important neurologic and neurosurgical emergencies. They are discussed in Chap. 44 with other diseases of the spinal column and spinal cord.

INTRACRANIAL SEPTIC THROMBOPHLEBITIS (SEE ALSO CHAP. 34)

The dural sinuses drain blood from all of the brain into the jugular veins. The largest and most important of these, and the ones usually involved by infection, are the lateral (transverse), cavernous, petrous, and, less frequently, the longitudinal (sagittal) sinuses. A complex system of lesser sinuses and cerebral veins connects these large sinuses to one another as well as to the diploic and meningeal veins and veins of the face and scalp. The basilar venous sinuses are contiguous to several of the paranasal sinuses and mastoid cells.

Usually there is evidence that septic thrombophlebitis of the large dural sinuses has extended from an infection of the middle ear and mastoid cells, the paranasal sinuses, or skin around the upper lip, nose, and eyes. Other forms of intracranial infection frequently complicate these cases, including meningitis, epidural abscess, subdural empyema, and brain abscess. Occasionally, infection may be introduced by direct trauma to large veins or dural sinuses. A variety of organisms, including all the ones that ordinarily inhabit the paranasal sinuses and skin of the nose and face, may give rise to intracranial thrombophlebitis. Streptococci and staphylococci are the ones most often incriminated. With the exception of fever and poorer outcome, the syndromes associated with septic phlebitis discussed below are similar to those produced by bland thrombosis of the veins, as discussed in Chap. 34, on cerebrovascular diseases.

Septic Lateral (Transverse) Sinus Thrombophlebitis

In lateral (transverse) sinus thrombophlebitis, which usually follows chronic infection of the middle ear, mastoid, or petrous bone, earache and mastoid tenderness are succeeded, after a period of a few days to weeks by generalized headache and in some instances, papilledema. If the thrombophlebitis remains confined to the transverse sinus, there are no other neurologic signs. Spread to the jugular bulb may give rise to the syndrome of the jugular foramen (see Table 47-1) and involvement of the torcula, leading to increased intracranial pressure. One lateral sinus, usually the right, is normally larger than the other, which may account for greatly elevated pressure when it is occluded. However, contiguous involvement of the superior sagittal sinus and cortical veins emanating from it causes seizures and focal cerebral signs (see below). Fever, as in all forms of septic intracranial thrombophlebitis tends to be present but intermittent, and other signs of the septic state may be prominent. The CSF has increased pressure but the formula is usually normal but may show a small number of cells and a modest elevation of protein content. The term "otitic hydrocephalus" was introduced for this condition by Sir Charles Symonds, giving the erroneous impression that hydrocephalus was the cause of raised intracranial pressure. It is mentioned here because his clinical description, as for many other conditions, remains an outstanding source.

Imaging by MR and CT with contrast infusion has supplanted cerebral venography, arteriography, and the various older tests involving compression of the jugular veins in the diagnosis of venous sinus thrombosis. MRI sequences that are appropriate to the slow blood flow in the cerebral venous system must be selected and imaging planes carefully chosen to pass through the venous sinuses. CT and MRI are also able to detect abscess and hydrocephalus.

Prolonged administration of high doses of antibiotics is the mainstay of treatment. Anticoagulation, shown to be beneficial in aseptic venous occlusion, is still of uncertain value, but it is usually administered as well (see Chap. 34).

Septic Cavernous Sinus Thrombophlebitis

This condition is usually secondary to infections of the ethmoid, sphenoid, or maxillary sinuses or the skin around the eyes and nose, sometimes originating in a seemingly innocuous lesion. Occasionally, no antecedent infection can be recognized. In addition to headache, high fluctuating fever, and signs of systemic toxicity, there are characteristic local effects. Obstruction of the ophthalmic veins leads to chemosis, proptosis, and edema of the ipsilateral eyelids, forehead, and nose. The retinal veins become engorged, which may be followed by retinal hemorrhages and papilledema. More often, however, vision in the affected eye is lost by a yet undefined type of optic neuropathy as noted below, without visible alterations in the fundus. Involvement of the third, fourth, sixth, and ophthalmic division of the fifth cranial nerves, which lie in the lateral wall of the cavernous sinus

(see Chap 34), leads to ptosis, varying degrees of ocular palsy, pain around the eye, and sensory loss over the forehead. Within a few days, spread through the circular sinus to the opposite cavernous sinus results in bilateral symptoms. The posterior part of the cavernous sinus may become infected via the superior and inferior petrosal veins without the occurrence of orbital edema or ophthalmoplegia but usually with abducens and facial paralysis. The CSF is usually normal unless there is an associated meningitis or subdural empyema.

The only effective therapy in the fulminant variety, associated with thrombosis of the anterior portion of the sinus, is the administration of high doses of antibiotics aimed at coagulase-positive staphylococci, and probably gram-negative pathogens and anaerobes if there has been sinusitis. As with septic lateral sinus phlebitis, anticoagulants have been used, but their value has not been proved. In our cases, the cranial-nerve palsies have resolved to a large extent, but visual loss, if it occurs, tends to remain, with findings suggestive of infarction of the retroorbital part of the optic nerve; the mechanism of this complication is not clear. Cavernous sinus thrombosis must be differentiated from mucormycosis infection of the sinuses and from orbital cellulitis, which usually occur in patients with uncontrolled diabetes, and from other fungus infections (notably *Aspergillus*), carcinoma-tous invasion of the sphenoid bone, Wegener granulomatosis, and sphenoid wing meningioma.

Septic Thrombosis of the Superior Sagittal Sinus

Now less common than at a time when uncontrolled ear and sinus infections were common, this may be asymptomatic but more often there is a clinical syndrome of fever, headache, unilateral convulsions, and motor weakness, first on one side of the body, then on the other, as a result of extension of the thrombophlebitis into the superior cerebral veins. Papilledema and increased intracranial pressure almost always accompany these signs. Severe generalized and vertex headache is a typical but not invariable complaint. Because of the localization of function in the cortex that is drained by the sinus, the weakness may take the form of a crural (lower limb) monoplegia or, less often, of paraplegia. A corticosensory loss may occur in the same distribution. Homonymous hemianopia or quadrantanopia, aphasia, paralysis of conjugate gaze, and urinary incontinence (in bilateral cases) have also been observed.

As in the case of aseptic thrombosis, loss of the flow void in the superior sagittal sinus in the MRI is diagnostic, and the clot may be visualized if the correct imaging sequences are used. A similar change can be seen on axial images of the contrast-enhanced CT scan by altering the viewing windows so as to show the clot within the posterior portion of the sagittal sinus. The CT scan performed early in the illness without contrast infusion usually shows the high-density clot within cortical veins as well, but only if carefully studied by altering the viewing window at the machine's console.

Treatment consists of high doses of antibiotics and temporization until the thrombus recanalizes. Although

not of proven benefit (as it is in bland cerebral vein thrombosis), we have used heparin in these circumstances unless there are very large biparietal hemorrhagic infarctions. Because of the highly epileptogenic nature of the attendant venous infarction, we have also administered antiepileptic drugs prophylactically, but there is no clinical study to guide the clinician in this regard. Recovery from paralysis may be complete, or the patient may be left with seizures and varying degrees of spasticity in the lower limbs.

It should be reiterated that all types of thrombophlebitis, especially those related to infections of the ear and paranasal sinuses, may be simultaneously associated with other forms of intracranial purulent infection, namely bacterial meningitis, subdural empyema, or brain abscess. Therapy in these complicated forms of infection must be individualized. As a rule, the best plan is to institute antibiotic treatment of the intracranial disease and to decide, after it has been brought under control, whether surgery on the offending ear or sinus is necessary. To operate on the primary focus before medical treatment has taken hold is to court disaster. In cases complicated by bacterial meningitis, treatment of the latter usually takes precedence over the surgical treatment of complications, such as brain abscess and subdural empyema.

Aseptic thrombosis of intracranial venous sinuses and cerebral veins is discussed in Chap. 34 on cerebrovascular disease; aspects related to intracranial pressure are discussed in Chap. 30, on CSF circulation.

BRAIN ABSCESS

With the exception of a small proportion of cases (approximately 10 percent) in which infection is introduced from the outside (compound fractures of the skull, intracranial operation, bullet wounds), brain abscess is always secondary to bacteremia and a bacterial focus elsewhere in the body. Purulent pulmonary infections (abscess, bronchiectasis) and bacterial endocarditis account for the largest number of brain abscesses in the modern era. A decreasing proportion of brain abscesses in the current era is related to disease of the paranasal sinuses, middle ear, and mastoid cells. Of those originating in the ear, about one-third lie in the anterolateral part of the cerebellar hemisphere; the remainder occurs in the middle and inferior parts of the temporal lobe. The sinuses most frequently implicated are the frontal and sphenoid, and the abscesses derived from them are in the frontal and temporal lobes, respectively.

Pathogenesis

Otogenic and rhinogenic abscesses reach the nervous system by direct extension, in which the bone of the middle ear or nasal sinuses becomes the seat of an osteomyelitis, with penetration of the dura and leptomeninges, infection may spread along the major intracranial veins. Thrombophlebitis of the pial veins and dural sinuses, by infarcting brain tissue, renders the latter more vulnerable to invasion by infectious material. The close anatomic relationship of the lateral (transverse) sinus to the

cerebellum explains the frequency with which this portion of the brain is infected via the venous route. The spread along venous channels also explains how an abscess may sometimes form at a considerable distance from the primary focus in the middle ear or paranasal sinuses.

As mentioned, the majority of brain abscesses is metastatic, i.e., hematogenous. These are traceable to bacterial endocarditis or to a primary septic focus in the lungs or pleura, as indicated earlier. Other metastatic abscesses are related to a congenital cardiac defect or pulmonary arteriovenous malformation that permits infected emboli to bypass the pulmonary circulation and reach the brain. Occasional cases are associated with infected pelvic organs, skin, tonsils, abscessed teeth, and osteomyelitis of noncranial bones. In approximately 20 percent of cases, the source cannot be ascertained.

Metastatic abscesses from hematogenous spread are usually situated in the distal territory of the middle cerebral arteries (Fig. 32-1), and they sometimes multiply, in contrast to otogenic and rhinogenic abscesses. Also, almost all deep cerebral abscesses have a systemic source. It should also be noted that the clinical and radiologic features of a solitary abscess mimic those of a brain tumor. Small and miliary abscesses may progress to large ones.

A careful distinction had in the past been made between the neuropathologic effects of endocarditis caused by different organisms. What had been divided into acute bacterial endocarditis (ABE) and subacute bacterial endocarditis (SBE) are now instead characterized by the virulence of the causative organism. For example, endocarditis from the implantation in the brain of streptococci of low virulence (alpha and gamma streptococci) or similar organisms on valves previously damaged by rheumatic fever seldom gives rise to a brain abscess. In contrast, organisms such as *S. aureus* and gram-negative bacteria have a propensity to cause abscesses. The cerebral lesions in all forms of endocarditis are a result of embolic occlusion of vessels by fragments of vegetations and bacteria, which cause infarction of brain tissue and a restricted inflammatory response around the involved blood vessels and the overlying meninges (cerebritis). It is the subsequent evolution of the process that is dependent on the inherent tendency of the organism to be invasive. Therefore, the former distinction between acute and subacute bacterial endocarditis has become less useful. The cerebral symptoms of a stroke may be the first clinical manifestations of the disease. Over time, sometimes within days but usually longer, the inflamed artery may form an aneurysm (mycotic aneurysm) that later gives rise to parenchymal or subarachnoid hemorrhage (see Chap. 34). Bacterial meningitis rarely develops with abscess and most often the CSF is sterile but there are exceptions.

Rapidly evolving cerebral signs in patients with acute endocarditis are nearly always caused by septic embolic infarction or hemorrhage. Anticoagulation has not been shown to reduce the incidence of embolization from endocarditis; the risk of inducing hemorrhage is uncertain but may have been overestimated in the past. In patients with endocarditis on a prosthetic heart valve, anticoagulation may be continued, but this treatment is suspended if there is a hemorrhagic brain infarction.

Figure 32-1. MRI showing a right frontal brain abscesses associated with bacterial endocarditis (*S. aureus*) in a 55-year-old man. There is characteristic rim enhancement with gadolinium (*left panel*) and restricted diffusion within the abscess (*right panel*).

Existing anticoagulation need not be reversed unless a cerebral hemorrhage evolves.

It is estimated that 5 percent of cases of *congenital heart disease* are complicated by brain abscess (Cohen; Newton). Viewed from another perspective, in children, more than 60 percent of cerebral abscesses are associated with congenital heart disease. The abscess is usually solitary; this fact, coupled with the potentially correctable underlying cardiac abnormality, makes the recognition of brain abscess in congenital heart disease a matter of considerable practical importance. For some unknown reason, brain abscess associated with congenital heart disease is rarely seen before the third year of life. The tetralogy of Fallot is by far the most common anomaly implicated, but the abscesses may occur with any right-to-left intracardiac or pulmonary shunt that allows venous blood returning to the heart to enter the systemic circulation without first passing through the lungs. Pulmonary emboli, by increasing the back pressure in the right heart, may open (make patent) an occult foramen ovale. A pulmonary arteriovenous malformation has a similar effect. Nearly half of the reported cases of pulmonary arteriovenous fistulas have *Osler-Rendu-Weber telangiectasia*. When the filtering effect of the lungs is thus circumvented, pyogenic bacteria or infected emboli from a variety of sources may gain access to the brain, where, aided by the effects of venous stasis and perhaps of infarction, an abscess is established.

Etiology

The most common organisms causing bacterial cerebral abscess are virulent streptococci, many of which are

anaerobic or microaerophilic. These organisms are often found in combination with other anaerobes, notably *Bacteroides*, *Fusibacterium*, and *Prevotella* and less often, *Propionibacterium* (diphtheroids), and may be combined with *Hemophilus species*, Enterobacteriaceae, such as *E. coli* and *Proteus*. Staphylococci also commonly cause brain abscess, but pneumococci, meningococci, and *H. influenzae* rarely do. In addition, the gram-positive higher bacteria *Actinomyces* and *Nocardia* and certain fungi discussed later, notably *Candida*, *Mucor*, and *Aspergillus*, are isolated in some cases.

The type of organism tends to vary with the source of the abscess; staphylococcal abscesses are usually a consequence of accidental or surgical trauma, sometimes of endocarditis, especially in drug addicts who inject themselves; enteric organisms are almost always associated with otitic infections; and anaerobic streptococci are commonly metastatic from the lung and paranasal sinuses. Predisposing to nocardial brain abscess is pulmonary nocardial infection, often in immunosuppressed patients; this diagnosis is doubtful without a pneumonic infiltrate. Thus knowledge of the antecedent history enables one to institute appropriate therapy while awaiting the results of bacterial and fungal cultures. In immunosuppressed patients, brain abscess is usually from a nonbacterial organism; fungi and parasites (toxoplasmosis) prevail.

Pathology

Localized inflammatory exudate, septic thrombosis of vessels, and aggregates of degenerating leukocytes

represent the early reaction to bacterial invasion of the brain. Surrounding the necrotic tissue are macrophages, astroglia, microglia, and many small veins, some of which show endothelial hyperplasia, contain fibrin, and are cuffed with polymorphonuclear leukocytes. There is interstitial edema in the surrounding white matter. At this stage, which is rarely observed postmortem, the lesion is poorly circumscribed and tends to enlarge by a coalescence of inflammatory foci. The term *cerebritis* is loosely applied to this local suppurative encephalitis or immature abscess.

Within several days, the intensity of the reaction begins to subside and the infection tends to become delimited. The center of the abscess takes on the character of pus; at the periphery, fibroblasts proliferate from the adventitia of newly formed blood vessels and form granulation tissue, which is readily identified pathologically within 2 weeks of the onset of the infection but it is evident earlier as restriction of diffusion on MRI. As the abscess becomes more chronic, the granulation tissue is replaced by collagenous connective tissue. It has also been noted, both in experimental animals and in humans, that the capsule of the abscess is not of uniform thickness, frequently being thinner on its medial (paraventricular) aspect. These factors account for the propensity of cerebral abscesses to spread deeply into the white matter and to produce daughter abscesses or a chain of abscesses and extensive surrounding cerebral edema. In some instances, the process culminates in a catastrophic rupture into the ventricles.

Clinical Manifestations

Headache is probably the most frequent initial symptom of intracranial abscess but this varies and a considerable number of cases are revealed incidentally. Other early symptoms, roughly in order of their frequency are drowsiness and confusion; focal or generalized seizures; and focal motor, sensory, or speech disorders. Fever and leukocytosis are not consistently present, depending on the phase of the development of the abscess at the time of presentation (see below). In patients who harbor chronic ear, sinus, or pulmonary infections, a recent activation of the infection frequently precedes the onset of cerebral symptoms. In patients without an obvious focus of infection, headache or other cerebral symptoms may appear abruptly on a background of mild general ill health or congenital heart disease. In some patients, bacterial invasion of the brain may be asymptomatic or may be attended only by a transitory focal neurologic disorder, as might happen when a septic embolus briefly lodges in a brain artery. Sometimes stiff neck accompanies generalized headache, suggesting the diagnosis of meningitis (especially a partially treated one).

Localizing neurologic signs become evident sooner or later, but, like papilledema, they occur relatively late in the course of the illness. The nature of the focal neurologic defect will, of course, depend on the location of the abscess as fully explicated in Chap. 22. In *cerebellar abscess*, the headache is generally postauricular or occipital; the signs are those expected for disease of this part of the brain.

The treacherous aspect of brain abscess is that the signs of systemic infection may be entirely absent. The invasive stage of cerebral infection may be so inconspicuous, and the course so indolent, that the entire clinical picture may not differ from that of malignant brain tumor. Although slight *fever* is characteristic of the early invasive phase of cerebral abscess, the temperature may return to normal as the abscess becomes encapsulated; the same is true of leukocytosis. The sedimentation rate is usually elevated. Although lumbar puncture is not recommended, in the early stages of abscess formation the CSF pressure is moderately increased; and there is a mild to moderate pleocytosis with 10 to 80 percent neutrophils; and the protein content is modestly elevated, rarely more than 100 mg/dL. Glucose values are not lowered, and the CSF is sterile unless there is concomitant bacterial meningitis. As already mentioned, the combination of brain abscess and acute bacterial meningitis occurs only infrequently. In some patients, abscess is combined with subdural empyema; in these instances the clinical picture can be very complicated, although headache, fever, and focal signs again predominate. In a small number of cases, especially partially treated ones, there are no spinal fluid abnormalities and the sedimentation rate may be normal.

It is apparent from this overview that the clinical picture of brain abscess is far from stereotyped. Whereas headache is the most prominent feature in most patients, seizures or certain focal signs may predominate in others, and a considerable number of patients will present with only signs of increased intracranial pressure. In some instances the symptoms evolve swiftly over a week, new ones being added day by day. In such cases the abscess may become apparent only when cerebral imaging performed for the evaluation of headache or other symptoms discloses a ring-enhancing mass. Even then, the radiologic distinction between tumor and abscess is not straightforward, depending often on the presence of a uniform, enhancing capsule that is typical of a mature abscess (see below). An impressive feature of cerebral abscess is the unpredictability with which the symptoms may evolve, particularly in children. Thus, a patient whose clinical condition seems to have stabilized may, in a matter of hours or a day or two, advance to an irreversible state of coma. Often this is caused by rupture of the abscess into the subarachnoid or ventricular CSF.

Diagnosis

CT and MRI are the most important diagnostic tools. In the CT scan, the capsule of the abscess enhances and the center of the abscess and surrounding edematous white matter are hypodense. With MRI, in T1-weighted images, the capsule enhances and the interior of the abscess is hypointense and shows restricted diffusion; in T2-weighted images, the surrounding edema is apparent and the capsule is hypointense and there is variable diffusion restriction within the lesion (Fig. 32-1, right). The abscess capsule tends to be thinner on the side directed to the lateral ventricle. Cerebritis appears as dot-sized areas of decreased density that enhance with gadolinium. Practically all abscesses larger than 1 cm produce positive scans. There is almost

no likelihood of cerebral abscess if enhanced CT and MRI studies are negative. Blood cultures, sedimentation rate, and chest radiography are indispensable in the complete diagnosis of brain abscess, although it must be acknowledged that blood cultures are likely to be unrevealing except in cases of acute endocarditis.

If there is no apparent source of infection and there are only signs and symptoms of a mass lesion, the differential diagnosis includes tuberculous or fungal abscess, glioma, metastatic carcinoma, toxoplasmosis, subdural hematoma, subacute infarction of the basal ganglia or thalamus, and resolving cerebral hemorrhage or infarction. Sometimes only surgical exploration will settle the issue, but one must be cautious in interpreting the stereotactic biopsy if only inflammatory and gliotic tissue is obtained, as these changes may appear in the neighborhood of either abscess or tumor.

Treatment

During the stage of cerebritis and early abscess formation, which is essentially an acute focal encephalitis, intracranial operation accomplishes little and probably adds only further injury and swelling of brain tissue and possibly dissemination of the infection. Some cases can be cured at this stage by the adequate administration of high-dose antibiotics. Even before bacteriologic examination of the intracerebral mass, certain antibiotics can be given, with the choice based on the predisposing condition (vancomycin, a second- or third-generation cephalosporin such as ceftriaxone, and either meropenem or metronidazole). If a penicillin- or oxacillin-sensitive organism is suspected or isolated, those agents are superior to vancomycin. These drugs are given intravenously in divided daily doses. Metronidazole is so well absorbed from the gastrointestinal tract that it can be administered orally, 500 mg q6h.

This choice of antimicrobial agents is based on the fact that anaerobic streptococci and *Bacteroides* are often among the causative organisms. Evidence of staphylococcal infection can be presumed if there has been recent neurosurgery or head trauma or a demonstrable bacterial endocarditis with this organism. Abscesses caused by bacteria of oral origin do not respond well to any of these regimens because of the frequency of gram-negative organisms; penicillin and metronidazole are usually adequate for odontogenic infections but a third- or fourth-generation cephalosporin, such as cefotaxime, 2 g q4h intravenously, is often used. In all cases, several weeks of treatment are advised.

The initial elevation of intracranial pressure and threatening temporal lobe or cerebellar herniation can be managed by the use of intravenous mannitol (or hypertonic saline) and dexamethasone, 6 to 12 mg q6h. If improvement does not begin promptly, it becomes necessary to aspirate the abscess stereotactically or remove it by an open procedure that also allows precise etiologic diagnosis (Gram stain and culture). The decision regarding aspiration or open removal of the abscess is governed by its location and the course of clinical signs and by the degree of mass effect and surrounding edema as visualized by repeated scans.

Only if the abscess is solitary, superficial, and well encapsulated or associated with a foreign body should total excision be attempted; if the abscess is deep, aspiration performed stereotactically and repeated if necessary is currently the method of choice. If the location of the abscess is such that it causes obstructive hydrocephalus, for example, in the thalamus adjacent to the third ventricle or in the cerebellum, it is advisable to remove or aspirate the mass and to drain the ventricles externally for a limited time. While it has been our practice to recommend either complete excision for posterior fossa and fungal abscesses or aspiration if they are deep, there is still a lack of unanimity as to the optimal surgical approach. Some neurosurgeons instill antibiotics into the abscess cavity following aspiration, but the efficacy of this treatment is difficult to judge.

The least satisfactory results are obtained if the patient is comatose before treatment is started; more than 50 percent of such patients in the past have died. If treatment is begun while the patient is alert, the mortality is in the range of 5 to 10 percent, and even multiple metastatic abscesses may respond. Approximately 30 percent of surviving patients are left with neurologic residua. Of these, focal epilepsy is the most troublesome. Following successful treatment of a cerebral abscess in a patient with congenital heart disease, correction of the cardiac anomaly is indicated to prevent recurrence. One may even consider closing a patent foramen ovale using interventional or open surgical methods if no other explanation for the abscess is apparent.

SUBACUTE AND CHRONIC FORMS OF MENINGITIS

There are many infectious processes that induce an inflammation of the leptomeninges of lesser intensity and more chronicity than the acute forms described earlier. Included are some bacterial and most fungal infections, tuberculosis, syphilis, Lyme disease, HIV infection, and presumed noninfectious causes, such as lymphoma, sarcoidosis, Wegener granulomatosis, and others. As pointed out by Ellner and Bennett many decades ago, the clinical syndrome of chronic meningitis comprises confusion or cognitive decline, seizures, an absence of lateralizing and focal cerebral signs, with or without headache, and mild stiffness of the neck. In most cases there is little or no fever or other manifestation of infection. The CSF will often not divulge the causative agent, as the organisms are usually by nature more difficult to detect and culture. The main identifiable forms of subacute and chronic meningitis are described below. Chapter 33 addresses the approach to the complicated problem of chronic nonbacterial meningitis (aseptic meningitis) in which no cause can be found, and should be referred to along with this section.

Tuberculous Meningitis

In the United States and in most western countries, the incidence of tuberculous meningitis, which parallels the

frequency of systemic tuberculosis, has, until recently, decreased steadily and markedly since World War II. Since 1985, however, there has been a moderate increase in the incidence of systemic tuberculosis (and tuberculous meningitis) in the United States—a 16 percent annual increase compared to an average annual decline of 6 percent during the preceding 30 years (Snider and Roper). This trend has recently been reversed in the United States because HIV is under better control. In fact, tuberculosis may be the first clinical manifestation of HIV infection (Barnes et al); among patients with full-blown AIDS, the incidence of tuberculosis is almost 500 times the incidence in the general population (Pitchenik et al). In developing countries, particularly in sub-Saharan Africa, recent estimates of the incidence of tuberculosis suggest that it is 25 times more frequent than in the United States, again largely because of the prevalence of HIV infection.

Pathogenesis

Tuberculous meningitis is usually caused by the acid-fast organism *Mycobacterium tuberculosis* and exceptionally by *Mycobacterium bovis*, *Mycobacterium avian*, *Mycobacterium kansasii*, and *Mycobacterium fortuitum* (the last of these after neurosurgical procedures and cranial trauma). The emergence of AIDS has led to a marked increase in cases caused by both the main organism and also by the two atypical mycobacteria. In a monograph as informative today as it was 70 years ago, Rich described two stages in the pathogenesis of tuberculous meningitis: first a bacterial seeding of the meninges and subpial regions of the brain with the formation of tubercles, followed by the rupture of one or more of the tubercles and the discharge of bacteria into the subarachnoid space. Whether the meningitis always originates in this way is unlikely. It can be said, however, that the meningitis may occur as a terminal event in cases of miliary tuberculosis or as part of generalized tuberculosis with only a single focus (tuberculoma) in the brain.

Pathologic Findings

Small, discrete white tubercles are scattered over the base of the cerebral hemispheres and to a lesser degree on the convexities. The brunt of the pathologic process falls on the basal meninges, where a thick, gelatinous exudate accumulates, obliterating the pontine and interpeduncular cisterns and extending to the meninges around the medulla, the floor of the third ventricle and subthalamic region, the optic chiasm, and the undersurfaces of the temporal lobes. There may be multiple small abscesses (Fig. 32-2) or a more uniform exudate in the leptomeninges. By comparison, the convexities are little involved, possibly because the associated hydrocephalus obliterates the cerebral subarachnoid space. Microscopically, the meningeal tubercles are like those in other parts of the body, consisting of a central zone of caseation surrounded by epithelioid cells and some giant cells, lymphocytes, plasma cells, and connective tissue. The exudate is composed of fibrin, lymphocytes, plasma cells, other mononuclear cells, and some polymorphonuclear leukocytes. The ependyma and choroid plexus are studded with minute glistening tubercles. The exudate also surrounds the spinal cord. Unlike the typical bacterial

Figure 32-2. MRI in tuberculous meningitis showing gadolinium enhancement of the basal meninges, reflecting microabscesses and intense inflammation, accompanied by hydrocephalus and cranial nerve palsies.

meningitides, the disease process is not confined to the subarachnoid space but frequently penetrates the pia and ependyma and invades the underlying brain, so that the process is truly a *meningoencephalitis*.

Other pathologic changes depend on the chronicity of the disease process and recapitulate the changes that occur in the subacute and chronic stages of the other bacterial meningitides (see Table 32-1). Cranial nerves are often involved by the inflammatory exudate as they traverse the subarachnoid space, indeed, far more often than with typical bacterial meningitis. Arteries may become inflamed and occluded, with infarction of brain. Blockage of the basal cisterns frequently results in a meningeal, obstructive hydrocephalus. Marked ependymitis with blocking of the CSF in the aqueduct or fourth ventricle is a less-common cause. The exudate occasionally predominates around the spinal cord, leading to multiple spinal radiculopathies and compression of the cord.

Clinical Features

Tuberculous meningitis occurs in persons of all ages. Formerly, it was more frequent in young children, but now it is more frequent in adults, at least in the United States. The early manifestations are usually low-grade fever, malaise, headache (more than 50 percent of cases), lethargy, confusion, and stiff neck (75 percent of cases), with Kernig and Brudzinski signs. Characteristically, these symptoms evolve much less rapidly in tuberculous than in bacterial meningitis, usually over a period of a week or two, sometimes longer. In young children and infants, apathy, hyperirritability, vomiting, and seizures are the usual symptoms; however, stiff neck may not be prominent or may be absent altogether.

Because of the inherent chronicity of the disease, signs of cranial nerve involvement (usually ocular palsies, less-often facial palsies or deafness) and papilloedema may be present at the time that the infection is recognized (20 percent of cases). Occasionally, the disease may present with the rapid onset of a focal neurologic deficit because of hemorrhagic infarction, with signs of raised intracranial pressure or with symptoms referable to the spinal cord and nerve roots. Hypothermia and hyponatremia have been additional features in several of our cases at the time of discovery of the meningitis.

In approximately two-thirds of patients with tuberculous meningitis there is evidence of active tuberculosis elsewhere, usually in the lungs and occasionally in the small bowel, bone, kidney, or ear. In some patients, however, only inactive pulmonary lesions are found, and in others there is no evidence of tuberculosis outside of the nervous system. As mentioned, among our adult patients, tuberculous meningitis is now seen largely in those with AIDS, but also in alcoholics, and in people who have emigrated from Asia, Africa, and India, and certain locations in the former Soviet Union. Except for the emergence of drug-resistant organisms, the HIV infection does not appear to much change the clinical manifestations or the outcome of tuberculous meningitis. However, others disagree with this statement, pointing out that the course of the bacterial infection is accelerated in AIDS patients, with more frequent involvement of organs other than the lungs. Whether or not HIV infection alters the natural history of tuberculous meningitis, treatment of the HIV infection is of paramount importance and should be started within 2 weeks of the onset of antituberculous therapy.

If tuberculous meningitis is untreated, its course is characterized by confusion and progressively deepening stupor and coma, coupled with cranial-nerve palsies, pupillary abnormalities, focal neurologic deficits, raised intracranial pressure, and decerebrate postures; invariably, untreated, a fatal outcome then follows within 4 to 8 weeks of the onset.

Laboratory Studies

The most important diagnostic test is lumbar puncture, which preferably should be performed before the administration of antibiotics. The CSF is usually under increased pressure and contains between 50 and 500 white cells per cubic millimeter, rarely more. Early in the disease there may be a more-or-less-equal number of polymorphonuclear leukocytes and lymphocytes, but after several days lymphocytes predominate in the majority of cases. In some cases, however, *M. tuberculosis* causes a *persistent polymorphonuclear pleocytosis*, the other usual causes of this CSF formula being *Nocardia*, *Aspergillus*, and *Actinomyces* (Peacock). The protein content of the CSF is always elevated, between 100 and 200 mg/dL in most cases, but much higher if the flow of CSF is blocked around the spinal cord. Glucose is reduced to levels below 40 mg/dL, but rarely to the very low values observed in pyogenic meningitis; the glucose falls slowly and a reduction may become manifest only several days after the patient has been admitted to the hospital. The serum sodium and

chloride and CSF chloride are often reduced, in most instances because of inappropriate ADH secretion or an Addisonian state due to tuberculosis of the adrenals.

Most children with tuberculous meningitis have positive tuberculin skin tests (85 percent) but the rate is far lower in adults with or without AIDS: 40 to 60 percent in most series.

The previously conventional methods of demonstrating tubercle bacilli in the spinal fluid are inconsistent and often too slow for immediate therapeutic decisions. Success with the traditional identification of tubercle bacilli in smears of CSF sediment stained by the Ziehl-Neelsen method is a function not only of their number but also of the persistence with which they are sought. There are effective means of culturing the tubercle bacilli; because their quantity is usually small, however, attention must be paid to proper technique. The amount of CSF submitted to the laboratory is critical; the more that is cultured, the greater the chances of recovering the organism. Unless one of the newer techniques is used, growth in culture media is not seen for 3 to 4 weeks.

More widely used test now is polymerase chain reaction amplification from the CSF, which rapidly permits the detection of small amounts of tubercle bacilli. The sensitivity of this test is stated to be close to 80 percent but there is a 10 percent false-positive rate. There is also a rapid culture technique that allows identification of the organisms in less than 1 week. However, even these new diagnostic methods may give uncertain results or take several days to demonstrate the organism and they cannot be counted on to exclude the diagnosis. For these reasons, if a presumptive diagnosis of tuberculous meningitis has been made and cryptococcosis and other fungal infections and meningeal neoplasia have been reasonably excluded, treatment can be instituted without waiting for the results of bacteriologic study.

Other diagnostic procedures (CT, MRI) are necessary in patients who present with or develop raised intracranial pressure, hydrocephalus, or focal neurologic deficits. One or more tuberculomas may also be visualized (Fig. 32-2 and 32-3) or there may be deep cerebral infarction from occlusion of vessels of the circle of Willis or one of its primary branches. MR or CT angiography may demonstrate vascular occlusive disease from granulomatous infiltration of the walls of arteries.

Other Forms of Central Nervous System Tuberculosis

Tuberculous Serous Meningitis

This condition, which is essentially a self-limited meningitis, is observed with some frequency in countries where tuberculosis is prevalent. The CSF shows a modest pleocytosis in some, but not all, cases, a normal or elevated protein content, and normal glucose levels. Headache, lethargy, and confusion are present in some cases and there are mild meningeal signs. Lincoln, who was the first to call attention to this syndrome, believed it to be a meningeal reaction to an adjacent tuberculous focus that did not progress to frank meningitis but this form of meningitis is not always self-limited.

Figure 32-3. A tuberculoma of the pons on a gadolinium-enhanced MRI (*left panel*). There is a thick, uniform enhancing rim. The mass behaved clinically like a malignant brain tumor. The right panel shows the same lesion after antituberculous treatment.

Tuberculoma

These are tumor-like masses of tuberculous granulation tissue, most often multiple but also occurring singly, that form in the parenchyma of the brain and range from 2 to 12 mm in diameter (Fig. 32-3). The larger ones may produce symptoms of a space-occupying lesion and periventricular ones may cause obstructive hydrocephalus, but many are unaccompanied by symptoms of focal cerebral disease. In the United States, tuberculomas are rare; in developing countries, however, they constitute from 5 to 30 percent of all intracranial mass lesions. In some tropical countries, cerebellar tuberculomas are the most frequent intracranial tumors in children. Because of their proximity to the meninges, the CSF often contains a small number of lymphocytes and increased protein (serous meningitis), but the glucose level is not reduced. True tuberculous abscesses of the brain are rare except in AIDS patients. In two of our patients who presented with a brainstem tuberculoma, there was a serous meningitis that progressed to a fatal generalized tuberculous meningitis.

Myeloradiculitis

The spinal cord may be affected in a number of ways in the course of tuberculous infection. In addition to compressing spinal roots and cord, causing spinal block, the inflammatory meningeal exudate may invade the underlying parenchyma, producing signs of posterior and lateral column and spinal root disease. Spinal cord symptoms may also accompany tuberculous osteomyelitis of the spine with compression of the cord by an epidural

abscess, a mass of granulation tissue (Pott disease, “Pott paraplegia”), or, less frequently, by the mechanical effects of angulation of the vertebral column. Pott disease, a tuberculous osteomyelitis of the spine that leads to compression of vertebral bodies and a highly characteristic kyphotic deformity at the thoracic or upper lumbar level, is discussed in Chap. 44.

Treatment of Central Nervous System Tuberculous Infections

The treatment of tuberculous meningitis consists of the administration of a combination of four drugs—isoniazid (INH), rifampin (RMP), ethambutol (EMB), and/or pyrazinamide (PZA) for the first 2 months. Some regimens omit the last drug but recent recommendations from various U.S. societies prefer the four-drug combination. An alternative regimen is INH, PZA, high-dose RMP, and moxifloxacin. All of these drugs have the capacity to penetrate the blood–brain barrier, with INH and PZA ranks higher than the others in this respect. Resistant strains of tuberculous organisms are emerging, requiring the use of second-line drugs. It has been pointed out that individuals from certain countries (e.g., Vietnam, Haiti, Philippines, former Soviet Union) have high rates of INH, and sometimes EMB-resistant organisms. In these cases of multidrug resistance, ethionamide (ETA) must be added as a fifth drug. Antibiotics must be given for a prolonged period, 9 to 12 months if first-line treatment has been given (although it may not be necessary to give all 3 or 4 drugs for the entire period).

INH is the single most effective drug. It can be given in a single daily dose of 5 mg/kg in adults and 10 mg/kg in children. Its most important adverse effects are neuropathy (see Chap. 40) and hepatitis, particularly in alcoholics. Neuropathy can be prevented by the administration of 50 mg pyridoxine daily. In patients who develop the symptoms of hepatitis or who have abnormal liver function tests, INH should be discontinued. The usual dose of RMP is 10 mg/kg daily for adults, 15 mg/kg for children. Ethambutol is given in a single daily dose of 15 mg/kg. The dosage of ETA is 15 to 25 mg/kg daily for adults; because of its tendency to produce gastric irritation, it is given in divided doses, after meals. The latter two drugs (EMB and ETA) may cause optic neuropathy, so that patients taking them should have regular examinations of visual acuity and red-green color discrimination. Pyrazinamide is given once daily in doses of 20 to 35 mg/kg. Rash, gastrointestinal disturbances, and hepatitis are the main adverse effects. Except for INH, all these drugs can be given only orally or by stomach tube. INH and rifampin may be given parenterally.

Corticosteroids may be used in patients whose lives are threatened by the effects of subarachnoid block or raised intracranial pressure but only in conjunction with antituberculous drugs. A randomized study conducted in Vietnam, including patients with and without AIDS, showed that the addition of intravenous dexamethasone (0.4 mg/kg daily for a week and then tapering doses for 3 to 6 weeks) reduced mortality from 41 percent to 32 percent but had no effect on residual disability (Thwaites et al).

Intracranial tuberculoma calls for a similar course of antibiotics, as outlined above. Under the influence of these drugs, the tuberculoma(s) may decrease in size and small ones ultimately disappear or calcify, as judged by the CT scan; if they do not, and especially if there is "mass effect," excision may be necessary. Patients with spinal osteomyelitis or localized granulomas with instability or spinal cord compression (Pott paraplegia) should be explored surgically after an initial course of chemotherapy, and an attempt should be made to excise the tuberculous focus. We have, however, dealt successfully with tuberculous osteomyelitis of the cervical spine (without significant abscess or cord compression) by immobilizing our patient in a hard collar and administering triple-drug therapy (at the suggestion of the patient's father, who was a physician in India), once it was established that the spinal column was stable, the collar could be removed. Thus, flexion-extension x-rays can be valuable if they can be obtained safely.

The overall mortality of patients with CNS tuberculosis is still significant (approximately 10 percent), infants and the elderly being at greatest risk. Among HIV-infected patients, the mortality from tuberculous meningitis is considerably higher (21 percent in the series of Berenguer et al)—the result of delays in diagnosis and, more importantly, of resistance to antituberculous drugs in some patients (Snider and Roper). Most resistant tuberculosis in developed countries is a result of intermittent, ineffective therapy. Therefore, directly observed therapy for at least 2 months—"short course"

(DOTS) has become routine for patients in many areas. (See also "Tuberculous Myelitis" in Chap. 44.) Early diagnosis, as one might expect, enhances the chances of survival. In patients who are treated late in the disease, when coma has supervened, the mortality rate is nearly 50 percent. Between 20 and 30 percent of survivors manifest a variety of residual neurologic sequelae, the most important of which are diminished intellectual function, psychiatric disturbances, recurrent seizures, visual and oculomotor disorders, deafness, and hemiparesis. A detailed account of these has been given by Wasz-Hockert and Donner.

Sarcoidosis

The infectious etiology of sarcoidosis has never been established but the disease may suitably be considered at this point because of its close resemblance pathologically and clinically to tuberculosis and other granulomatous infections. Indeed, one still credible theory of causation considers sarcoidosis to be a modified form or product of the tubercle bacillus. This has not been proved, and the same can be said for various other infectious and noninfectious etiologies that from time to time have been proposed as the underlying cause. Current opinion favors the idea that sarcoidosis represents an exaggerated cellular immune response to a limited class of antigens or autoantigens (Baughman and Lower).

The essential lesion in sarcoidosis consists of focal collections of epithelioid cells surrounded by a rim of lymphocytes; frequently there are giant cells, but caseation is lacking. The sarcoid, noncaseating granuloma may be found in all organs and tissues, including the nerve roots, peripheral, and central nervous systems, but the most frequently involved are the mediastinal and peripheral lymph nodes, lungs, liver, skin, phalangeal bones, eyes, and parotid glands.

According to Iannuzzi and colleagues, sarcoidosis is accompanied by nervous system involvement (neurosarcoidosis) in approximately 25 percent of postmortem cases. This number overestimates the frequency of neurosarcoidosis because only a small percentage of all patients with sarcoidosis come to autopsy and among these, neurologic involvement is prevalent. Approximately 5 percent of patients with sarcoidosis prove to have nervous system involvement clinically. *Primary neurosarcoidosis*, by which is meant sarcoidosis isolated only to the nervous system, is even less common. If one excludes facial palsy, primary neurosarcoidosis is rare. Several other syndromes are caused by localized sarcoid involvement of the meninges, brain, and spinal cord (Table 32-5). In Scadding's series of 275 patients, only 3 developed CNS lesions; in other large series, the incidence of CNS involvement was greater but, as mentioned, most are in the range of 5 to 10 percent (of 285 studied by Chen and McLeod; and 33 of 649 studied by Stern et al). Delaney, in his review of the literature, found the neurologic involvement in sarcoidosis to be equally divided between the peripheral and central nervous systems.

Sarcoidosis in the nervous system may take one of several forms (see Table 32-5). As indicated in

Table 32-5

THE MAIN NERVOUS SYSTEM MANIFESTATIONS OF SARCOIDOSIS

Cranial neuropathy (see Chap. 47)
Facial palsy, unilateral, bilateral, or sequential ^a
Visual loss
Optic neuropathy
Uveitis
Retinal vasculopathy
Hearing loss, vertigo
Facial sensory loss or pain
Spinal cord and roots (see Chap. 44)
Polyradiculopathy
Granulomatous meningomyelitis, subacute or chronic
Cauda equina syndrome
Peripheral nervous system (see Chap. 46)
Lumbar or brachial plexopathy
Sensory-predominant polyneuropathy
Mononeuropathy and mononeuropathy multiplex
Brain lesions
Nodular masses
Perivascular infiltration
Basal granulomas with diabetes insipidus
Subacute meningitis and pachymeningitis

^aFacial palsies account for the majority of neurosarcoidosis.

Chaps. 13, 46, and 47, isolated sarcoid granulomas may involve peripheral or cranial nerves, giving rise to a subacute or chronic polyradiculopathy, neuropathy, or plexopathy of asymmetrical type (Jefferson). Polyneuropathy may occur, but is infrequent; Zuniga and colleagues summarized our experience with this process. Of the cranial nerves, the facial is the most frequently involved, either as part of the uveoparotid syndrome (Heerfordt syndrome) or independently. The facial palsy may be unilateral or bilateral; if the latter, the nerves may be affected simultaneously or in succession. Blindness is a rare complication that follows basal infiltration that encompasses the optic nerves as noted later (Fig. 32-4). Other causes of visual disturbance include uveitis and optic neuropathy.

There is also a well-described myopathy associated with sarcoidosis; it is discussed below, and also considered in Chap. 49. The neuropathy of sarcoidosis is discussed further in Chap. 46.

In the CNS, sarcoidosis takes the form of a granulomatous infiltration of the meninges and underlying parenchyma, most frequent at the base of the brain (see Fig. 32-4). The process is subacute or chronic in nature, mimicking other granulomatous lesions and neoplasms. One particular syndrome that has been associated with sarcoidosis consists of a circumscribed lesion of the stalk of the pituitary gland, optic chiasm, and hypothalamus, it causes visual disturbances, polydipsia, polyuria, or somnolence. Hydrocephalus, seizures, cranial-nerve palsies, and corticospinal and cerebellar signs are other occasional manifestations.

Rarely, sarcoid can be a cause of a chronic recurrent or persistent meningitis, or severe, steroid-responsive headache. Granulomas may present as a mass or as one or more focal infiltrating cortical and subcortical lesions that tend to follow the course of superficial cortical veins. Focal

Figure 32-4. Cerebral sarcoid. Gadolinium-enhanced MRI of the brain. *Top panel:* Sarcoid lesions coat the base of the brain and cerebellum and surround the pituitary stalk. The patient had pulmonary sarcoid, marked abulia, and panhypopituitarism. *Bottom panel:* Sarcoid infiltration of the basal pachymeninges and both optic nerves causing blindness. Visual acuity returned almost to normal after 2 weeks of corticosteroid administration.

cerebral signs, including seizures, presumably caused by deposits of sarcoid in the brain, are observed but are uncommon. Among the odd focal syndromes reported are an amnesic or dementing condition from infiltration of the medial temporal lobes and psychotic and related behavioral aberrations. In addition to this leptomeningitis, there is an infiltration of the dura, a pachymeningitis.

The spinal meninges and spinal cord may be infiltrated, usually independently of brain involvement, imparting a picture of chronic adhesive arachnoiditis or an inflammatory myelopathy. There is more prominent focal contrast enhancement and T2 signal abnormality on MRI than is usual for a demyelinating disease. It is one of the causes of a "longitudinally extensive myelopathy" (see Chap. 36). Characteristic of the spinal lesion is enhancement on the

surface of the cord and a degree of expansion at the level of the myelitic lesion (see "Sarcoid Myelitis" in Chap. 44). We have had experience with several such cases in which the only evidence of sarcoid was a lesion in the thoracic cord. Biopsy of the spinal cord lesion, a risky procedure, was necessary for diagnosis in some of these cases.

Diagnosis

A slight lymphocytic pleocytosis (10 to 200 cells/mm³) and a moderate increase in protein content (generally without oligoclonal bands), consistent with meningeal involvement are the usual CSF findings but many cases show no change. The glucose content is normal or slightly reduced. The spinal form may be associated with CSF block and a resultant greatly raised protein content.

The *diagnosis* of neurosarcoidosis is made on the basis of the clinical features together with clinical and biopsy evidence of sarcoid granulomas in other tissues (lymph nodes, lungs, bones, uvea, skin, and muscle). The history or presence of erythema nodosum or iritis further raises suspicion of this process. If a conventional chest radiograph does not disclose the characteristic bilateral hilar adenopathy of sarcoidosis, a thoracic CT scan may be obtained. In patients in whom the clinical suspicion remains high, positron emission tomography (PET) scanning may be useful to identify inflamed lymph nodes that are amenable to biopsy. If PET scanning is not available, radionuclide scanning with gallium-67 also shows uptake in the chest, spleen, and salivary or lacrimal glands in almost half of patients and can be a useful ancillary test.

The contrast-enhanced CT or MRI are useful means of detecting meningeal involvement and MRI may disclose periventricular and white matter lesions, although the latter pattern is usually not at all specific. Nodular or streak-like perivenular enhancement may be found on the contrast-enhanced MRI, as described by Sherman and Stern and by Christoforidis and colleagues. The intensity of enhancement may be reduced after the administration of corticosteroids.

Of historical interest is the Kveim-Siltzbach skin reaction, a granuloma in response to homogenate of spleen or lymph node from patients with known sarcoidosis. Most patients are allergic to multiple antigens including purified protein derivative (for tuberculosis) and *Candida* antigen, injected intradermally. Mild anemia, lymphocytopenia (occasional eosinophilia), slightly elevated sedimentation rate, hypercalcemia, and hyperglobulinemia are common findings in active disease. Serum levels of angiotensin-converting enzyme (ACE) are increased in two-thirds of patients with active pulmonary sarcoid but only one-fifth of those with chronic disease. Therefore it may not be helpful in instances of neurosarcoidosis. There is scant evidence that the concentration of ACE in the spinal fluid is helpful in the diagnosis of CNS sarcoidosis.

The differential diagnosis of neurosarcoidosis is broad and includes multiple sclerosis as well as entities such as Sjögren syndrome, systemic lupus, lymphoma, lymphomatoid granulomatosis, cryptococcosis and other fungal infections that cause abscesses and chronic meningitis, syphilis, Wegener granulomatosis, Whipple disease, and, of course, tuberculosis.

Treatment

Administration of corticosteroids is the main therapy for neurosarcoidosis, but it has not been subjected to an adequate trial. Other immunosuppressive drugs are effective; methotrexate, cyclophosphamide, and the anti-TNF agents (infliximab, etanercept, and adalimumab). Radiation of focal lesions had in the past found favor but is now infrequently used.

The major problem is in knowing when to treat the patient, because neurosarcoid may remit spontaneously in about half the cases. The recent onset of neurologic symptoms, indicating an active phase of the disease, or a disabling syndrome such as myelopathy, is the most certain indication for steroid therapy. One approach is to use prednisone in daily doses of 40 mg, given for 2 weeks, followed by 2-week periods in which the dose is reduced by 5 mg, until a maintenance dose of 15 to 10 mg is reached. Therapy should be continued for at least several months and in many cases is required for several years. If patients become resistant or intolerant to corticosteroids, most often one of the anti-TNF drugs is added.

Neurosyphilis

The incidence of neurosyphilis, like that of CNS tuberculosis, declined dramatically in the decades following World War II, with the advent of penicillin. In the United States, for instance, the rate of first admissions to mental hospitals because of neurosyphilis fell from 4.3 per 100,000 population (in 1946) to 0.4 per 100,000 (in 1960). However, in more recent years, the number of reported cases of early syphilis has increased, both in nonimmunocompromised individuals and particularly in HIV-infected ones. Notable also is the shift in clinical presentation of neurosyphilis from parenchymal damage, now quite rare, to one of chronic meningovascular disease, particularly in patients with AIDS. Congenital syphilis represents a special problem, which is discussed with developmental diseases in Chap. 37.

Etiology and Pathogenesis

Syphilis is caused by *Treponema pallidum*, a slender, spiral, motile organism. In this chapter, only the basic facts regarding the neurosyphilitic infection are enumerated. Figure 32-5 summarizes the neurosyphilitic diseases.

The treponeme usually invades the CNS within 3 to 18 months of inoculation with the organism. If the nervous system is not involved by the end of the second year, as shown by completely negative CSF, there is only one chance in 20 that the patient will develop neurosyphilis as a result of the original infection; if the CSF is negative at the end of 5 years, the likelihood of developing neurosyphilis falls to 1 percent. *The initial event in the neurosyphilitic infection is meningitis, which occurs in approximately 25 percent of all cases of syphilis.* Usually the meningitis is asymptomatic and can be discovered only by lumbar puncture. Exceptionally, it is more intense and causes cranial-nerve palsies, seizures, stroke, and symptoms of increased intracranial pressure. In the current era, clinicians understandably neglect to consider

Figure 32-5. Diagram of the evolution of neurosyphilis.

the possibility of neurosyphilis with these syndromes. The meningitis may persist in an asymptomatic state and, ultimately, after a period of years, may lead to parenchymal damage. In some cases, however, there is a natural subsidence of the meningitis.

All forms of neurosyphilis begin as meningitis and meningeal inflammation are the invariable accompaniment of all forms of neurosyphilis. The early clinical syndromes are aseptic meningitis and meningovascular syphilis; the late (secondary) ones are vascular syphilis (1 to 12 years), followed even later by tertiary syphilis, general paresis, tabes dorsalis, optic atrophy, or subacute myelitis. In each case this pathologic sequence results from chronic syphilitic meningitis. The intermediate mechanisms, whereby transformation occurs from persistent asymptomatic syphilitic meningitis or relapsing meningitis, to the late forms of parenchymal neurosyphilis are unknown.

From a clinical point of view, asymptomatic neurosyphilis is perhaps the most important form because, if discovered and adequately treated, the symptomatic varieties would be prevented in most instances. Because asymptomatic neurosyphilis can be recognized only by the changes in the CSF, it is advisable that all patients with syphilis should have a spinal fluid examination.

Clinical syndromes such as syphilitic meningitis, meningovascular syphilis, general paresis, tabes dorsalis, optic atrophy, and meningomyelitis seldom exist in pure form. Because all of them appear to have a common origin in meningitis, there is usually a combination of two or more syndromes with one predominating, e.g., meningitis and vascular syphilis, tabes and paresis. Even though the patient's symptoms may have been referable to only one

part of the nervous system, postmortem examination usually discloses diffuse changes, in both brain and spinal cord, which were of insufficient severity to be detected clinically.

The clinical syndromes and pathologic reactions of congenital syphilis are similar to those of the late-acquired forms, differing only in the age at which they occur. All the aforementioned biologic events are equally applicable to congenital and childhood neurosyphilis.

The CSF has been a sensitive indicator of the presence of active neurosyphilitic infection. The CSF abnormalities consist of (1) a pleocytosis of up to 100 cells/mm³, sometimes higher, mostly lymphocytes and a few plasma cells and other mononuclear cells (the counts may be lower in patients with AIDS and those with leukopenia); (2) elevation of the total protein, from 40 to 200 mg/dL; (3) an increase in gamma globulin (IgG), usually with oligoclonal banding; and (4) positive serologic tests. Elevated gamma globulin in the CSF is produced intrathecally and has been shown to be adsorbed to *T. pallidum* (Vartdal et al). Hence the gamma globulin represents a specific antibody response to this organism and is recognized as the presence of oligoclonal banding of CSF protein. The glucose content is usually normal. In congenital (but not adult) neurosyphilis, the earliest changes in the CSF, consisting of pleocytosis and an elevation of protein, may occur in the first few weeks of the infection, before the serologic tests become positive. Later, the CSF changes may vary. With either spontaneous or therapeutic remission of the disease, the cells disappear first; next the total protein returns to normal; then the gamma globulin concentration is reduced. The positive serologic tests are the last to revert to normal. Some caution is advisable in interpreting the CSF results in patients with concurrent

AIDS. On the one hand, an aseptic reaction may be the result of HIV alone; on the other hand, those with profound leukopenia or T-cell deficiencies may show little or no cellular reaction in the CSF.

Frequently, the CSF serology remains positive, despite repeated courses of therapy and the subsidence of all signs of inflammatory activity. When this occurs, it may be safely concluded that the syphilitic inflammation in the nervous system is burned out and that further progression of the disease probably will not occur. If treatment restores the CSF to normal, particularly the cell count and protein, arrest of the clinical symptoms almost always occurs. A return of cells and elevation of protein precedes or accompanies clinical relapse.

Serologic Diagnosis of Syphilis This depends on the demonstration of one of two types of antibodies: nonspecific or nontreponemal (reagin) antibodies and specific treponemal antibodies. The common tests for reagin are the Kolmer, which uses a complement fixation technique, and the Venereal Disease Research Laboratory (VDRL) slide test, which uses a flocculation technique. These reagin tests, if positive in the CSF, are virtually diagnostic of neurosyphilis. Serum reactivity alone demonstrates exposure to the organism in the past, but does not imply the presence of neurosyphilis. However, serum reagin tests are negative in a significant proportion of patients with late syphilis and in those with neurosyphilis in particular (*seronegative syphilis*). In such patients (and in patients with suspected false-positive test in the serum) it is essential to employ tests for antibodies that are directed specifically against treponemal antigens. The latter are positive in the serum of practically every instance of neurosyphilis. The fluorescent treponemal antibody absorption (FTA-Abs) test is more than adequate for the majority of clinical situations. The *T. pallidum* immobilization (TPI) test is the most reliable, but it is expensive, difficult to perform, and available in only a few laboratories.

Principal Types of Neurosyphilis

Asymptomatic Neurosyphilis

In this condition, there are no symptoms or physical signs except, in rare cases, abnormal pupils, which are light-unreactive but constrict as part of the near response (accommodate with convergence) (Argyll Robertson pupils, Chap. 14). The diagnosis is based entirely on the CSF findings, which vary, as mentioned above.

Meningeal Syphilis

Symptoms of meningeal involvement may occur at any time after infection but typically does so within the first 2 years. The most common symptoms are headache, stiff neck, cranial-nerve palsies, convulsions, and mental confusion. Occasionally, headache, papilledema, nausea, and vomiting—as a result of the presence of increased intracranial pressure—are added to the clinical picture. The patient is afebrile, unlike the case in tuberculous meningitis. The CSF always has a lymphocytic reaction, more so than in asymptomatic syphilitic meningitis. Obviously the meningitis is more intense in the symptomatic type and may be associated with hydrocephalus.

With adequate treatment, the prognosis is good. The symptoms usually disappear within days to weeks, but if the CSF remains abnormal, it is likely that some other form of neurosyphilis will subsequently develop if treatment is not continued.

Meningovascular Syphilis

As indicated earlier, this clinical syndrome is now probably the most common form of neurosyphilis. Whereas in the past, strokes from syphilitic meningitis accounted for only 10 percent of neurosyphilitic syndromes, their frequency is now estimated to be 35 percent. The most common time of occurrence of meningovascular syphilis is 6 to 7 years after the original infection, but it may be as early as 9 months or as late as 10 to 12 years. It is therefore the main manifestation of what has been termed “secondary syphilis.”

The CSF almost always shows some abnormality, usually an increase in cells, protein content, and gamma globulin, as well as a positive serologic test.

The pathologic changes in this disorder consist not only of meningeal infiltrates but also of inflammation and fibrosis of small arteries (*Heubner arteritis*), which lead to narrowing and, finally, occlusion. Most of the infarctions occur in the distal territories of medium- and small-caliber lenticulostriate branches that arise from the stems of the middle and anterior cerebral arteries. Most characteristic perhaps is an internal capsular lesion, extending to the adjacent basal ganglia. The presence of multiple small but not contiguous lesions adjacent to the lateral ventricles is another common pattern. Small, asymptomatic lesions are often seen in the caudate and lenticular nuclei. Several of our patients have had transient prodromal neurologic symptoms.

The neurologic signs that remain after 6 months will usually be permanent but adequate treatment will prevent further vascular episodes. If repeated strokes occur despite adequate therapy, one should consider the possibility of nonsyphilitic vascular disease of the brain.

Paretic Neurosyphilis (General Paresis, Dementia Paralytica)

The general setting of this form of cerebral syphilis is long-standing meningitis; hence, with tabes, it is a form of “tertiary syphilis.” As remarked above, some 15 to 20 years usually separate the onset of general paresis from the original infection. The history of the disease is entwined with many of the major historical events in neuropsychiatry. Haslam in 1798 and Esquirol at about the same time first delineated the clinical state. Bayle in 1822 commented on the arachnoiditis and meningitis, and Calmeil, on the encephalitic lesion. Nissl and Alzheimer added details to the pathologic descriptions. The syphilitic nature of the disease was suspected by Lasegue and others long before Schaudinn’s discovery of the spirochete; it was finally confirmed by Noguchi in 1913. Kraepelin’s monograph *General Paresis* (1913) is one of the classic reviews (see Merritt et al for these and other historical references).

Once a major cause of various forms of mental illness, accounting for some 4 to 10 percent of admissions to

asylums (hence the term “general paresis of the insane,” or GPI), general paresis is now a rarity. Because syphilis is acquired mainly in late adolescence and early adult life, the middle years (35 to 50) are the usual time of onset of the paretic symptoms. There have not been many cases of this process in patients with AIDS; possibly the immunodeficiency has altered the biologic reaction to the organism.

The clinical picture in its fully developed form includes progressive dementia, dysarthria, myoclonic jerks, action tremor, seizures, hyperreflexia, Babinski signs, and Argyll Robertson pupils. However, greater importance attaches to diagnosis at an earlier stage, when few of these manifestations are conspicuous. The insidious onset of memory defect, impairment of reasoning, and reduction in critical faculties—along with minor oddities of deportment and conduct, irritability, and lack of interest in personal appearance—are not too different from the general syndrome of dementia outlined in Chap. 21, especially of the frontotemporal variety. One can appreciate how elusive the disease may be at any one point in its early evolution. Indeed, with the currently low index of suspicion of the disease, diagnosis at this predegenerated stage is more often accidental than deliberate.

Although former writings have stressed the development of delusional systems, most dramatically in the direction of mania, such symptoms are exceptional in the early or preparalytic phase. More usual has been a simple dementia with reduction of intellectual capacities, forgetfulness, disorders of speaking and writing, and vague concerns about health. In a few patients the first hint of a syphilitic encephalitis, as mentioned earlier, may be facial quivering; tremulousness of the hands; indistinct, hurried speech; myoclonus; and seizures—reminiscent of delirium or acute viral encephalitis. As the deterioration continues into the paralytic stage, intellectual function progressively declines, and aphasia, agnosias, and apraxias intrude themselves.

Physical dissolution progresses concomitantly—impaired station and gait, debility, unsteadiness, dysarthria, and tremor of the tongue and hands. All these disabilities lead eventually to a bedridden state; hence the term *paretic*. Other symptoms are hemiplegia, hemianopia, aphasia, cranial-nerve palsies, and seizures with prominent focal signs of unilateral frontal or temporal lobe disease—a syndrome known pathologically as Lissauer cerebral sclerosis.

Agitated, delirious, depressive, and schizoid psychoses are special psychiatric syndromes that can be differentiated from general paresis by the lack of mental decline, neurologic signs, and CSF findings. The neuropsychiatric features of this disease create a picture unlike that of most degenerative diseases—with the notable exception of the category of frontotemporal dementias discussed in Chap. 39. It is well to remember that many of our ideas about the brain and the mind were shaped historically by this disease.

Pathologic Changes This consists of meningeal thickening, brain atrophy, ventricular enlargement, and granular ependymitis. Microscopically, the perivascular spaces are filled with lymphocytes, plasma cells, and mononuclear cells; nerve cells have disappeared; there are numerous rod-shaped microglia and plump

astrocytes in parts of the cortex devastated by neuronal loss; iron is deposited in mononuclear cells; and, with special stains, spirochetes are visible in the cortex. The changes are most pronounced in the frontal and temporal lobes. The ependymal surfaces of the ventricles are studied with granular elevations protruding between ependymal cells (granular ependymitis). Meningeal fibrosis with obstructive hydrocephalus is present in many cases.

Treatment The prognosis in early treated cases with antibiotics has in the past been fairly good; 35 to 40 percent of patients made some occupational readjustment; in another 40 to 50 percent, the disease was arrested but left the patient dependent. Without treatment as discussed below there is progressive mental decline, and death occurs within 3 to 4 years.

Tabetic Neurosyphilis (Tabes Dorsalis)

This type of neurosyphilis, described by Duchenne in his classic monograph *L'ataxie locomotrice progressive* (1858), usually develops 15 to 20 years after the onset of the infection. The major symptoms are lightning pains, ataxia, and urinary incontinence; the chief signs are absent tendon reflexes at knee and ankle, impaired vibratory and position sense in feet and legs, and a Romberg sign. The ataxia is purely a result of the sensory defect. Power, by contrast, is fully retained in most cases. The pupils are abnormal in more than 90 percent of cases, usually Argyll Robertson in type, and the majority of patients show ptosis or some degree of ophthalmoplegia. Optic atrophy is frequent. The lancinating or lightning pains (present in more than 90 percent of cases) are, as their name implies, sharp, stabbing, and brief, like a flash of lightning. They are more frequent in the legs than elsewhere but roam over the body from face to feet, sometimes playing persistently on one spot “like the repeated twanging of a fiddle string,” as Wilson remarked. They may come in bouts lasting several hours or days. “Pins and needles” feelings, coldness, numbness, tingling, and other paresthesias are also present and are associated invariably with impairment of tactile, pain, and thermal sensation. The bladder is insensitive and hypotonic, resulting in unpredictable overflow incontinence. Constipation and megacolon as well as impotence are other expressions of dysfunction of the sacral roots and ganglia.

In the established phase of the disease, now seldom seen, ataxia is the most prominent feature. The patient totters and staggers while standing and walking. In mild form it is best seen as the patient walks between obstacles or along a straight line, turns suddenly, or halts. To correct the instability, the patient places his feet and legs wide apart, flexes his body slightly, and repeatedly contracts the extensor muscles of his feet as he sways (*la danse des tendons*). In moving forward, the patient flings his stiffened leg abruptly, and the foot strikes the floor with a resounding thump in a manner quite unlike that seen in the ataxia of cerebellar disease. The patient clatters along in this way with eyes glued to the floor. If his vision is blocked, he is rendered helpless. When the ataxia is severe, walking becomes impossible despite relatively normal strength of the leg muscles. A Romberg sign is grossly manifest.

Trophic lesions, perforating ulcers of the feet, and Charcot joints are characteristic complications of the tabetic state.

The deformity of deafferented *Charcot joints* occurs in less than 10 percent of tabetics (the most common cause nowadays is diabetic neuropathy, which is also a cause of lancinating pains). Most often the hips, knees, and ankles are affected, but occasionally also the lumbar spine or upper limbs are affected. The process generally begins as an osteoarthritis, which, with repeated injury to the insensitive joint, progresses to destruction of the articular surfaces. Osseous architecture disintegrates, with fractures, dislocations, and subluxations, only some of which occasion discomfort. The arthropathy has been observed to occur as frequently in the burned-out as in the active phase of tabes; hence it is only indirectly related to the syphilitic process. Although the basic abnormality appears to be repeated injury to an anesthetic joint, the process need not be painless. Presumably a deep and incomplete hypalgesia and loss of autonomic function are enough to interfere with protective mechanisms. The Charcot joint is addressed further in Chap. 46 in the context of sensory polyneuropathies. Visceral crises represent another interesting manifestation of this disease, now rarely seen. The gastric ones are the best known. The patient is seized abruptly with epigastric pain that spreads around the body or up over the chest. There may be a sense of thoracic constriction as well as nausea and vomiting—the latter repeated until nothing but blood-tinged mucus and bile are raised. The symptoms may last for several days; a barium swallow sometimes demonstrates pylorospasm. The attack subsides as quickly as it came, leaving the patient exhausted, with a soreness of the epigastric skin. Intestinal crises with colic and diarrhea, pharyngeal and laryngeal crises with gulping movements and dyspneic attacks, rectal crises with painful tenesmus, and genitourinary crises with strangury and dysuria are all less frequent but well-documented types.

In most cases now seen, the CSF is normal when the patient is first examined (so-called burned-out tabes). It is abnormal less often than in general paresis.

Pathology *Pathologic study* reveals a striking thinness and grayness of the posterior roots, principally lumbosacral, and thinning of the spinal cord mainly as a result of the degeneration of the posterior columns. Only a slight outfall of neurons is observed in the dorsal root ganglia; the peripheral nerves are essentially normal. For many years there was an argument as to whether the spirochete first attacked the posterior columns of the spinal cord, the posterior root as it pierced the pia, the more distal part of the radicular nerve where it acquires its arachnoid and dural sheaths, or the dorsal root ganglion cell. The observations of our colleagues of rare active cases have shown the inflammation to be all along the posterior root; the slight dorsal ganglion cell loss and posterior column degeneration were found to be secondary.

The hypotonia, areflexia, and ataxia relate to destruction of proprioceptive fibers in the sensory roots. The hypotonia and insensitivity of the bladder are caused by deafferentation at the S2 and S3 levels; the same is true

of the impotence and obstipation. Lightning pains and visceral crises cannot be fully explained but are probably attributable to incomplete posterior root lesions at different levels. Analgesia and joint insensitivity relate to the partial loss of A and C fibers in the roots.

Treatment If the CSF is positive, the patient should be treated with penicillin, as described below. If, however, there is no pleocytosis, the CSF protein content is normal, and there is no evidence of cardiovascular or other types of syphilis, antisyphilitic treatment is not necessary. We are uncertain of the proper course of treatment in patients with tabes who have survived many decades with HIV. Residual symptoms in the form of lightning pains, gastric crises, Charcot joints, or urinary incontinence frequently continue long after all signs of active neurosyphilitic infection have disappeared. These should be treated symptomatically rather than by antisyphilitic drugs.

Syphilitic Optic Atrophy

This takes the form of progressive blindness beginning in one eye and then involving the other. The usual finding is a constriction of the visual fields, but scotomata may occur in rare cases. The optic discs are gray-white. Other forms of neurosyphilis, particularly tabes dorsalis, not infrequently coexist. The CSF is almost invariably abnormal, although the degree of abnormality may be slight in some cases. The prognosis is poor if vision in both eyes is greatly reduced. If only one eye is badly affected, sight in the other eye can usually be saved. In exceptional cases, visual impairment may progress, even after the CSF becomes negative. The pathologic changes consist of perioptic meningitis, with subpial gliosis and fibrosis replacing degenerated optic nerve fibers. Exceptionally there are vascular lesions with infarction of central parts of the nerve.

Spinal Syphilis

There are several types of spinal syphilis other than tabes. Two of them, *syphilitic meningomyelitis* (formerly called Erb spastic paraplegia because of the predominance of bilateral corticospinal tract signs) and *spinal meningovascular syphilis*, are observed from time to time, although less often than tabes. Spinal meningovascular syphilis may occasionally take the form of an anterior spinal artery syndrome. In meningomyelitis, there is subpial loss of myelinated fibers and gliosis as a direct result of the chronic fibrosing meningitis. Gumma of the spinal meninges and cord seldom is found. It was not present in a single case in Merritt and Adams' study of spinal syphilis. Progressive muscular atrophy (syphilitic amyotrophy) is a very rare disease of questionable syphilitic etiology; most cases are degenerative (see Chap. 39). Also rare is syphilitic hypertrophic pachymeningitis or arachnoiditis, which allegedly gives rise to radicular pain, amyotrophy of the hands, and signs of long tract involvement in the legs (*syphilitic amyotrophy with spastic-ataxic paraparesis*). In all these syndromes there is an abnormal CSF, unless, of course, the neurosyphilitic infection is burned out (see Chap. 44).

The prognosis in spinal neurosyphilis is uncertain. There is improvement or at least an arrest of the disease

process in most instances, although a few patients may progress slightly after treatment is begun. A steady advance of the disease in the face of a negative CSF usually means that there has been a secondary constrictive myelopathy or that the original diagnosis was incorrect and the patient suffers from some other disease, e.g., a spinal form of multiple sclerosis as a degenerative disease.

Syphilitic Nerve Deafness and Vestibulopathy

This may occur in either early or late syphilitic meningitis and may be combined with other syphilitic syndromes. Because this may produce a treatable vestibular syndrome of vertigo, with or without hearing loss, syphilis serology should be tested in patients with cryptic vestibular dysfunction. Some of the characteristics of vestibular neurosyphilis are identical to those of Ménière disease, including episodic loss of function (Baloh and Honrubia). Curiously, there is seldom a history of clear primary syphilitic infection. The pathology, mainly endarteritis in the cochlea and labyrinths, is identical to the more common congenital syphilitic deafness, which is described in Chap. 37.

Treatment of Neurosyphilis

The treatment of all of these forms of neurosyphilis consists of the administration of penicillin G, given intravenously in a dosage of 18 to 24 million units daily (3 to 4 million units q4h) for 10 to 14 days. The CDC recommends procaine penicillin and probenecid and ceftriaxone as an alternative. Penicillin is so much preferred that even these patients are ideally desensitized to the drug. The Jarisch-Herxheimer reaction, which occurs after the first dose of penicillin and is a matter of concern in the treatment of primary syphilis, is of little consequence in neurosyphilis; it usually consists of no more than a mild temperature elevation and leukocytosis.

The effects of treatment on certain symptoms of neurosyphilis, especially of tabetic neurosyphilis, are unpredictable and often little influenced by treatment with penicillin; they require symptomatic measures. Lightning pains may respond to gabapentin or carbamazepine. Analgesics may be helpful, but opiates should generally be avoided. Neuropathic (Charcot) joints require bracing or fusion. Atropine and phenothiazine derivatives are said to be useful in the treatment of visceral crises.

In all forms of neurosyphilis, the patient should be reexamined every 3 to 6 months after treatment and the CSF should be retested after a 6-month interval. If after 6 months the patient is free of symptoms and the CSF abnormalities have been reversed (disappearance of cells as well as reduction in protein, gamma globulin, and serology titers), no further treatment is indicated. Followup should include clinical examinations at approximately 12 months and another lumbar puncture. If a pleocytosis remains, these procedures should be repeated every 6 months. In the opinion of most experts, a persistent weakly positive serologic (VDRL) test after the cells and protein levels have returned to normal does not constitute an indication for additional treatment. Such a CSF formula ensures that the disease is quiescent or arrested. Others are not convinced of the reliability of this

concept and prefer to give more penicillin. If at the end of 6 months there are still an increased number of cells and an elevated protein in the fluid, another full course of penicillin should be given. Clinical relapse is almost invariably attended by recurrence of cells and increase in protein levels. Rapid clinical progression in the face of a negative CSF suggests the presence of a nonsyphilitic disease of the brain or cord.

Lyme Disease (Erythema Chronicum Migrans; Borreliosis)

Until comparatively recently, the nonvenereal spirochetes were of little interest to neurologists of the Western world. Yaws, pinta, and endemic syphilis rarely, if ever, affected the nervous system. Leptospirosis was essentially an acute liver disease with only one variant causing nonicteric lymphocytic meningitis; tick- and louse-borne relapsing fevers were medical curiosities that did not involve neurologists. However, in the late 1970s, a multisystem disease with prominent neurologic features was recognized in the eastern United States (it had been known in Northern Europe). It was named after the town of Lyme, Connecticut, where a cluster of cases was first recognized in 1975. An early skin manifestation of the disease had previously been described in Western Europe and referred to as *erythema chronicum migrans*. In 1982, Burgdorfer and colleagues identified the causative spirochetal agent, *Borrelia burgdorferi*. Later manifestations of the disease—taking the form of acute radicular pain followed by chronic lymphocytic meningitis and frequently accompanied by peripheral and cranial neuropathies—had long been known in Europe as the Bannwarth or Garin-Bujadoux syndrome. The identity of these diseases has been established, as well as their close relationship to relapsing fever—a disease that is also caused by spirochetes of the genus *Borrelia* and transmitted by ticks. The entire group is now classed as the borrelioses but there are notable clinical and serologic differences between the American and European varieties of the disease.

In humans, all these spirochetoses, if untreated, induce a subacute or chronic illness that evolves in ill-defined stages, with early spirochetemia, vascular damage in many organs, and a high level of neurotropism. As in syphilis, the nervous system is invaded early in the form of asymptomatic meningitis. Later, neurologic abnormalities appear, but only in small a proportion of such cases. The early neurologic complications are mainly derivations of meningitis. Unlike syphilis, peripheral and cranial nerves are often damaged (see further on and Chap. 46). Immune factors may be important in the later phases of the disease and in the development of the neurologic syndromes.

Lyme disease is less acute than leptospirosis (Weil disease) and less chronic than syphilis. It successively involves the skin, nervous system, heart, and articular structures over a period of a year or longer although one aspect or another may predominate. The responsible organism, as stated earlier, is the spirochete *B. burgdorferi* and the vector in the United States is the common ixodid tick. The precise roles of the infecting spirochete, the antibodies it induces, and other features of the human

host response in the production of clinical symptoms and signs are not fully understood, but the development of an animal model by Pachner and colleagues suggests that there may be a chronic form of *Borrelia* infection.

Lyme borreliosis has a worldwide distribution but the typical neurologic manifestations differ slightly in Europe and America, as emphasized in the review by Garcia-Monico and Benach (as does the serologic testing). In the United States, where approximately 15,000 cases are reported annually, the disease is found mainly in the Northeast and the North Central states. Most infections are acquired from May to July. In 60 to 80 percent of cases, a skin lesion (erythema chronicum migrans, or erythema migrans) at the site of a tick bite is the initial manifestation, occurring within 30 days of exposure. It is a solitary, enlarging, ring-like erythematous lesion that may be surrounded by annular satellite lesions. Usually fatigue and influenza-like symptoms (myalgia, arthralgia, and headache) are associated, and these seem to be more prominent in the North American (*B. burgdorferi*) than the European form of the illness (*Borrelia afzelii* and *Borrelia garinii*)—possibly attributable to a more virulent species of spirochete (Nadelman and Wormser). This assumes importance in patients who may have acquired the illness in another part of the world in whom the correct diagnosis may be missed if the specific antibody for the regional organism is not sought. The European variant has a propensity to cause the painful lymphocytic meningoradiculitis, Bannwarth syndrome, as summarized in the review by Pachner and Steiner.

Weeks to months later, neurologic or cardiac symptoms appear in 15 and 8 percent of the cases, respectively. Still later, if the patient remains untreated, arthritis or, more precisely, synovitis develops in approximately 60 percent of the cases. Death from this disease does not occur; consequently, little is known of the pathology. A long period of disability is to be expected if the disease is not recognized and treated.

Diagnosis is not difficult during the summer season in regions where the disease is endemic and when all the clinical manifestations are present. But in some cases, a skin lesion is not observed or may have been forgotten, or there may have been only a few or no secondary lesions and the patient is first seen in the neurologic phase of the illness. Then clinical diagnosis may be difficult.

Neurologic Manifestations

The usual pattern of neurologic involvement is one of aseptic meningitis or a fluctuating meningoencephalitis with cranial or peripheral neuritis, lasting for months (Reik). By the time the neurologic disturbances appear, the systemic symptoms and skin lesions may have long since receded, usually by many weeks or months. A cardiac disorder, which may accompany or occur independently of the neurologic changes, takes the form of myocarditis, a pericarditis, or an atrioventricular block.

The initial nervous system symptoms are rather nonspecific. They consist of headache, mild stiff neck, nausea and vomiting, malaise, and chronic fatigue, fluctuating over a period of weeks to months. Mild meningism without pleocytosis has been seen early in the syndrome

and it may be worth repeating the studies in highly suspicious cases. These symptoms relate to the meningitis. There is a CSF lymphocytosis with cell counts from 50 to 3,000/mL and protein levels from 75 to 400 mg/dL, but both values are typically in the lower part of the range. Polymorphonuclear cells may be prominent in the early part of the illness. Usually the glucose content is normal. Somnolence, irritability, faulty memory, depressed mood, and behavioral changes have been interpreted as marks of encephalitis but are difficult to separate from the effects of meningitis. Seizures, choreic movements, cerebellar ataxia, and dementia have been reported but are infrequent. A myelitic syndrome, causing quadriplegia, is also documented as another rare manifestation.

In about half the cases, cranial neuropathies become manifest within weeks of onset of the meningitic illness. The most frequent is a unilateral or bilateral facial palsy but involvement of other cranial nerves, including the abducens and optic nerve has been observed, usually in association with meningitis. One-third to one-half of the patients with meningitis have multiple radicular or peripheral nerve lesions in various combinations. These are described in Chap. 46. In addition to facial palsies, a severe and painful meningoradiculitis of the cauda equina (Bannwarth syndrome) is particularly characteristic and seems to be more common in Europe than in the United States (there are other causes of this syndrome, including herpesvirus and cytomegalovirus). There is also an infrequent occurrence of Guillain-Barré syndrome following Lyme infection, again apparently more common in Europe, but there is no reason to believe that the illness then differs from other cases of the acute inflammatory demyelinating polyneuropathy that follows numerous other infections.

Because of the paucity of autopsy material, knowledge of the nature of Lyme encephalitis is still imprecise. Such pathologic material as is available has shown a perivascular lymphocytic inflammatory process of the leptomeninges and the presence of subcortical and periventricular demyelinating lesions, like those of multiple sclerosis. Oksi and colleagues have recovered *B. burgdorferi* DNA from the involved areas, suggesting that the encephalitis is caused by direct invasion by the spirochete.

In the peripheral nerves (see Chap. 46) there are scattered lymphocytic infiltrates, without vasculitis. It seems likely to us that the organism will eventually be found in nervous tissue as the cause of disease, as there is active antibody production reflected in the CSF.

A problematic aspect of Lyme disease relates to the development in some patients of a mild chronic encephalopathy coupled with fatigue. That such a disorder may occur after a well-documented attack of Lyme disease is undoubted. However, in the absence of a history of the characteristic rash, arthritis, or aseptic meningitis, the attribution to Lyme disease of fatigue alone or various other vague mental symptoms, such as difficulty in concentration, is almost always erroneous, even if there is serologic evidence of exposure to the spirochete. It would be an understatement that a large number of patients are persuaded that various symptoms are the result of Lyme infection and seek and receive unnecessary treatment.

Laboratory Diagnosis

In acute and subacute cases that involve the spinal or cranial nerve roots or spinal cord, the CSF routinely shows a pleocytosis (20 to 250 lymphocytes/mm³) with moderately elevated protein; the glucose concentration is usually normal but may be slightly depressed. The majority of cases with facial palsy alone are associated with this CSF formula, but there are exceptions.

Serologic tests are of great value but must be interpreted with caution if there has not been an inciting clinical syndrome of erythema migrans or arthritis or a well-documented tick bite. The most valuable initial screening is performed by the ELISA; if both acute and convalescent sera are tested, approximately 90 percent of patients have a positive IgM response. After the first few weeks, most patients have elevated IgG antibody responses to the spirochete (Berardi et al); a positive test of this nature may simply reflect prior exposure. The ratio of IgG intrathecal anti-*Borrelia* antibody to that of the serum is greater than 2 in cases of neuroborreliosis; this elevated ratio is a necessary criterion for the diagnosis in Europe. However, Blanc and colleagues studied a sample of 123 consecutive patients with clinical signs of neurologic involvement and found the sensitivity of the index was only 75 percent and the specificity was 97 percent. These authors have proposed more pragmatic diagnostic, but somewhat contrived, criteria for neuroborreliosis, consisting of the presence of 4 of the following 5 items: no past history of neuroborreliosis, active CSF ELISA serology, anti-*Borrelia* antibody index greater than 2, favorable outcome after specific antibiotic treatment, and no alternative diagnosis. False-positive tests do occur in some of the conditions that react to syphilitic reagent; *B. burgdorferi*-specific antibodies can also be demonstrated in the CSF (these are also reflected by the presence of oligoclonal bands).

Positive ELISA testing should be pursued further with Western blot or immunoblot analysis or other more specific serologies in clinically uncertain cases. Although these latter tests are difficult to carry out and have not been entirely standardized, the presence of both IgG and IgM antibodies is strongly supportive of a recent infection, whereas the IgG is useful in later cases. These laboratory diagnostic issues are discussed and put in perspective by Golightly. If the European variety of borreliosis is suspected, different serologic tests are required but the general principles of diagnosis are the same as for cases in the United States and elsewhere.

In only approximately 30 percent of cases, the organism can be detected in the spinal fluid using PCR techniques, usually early in the neurologic illness.

In the chronic phase of the disease, CT and MRI in cases of encephalopathy may display multifocal and periventricular cerebral lesions but these are by no means indicative alone of Lyme disease, as they also appear in numerous other conditions.

Treatment

The recommended treatment in the first stage of the disease, mainly referring to the initial rash and the subsequent presence of facial or other cranial nerve palsies alone, is oral or doxycycline (100 mg bid) for 14 days.

Alternate therapies include amoxicillin 500 mg tid, used sometimes in children, or cefuroxime axetil 500 mg bid. CNS cardiac and arthritic disease can thereby be prevented in almost all cases. It follows that one is justified in being suspect of cases of "late Lyme" that have undergone adequate early treatment. Once the meninges and central or peripheral nervous system are implicated probably most effective is ceftriaxone, 2 g daily, usually given intravenously for a similar period.

Tetracycline, 500 mg qid for 30 days, is recommended by Reik for patients who are allergic to these intravenous drugs. Other alternative drugs are cefotaxime 2 g IV q8h and penicillin G 18 to 20 million units per day in divided doses q4h. For late abnormalities, no treatment has proved to be effective. However, most of the symptoms tend to regress regardless of the type of treatment given.

According to Kaiser, more than 90 percent of subacute neuropathies and facial palsies resolve by 1 year after treatment, but a smaller proportion of spastic and ataxic myelopathy cases are improved. In other studies, up to a fifth of children with facial palsies have residual weakness.

Leptospirosis

This systemic spirochetal infection, caused by *Leptospira interrogans*, is characterized primarily by hepatitis but may include aseptic meningitis during the second part of a biphasic illness. Initially there is high fever, tender muscles, chest and abdominal pain, and cough. An extreme form (Weil disease) comprises hepatic and renal failure. Prominent conjunctival suffusion and photophobia are typical of leptospirosis and should draw attention to the diagnosis. The CSF during the meningitic stage contains approximately 100 lymphocytes/mm³, but cell counts in excess of 10,000 have been reported and the protein concentration may reach high levels. Subarachnoid and intracerebral bleeding, probably from inflamed blood vessels, is known to occur. The diagnosis is made by serologic methods (ELISA, indirect hemagglutination assay, followed by specific agglutination tests and culture).

Treatment Antibiotic treatment seems to be effective only if implemented during the initial febrile phase. Penicillin, doxycycline, or ceftriaxone have been used. The meningitis is usually self-limited.

FUNGAL INFECTIONS OF THE NERVOUS SYSTEM

Described in the following pages are a number of infectious diseases, much less common than bacterial ones, in which a systemic fungal infection secondarily involves the CNS. For the neurologist, the diagnosis rests on two lines of clinical information: evidence of infection in the lungs, skin, or other organs and the appearance of a subacute meningeal or multifocal encephalitic disorder. Although a large number of fungal diseases may involve the nervous system, only a few do so with regularity. Of 57 cases assembled by Walsh and coworkers, there were 27 of candidiasis, 16 of aspergillosis, and 14 of cryptococcosis. Among the opportunistic mycoses (see below), the

majority is accounted for by species of *Aspergillus* and *Candida*. Mucormycosis and coccidioidomycosis are less frequent, and blastomycosis and actinomycosis (*Nocardia*) occur in isolated instances. However, of all of these infections, cryptococcal meningitis, which can occur in immunocompetent patients, is being seen more frequently as a result of its association with AIDS. Infections related to impairment of the body's protective mechanisms are referred to as *opportunistic* and include not only fungal infections but also those caused by certain bacteria (*Pseudomonas* and other gram-negative organisms, *L. monocytogenes*), protozoa (*Toxoplasma*), and viruses (cytomegalovirus, herpes simplex, and varicella zoster). It follows that these types of infections should be considered in the aforementioned clinical situations.

General Features

Fungal infections of the CNS may arise without obvious predisposing cause, but they typically complicate some other disease process that suppresses immune function such as AIDS, cancer chemotherapy, organ transplantation, severe burns, leukemia, lymphoma or other malignancy, diabetes, collagen vascular disease, or prolonged corticosteroid therapy. The factors operative in these clinical situations are the interference with the body's normal flora and impaired T-cell and humoral responses. Thus fungal infections tend to occur in patients with leukopenia, inadequate T-lymphocyte function, or insufficient antibodies.

Fungal meningitis develops insidiously, as a rule, over a period of several days or weeks, similar to tuberculous meningitis; the symptoms and signs are also much the same as with tuberculous infection. Involvement of several cranial nerves, arteritis with thrombosis and infarction of brain, multiple cortical and subcortical microabscesses, and hydrocephalus frequently complicate the course of fungal meningitis, just as they do in all chronic meningitides. Sometimes the patient is afebrile or has only intermittent fever.

The spinal fluid changes in fungal meningitis are like those of tuberculous meningitis. Pressure is elevated to a varying extent, pleocytosis is moderate and lymphocytes predominate. Exceptionally, in acute cases, a pleocytosis above 1,000/mm³ and a predominant polymorphonuclear response are observed (also seen with the bacterial infections, nocardia, and actinomycosis). On the other hand, in patients with AIDS or with pronounced leukopenia for other reasons, the pleocytosis may be minimal or even absent. Glucose is subnormal and protein is elevated, sometimes to very high levels.

The specific diagnosis is made from smears of the CSF sediment, from cultures and by demonstrating antigens of the organism by immunodiffusion, latex particle agglutination, or comparable antigen recognition tests. The CSF examination should also include a search for tubercle bacilli and abnormal white cells because of the not infrequent concurrence of fungal infection and tuberculosis, leukemia, or lymphoma.

Some of the special features of the more common fungal infections are indicated later.

Cryptococcosis (Torulosis, European Blastomycosis)

Cryptococcosis (formerly called *torulosis*) is one of the more frequent fungal infections of the CNS and it occurs in both normal and immunocompromised hosts. The causative organism is usually *Cryptococcus neoformans* but *Cryptococcus gattii* has also been implicated. *Cryptococcus* is a common soil fungus found in the roosting sites of birds, especially pigeons. Usually the respiratory tract is the portal of entry, less often the skin and mucous membranes. The pathologic changes are those of granulomatous meningitis; in addition, there may be small granulomas and cysts within the cerebral cortex, and sometimes larger granulomas and cystic nodules deep in the brain (cryptococcomas). The cortical cysts contain a gelatinous material and large numbers of organisms; the solid granulomatous nodules are composed of fibroblasts, giant cells, aggregates of organisms, and areas of necrosis.

Cryptococcal meningitis has an indistinct clinical syndrome. Most cases evolve subacutely, like other fungal infections and tuberculosis. In most cases, headaches, fever, and stiff neck are lacking altogether, and the patient presents with symptoms of gradually increasing intracranial pressure because of hydrocephalus (papilledema is present in half such patients) or with a confusional state, dementia, cerebellar ataxia, or spastic paraparesis, usually without other focal neurologic deficit. A few cases have had an explosive onset, rendering the patient quite ill in a day. Large series of affected patients indicate that 20 to 40 percent of patients have no fever when first examined (the figure applies to patients without AIDS). Cranial-nerve palsies are infrequent. Rarely, a granulomatous lesion forms in one part of the brain, and the only clue to the etiology of the cerebral mass is a lung lesion and an abnormality of the CSF.

Meningovascular lesions, presenting as small deep strokes in an identical manner to meningovascular syphilis, may be superimposed on the clinical picture. A pure motor hemiplegia, like that caused by a hypertensive lacune, has been the most common type of stroke in our experience.

The course of the disease is quite variable. It may be fatal within a few weeks if untreated. More often, it is steadily progressive over a period of several weeks or months; in a few patients, it may be remarkably indolent, lasting for years, during which there may be periods of clinical improvement and normalization of the CSF. Lymphoma, Hodgkin disease, leukemia, carcinoma, tuberculosis, and other debilitating diseases that alter the immune responses are predisposing factors in as many as half the patients. As already emphasized, patients with AIDS are particularly vulnerable to cryptococcal infection; estimates are that 6 to 12 percent of AIDS patients are subject to meningoencephalitis with the organism but this seems higher than we have observed.

The spinal fluid shows a variable lymphocytic pleocytosis, usually less than 50 cells/mm³, but there may be few or no cells in a patient with AIDS (two-thirds have 5 or fewer cells/mm³). The initial CSF formula may

display polymorphonuclear cells but it rapidly changes to a lymphocytic predominance. The glucose is reduced in three-fourths of cases (again, it may be normal in AIDS patients) and the protein may reach high levels.

Specific diagnosis in developed regions depends on finding *C. neoformans* antigens in the CSF. The organism may be seen as spherical cells, 5 to 15 μm in diameter, which retain Gram stain and are surrounded by a thick, refractile capsule. India ink preparations are distinctive and diagnostic in experienced hands (debris and talc particles from the gloves used in lumbar puncture may be mistaken for the organism) but the rate of positive tests under the best circumstance is 75 percent. The carbon particles of the dye fail to penetrate the capsule, leaving a wide halo around the doubly refractile wall of the organism. Large volumes of CSF (20 to 40 mL) may be needed to find the organism, but in others they are prolific. The search for these organisms is particularly important in AIDS patients, in whom the CSF values for cells, glucose, and proteins may be entirely normal but difficulties interpreting the India ink preparation have led to its being used less often. A latex agglutination test for the cryptococcal polysaccharide antigen in the CSF is now widely available and gives rapid results. The latter test, if negative, excludes cryptococcal meningitis with approximately 90 percent reliability in AIDS patients and slightly less in others (Chuck and Sande). In most cases the organisms grow readily in Sabouraud glucose agar at room temperature and at 37°C (98.6°F), but these results may not appear for days. Newer enzyme-linked immunoadsorption tests are being evaluated.

The principal diseases to be considered in diagnosis are tuberculous meningitis; granulomatous cerebral vasculitis (normal glucose values in CSF); unidentifiable forms of viral meningoencephalitis (normal CSF glucose values); sarcoidosis; and lymphomatosis or carcinomatosis of meninges (neoplastic cells in CSF).

Treatment In patients without AIDS, this consists of intravenous administration of amphotericin B, given in a dose of 0.7 to 1.0 mg/kg/d. Intrathecal administration of the drug in addition to the intravenous route appears not to be essential. Administration of the drug should be discontinued if the blood urea nitrogen reaches 40 mg/dL and resumed when it descends to normal levels. Renal tubular acidosis also frequently complicates amphotericin B therapy. The addition of flucytosine (100 mg/kg/d) to amphotericin B results in fewer failures or relapses, more rapid sterilization of the CSF, and less nephrotoxicity than the use of amphotericin B alone because it permits the reduction of the amphotericin dose to 0.3 to 0.5 mg/kg/d. Both medications are usually continued for at least 6 weeks—longer if CSF cultures remain positive.

However, this regimen, which has a success rate of 75 to 85 percent in immunocompetent patients, has proven to be much less effective in patients with AIDS. The recommended treatment in these circumstances is amphotericin supplemented by flucytosine for 2 weeks. Subsequently, fluconazole, an oral triazole antifungal agent, is given (or less preferably, oral itraconazole),

for up to 1 year or indefinitely to prevent relapse (Saag et al; Powderly et al). The optimum use of these drugs has not been settled, and some trials have yielded ambiguous results in both AIDS and other patients. A current perspective on treatment can be obtained in the reference of Tunkel and Scheld and details of a randomized trial in AIDS comparing amphotericin as above to a regimen of additional flucytosine is given by Day and colleagues. They showed no advantage to an initial regimen of both drugs over amphotericin alone.

Mortality from cryptococcal meningoencephalitis, even in the absence of AIDS or other disease, is high.

Candidiasis (Moniliasis)

Candidiasis is probably the most frequent opportunistic fungus infection. The notable antecedents of *Candida* sepsis are severe burns and the use of total parenteral nutrition, especially in children. Urine, blood, skin, and particularly the heart (myocardium and valves) and lungs (alveolar proteinosis) are the usual sites of primary infection. No special features distinguish this fungal infection from others; meningitis, meningoencephalitis, and cerebral abscess, usually multiple and small, are the main modes of clinical presentation. Generally, the CSF contains several hundred (up to 2,000) cells/mm³. Yeast can be seen on direct microscopy in half the cases. Even with treatment (intravenous amphotericin B), the prognosis is extremely grave.

Aspergillosis

In most instances, this infection has presented as a chronic sinusitis (particularly sphenoidal), with osteomyelitis at the base of the skull or as a complication of otitis and mastoiditis. Cranial nerves adjacent to the infected bone or sinus may be involved. We have also observed brain abscesses and cranial and spinal dural granulomas. In one of our patients, the *Aspergillus* organisms had formed a granulomatous mass that compressed the cervical spinal cord. Aspergillosis does not present as meningitis but hyphal invasion of cerebral vessels may occur, with thrombosis, necrosis, and hemorrhage; i.e., it is an infectious vasculitis. In some cases, the infection is acquired in the hospital, and in most it is preceded by a pulmonary infection that is unresponsive to antibiotics. Diagnosis can often be made by finding the organism in a biopsy specimen or by culturing it directly from a lesion. Also, specific antibodies and galactomannan are detectable in the blood.

Treatment Liposomal amphotericin in combination with voriconazole, and echinocandins in some cases, is the recommended treatment, but this regimen is not as effective for aspergillosis as it is for cryptococcal disease. The addition of itraconazole, 200 mg bid, in less-immunocompromised patients is recommended. If amphotericin B is given after surgical removal of the infected material, some patients recover.

Mucormycosis (Zygomycosis, Phycomycosis)

This is a malignant infection of cerebral vessels with one of the Mucorales. It occurs as a rare complication in patients with diabetes, especially during diabetic acidosis,

in drug addicts, and in those with leukemia and lymphoma, particularly those treated with corticosteroids and cytotoxic agents.

The cerebral infection begins in the nasal turbinates and paranasal sinuses and spreads from there along infected vessels to the retroorbital tissues (where it results in proptosis, ophthalmoplegia, and edema of the lids and retina) and then to the adjacent brain, causing hemorrhagic infarction. Numerous hyphae are present within the thrombi and vessel wall, often invading the surrounding parenchyma. The cerebral form of mucormycosis is usually fatal in short order. Rapid correction of hyperglycemia and acidosis and treatment with liposomal amphotericin or posaconazole have resulted in recovery in some patients. The differential diagnosis is typically from septic cavernous sinus thrombosis in a diabetic.

Coccidioidomycosis, Histoplasmosis, Blastomycosis, and Actinomycosis

Coccidioidomycosis is a common infection in the southwestern United States. It usually causes only a benign, influenza-like illness with pulmonary infiltrates that mimic those of nonbacterial pneumonia, but in a few individuals (0.05 to 0.2 percent), the disease takes a disseminated form, of which meningitis may be a part. The pathologic reactions in the meninges and CSF and the clinical features are very much like those of tuberculous meningitis. *Coccidioides immitis* is recovered with difficulty from the CSF but readily from the lungs, lymph nodes, and ulcerating skin lesions. Diagnosis is made from CSF serology.

Treatment consists of the intravenous administration of amphotericin B coupled with implantation of an Ommaya reservoir into the lateral ventricle, permitting injection of the drug for a period of years. Instillation of the drug by repeated lumbar punctures is an alternative, albeit cumbersome, procedure. Even with the most assiduous programs of treatment, only about half the patients with meningeal infections survive.

A similar type of meningitis may occasionally complicate *histoplasmosis*, *blastomycosis*, and the anaerobic bacterium *actinomycosis*. These chronic meningitides possess no specific features except that actinomycosis, like some cases of tuberculosis and nocardiosis, may cause a *persistent polymorphonuclear pleocytosis* (see "Chronic Persistent and Recurrent Meningitis" in Chap. 33). The CSF yields an organism in a minority of patients, so that diagnosis depends on culture from extraneural sites, biopsy of brain abscesses if present, as well as knowledge of the epidemiology of these fungi. Patients with chronic meningitis in whom no cause can be discovered should also have their CSF tested for antibodies to *Sporothrix schenckii*, an uncommon fungus that is difficult to culture. Several even rarer fungi that must be considered in the diagnosis of chronic meningitis are discussed in the article by Swartz.

Treatment The current preferred treatment is fluconazole and amphotericin B and supplemental antifungal agents are used in the others. Intrathecal via a reservoir amphotericin is administered in patients who relapse.

INFECTIONS CAUSED BY RICKETTSIAS, PROTOZOA, AND WORMS

Rickettsial Diseases

Rickettsias are obligate intracellular parasites that appear microscopically as pleomorphic coccobacilli. The major ones are maintained in nature by a cycle involving an animal reservoir, an insect vector (lice, fleas, mites, and ticks), and humans. Epidemic typhus is an exception, involving only lice and human beings, and Q fever is probably contracted by inhalation. At the time of World War I, the rickettsial diseases, typhus in particular, were remarkably prevalent and of the utmost gravity. In Eastern Europe, between 1915 and 1922, there were an estimated 30 million cases of typhus with 3 million deaths. Now, the rickettsial diseases are of minor importance, the result of insect control by dichlorodiphenyltrichloroethane (DDT) and other chemicals and the therapeutic effectiveness of broad-spectrum antibiotics. In the United States these diseases are quite rare, but they assume significance because, in some types, up to one-third of patients have neurologic manifestations. About 200 cases of Rocky Mountain spotted fever (the most common rickettsial disease) occur each year in the United States, with a mortality of 5 percent or less. Neurologic manifestations occur in a small portion, and neurologists may not encounter a single instance in a lifetime of practice. For this reason, the rickettsial diseases are simply tabulated here.

The following are the major rickettsial diseases:

1. *Epidemic typhus*, small pockets of which are present in many undeveloped parts of the world. It is transmitted from lice to humans and from person to person.
2. *Murine (endemic) typhus*, which is present in the same areas as Rocky Mountain spotted fever (see below). It is transmitted by fleas from rats to humans.
3. *Scrub typhus* or *tsutsugamushi fever*, which is confined to eastern and southeastern Asia. It is transmitted by mites from infected rodents or humans.
4. *Rocky Mountain spotted fever*, first described in Montana, is most common in Long Island, Tennessee, Virginia, North Carolina, and Maryland. It is transmitted by special varieties of ticks.
5. *Q fever*, which has a worldwide distribution (except for the Scandinavian countries, New Zealand, and the tropics). It is transmitted in nature by ticks but also by inhalation of dust and handling of materials infected by the causative organism, *Coxiella burnetii*.

With the exception of Q fever, the clinical manifestations and pathologic effects of the rickettsial diseases are much the same, varying only in severity. Typhus may be taken as the prototype. The incubation period varies from 3 to 18 days. The onset is usually abrupt, with fever rising to extreme levels over several days; headache, often severe; and prostration. A macular rash, which resembles that of measles and involves the trunk and limbs, appears on the fourth or fifth febrile day. An important diagnostic sign in scrub typhus is the necrotic ulcer and eschar at

the site of attachment of the infected mite. Delirium—followed by progressive stupor and coma, sustained fever, and occasionally focal neurologic signs and optic neuritis—characterizes the untreated cases. Stiffness of the neck is noted only rarely, and the CSF may be entirely normal or show only a modest lymphocytic pleocytosis.

In fatal cases, the rickettsial lesions are scattered diffusely throughout the brain, affecting gray and white matter alike. The changes consist of swelling and proliferation of endothelial cells of small vessels and a microglial reaction, with the formation of so-called typhus nodules.

Q fever, unlike the other rickettsioses, is not associated with an exanthem. In the few cases with which we are familiar, the main symptoms were those of a low-grade meningitis. Rare instances of encephalitis, cerebellitis, and myelitis are also reported, possibly as postinfectious complications. There is usually a tracheobronchitis or atypical pneumonia (one in which no organism can be cultured from the sputum) and a severe prodromal headache. In these respects, the pulmonary and neurologic illnesses resemble that of the other main cause of "atypical pneumonia," *M. pneumoniae*. The Q fever agent (*Coxiella*) should be suspected if there are concomitant respiratory and meningoencephalitic illnesses and there has been exposure to parturient animals, to livestock (including abattoir workers, who are also exposed to *Brucella* and anthrax), or to wild deer or rabbits. The diagnosis can be made by the finding of a severalfold increase in specific immunofixation antibodies. Patients who survive the illness usually recover completely; a few are left with residual neurologic signs.

Treatment

This consists of the administration of doxycycline or chloramphenicol, which are highly effective in all rickettsial diseases. If these drugs are given early, coincident with the appearance of the rash, symptoms abate dramatically and little further therapy is required. Cases recognized late in the course of the disease require considerable supportive care, including the administration of corticosteroids, maintenance of blood volume to overcome the effects of the septic-toxic reaction, and hypoproteinemia.

Protozoal Diseases

Toxoplasmosis

This disease is caused by *Toxoplasma gondii*, a tiny (2- to 5- μm), obligate, intracellular parasite that is readily recognized in Wright- or Giemsa-stained preparations. It has assumed greater importance in recent decades because of the frequency with which it involves the brain in patients with AIDS. Infection in humans is either congenital or acquired postnatally. Congenital infection is the result of parasitemia in the mother who happens to be pregnant at the time of her initial (asymptomatic) *Toxoplasma* infection. (Treated mothers can be assured, therefore, that there is little carryover risk of producing a second infected infant.) Several modes of transmission of the late-acquired form have been described—eating raw beef, handling uncooked mutton (in Western Europe),

and, most often, contact with cat feces, the cat being the natural host of *Toxoplasma*. Most infections in AIDS patients occur in the absence of an obvious source.

The congenital infection has attracted attention because of its severe destructive effects on the neonatal brain, as discussed in Chap. 38. Signs of active infection—fever, rash, seizures, hepatosplenomegaly—may be present at birth. More often, chorioretinitis, hydrocephalus or microcephaly, cerebral calcifications, and psychomotor retardation are the major manifestations. These may become evident soon after birth or, more often, the infection is asymptomatic and becomes manifest only several months or years later with chorioretinitis. Most infants succumb; others survive with varying degrees of the aforementioned abnormalities.

Serologic surveys indicate that the exposure to toxoplasmosis in adults is widespread (approximately 40 percent of American city dwellers have specific antibodies); cases of clinically evident active infection, however, are rare. It is of interest that in 1975 the medical literature contained only 45 well-documented cases of acquired adult toxoplasmosis (Townsend et al); moreover, in half of them there was an underlying systemic disease (malignant neoplasms, renal transplants, collagen vascular disease) that had been treated intensively with immunosuppressive agents. Now, innumerable cases of acquired toxoplasmosis are being seen because it is the most common cause of focal cerebral lesions in patients with AIDS (see Chap. 33). Frequently, the symptoms and signs of infection with *Toxoplasma* are assigned to the primary disease with which toxoplasmosis is associated, and an opportunity for effective therapy is missed.

Most cases in adults are reactivations of the congenital infection. The clinical picture in patients without AIDS varies. Most often it is a subclinical process or manifested by a painless lymphadenopathy, a mononucleosis-like syndrome, or acute chorioretinitis. There is a rare fulminant, widely disseminated infection with a rickettsia-like rash, encephalitis, myocarditis, and polymyositis. Or the neurologic signs may consist only of myoclonus and asterixis, suggesting a metabolic encephalopathy. Often, there are signs of a meningoencephalitis, i.e., seizures, mental confusion, meningeal irritation, coma, and a lymphocytic pleocytosis and increased CSF protein. The brain in such cases shows one or more foci of inflammatory necrosis, essentially an abscess, (Fig. 32-6), with free and encysted *T. gondii* organisms scattered throughout the white and gray matter. Rarely, large areas of necrosis manifest themselves as one or more mass lesions. Sometimes, a nodular lesion is detected on MR or CT imaging that is performed for other reasons.

A presumptive diagnosis can be made on the basis of a rising antibody titer or a positive IgM indirect fluorescent antibody or other serologic test. The diagnosis may be confirmed by the infrequent finding of organisms in CSF sediment and in biopsy specimens of muscle or lymph node. Patients with AIDS and those who are otherwise immunocompromised, however, usually do not display an antibody response or an elevation of titers (those with lymphoma do have positive serologic tests). Excepting AIDS cases, a clinical syndrome and radiologic

Figure 32-6. MRI showing a rim-enhancing *Toxoplasma* abscess in the deep left cerebral hemisphere in an AIDS patient. There is mass effect and surrounding edema, features which are variable in other similar cases.

features that are consistent with toxoplasmosis and a greatly elevated IgG titer are thought to be diagnostic. In the setting of AIDS, patients with multiple nodular or ring-enhancing brain lesions are treated initially with antibiotics for toxoplasmosis, and further evaluation (mainly for cerebral lymphoma) is undertaken only if there is no response, as discussed in Chap. 33.

Treatment Patients with a presumptive diagnosis are treated with oral sulfadiazine (4 g initially, then 4 to 6 g daily) and pyrimethamine (200 mg initially, then 50 to 100 mg daily). Leucovorin, 15 to 20 mg daily, should be given to counteract the antifolate action of pyrimethamine. Treatment must be continued for at least 6 weeks. In patients with AIDS, treatment at lower doses is continued until the CD4 count exceeds 200 to 250 for 6 months or more; otherwise treatment must be lifelong so as to prevent relapses.

Amebic Meningoencephalitis

This disease is caused by free-living flagellate amoebae, usually of the genus *Naegleria* and less frequently of the genera *Acanthamoeba* and *Balamuthia*. *Naegleria* is acquired by swimming in ponds or lakes where there is warm fresh water. One outbreak in Czechoslovakia followed swimming in a chlorinated indoor swimming pool. Most of the cases in the United States have occurred in the Southeastern states. It is a rare but lethal illness with several dozen instances in the last decade in the United States.

The onset of the illness caused by *Naegleria* is usually abrupt, with severe headache, fever, nausea and vomiting, and stiff neck. The course is inexorably

progressive—with seizures, increasing stupor and coma, and focal neurologic signs—and the outcome is practically always fatal, usually within a week of onset. The reaction in the CSF is like that in acute bacterial meningitis: increased pressure, a large number of polymorphonuclear leukocytes (not eosinophils, as in the parasitic infestations discussed further on), and increased protein and decreased glucose content. The diagnosis is supported by a history of swimming in fresh warm water, particularly of swimming underwater for sustained periods, and on finding viable trophozoites in a wet preparation of unspun spinal fluid. Gram stain and ordinary cultures do not reveal the organism.

Autopsy discloses purulent meningitis and numerous quasigranulomatous microabscesses in the underlying cortex.

Subacute and chronic granulomatous meningoencephalitis from amoeba is a rare disease in humans. Isolated instances have been reported in debilitated and immunosuppressed patients (Gonzalez et al). The organism may be difficult to culture from the CSF; most diagnoses are made from biopsy. A fatal case of ours, in a leukopenic patient who had been receiving granulocyte-stimulating factor, ran a subacute course over 1 month with headache, mild fever, stupor, and unmeasurably low CSF glucose toward the end of life (Katz et al). Initially, there were scattered, round, enhancing lesions on the MRI that disappeared with corticosteroids, much like lymphoma; later, there were more irregular confluent white matter lesions. A brain biopsy revealed amoebae that could have been easily mistaken for macrophages or cellular debris; the organism proved to be *Balamuthia*.

Treatment with the usual antiprotozoal agents is largely ineffective. Because of the in vitro sensitivity of *Naegleria* to amphotericin B, this drug should be used by the same schedule as for cryptococcal meningitis. With such a regimen in combination with rifampin, recovery is rarely possible.

Malaria

A number of other protozoal diseases are of great importance in tropical regions. One is *cerebral malaria*, which complicates approximately 2 percent of cases of *falciparum malaria*. This is a rapidly fatal disease characterized by headache, seizures, and coma, with diffuse cerebral edema and only very rarely by focal features such as hemiplegia, aphasia, hemianopia, or cerebellar ataxia. Bruxism and hiccoughs have been commented on as common features in case reports. Cerebral capillaries and venules are packed with parasitized erythrocytes and the brain is dotted with small foci of necrosis surrounded by glia (Dürck nodes). A retinopathy consisting of macular whitening, orange or white discoloration of retinal vessels, and intraretinal blot-type hemorrhages, has been suggested as a dependable sign of severe malaria as summarized by Beare and colleagues.

These findings have been the basis of several hypotheses (one of which attributes the cerebral symptoms to mechanical obstruction of the vessels), but none is entirely satisfactory. Also, it seems unlikely that a disorder of immune mechanisms is directly involved in the

pathogenesis (see the reviews by Newton et al and by Turner for a discussion of current hypotheses).

Usually the neurologic symptoms appear in the second or third week of the infection, but they may be the initial manifestation. Children in hyperendemic regions are the ones most susceptible to cerebral malaria. Among adults in nonendemic areas, only pregnant women and nonimmune individuals who discontinue prophylactic medication are liable to CNS involvement (Toro and Roman). Useful laboratory findings are anemia and parasitized red blood cells. The CSF may be under increased pressure and sometimes contains a few white blood cells, and the glucose content is normal. With *Plasmodium vivax* infections, there may be drowsiness, confusion, and seizures without invasion of the brain by the parasite.

Treatment Quinine and artesunate, and related drugs are curative if the cerebral symptoms are not pronounced, but once coma and convulsions supervene, 20 to 30 percent of patients do not survive. Newer drugs such as mefloquine, artemether with lumefantrine, and atovaquone are increasingly used. It had been stated that the administration of large doses of dexamethasone, given as soon as cerebral symptoms appear, may be lifesaving, but most studies, including those of our colleagues, demonstrate that corticosteroids are ineffective. Blood or exchange transfusions may confer a modest benefit on survival in severe cases.

Trypanosomiasis

This is a common disease in equatorial Africa and in Central and South America. The African type ("sleeping sickness") is caused by *Trypanosoma brucei*, *rhodesiense*, and *gambiense* and is transmitted by several species of the tsetse fly. Most cases in the United States have been due to the second type in travelers returning from safari. There was an alarming increase in this disease in sub-Saharan Africa during past decades but now, fewer than several thousand cases have been reported because of active control interventions. The infection begins with a chancre at the site of inoculation and localized lymphadenopathy. Posterior cervical adenopathy is highly characteristic of CNS infection (Winterbottom sign); another sign of neurologic interest is pronounced pain at sites of minor injury (called Kerandel hyperesthesia). Later, episodes of parasitemia occur, and at some time during this stage of dissemination, usually in the second year of the infection, the trypanosomes give rise to a diffuse meningoencephalitis. The latter expresses itself clinically as a chronic progressive neurologic syndrome consisting of a reversal or disruption of circadian sleep rhythm, vacant facial expression, and in some, ptosis and ophthalmoplegia, dysarthria, and then muteness, seizures, progressive apathy, stupor, and coma.

The South American variety of trypanosomiasis (Chagas disease) is caused by *Trypanosoma cruzi* and is transmitted from infected animals to humans by the bite of reduviid bugs. There have been rare cases from blood transfusion and organ transplantation. The sequence of local lymphadenopathy, hematogenous dissemination, and chronic meningoencephalitis is like that of African trypanosomiasis. Serologic tests are available to confirm the diagnosis.

Treatment Treatment is with pentavalent arsenicals, mainly melarsoprol, which are more effective in the African than in the South American form of the disease but is highly toxic. An encephalopathy occurs in 10 percent of cases during the institution of treatment; half of these are fatal. As pointed out by Braakman and colleagues, the arsenical encephalopathy is characterized by multiple white matter lesions, sometimes with hemorrhage, and is often quite severe, lethal in between 50 and 75 percent of cases. Newer drugs or combinations, particularly eflornithine with nifurtimox are being used for the gambiense disease. Unusually high rates of relapse are being reported after treatment. A review of the subject of trypanosomiasis has been given by Kennedy. The treatment of Chagas disease has been with nifurtimox and benznidazole.

Diseases Caused by Nematodes (Table 32-6)

Of these, trichinosis is of greatest importance to neurologists. Infections with other roundworms, such as *Angiostrongylus*, cause an eosinophilic meningitis, as discussed further on.

Trichinellosis, Trichinosis (See also Chap. 49)

This disease is caused by the intestinal nematode *Trichinella spiralis*. Infection in humans results from the ingestion of uncooked or undercooked pork (occasionally bear meat) containing the encysted larvae of *T. spiralis*. The larvae are liberated from their cysts by the gastric juices and develop into adult male and female worms in the duodenum and jejunum. After fertilization, the female burrows into the intestinal mucosa, where she deposits several successive batches of larvae. These make their way—via the lymphatics, regional lymph nodes, thoracic duct, and bloodstream—into all parts of the body. The new larvae penetrate all tissues but survive only in striated muscle, where they become encysted and eventually calcify. Animals are infected in the same way as humans, and the cycle can be repeated only if a new host ingests the encysted larvae. Gould has written an authoritative review of this subject.

The early symptoms of the disease, beginning a day or two after the ingestion of pork, are those of a mild gastroenteritis. Later symptoms coincide with invasion of muscle by larvae. The latter begins about the end of the first week and may last for 4 to 6 weeks. Low-grade fever, pain and tenderness of muscles, edema of the conjunctivae and particularly of the eyelids, and fatigue are the usual manifestations. The myopathic aspects of *Trichinella* infestation are considered fully in Chap. 49.

Particularly heavy infection may be associated with a CNS disorder from larval migration through the nervous system without encystation. Headache, stiff neck, and a mild confusional state are the usual symptoms. Delirium, coma, hemiplegia, and aphasia have also been observed on occasion. The spinal fluid is usually normal but may contain a moderate number of lymphocytes and, rarely, parasites.

An eosinophilic leukocytosis usually appears when the muscles are invaded. Serologic (precipitin) tests

Table 32-6

PARASITIC CAUSES OF CENTRAL NERVOUS SYSTEM LESIONS

DISEASE (ORGANISM)	CLINICAL FEATURES	RADIOGRAPHIC FEATURES
Cestodes (tapeworms)		
Cysticercosis (<i>Taenia solium</i>) and coenuriasis (<i>Taenia multiceps</i>)	Seizures with mature lesions, hydrocephalus, ventricular and multiple subarachnoid implantation	Cyst with scolex; late calcification
Sparganosis (<i>Spirometra</i>)	Subcutaneous nodule, seizures	Migrating granuloma or mass
Hydatid disease (<i>Echinococcus</i>)	Focal cerebral findings, raised intracranial pressure	Large fluid-filled cyst, solid "chitinoma"
Nematodes (roundworms)		
Trichinosis	Skin lesions, severe myositis, brain lesions, eosinophilia, meningitis, encephalitis (rare)	Granuloma
Angiostrongyloidiasis (<i>Angiostrongylus cantonensis</i>)	Meningoencephalitis, eosinophilia	Granuloma, nodule, migrating track
Gnathostomiasis (<i>Gnathostoma spini gerum</i>)	Eosinophilic meningoencephalitis	
Baylisascariasis (<i>Baylisascarus procyonis</i>)	Eosinophilic meningoencephalitis (from racoon bites)	
Strongyloidiasis (<i>Strongyloides stercoralis</i>)	Encephalitis, myelitis, seizures	Irregular nodular enhancing lesions, may change position
Visceral larva migrans (<i>Toxocara canis</i> , <i>T. cati</i>)	Eosinophilic meningoencephalitis	
Trematodes (flukes)		
Schistosomiasis (<i>Schistosoma japonicum</i> , <i>S. mansoni</i> , <i>S. haematobium</i>)	Myelopathy, seizures, tumor symptoms, swimmer's itch	Single granuloma, may be large
Paragonimiasis	Seizures, meningoencephalitis, pulmonary lesions	Single granuloma
Other tropical and parasitic infections		
Toxoplasmosis (<i>T. gondii</i>)	Seizures, focal cerebral findings	Single or multiple enhancing lesions
Amebiasis	Colitis, liver abscess, rare brain abscess	Abscess or encephalopathy
<i>Entamoeba histolytica</i> , <i>N. fowleri</i> , <i>B. mandrallis</i>	Primary amebic meningoencephalitis, seizures (after swimming)	Multiple small abscess lesions
Tuberculoma (<i>M. tuberculosis</i> and atypical forms)	Seizure	Granuloma

become positive early in the third week. The heart is often involved, manifested by tachycardia and electrocardiographic changes; sterile brain embolism may follow the myocarditis. These findings may aid in the diagnosis, which can be confirmed by finding the larvae in a muscle biopsy, using the technique of low-power scan of wet tissue pressed between two glass slides.

Trichinosis is seldom fatal. Most patients recover completely, although myalgia may persist for several months. Once recurrent seizures and focal neurologic deficits appear, they may persist indefinitely. The latter are based on the rare occurrence of trichina encephalitis (the filiform larvae may be seen in cerebral capillaries and in cerebral parenchyma) and emboli from mural thrombi arising in infected heart muscle.

Treatment (See also Chap. 49.) In the treatment of severe trichinosis, albendazole, an antihelminthic agent, and corticosteroids are of value. This drug prevents larval reproduction and is therefore useful in patients known to have ingested trichinous meat. It also interferes with the metabolism of muscle-dwelling larvae. Fever, myalgia, and eosinophilia respond well to the antiinflammatory and immunosuppressant effects of prednisone (40 to 60 mg daily), and a salutary effect has been noted on the cardiac and neurologic complications as well.

Other nematodes, mainly toxocara (the cause of visceral larva migrans), strongyloides, and angiostrongyloides may rarely migrate to the brain, but each is characterized by a systemic illness, which is far more common than the neurologic one. Parasitic meningitis is discussed later.

Diseases Caused by Cestodes

Cysticercosis (See Table 32-6)

This is the larval or intermediate stage of infection with the pork tapeworm *Taenia solium*. In Central and South America and in parts of Africa and India, cysticercosis is a leading cause of epilepsy and other neurologic disturbances. Because of a considerable emigration from these endemic areas, patients with cysticercosis are now being seen with some regularity in countries where the disease had previously been unknown. Usually the diagnosis is suggested by CT or MRI of the brain but can also be made by the presence of multiple calcified lesions in the thigh, leg, and shoulder muscles and in the cerebrum.

The cerebral manifestations of cysticercosis are diverse, related to the encystment and subsequent calcification of the larvae in the cerebral parenchyma, subarachnoid space, and ventricles (Fig. 32-7). The lesions are most

Figure 32-7. Cysticercosis on CT without contrast. Multiple vesicular lesions, some with visible scolices and without mass effect (left panel) that became calcified 2 years later (right panel).

often multiple but may be solitary; in the United States and nonendemic countries, single cysts are more common. Before the cyst degenerates and eventually calcifies, CT scanning and MRI may actually visualize the scolex. Most often the neurologic disease presents with seizures, although many patients are entirely asymptomatic, the cysts being discovered radiologically. It is only when the cyst degenerates, many months or years after the initial infestation that an inflammatory and granulomatous reaction is elicited and focal symptoms arise.

In some patients, a large subarachnoid or intraventricular cyst may obstruct the flow of CSF, in which case the surgical removal of the cyst or a shunt procedure becomes necessary. Proano and colleagues, however, have reported on a series of such cases with cysts larger than 5 cm in diameter, which they have treated medically. In a more malignant form of the disease, the cysticerci are located in the basilar subarachnoid space, where they induce an intense inflammatory reaction leading to hydrocephalus, vasculitis, and stroke as well as cranial nerve palsies. This so-called racemose form of the illness is little altered by the use of praziquantel or any other form of therapy (Estanol et al) but responds less well than the cystic form.

Treatment For a comprehensive treatment of the subject of neurocysticercosis the reader is referred to the review by Nash and colleagues. The following is a summary of current treatment principles. The therapy of this disorder has been greatly improved in recent years by the use of CT and MRI and the administration of albendazole or praziquantel, an antihelminthic agent that is also active against all species of schistosomes. Albendazole is given as 5 mg/kg tid for 15 to 30 days. Initially, treatment may seem to exacerbate neurologic symptoms, with an increase in cells and protein in the CSF, but then the

patient improves and may become asymptomatic, with a striking decrease in the size and number of cysts on CT scanning. Corticosteroids are usually used at the onset of antihelminthic treatment and particularly if a large single lesion is causing symptoms by its mass effect.

Other Cestode Infections

Infection with *Echinococcus* occasionally affects the brain. The usual sources of infection are water and vegetables contaminated by canine feces. After they are ingested, the ova hatch and the freed embryos migrate, primarily to lung and liver, but sometimes to brain (approximately 2 percent of cases), where a large solitary (hydatid) cyst may be formed. The typical lesion is a large fluid-filled cyst with the parasite visible by imaging procedures, but a solid nodular brain lesion, a "chitinoma," is also known to occur. We have also observed a compressive spinal cord lesion. Treatment with the albendazole or mebendazole is recommended when surgery is not feasible.

Cerebral coenuriasis (*coenurus cerebralis*) is an uncommon infestation by larvae of the tapeworm *Taenia multiceps*. It occurs mainly in sheep-raising areas where there are many dogs, the latter being the definitive hosts. The larvae form grape-like cysts, most often in the posterior fossa, which obstruct the spinal fluid pathways and cause signs of increased intracranial pressure. Surgical removal is possible.

Another cestode, *Spirometra mansoni*, may migrate within the brain, leaving a visible track as it moves. Subcutaneous nodules are the most common lesions. This parasite is found predominantly in the Far East.

The nervous system may also be invaded directly by certain worms (*Ascaris, filaria*) and flukes (*Schistosoma, Paragonimus*). These diseases are virtually nonexistent in the United States except among those who have recently

returned from endemic areas. Schistosomiasis, however, is of such great importance and often invades the nervous system in such characteristic ways that it is considered below in detail.

Diseases Caused by Trematodes

Schistosomiasis (See Table 32-6)

The ova of *trematodes* seldom involve the nervous system, but when they do, the infecting organism is usually *Schistosoma japonicum* and, less often, *Schistosoma haematobium* or *Schistosoma mansoni*. It is said that *S. japonicum* has a tendency to localize in the cerebral hemispheres and *S. mansoni* in the spinal cord, but there have been many exceptions. The cerebral lesions form in relation to direct parasitic deposition of eggs in blood vessels and take the form of mixed necrotizing and ischemic parenchymal foci that are infiltrated by eosinophils and giant cells (Fig. 32-8) (Scrimgeour and Gajdusek). The lesions do not calcify.

Schistosomiasis is widespread in tropical regions; 80 percent of cases are in sub-Saharan Africa. North American neurologists have little contact with it except in travelers who have bathed in lakes or rivers where the snail hosts of the parasite are plentiful. The initial manifestation may be a local skin irritation at the site of entry of the parasite (swimmer's itch), or a large serpiginous urticarial rash on the trunk, Katayama fever, particularly likely to occur in prior exposure, but the patient frequently does not offer this information unless sought. A small proportion of patients develop neurologic symptoms several months after exposure.

Figure 32-8. MRI of schistosomiasis (*S. mansoni*) with gadolinium enhancement of patchy lesions in the left temporal lobe in a traveler returning from Ghana.

Headaches, convulsions (either focal or generalized), and other cerebral signs appear; with lesions of larger size, papilledema may develop, simulating a brain tumor. It has been hypothesized that travelers are more prone to develop symptomatic nervous system disease because of an intense inflammatory reaction surrounding the deposited eggs.
