Secondary hyperparathyroidism also may occur as a result of defective renal production of $1,25(\text{OH})_2\text{d}$ combined with an increased serum phosphate concentration and calcium-phosphate precipitation into soft tissues (see Chapters 72 and 73). This circumstance evokes a marked increase in PTH secretion that causes significant increases in bone turnover, demineralization, and fracture. These patients may respond dramatically to oral or parenteral replacement of $1,25(\text{OH})_2\text{d}$ or the calcium receptor mimetic cinacalcet, or both.

Other patients with renal osteodystrophy have adequately controlled serum levels of calcium and phosphate as a result of adequate oral calcium supplementation and phosphate binders and therefore have standard PTH levels, but they have severe osteomalacia characterized by bone pain, reduced bone mineral density on DEXA or bone biopsy, and thickened osteoid seams with a mineralization defect seen on bone biopsy (see Fig. 74-1G). These patients may respond dramatically to $1,25(\text{OH})_2\text{d}$ replacement.

Some patients with renal osteodystrophy have combinations of secondary hyperparathyroidism and osteomalacia (see Fig. 74-1G). Others have low bone turnover or aplastic bone disease. The latter terms describe patients on dialysis who have little or no osteoblastic activity, osteoid, or osteoclastic activity—the opposite of secondary hyperparathyroidism and osteomalacia. The condition may result from previous use of inhibitors of bone turnover (e.g., aluminum intoxication); from excessive treatment with $1,25(\text{OH})_2\text{d}$ with suppression of PTH, causing low bone turnover; or from unidentified causes.

For all bone diseases, determining the cause is essential for effective treatment. Early recognition enables treatment before bone pain and fractures occur.

Genetic Diseases

Monogenic disorders that lead to reductions in bone mass are uncommon but are seen with some frequency in practices devoted to skeletal disease. The most common of these disorders is osteogenesis imperfecta, which may be very mild or very severe

and may manifest in neonates or older people, depending on the mutation involved. Patients with osteogenesis imperfecta have bone fragility and deformities, and they may have involvement of collagen-containing tissues, including the tendons, skin, and eyes.

Osteogenesis imperfecta most often results from mutations in the genes for type I collagen. In contrast, hypophosphatasia results from mutations in the tissue-nonspecific alkaline phosphatase gene (*ALPL*). These patients have demineralization, fracture, and bone pain, and they have little or no measurable serum alkaline phosphatase.

New monogenic causes of bone disease continue to appear. For example, the rare osteoporosis-pseudoglioma syndrome (i.e., severe autosomal dominant osteoporosis with blindness) results from inactivating mutations in the low-density lipoprotein receptor-related protein 5 gene (*LRP5*). Activating mutations in this gene lead to an autosomal dominant form of very high bone mass.

Infiltrative Diseases

Patients with multiple myeloma or Waldenström's macroglobulinemia classically develop skeletal demineralization, which is also true for some patients with leukemia and marrow lymphomas (see Fig 74-1H). Other disorders associated with diffuse marrow infiltration by benign or less malignant processes can lead to diffuse osteopenia, bone pain, and fracture, and they should be considered in the evaluation of unexplained osteoporosis. Examples include hemolytic anemias such as thalassemia or sickle cell disease, sarcoidosis with diffuse marrow involvement, Gaucher's disease with lipid-laden marrow giant cells, malignant mastocytosis, and diffuse histiocytosis.

Transplantation Osteodystrophy

Patients who have undergone or are undergoing organ transplantation commonly have severe osteoporosis. In some patients, this condition is caused by treatment with immunosuppressive drugs such as glucocorticoids, tacrolimus, or cyclosporine, which are potent inhibitors of bone formation and regularly lead to reductions in bone mass.

In many patients, decreased bone mineral density exists before transplantation as a result of organ failure or its treatment. For example, those with primary biliary cirrhosis also may have osteoblast failure and calcium or vitamin D deficiency. In those with end-stage lung or cardiac disease, physical inactivity and generalized malnutrition may contribute to bone demineralization. Patients with end-stage renal disease have all of the components of renal osteodystrophy. This disorder can be expected to become increasingly common as the number of organ transplantations increases.

TREATMENT

Treatment depends on the underlying disorder. If clinically indicated, primary and tertiary hyperparathyroidism are treated with surgical resection of the affected parathyroid tissue. Osteomalacia and rickets improve when the appropriate replacement drug is administered (i.e., vitamin D, calcium, or phosphate alone or in combination) or the offending agent (e.g., anticonvulsants) is removed.

Secondary hyperparathyroidism in a patient on dialysis can be treated with a combination of the active form of vitamin D ($1,25[\text{OH}]_2\text{D}_3$ [calcitriol] or analogues), calcium supplementation, phosphate binders, and cinacalcet, depending on the clinical situation. Secondary hyperparathyroidism due to vitamin D deficiency should be treated with the oral parent compound, vitamin D. Other items in [Table 74-1](#) require attention during treatment of the underlying disorder.

These disorders are commonly amenable to treatment, and patients can have dramatic and satisfying responses to therapy. The main stumbling block is that these diagnoses may not be considered; instead, the DEXA report of osteoporosis is passively accepted without further investigation. When a patient is diagnosed with osteoporosis on the basis of a bone density study or radiograph, the physician should review the checklist in [Table 74-1](#) and eliminate or investigate alternative disorders.

 For a deeper discussion on this topic, please see [Chapter 242, "Approach to the Patient with Metabolic Bone Disease,"](#) in *Goldman-Cecil Medicine, 25th Edition*.

Osteoporosis

Susan L. Greenspan

INTRODUCTION

Osteoporosis, the most common disorder of bone and mineral metabolism, affects about 50% of women and 25% of men older than 50 years. The National Institutes of Health Consensus Development Panel on Osteoporosis Prevention defines osteoporosis as a skeletal disorder characterized by compromised bone strength, predisposing a person to an increased risk of fracture. Bone strength has two main components: bone density and bone quality. Bone density reflects the peak adult bone mass and the amount of bone lost in adulthood. Bone quality is determined by bone architecture, bone geometry, bone turnover, mineralization, and damage accumulation (i.e., microfractures) (Fig. 75-1).

DEFINITION AND EPIDEMIOLOGY

In the United States, 2 million osteoporotic fractures occur each year. There are almost 300,000 hip fractures each year, which are associated with a mortality rate of more than 20% during the first

year. More than 50% of patients with hip fracture are unable to return to their previous ambulatory state, and about 20% of them are placed in long-term care facilities. When defined by bone mineral densitometry, 48 million Americans have low bone mass, and 9 million have osteoporosis. Although morbidity is less with vertebral fractures, the 5-year mortality rate is similar to that for hip fractures. Only one third of radiologically diagnosed vertebral fractures receive medical attention.

PATHOLOGY AND RISK FACTORS

Peak bone mass is determined primarily by genetic factors. Men have a higher bone mass than women, and African Americans and Hispanics have a higher bone mass than whites. Other factors that contribute to the development of peak bone mass are the use of gonadal steroids, timing of puberty, calcium intake, exercise, and growth hormone.

The causes of bone loss in adults are multifactorial. The pattern of bone loss is different in women than in men, and bone

FIGURE 75-1 Three-dimensional reconstruction by microcomputed tomography of a lumbar spine sample from a young adult normal woman and from a woman with postmenopausal osteoporosis. In the osteoporotic woman, bone mass is reduced and microarchitectural bone structure is deteriorated. Whereas the platelike structure in the normal case is very isotropic, the structure in the osteoporotic case shows preferential loss of horizontal struts; the plates have become rods that are thin and farther apart, and there is a concomitant loss of trabecular connectivity. These changes lead to a reduction in bone strength that is more than would be predicted by the decrease in bone mineral density. (From Riggs BL, Khosla S, Melton LJ 3rd: Sex steroids and the construction and conservation of the adult skeleton, *Endocr Rev* 23:279–302, 2002; Courtesy Ralph Mueller, PhD, Swiss Federal Institute of Technology [ETH] and University of Zurich, Switzerland.)

loss is greater in sites rich in trabecular bone (e.g., spine) than cortical bone (e.g., femoral neck) (Fig. 75-2). Women lose significantly more trabecular bone than men. Estrogen deficiency during menopause contributes significantly to bone loss in women, and they may lose 1% to 5% of bone mass per year in the first few years after menopause. Women continue to lose bone mass throughout the remainder of their lives, with another acceleration of bone loss occurring after age 75 years. The mechanism of this accelerated loss in old age is not clear.

Multiple causes of secondary bone loss contribute to osteoporosis and fractures. Medications that commonly cause bone loss include glucocorticoids, antiepileptic medications, excess thyroid hormone, heparin, androgen deprivation therapy, aromatase inhibitors, and depo-medroxyprogesterone. Endocrine diseases resulting in female or male hypogonadism also lead to bone loss. Hyperparathyroidism, hyperthyroidism, and hypercortisolism commonly cause bone loss, as can vitamin D deficiency. Gastrointestinal problems can contribute to decreased absorption of calcium and vitamin D (Table 75-1). Risk factors for falls (e.g., age, poor vision, previous falls, immobility, orthostatic hypotension, cognitive impairment, vitamin D insufficiency, poor balance, gait problems, weak muscles) also contribute to fractures.

CLINICAL PRESENTATION

Unlike many other chronic diseases with multiple signs and symptoms, osteoporosis is considered a silent disease until fractures occur. Whereas 90% of hip fractures occur after a fall, two thirds of vertebral fractures are silent and occur with minimal stress, such as lifting, sneezing, and bending. An acute vertebral fracture may result in significant back pain that decreases gradually over several weeks with analgesics and physical therapy. Patients with significant vertebral osteoporosis may have height loss, kyphosis, and severe cervical lordosis, also known as a *dowager's hump*. Prolonged bisphosphonate use (>5 years) may result in an atypical femoral fracture, which may manifest as unilateral or bilateral thigh pain and result in a femoral shaft fracture with no or minimal trauma.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of osteoporosis is made after an acute clinical vertebral or hip fracture or on assessment of bone mineral density.

Radiography

Radiographs can reveal a vertebral compression fracture (Fig. 75-3). However, low bone mass may not be evident on radiographs until 30% of the mass has been lost. When assessing bone mass, radiographs may be read inappropriately as a result of overpenetration or underpenetration of the film. Radiographs therefore are a poor indicator of osteoporosis (with the exception of vertebral fractures), and the diagnosis is instead often based on bone mineral densitometric results.

Bone Mineral Density and Other Bone Mass Assessments

In 1994, the World Health Organization (WHO) developed a classification system for osteoporosis and low bone mass based on data from white, postmenopausal women (Table 75-2). Osteoporosis is defined as a bone mineral density less than or equal to 2.5 standard deviations (SDs) below young adult peak bone mass (T-score ≤ -2.5 SD). Low bone mass (i.e., osteopenia) is defined as a bone mass measurement between 1.0 and 2.5 SDs below adult peak bone mass (T-score between -1.0 and -2.5 SD). Normal bone mineral density is defined as assessments above 1.0 SD below adult peak bone mass (T-score ≥ -1.0 SD).

The standard for assessing bone mineral density is dual-energy x-ray absorptiometry (DEXA), which has excellent precision and accuracy. Measurements are made at the hip and spine, and in about 30% of cases, discordance is found between these measurements (Fig. 75-4). Classification should be made only if two or more vertebrae are available for analysis because of the high error rate when a single vertebra is assessed. Classification is based on the lowest value (i.e., total spine, total hip, or femoral neck).

In patients with hyperparathyroidism, in which cortical bone loss is often seen, forearm DEXA using the one-third distal radius site should also be assessed. Forearm assessments may be helpful in older patients who often have falsely elevated bone mineral density measurements at the spine as a result of atypical calcifications from degenerative joint disease, sclerosis, or aortic calcifications or in obese patients whose weight exceeds the table limit.

Bone mineral density can be measured by hip or spine quantitative computed tomography (QCT). However, less normative data are available for hip QCT, vertebral precision is inferior to

FIGURE 75-2 Patterns of age-related bone loss in women and in men. *Dashed lines* represent trabecular bone, and *solid lines* represent cortical bone. The figure is based on multiple cross-sectional and longitudinal studies using dual-energy x-ray absorptiometry. BMD, Bone mineral density. that of DEXA, and radiation doses are significantly higher than those of DEXA. Single-photon absorptiometry of the forearm and peripheral measures, such as heel ultrasound, have also been used to assess bone mass. However, the WHO classification should be used only with the central DEXA measurements.

TABLE 75-2 WORLD HEALTH ORGANIZATION CLASSIFICATION FOR OSTEOPOROSIS

CLASSIFICATION	CRITERIA FOR BONE MINERAL DENSITY
Normal	Above -1.0 SD of young adult peak mean value
Low bone mass (osteopenia)	Between -1.0 and -2.5 SD of young adult peak mean value
Osteoporosis	Below -2.5 SD of young adult peak mean value

SD, Standard deviation.

The National Osteoporosis Foundation (NOF) recommends obtaining a bone mineral density assessment in all women 65 years old or older and postmenopausal women younger than 65 years with a risk factor (Table 75-3). The U.S. Preventive Services Task Force (USPSTF) recommends bone density tests in all women age 65 or older and women between 60 and 64 years of age with a risk factor. The NOF recommends obtaining a bone mineral density value for men 70 years old or older; the USPSTF has not recommended screening in men. Databases are available for white, African American, Asian, and Hispanic men and women. These guidelines from the NOF and USPSTF for screening patients for osteoporosis are relatively similar for postmenopausal women but differ for older men. At the time of their review, the USPSTF did not feel there was ample evidence to determine screening guidelines for men.

The WHO developed a fracture risk assessment tool (FRAX) to predict the 10-year risk for hip or any major osteoporotic fracture for women and men between 40 and 90 years of age. The FRAX for the individual patient incorporates femoral neck

FIGURE 75-4 **Left**, This patient has a lumbar spine (L1 through L4) bone mineral density (BMD) of 0.733 g/cm² (white circle with cross on the graph) as measured by dual-energy x-ray absorptiometry (DEXA) and a T-score of -2.9. The reference database graph displays age- and sex-matched mean BMD levels ± 2 standard deviations (SDs) (shaded areas) derived from a normative database from the manufacturer (Hologic, Inc., Bedford, Mass.). The T-score indicates the difference in SD between the patient's BMD and that of the predicted sex-matched mean peak of a young adult; the z-value is the difference in SD between the patient's BMD and the sex-, age-, and ethnicity-matched mean BMD; and the percentage of mean is the patient's BMD as a percentage of the mean peak young adult BMD or age-matched BMD level. **Right**, This patient has a total hip BMD of 0.499 g/cm² (white circle with cross on the graph) as measured by DEXA, a femoral neck T-score of -4.0, and a total hip T-score of -3.6. The reference database graph displays age- and sex-matched mean BMD levels ± 2 SDs (shaded areas) derived from the third National Health and Nutrition Examination Survey. The T-score indicates the difference in SD between the patient's BMD and the predicted sex-matched mean peak young adult BMD; the z-score is the difference in SD between the patient's BMD and the sex-, age-, and ethnicity-matched mean BMD; and the percentage of mean is the patient's BMD as a percentage of the mean peak young adult BMD or age-matched BMD level. (Bone densitometry report for the QDR-4500A bone densitometer, Bedford, Mass., Hologic, Inc.)

T-score, age, gender, height, weight, and specific risk factors, including history of adult fracture, parental hip fracture, current smoking, glucocorticoid use, rheumatoid arthritis, alcohol (≥ 3 drinks per day), and secondary osteoporosis. The fracture risk prediction is specific for race and country and should be used for patients not on therapy.

Bone mineral density determined by DEXA usually can be monitored after 2 years of therapy, depending on the site to be

assessed and the type of therapy prescribed. For example, trabecular bone, which has greater surface area and is more metabolically active than cortical bone, is more likely to show improvements with stronger-acting antiresorptive agents. Changes in bone mass with potent antiresorptive therapy are more prominent in the spine compared with other areas. Seeing no changes in forearm bone mineral density over time is common despite good precision. Although the heel has a high percentage

TABLE 75-3 NATIONAL OSTEOPOROSIS FOUNDATION RECOMMENDATIONS FOR BONE MINERAL DENSITY TESTING

- Women age ≥ 65 yr and men ≥ 70 yr, regardless of clinical risk factors
- Younger postmenopausal women, women in the menopausal transition, and men age 50-69 yr with clinical risk factors for fracture
- Adults who have a fracture after age 50 yr
- Adults who have a condition (e.g., rheumatoid arthritis) or are taking a medication (e.g., glucocorticoids in a daily dose of ≥ 5 mg prednisone or equivalent for ≥ 3 mo) associated with low bone mass or bone loss

of trabecular bone, precision is poor, and monitoring should not be done at this site.

All patients with osteoporosis or low bone mass should have a work-up for secondary causes of bone loss. It should include a serum calcium level (corrected for albumin) to rule out hyperparathyroidism or malnutrition; a 25-hydroxyvitamin D level to assess for vitamin D deficiency or insufficiency; an alkaline phosphatase level to assess for Paget's disease, malignancy, cirrhosis, or vitamin D deficiency; liver and renal function tests to assess for abnormalities; a 24-hour urine calcium and creatinine assay to evaluate for hypercalciuria or malabsorption; a test for sprue in patients with anemia, malabsorption, or hypocalciuria; a thyrotropin level to rule out hyperthyroidism; and serum protein electrophoresis to rule out myeloma in older adults with anemia. Measurement of the parathyroid hormone (PTH) level often is needed to interpret the calcium and vitamin D levels. Total testosterone levels are recommended for men.

A more extensive work-up can be done in severe or unusual cases. A bone biopsy is rarely needed. Markers of bone turnover vary considerably in clinical practice, and these tests usually are reserved for research. However, they may be useful for assessing the rate of bone turnover after prolonged bisphosphonate use or a bisphosphonate holiday.

PREVENTION

General preventive measures for all patients include adequate calcium and vitamin D intake, exercise, and fall prevention techniques. The recommended daily allowance of calcium for adults, as reviewed by the Institute of Medicine, is 1200 mg. Calcium intake can be accomplished by dietary consumption, supplementation, or the combination of diet plus supplement. The supplements should be pure calcium carbonate or pure calcium citrate, taken in divided doses of about 500 to 600 mg twice daily. Calcium carbonate should be taken with meals for best absorption, whereas calcium citrate may be taken with or without food. Calcium supplements are available as tablets and in chewable and liquid forms. Foods such as orange juice, cereals, breads, and nutrition bars are calcium fortified. There is no benefit to taking more than 1200 mg per day, and excess intake may increase the risk of kidney stones and cardiovascular disease (although data are controversial).

Vitamin D is important for calcium absorption and bone mineralization. Vitamin D has nonskeletal benefits and has been associated with improvement in muscle strength and prevention of falls. Vitamin D comes from two sources: diet and photosynthesis. Because dietary sources of vitamin D are limited (e.g., fortified milk, yogurt) and patients are often advised to avoid sun

TABLE 75-4 NATIONAL OSTEOPOROSIS FOUNDATION GUIDELINES FOR TREATMENT

- An adult hip or vertebral fragility fracture
- Osteoporosis by DEXA T-score ≤ -2.5 SD for lumbar spine, total hip, or femoral neck after appropriate evaluation
- Low bone mass by DEXA T-scores between -1.0 and -2.5 SD at the lumbar spine or femoral neck and a WHO FRAX 10-year probability of a hip fracture $\geq 3\%$ or a 10-year probability of major osteoporosis-related fractures $\geq 20\%$ based on a WHO algorithm

DEXA, Dual-energy x-ray absorptiometry; FRAX, fracture risk assessment tool; SD, standard deviation; WHO, World Health Organization.

exposure for prevention of skin cancer and wrinkles, many studies have documented vitamin D deficiency and insufficiency in older adults. Older patients have a reduced ability to synthesize vitamin D in the skin. Low vitamin D levels can lead to secondary hyperparathyroidism.

Vitamin D can be taken in a multivitamin, in a calcium supplement, or in pure form and is available as cholecalciferol (D_3) or ergocalciferol (D_2). Based on data from noninstitutionalized patients without osteoporosis, the daily dose recommended by the Institute of Medicine is 600 IU per day for adults up to age 70 and 800 units for those older than 70 years to achieve a level of at least 20 ng/dL (50 nmol/L). However, the NOF suggests 800 to 1000 IU per day. Elderly patients, those with malabsorption, and obese patients may need greater amounts of vitamin D. Older patients with severe vitamin D deficiency may be given 50,000 IU of vitamin D once per week for 3 months to bring serum vitamin D into the normal range. Activated vitamin D is rarely needed and should not be given on a regular basis for postmenopausal osteoporosis.

Weight-bearing exercise is important for maintaining skeletal integrity. Study results are controversial concerning different types and durations of exercise by postmenopausal women and men. However, weight-bearing or resistance training exercises usually are suggested and have been shown to improve bone mass or maintain skeletal integrity. In patients with new vertebral fractures, physical therapy is important for improving posture and increasing the strength of back muscles.

Because 90% of hip fractures and a significant number of vertebral fractures occur during a fall, preventive measures are suggested for frail older patients at risk for falling. Fall-proofing the household includes installing grab bars in the bathroom and hand rails on stairways, avoiding loose throw rugs and cords, ensuring good lighting by the bedside, and moving objects within easy reach in the kitchen. Other fall prevention measures include eliminating medications that cause dizziness or postural hypotension (if possible), assessing the need for assistive devices (e.g., canes, walkers), and ensuring appropriate footwear and good vision. The benefits of hip protectors for hip fracture reduction are disappointing and controversial, and compliance with these products is often poor.

TREATMENT AND PROGNOSIS

The NOF developed treatment guidelines that incorporate a 10-year fracture risk prediction. The NOF suggests treatment for postmenopausal women and men 50 years old or older, as shown in Table 75-4.

Patients taking glucocorticoids can fracture despite having normal bone density. The American College of Rheumatology suggests that patients starting glucocorticoids who will be treated for 3 months or longer have a bone density test and start antiresorptive therapy if indicated according to their guidelines.

Bisphosphonates

Bisphosphonates are the mainstay of osteoporosis prevention and treatment. They inhibit the cholesterol synthesis pathway in osteoclasts, causing early apoptosis and inhibiting osteoclast migration and attachment. Unlike other agents, bisphosphonates are incorporated into bone, the half-life is long, and the agent may be recycled.

In the United States, the bisphosphonates alendronate, risedronate, ibandronate, and zoledronic acid have been approved for the prevention and treatment of osteoporosis. Alendronate can increase bone mass by about 8% at the spine and 4% at the hip over 3 years. This increase has been associated with an approximately 50% reduction in spine, hip, and forearm fractures (Table 75-5). Alendronate is prescribed at 35 mg once weekly for osteoporosis prevention and 70 mg once weekly for the treatment of osteoporosis. Alendronate has been approved for use in men and patients with glucocorticoid-induced osteoporosis.

Risedronate is approved for the prevention and treatment of osteoporosis at a dose of 35 mg per week or 150 mg per month or as a delayed dose after breakfast of 35 mg per week. Large-scale, multicenter studies have shown improvements in bone mass of about 6% to 7% at the spine and 3% at the hip over 3 years. These studies revealed a 50% reduction in vertebral fractures, 40% reduction in nonvertebral fractures, and 40% reduction in hip fractures (see Table 75-5). Risedronate is approved for the treatment of osteoporosis in men and for the prevention and treatment of patients with glucocorticoid-induced osteoporosis.

Oral ibandronate is approved for the prevention and treatment of postmenopausal osteoporosis. After 3 years of treatment, ibandronate increased bone density by 6.5% at the spine and 3.4% at the hip, and it reduced new vertebral fractures by 62%. No reductions in nonvertebral or hip fractures occurred. Ibandronate is

approved at an oral dose of 150 mg monthly and for treatment at an intravenous dose of 3 mg every 3 months.

Zoledronic acid is approved for the treatment of postmenopausal osteoporosis, osteoporosis in men, and steroid-induced bone loss. The 3-year pivotal trial demonstrated increases of 6.9% of bone density at the spine and 6.0% at the hip, and the drug reduced spinal fractures by 70%, nonvertebral fractures by 25%, and hip fractures by 41%. Zoledronic acid is given at a dose of 5 mg intravenously once per year for treatment and 5 mg intravenously every 24 months for prevention.

Because oral bisphosphonates are poorly absorbed, they must be taken first thing in the morning on an empty stomach with a full glass of water. Patients must wait 30 minutes (when taking alendronate and risedronate) to 60 minutes (when taking ibandronate) before eating and must not lie down. A delayed-release form of risedronate can be taken after breakfast.

Potential side effects of bisphosphonates include epigastric distress, heartburn, and esophagitis. Intravenous bisphosphonates have been associated with an influenza-like syndrome after infusion. Bisphosphonates can also cause arthralgias and myalgias. They are contraindicated in patients with renal insufficiency (i.e., estimated glomerular filtration rate of 30 to 35 mL/minute). Osteonecrosis of the jaw is a rare adverse event of abnormal bone growth in the jaw, which is more often associated with high-dose intravenous bisphosphonates in patients with cancer and poor oral hygiene. Atypical femoral shaft fractures have been reported rarely after long-term use (>5 years) of bisphosphonates. These fractures may manifest with a prodrome of unilateral or bilateral thigh pain, and fractures may occur with minimal activity. These fractures are rare after osteoporosis treatment but common in cancer patients receiving frequent high doses intravenously.

Calcitonin

Calcitonin is a 32-amino-acid peptide produced by the parafollicular cells of the thyroid gland. The pivotal clinical treatment trial did not show significant changes in bone mineral density after 3 years. However, the 200-IU dose of nasal calcitonin was associated with a 50% reduction in vertebral fractures (see

TABLE 75-5 U.S. FOOD AND DRUG ADMINISTRATION–APPROVED THERAPIES FOR PREVENTION AND TREATMENT OF OSTEOPOROSIS

AGENT	PREVENTION/TREATMENT	DOSAGE	VERTEBRAL FRACTURE REDUCTION	HIP FRACTURE REDUCTION	WOMEN/MEN	STEROID-INDUCED OP

OP, Osteoporosis; PO, oral administration; prev, prevention; PTH, parathyroid hormone; SC, subcutaneous administration; Treat, treatment.

*Alendronate, risedronate, ibandronate, and zoledronic acid are bisphosphonates.

¹Oral only.

²Short-term prevention or management.

³For management.

Table 75-5). No reduction in nonvertebral or hip fractures was found. The U.S. Food and Drug Administration (FDA) advisory panel is reviewing an association with cancer.

Denosumab

The receptor activator of nuclear factor- κ B (RANK) and its ligand (RANKL) are mediators of osteoclast activity. Compared with placebo, denosumab, an antibody to RANKL, produced a relative increase in bone mineral density at the spine of 9.2% and hip of 6.0% over 3 years, and it reduced fractures by 68% at the spine, 40% at the hip, and 20% at nonvertebral sites. Denosumab is approved for postmenopausal women and men with osteoporosis, for men with prostate cancer on androgen deprivation therapy, and for postmenopausal women with breast cancer on aromatase inhibitors. It is given as a subcutaneous 60-mg injection every 6 months.

Estrogen Agonists-Antagonists

Estrogen agonists-antagonists were previously called selective estrogen receptor modulators (SERMs) because they have some estrogen-like and anti-estrogen-like benefits. Raloxifene is approved for the prevention and treatment of osteoporosis. The Multiple Outcomes of Raloxifene Evaluation (MORE) trial found that bone mass was increased by 4% at the spine and 2.5% at the femoral neck over 3 years. This increase was associated with a 50% reduction in vertebral fractures. No reduction in nonvertebral or hip fractures was seen (see Table 75-5). Treatment was associated with improved lipid status, as shown by decreased total and low-density lipoprotein cholesterol.

Raloxifene is not associated with endometrial hyperplasia, and patients should not have bleeding or spotting. They do not have breast tenderness or swelling. Raloxifene reduces the risk for invasive breast cancer in postmenopausal women with osteoporosis and in women at high risk for invasive breast cancer. Patients have the same small risk of deep vein thrombosis or pulmonary embolus that is found with hormone therapy. Raloxifene does not relieve postmenopausal symptoms and may exacerbate hot flashes. Studies have not found a significant impact on cardiovascular disease. Raloxifene can be given with or without food in a daily oral dose of 60 mg per day.

Hormone Therapy

Investigators of the Women's Health Initiative, a large, randomized, placebo-controlled, multicenter trial evaluating hormone therapy, reported a 36% reduction in hip and vertebral fractures after 5.2 years. In addition to improvements in bone mass, benefits include an improved lipid profile, decreased colon cancer incidence, and decreased menopausal symptoms. However, because of the potential risks of hormone therapy (i.e., cardiovascular events, breast cancer, deep vein thrombosis, pulmonary embolus, and gallbladder problems), it should be used only for prevention or management of menopausal symptoms, and other agents should be used for the treatment of osteoporosis.

Parathyroid Hormone

Recombinant human PTH (1-34), or teriparatide, is an osteoanabolic agent that increases spinal bone mineral density by 9.7%

and hip bone mineral density by 2.6% in 18 months. It is associated with a 65% reduction in vertebral fractures and a 53% reduction in nonvertebral fractures. Teriparatide is taken for up to 2 years as a subcutaneous, 20- μ g daily dose for postmenopausal women and men at high risk for fracture. After therapy, patients benefit from antiresorptive therapy to prevent bone loss. Recombinant human PTH (1-84) is approved for use in Europe.

Alternative Therapies

Medical Therapies

Strontium ranelate is an approved agent for the treatment of osteoporosis in Europe, but it is not FDA approved in the United States. The mechanism of action is not fully understood, but strontium is thought to stimulate osteoblast proliferation and inhibit osteoclast formation. Inhibition of the protease cathepsin K appears to prevent bone resorption with no major impact on bone formation. Another promising osteoanabolic therapeutic target is the inhibition of sclerostin, a potent inhibitor of bone formation, with an antibody.

Combination therapy has been examined with two antiresorptive agents or an antiresorptive and osteoanabolic agent together. Overall, studies with combination therapy have suggested minor improvements in bone mass over therapy with single agents. Because studies have not shown greater fracture reduction, this type of combination therapy with two antiresorptive agents or an antiresorptive plus an osteoanabolic usually is not recommended. However, it is recommended to follow osteoanabolic therapy using teriparatide with an antiresorptive therapy such as a bisphosphonate to maintain the gain.

Vertebroplasty and Kyphoplasty

Vertebroplasty involves injection of cement (i.e., polymethylmethacrylate) into a compressed vertebra to prevent the vertebral body from further collapse. Kyphoplasty introduces a balloon into the vertebral body to expand it, followed by cement placement inside the vertebral body. This approach expands the vertebral body and may increase height. Some studies suggest a significant reduction in pain early on, but the long-term pain reduction may be similar to that of placebo. Ongoing studies are needed to determine whether differences in outcomes can be found between vertebroplasty and kyphoplasty. These procedures are recommended only for patients with significant pain from vertebral fractures and are not routinely performed in asymptomatic patients with vertebral osteoporosis.

Approach to the Patient with Rheumatic Disease

Niveditha Mohan

INTRODUCTION

Rheumatic diseases encompass a range of musculoskeletal and systemic disorders that involve the joints and periarticular tissues. Tissue degeneration results from autoimmune responses, chronic inflammation, local trauma, and infection, producing gout, osteoarthritis, and connective tissue diseases such as rheumatoid arthritis and systemic lupus erythematosus (SLE).

Differentiating localized from systemic processes, executing logical diagnostic procedures, and embarking on appropriate therapeutic courses demand careful clinical evaluation. The medical history and physical examination are paramount in this process. Laboratory tests are more confirmatory than diagnostic. The connective tissue screen is performed at the bedside, not in the laboratory. Confirmation or exclusion of systemic connective tissue disease on the basis of laboratory results is unreliable and therefore unwise.

MUSCULOSKELETAL HISTORY AND EXAMINATION

A logical approach to musculoskeletal complaints is indispensable in arriving at the correct diagnosis. Features in the medical history that are useful for distinguishing different types of arthritis are listed in [Tables 76-1](#) and [76-2](#). When a patient has a musculoskeletal complaint, a thorough history and physical examination usually provide the diagnosis, although further investigations may be necessary for confirmation.

The first step is to confirm that the complaint originates from the musculoskeletal system and is not referred pain caused by other organ system pathology (e.g., left shoulder pain due to cardiac disease). The next step is to define whether the problem is articular or extra-articular based on the history and clinical presentation.

Demographic data provide useful information. The age of the patient can point to a specific rheumatic disorder. The spondyloarthropathies are more commonly diagnosed in young men, SLE in young women, gout in middle-aged men and postmenopausal women, and osteoarthritis in the older population. Asymmetrical pain and swelling in the knees have different connotations in a 70-year-old patient than they do in a 20-year-old patient.

Immune status may affect the diagnosis of rheumatic disease. Immunocompromised patients should be evaluated for infectious arthritis. Patients with human immunodeficiency virus (HIV) infection may have a severe form of Reiter's syndrome or a sudden flare of psoriasis or psoriatic arthritis.

The patient's history provides the basis for differentiating inflammatory from noninflammatory arthropathies. Inflammatory arthritis is characterized by pain at rest, morning stiffness (i.e., gelling), joint swelling, and joint tenderness. In osteoarthritis and nonarthritic musculoskeletal problems, pain usually does not occur at rest and is precipitated by activity. Some osteoarthritic joints are stiff initially but are improved with activity. The onset of disease is abrupt in crystal-induced arthritis, less so in septic arthritis, and slow and insidious in most other disorders.

Patterns of joint involvement are typical of certain disorders: monoarthritis (one joint), as in septic or crystal-induced arthritis; pauciarthritis or oligoarthritis (two to four joints), as in Reiter's syndrome or psoriatic arthritis; and polyarthritis (five or more joints), as in rheumatoid arthritis or SLE. Symmetry, migratory features, large versus small joint involvement, and axial versus appendicular locations are characteristic features of specific diseases and should be sought in the patient's history. Enthesopathy (i.e., disease at the attachment of tendons or ligaments to bone) can indicate a spondyloarthropathy.

Constitutional features such as fatigue, weight loss, and fever are seen in systemic autoimmune disease and infection but not in localized conditions. A thorough review of systems can provide clues to the primary diagnosis by defining associated systemic syndromes. Although there are many exceptions to these demographic and clinical generalizations, they provide helpful starting points when a patient is being evaluated for the first time.

On physical examination, active and passive range of motion in all joints should be carefully assessed, and tenderness, swelling, warmth, erythema, deformity, and joint effusions should be evaluated ([Fig. 76-1](#)). Patients are frequently unaware of detectable joint abnormalities, including deformity and effusion, which are signs of joint disease. Reported pain may be referred from another site, which can be determined by examination. Pain in the knee

TABLE 76-1 CLINICAL FEATURES THAT ARE HELPFUL IN THE EVALUATION OF ARTHRITIS

Age, sex, ethnicity, family history	Constitutional symptoms and signs (e.g., fever, fatigue, weight loss)
Pattern of joint involvement	Synovitis, bursitis, tendinitis
Monoarticular, oligoarticular, polyarticular	Involvement of other organ systems (e.g., rash, mucous membrane lesions, nail lesions)
Large versus small joints	Arthritis-associated diseases (e.g., psoriasis, inflammatory bowel disease)
Symmetry	Anemia, proteinuria, azotemia
Insidious versus rapid onset	Erosive joint disease
Inflammatory versus noninflammatory pain (e.g., morning stiffness, gelling, night pain)	

TABLE 76-2 DIFFERENTIATING FEATURES OF COMMON ARTHRITIDES

DISEASE	DEMOGRAPHICS	JOINTS INVOLVED	SPECIAL FEATURES	LABORATORY FINDINGS
Gout	Men, postmenopausal women	Monoarticular or oligoarticular	Podagra, rapid onset of attack, polyarticular gout, tophi	SF: Crystals, high WBC count, >80% PMNs
Septic arthritis	Any age	Usually large joints	Fever, chills	SF: High WBC count, >90% PMNs, culture
Osteoarthritis	Increases with age	Weight-bearing, hands		Noninflammatory SF
Rheumatoid arthritis	Any age, predominantly women ages 20-50 yr	Symmetrical, small joints	Rheumatoid nodules, extra-articular	SF: High WBC count, >70% PMNs
Reactive arthritis (Reiter's syndrome)	Young males	Oligoarticular, asymmetrical	Urethritis, conjunctivitis, skin and mucous membranes	SF: Moderate WBC count, >50% PMNs
Spondyloarthropathy	Young to middle-aged men	Axial skeleton, pelvis (sacroiliac joints)	Uveitis, aortic insufficiency, enthesopathy	
Systemic lupus erythematosus	Women in childbearing years	Hands, knees	Nonerosive joint disease, autoantibodies, mostly mononuclear; multiorgan disease	SF: Low to moderate WBC count, almost 100% have antinuclear antibodies

PMNs, Neutrophils; SF, synovial fluid; WBC, white blood cell.

FIGURE 76-1 Anatomic structures of the musculoskeletal system (*left*). Locations of musculoskeletal disease processes (*right*). (From Gordon DA: Approach to the patient with musculoskeletal disease. In Bennett JC, Plum F, editors: Cecil textbook of medicine, ed 20, Philadelphia, 1996, WB Saunders, p 1440.)

is often a sign of hip disease and may be reproduced on examination of the hip. Palpable synovitis (i.e., thickening of the synovial membrane) is helpful in diagnosing inflammatory arthritides such as rheumatoid arthritis.

Different diseases have distinctive patterns of joint involvement, which provide critical diagnostic information. For example, prominent disease of distal interphalangeal joints is seen in psoriasis and inflammatory osteoarthritis. Wrist and metacarpophalangeal involvement are almost universal in rheumatoid arthritis but rare in osteoarthritis. Examination of the axial skeleton may reveal diminished lumbar flexion, decreased rotational motion of the spine, and decreased chest expansion, features of ankylosing spondylitis and other spondyloarthropathies. Patients may report symptoms in only a single joint, but finding additional affected joints on physical examination can change the entire evaluation.

Because rheumatic diseases may involve any organ system, a full physical examination should be performed for all patients. Alopecia and fundoscopic changes (in SLE), uveitis (in spondyloarthropathy and juvenile arthritis), conjunctivitis (in reactive

arthritis), sicca symptoms (in Sjögren syndrome), oral and other mucous membrane ulcers (in reactive arthritis, SLE, and Behçet syndrome), lymphadenopathy (in SLE and Sjögren syndrome), and cutaneous lesions (in psoriasis, dermatomyositis, scleroderma, SLE, and vasculitides) should be considered. Recurrent otorhinolaryngologic complaints, such as sinusitis, should raise suspicion for granulomatosis with polyangiitis (i.e., Wegener's granulomatosis). Lesions of psoriasis in the scalp, umbilicus, and anal crease; thickening of the skin on the fingers in scleroderma; and mucous membrane ulcers are often overlooked.

The lung examination may find evidence of interstitial fibrosis (in scleroderma, SLE, rheumatoid arthritis, and myositis), and a cardiac evaluation may reveal aortic insufficiency (in SLE and spondyloarthropathy), pulmonary hypertension (in systemic sclerosis), or evidence of cardiomyopathy (in systemic sclerosis, myositis, and amyloidosis). Pleural and pericardial rubs may be detected in SLE, rheumatoid arthritis, and scleroderma. Hepatosplenomegaly (in SLE and rheumatoid arthritis) and abdominal distention (in scleroderma) are also valuable clinical clues.

Muscle examination may reveal weakness from myositis, neuropathy (in vasculitis and SLE), myopathy (in steroid myopathy), or synovitis (in rheumatoid arthritis, SLE, and spondyloarthritis). A complete neurologic examination may reveal carpal tunnel syndrome, peripheral neuropathy such as mononeuritis multiplex (i.e., asymmetrical sensory or motor neuropathy seen in many vasculitides), and central nervous system disease (in SLE and vasculitis). Recurrent miscarriages, livedo reticularis, Raynaud's phenomenon, and recurrent thrombotic events indicate antiphospholipid antibody syndrome (in primary or secondary SLE).

The initial evaluation must determine whether diagnosis and treatment of the patient's problem requires urgent attention. Infectious processes need immediate treatment. Acute joint inflammation, fever, and systemic signs such as chills, night sweats, and leukocytosis provide supporting evidence for infection. Gouty arthritis may share some or all of these clinical features, but its onset tends to be more abrupt. Inflammation extending beyond the margins of the joint is characteristic of septic arthritis and is otherwise seen only in crystal disease and rheumatoid arthritis. Nonarticular processes such as cellulitis, septic bursitis, tenosynovitis, and phlebitis may mimic infectious arthritis. Analysis of synovial fluid is the key to diagnosis.

Acute nerve entrapment or spinal cord compression, tendon rupture, and fractures may occur in the absence of obvious trauma. Spinal cord compression may be the result of a herniated disk or vertebral subluxation. Tendon rupture may occur in inflammatory arthritides, particularly in the wrist of patients with rheumatoid arthritis. Pelvic and other insufficiency fractures may be seen in patients with osteoporosis or osteomalacia. Careful musculoskeletal and neurologic examinations help in the detection of these disorders, all of which require urgent treatment.

The onset of systemic rheumatic diseases is usually insidious, and the clinical course is prolonged. Treatment is usually not urgent and can be safely deferred, particularly if the diagnosis is uncertain. However, potential threats to life or the possibility of serious and irreversible organ damage may require urgent therapy. Patients with SLE or systemic vasculitis may have central or peripheral nervous system disease, including brain and peripheral nerve infarcts; glomerulonephritis; inflammatory or hemorrhagic lung disease; coronary artery involvement; intestinal infarcts; and digital infarcts. Threatened digit loss may also be seen in cases of scleroderma and Raynaud's disease. Renal crisis

may occur in scleroderma, with vasculopathy leading to renal infarcts, azotemia, microangiopathy, and severe hypertension. Acute blindness is a potential complication of giant cell arteritis, and the diagnosis requires urgent therapy even before confirmatory biopsy.

Acute inflammatory myositis should be promptly treated because it may progress rapidly and involve the respiratory musculature. In some cases, major organ involvement may be occult. When systemic disease is suggested, the patient's lungs and kidneys should be carefully evaluated.

LABORATORY TESTING

Synovial fluid analysis is an important part of the evaluation of arthritis (Table 76-3). It helps to distinguish between inflammatory and noninflammatory arthritis, and results can be diagnostic of infectious arthritis or crystal disease.

Synovial fluid consists of an ultrafiltrate of plasma plus hyaluronic acid that is secreted by synovial lining cells. Evaluation of synovial fluid should include a cell count and differential, examination for sodium urate and calcium phosphate dehydrate crystals, Gram stain, and culture. Synovial fluid glucose and protein levels are not useful tests. Synovial fluid examination should be performed for all acute arthritides and all situations in which joint infection is likely. It should be performed at least once to evaluate chronic inflammatory arthritis. Aspiration and analysis of fluid before therapy are essential for appropriate decision making.

Although autoantibodies are often considered the hallmark of rheumatic diseases, their utility in diagnosing individual patients is much less than commonly assumed. Although almost 95% of patients with SLE have antinuclear antibodies (ANAs), as do most patients with scleroderma and autoimmune myositis, the proportion of patients with other rheumatic diseases who have positive test results is much lower. Conversely, 15% to 25% of healthy persons have ANAs, sometimes in high titers, when commercial test kits are used. Older persons and patients with nonrheumatic systemic diseases such as malignancies and nonrheumatic autoimmune diseases such as thyroiditis or hypothyroidism have even higher frequencies of ANAs.

The very low specificity of a positive ANA result in the absence of clinical findings for an autoimmune disorder precludes its use as a screening test for disease in the general population. Other autoantibodies may be more useful and are discussed in subsequent chapters.

TABLE 76-3 CLASSIFICATION OF SYNOVIAL EFFUSIONS BY SYNOVIAL WHITE BLOOD CELL COUNT

GROUP	SAMPLE DIAGNOSES	APPEARANCE	SYNOVIAL FLUID WBC COUNT (MM ³)*	PMN CELLS (%)
Normal		Clear, pale yellow	0-200	<10
I. Noninflammatory	Osteoarthritis; trauma	Clear to slightly turbid	50-2000 (600)	<30
II. Mildly inflammatory	Systemic lupus erythematosus	Clear to slightly turbid	100-9000 (3000)	<20
III. Severely inflammatory (noninfectious)	Gout	Turbid	2000-160,000 (21,000)	≈70
	Pseudogout	Turbid	500-75,000 (14,000)	≈70
	Rheumatoid arthritis	Turbid	2000-80,000 (19,000)	≈70
IV. Severely inflammatory (infectious)	Bacterial infections	Very turbid	5000-250,000 (80,000)	≈90
	Tuberculosis	Turbid	2500-100,000 (20,000)	≈60

PMNs, Neutrophils; WBC, white blood cell.

*Range, with mean values in parentheses.

Rheumatoid factor is found in approximately 80% of patients with rheumatoid arthritis but also found in other rheumatic diseases, chronic infection, neoplasia, and almost any disease state that can cause chronic hyperglobulinemia. Neither positive nor negative test results are diagnostic, and the results should be interpreted only in the clinical context. Although the specificity of the rheumatoid factor is low, it does predict more aggressive joint disease and extra-articular joint manifestations.

Antibodies to cyclic citrullinated peptides are helpful in diagnosing rheumatoid arthritis because they have a high specificity (>90%). Their sensitivity varies from about 50% to 75%. Antibody tests should be ordered and repeated only if they can help in making the diagnosis, assessing the prognosis, or altering the treatment plan.

Tests for acute phase proteins, C-reactive protein, and the erythrocyte sedimentation rate are nonspecific, but positive results suggest an inflammatory disease. In some cases, such as in patients with giant cell arteritis and polymyalgia rheumatica, these tests may be useful for the diagnosis and monitoring the course of disease and therapy. Anemia may suggest chronic disease or hemolytic anemia. Leukopenia, especially lymphopenia, suggests SLE, and thrombocytosis indicates active inflammation. Leukocytosis may reflect inflammation or infection, and glucocorticoid therapy also elevates the neutrophil cell count by demarginalization. Urinalysis should always be performed for patients with systemic disease. Proteinuria, red blood cells, and casts should be considered evidence of occult renal disease. Laboratory tests should always be considered in the context of the clinical presentation.

RADIOGRAPHIC STUDIES

Radiographic studies often show changes characteristic of particular diseases. In patients with established rheumatoid arthritis, radiographs may demonstrate classically erosive disease of the small joints of the wrists, the ulnar styloid, the metacarpophalangeal and proximal interphalangeal joints, and the small joints in the foot. The erosions are bland and nonreactive. In contrast, erosive psoriatic arthritis causes a sclerotic reaction, and the patient may have characteristic telescoping of joints, also called *pencil-in-cup lesions*. Large erosions with overhanging sclerotic margins and even juxta-articular tophi may be seen in gout.

In ankylosing spondylitis, sacroiliitis is observed on pelvic x-ray films and has high diagnostic specificity. Syndesmophytes (i.e., calcification of the outer rim of the annulus fibrosus), bridging osteophytes, calcification of spinal ligaments, and a typical bamboo spine in the late stages are seen on lumbar and chest radiographs. Joint space narrowing, bony spurs, and sclerosis are seen in osteoarthritis. Chondrocalcinosis is a common finding. It may be asymptomatic or may lead to crystal arthritis (i.e., pseudogout). In acute arthritis, radiographs are much less helpful because bony changes take time to develop; only in septic joint disease is destruction observed in the early stages.

Imaging modalities such as magnetic resonance imaging (MRI), radionuclide scans, ultrasound, and computed tomography are often useful in assessing diseases of bones, joints, muscle, and soft tissues. Ultrasound may be used to detect synovial cysts, especially Baker's cysts of the knee, and it is being used more frequently in the outpatient setting to guide procedures.

MRI is the procedure of choice for evaluating early avascular necrosis of bone, especially the hips, and for meniscal or rotator cuff disease. MRI is preferred for evaluating intervertebral disk disease with radiculopathy and spinal stenosis, and it is useful for assessing solid lesions of bone and joints, including neoplastic lesions. The sensitivity of MRI for detecting edema (i.e., water) enables evaluation of infectious and noninfectious inflammatory muscle diseases. MRI is a sensitive but not a specific modality for evaluating osteomyelitis, properties shared with radionuclide imaging. MRI should not supplant clinical evaluation or plain radiography.

In many instances, diagnosis can be made with certainty only by pathologic examination of tissue. Muscle biopsy may be necessary to establish a diagnosis of inflammatory muscle disease, and nerve biopsy may be needed to detect vasculitis. Skin biopsy is useful in differentiating the many causes of rheumatologic skin disease. Renal biopsy is often needed for determination of the diagnosis, treatment, and prognosis.

SUMMARY

The evaluation of arthritis begins with a detailed history consisting of the location and pattern of joint involvement, differentiation of inflammatory from mechanical and other causes, and a thorough review of systems to determine the nonarticular systemic features. The patient's age and sex, family history, medication history, and coexisting medical conditions have a bearing on the diagnosis and treatment plan. Radiographic and laboratory studies, particularly synovial fluid analysis, provide confirmatory and sometimes diagnostic information.

 For a deeper discussion of these topics, please see Chapter 256, "Approach to the Patient with Rheumatic Disease," in Goldman-Cecil Medicine, 25th Edition.

Rheumatoid Arthritis

Rayford R. June and Larry W. Moreland

DEFINITION AND EPIDEMIOLOGY

Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory disorder of unknown cause that is characterized by symmetrical, polyarticular pain and swelling, morning stiffness, and fatigue. RA has a variable course, often with periods of exacerbations and, less frequently, true remissions. Outcomes range from rarely seen remitting disease to severe disease that produces disability and, for some patients, premature death.

Without treatment, most patients have progressive joint damage and significant disability within a few years. Since the introduction of tumor necrosis factor- α (TNF- α) inhibitors in the 1990s, there has been a change in the treatment paradigm, and many conventional and biologic therapies are now available to treat this previously debilitating chronic disease.

RA is a worldwide problem, with a prevalence of 0.5% to 1% of the adult population and an annual incidence of 0.03%. RA is three times more common among women than men, and the disease affects individuals at any age, including infants and the elderly. However, it occurs most commonly in women between the ages of 40 and 50 years. RA is uncommon among men younger than 45 years of age, but the incidence rises steeply with increasing age. Among women, the incidence rises until age 45, plateaus until age 75, and then declines. Numerous studies have demonstrated increased mortality rates for patients with RA compared with the general population. The increased mortality rate is attributed to infectious and cardiovascular complications.

The underlying cause of RA (i.e., triggers in the susceptible host) is unknown. RA may consist of multiple diseases now defined by common clinical manifestations, and there may not be a single predominant mechanism of initiation or perpetuation. As for most autoimmune diseases, RA is thought to result from a complex interaction of genetic and environmental factors. Smoking, obesity, silica exposure, mineral oil, and organic solvents have been associated with the development of RA. Smoking has the most impact, particularly on anti-cyclic citrullinated peptide (CCP) antibody-positive disease.

An individual's genetic profile also plays a critical role in the susceptibility to and severity of RA. Supporting a genetic component, studies have revealed a 15% concordance in monozygotic twins that is approximately four times greater than the rate in dizygotic twins. The genes with the greatest impact lie in the class II major histocompatibility (MHC) locus, which accounts for one third of the genetic risk for RA. A specific sequence on the HLA-DR haplotype involved in antigen recognition is called the *shared epitope* because it is strongly associated with more severe RA and extra-articular manifestations. Although

important, the shared epitope does not fully explain RA because it occurs in only 25% to 35% of the white population. The chance of developing RA in carriers is only 1 in 25.

The interplay between environmental and genetic factors is most clearly seen with the increased risk of RA associated with smoking and the MHC class II loci. The exact association between the two is unclear, but research has shown that the bacteria in periodontal disease, which are increased with smoking, can promote citrullination. Anti-CCP antibodies are associated with a more aggressive disease.

For a deeper discussion of these topics, please see Chapter 264, "Rheumatoid Arthritis," in Goldman-Cecil Medicine, 25th Edition.

PATHOLOGY AND PATHOGENESIS

RA is a heterogeneous disease with a complex pathogenesis. RA is a clinical diagnosis and a single phenotype, but the underlying genotype may not be unique. Instead, several signaling pathways may lead to the same clinical presentation.

Synovial inflammation characterizes RA, along with loss of tolerance, autoantibody production, bone destruction, and systemic inflammation. Many advances have been made in understanding the cell-cell interactions and cytokine signaling, but little is known about the loss of tolerance. Many of the insights into the pathogenesis of RA have resulted from analyzing the responses to cytokine inhibition (i.e., interleukin-1 [IL-1], TNF- α , and interleukin-6 [IL-6]) and to specific T- and B-cell-directed therapies.

The process of synovial inflammation and proliferation may be initiated by an interaction between antigen-presenting cells (APCs) and CD4⁺ T cells. APCs display complexes of class II MHC molecules and peptide antigens that bind to specific receptors on the T cells. Clonal expansion of T-cell subsets occurs with an appropriate second signal or costimulation delivered by the APC to the T cell. Activated T_H1 and T_H17 cell subsets appear to predominate in synovial tissues. These cell types stimulate synovial macrophages to secrete proinflammatory cytokines such as IL-1, TNF- α , and IL-6 to activate many inflammatory pathways.

The humoral immune system is also involved in the pathogenesis of RA. The autoantibodies found most frequently in patients with RA are immunoglobulin M (IgM) rheumatoid factor (RF) and anti-CCP. RF and anti-CCP are associated with aggressive, erosive RA (see [Diagnosis and Differential Diagnosis](#)) and are found in serum before the development of clinical RA. Although a causal link has not been confirmed, CCP antibodies, combined

with genetic and environmental factors (e.g., smoking, periodontal disease), are involved in the development of RA.

RA pathogenesis occurs in stages. In the induction phase, the joint's environment enables recruitment of inflammatory cells. Cigarette smoke, bacterial products, viral components, and other environmental stimuli may amplify this process. A genetic propensity for autoreactivity may initiate an irreversible pathway to RA.

The destructive phase, which can be antigen dependent or independent, involves mesenchymal elements such as fibroblasts and synoviocytes. Bone erosions result from local differentiation and activation of osteoclasts, whereas cartilage damage appears to be caused by proteolytic enzymes produced by synoviocytes, macrophages, and synovial fluid neutrophils. Counter-regulatory mechanisms (e.g., soluble TNF- α receptors, suppressive cytokines, protease inhibitors, natural cytokine antagonists) are not produced in high enough levels, leading to a loss of tolerance.

Cytokines, which are hormone-like proteins that regulate many immune cell functions, have been implicated in synovial inflammation. The inflammatory milieu of the joint is dominated by proinflammatory factors produced by macrophages and fibroblasts, especially in the synovial intimal lining. IL-1, IL-6, TNF- α , and many other cytokines and chemokines have been identified at the protein and mRNA levels in the synovium.

Joint damage in RA results from proliferation of the synovial intimal layer that forms a pannus that overgrows, invades, and destroys adjacent cartilage and bone (Fig. 77-1). Fibroblast-like

synoviocytes and macrophages are the predominant cellular components of the invading pannus of the synovium. Extracellular matrix damage resulting from synovial expansion is caused by several families of enzymes, including serine proteases, cathepsins, and matrix metalloproteinases.

For a deeper discussion of these topics, please see Chapter 264, "Rheumatoid Arthritis," in Goldman-Cecil Medicine, 25th Edition.

CLINICAL PRESENTATION

Articular Manifestations

RA manifests with a symmetrical polyarthritis that typically starts with the small joints of the hands, wrists, and feet and progresses to the synovium of the shoulders, elbows, hips, knees, and ankles. Patients have an insidious onset of inflammatory pain, which is pain and stiffness that is worse with inactivity and is improved with movement. Prolonged morning stiffness, usually lasting more than 1 hour, is a classic feature of RA (Table 77-1). Any diarthrodial (synovial) joint may be involved, including the apophyseal (spinal), temporomandibular, and cricoarytenoid joints. Involved joints are swollen, warm, and tender, and they may have effusions. The synovium, which is normally a few cell layers thick, becomes palpable on examination (i.e., synovitis).

Without treatment, RA progresses in some patients to joint destruction and deformity. Erosive lesions of bone and cartilage

FIGURE 77-1 Pathogenetic events in rheumatoid arthritis. The proliferative synovial pannus invades at the bone-cartilage interface. Interleukin-1 (IL-1) and tumor necrosis factor- α (TNF) activate synovial cells (SC) to produce prostaglandins and matrix metalloproteinases (MMPs). In the synovial fluid, polymorphonuclear leukocytes (PMN), activated by immune complexes and complement, produce mediators of inflammation and destruction. CD, Chondrocytes; MNC, mononuclear cell; OC, osteoclast.

TABLE 77-1 CLINICAL CHARACTERISTICS OF RHEUMATOID ARTHRITIS

ARTICULAR FEATURES	EXTRA-ARTICULAR FEATURES
Morning stiffness or gelling	Rheumatoid nodules: subcutaneous, pulmonary, sclera
Symmetrical joint swelling	Lung disease
Predilection for wrists and proximal interphalangeal, metacarpophalangeal, and metatarsophalangeal joints	Vasculitis, especially skin and peripheral nerves
Erosions of bone and cartilage	Pleuropericarditis
Joint subluxation and ulnar deviation	Scleritis and episcleritis
Inflammatory joint fluid	Leg ulcers
Carpal tunnel syndrome	Felty's syndrome
Baker's cyst	

often are visible radiographically at the margins of bone and cartilage, the sites of synovial attachment. However, not all patients with RA have erosive disease. Tenosynovitis (i.e., inflammation of tendon sheaths) leads to tendon malalignment and stretching or shortening.

Common deformities are ulnar deviation at the metacarpophalangeal joints and volar subluxation at those joints and at the wrists. Flexion and extension contractures in the proximal and distal interphalangeal (PIP and DIP) joints of the fingers lead to the characteristic swan-neck deformity (i.e., flexion contracture at the DIP joint and hyperextension at the PIP joint) or boutonnière deformity (i.e., flexion contracture at the PIP and hyperextension at the DIP joint).

Synovitis at the wrists can lead to median nerve compression and carpal tunnel syndrome. Rarely, long-standing cervical spine disease may lead to C1-C2 subluxation and spinal cord compression. Rupture of synovial fluid from the knee into the calf (i.e., Baker's cyst) may mimic deep vein thrombosis or occasionally imitate cellulitis.

Extra-articular Manifestations

RA is a systemic disease with multiple extra-articular manifestations (see [Table 77-1](#)). Constitutional symptoms include fatigue, low-grade fever, weight loss, and myalgia. Extra-articular manifestations are more common in RF-positive patients with uncontrolled articular disease. On the skin, grossly palpable subcutaneous rheumatoid nodules are common along other extensor tendon surfaces, especially at the elbows, and are associated with RF positivity. Less commonly, rheumatoid nodules may occur in the lungs, pleura, pericardium, sclerae, and other sites, including the heart in rare cases. In the eyes, RA commonly is associated with keratoconjunctivitis sicca with coexistent Sjögren syndrome and less often with scleritis and episcleritis.

Lung involvement in RA usually includes interstitial lung disease and may include pleuropericarditis, producing pleural and pericardial effusions. The cardiovascular effects of RA can range from long-term inflammation leading to progressive coronary artery disease to pericarditis to a small and medium-sized vasculitis. The vasculitis of RA can produce cutaneous lesions (e.g., ulcers, skin necrosis) and mononeuritis multiplex.

RA commonly has hematologic complications and is associated with anemia of chronic disease and thrombocytosis. Patients with RA also have an increased incidence of lymphoma. Felty's syndrome (i.e., splenomegaly, leukopenia, and recurrent

TABLE 77-2 2010 ACR/EULAR CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS

For patients who have at least 1 joint with definite synovitis and for whom the synovitis is not better explained by another disease, a score of at least 6 of 10 points is needed for the classification of definite rheumatoid arthritis.

- A. Joint involvement (0-5 points)
 - 1 large joint (0)
 - 2-10 large joints (1)
 - 1-3 small joints (with or without involvement of large joints) (2)
 - 4-10 small joints (or without involvement of large joints) (3)
 - >10 joints (with involvement of at least 1 small joint) (5)
- B. Serology (0-3 points)
 - Negative RF and negative anti-CCP (0)
 - Low-positive RF or low-positive anti-CCP (2)
 - High positive RF or high positive anti-CCP (3)
- C. Acute phase reactants (0-1 points)
 - Normal CRP and normal ESR (0)
 - Abnormal CRP or abnormal ESR (1)
- D. Duration of symptoms (0-1 points)
 - <6 weeks (0)
 - ≥6 weeks (1)

Aletaha D, Neogi T, Silman AJ, et al: 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative, *Arthritis Rheum* 62:2569-2581, 2010.

ACR, American College of Rheumatology; CCP, cyclic citrullinated peptide; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; RF, rheumatoid factor.

pulmonary infections) is a rare complication and is often accompanied by leg ulcers and vasculitis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

RA is a clinical diagnosis based on a thorough history and physical examination. Classic symptoms include morning stiffness associated with symmetrical synovitis of small joints. No single diagnostic test enables a diagnosis of RA to be made with certainty. Instead, the diagnosis depends on the accumulation of characteristic symptoms, signs, laboratory data, and radiologic findings.

Classification criteria are useful in guiding the clinical diagnosis of RA. The classification criteria have been updated to include early RA ([Table 77-2](#)) because prompt diagnosis and treatment are important to prevent disease progression, joint deformities, and disability.

The differential diagnosis for RA includes viral arthritis (e.g., parvovirus, rubella, hepatitis B and C), thyroid disorders, sarcoidosis, reactive arthritis, psoriatic arthritis, Sjögren syndrome, systemic lupus erythematosus (SLE), bacterial endocarditis, rheumatic fever, calcium pyrophosphate disease (CPPD), chronic tophaceous gout, polymyalgia rheumatic, erosive osteoarthritis, and fibromyalgia. A history and physical examination, including a thorough review of systems, help to determine the diagnosis.

RF is an antibody (typically IgM but also IgG or others) that binds to the Fc fragment of IgG. RF and IgG join to form immune complexes that are detectable in the serum of 70% to 80% of patients with RA. However, RF is not specific for RA and frequently occurs in patients with SLE, Sjögren syndrome, endocarditis, sarcoidosis, and lung and liver diseases (including hepatitis B and C infection) and in healthy individuals. In an individual patient, the titer does not correlate with disease activity, but high titers are associated with severe erosive arthritis and extra-articular disease. The finding of RF in serum alone does not

establish a diagnosis of RA, but it can help to confirm the clinical impression.

Anti-CCP antibodies are a more specific marker for RA. Anti-CCP antibodies have a higher specificity (>95%) than RF, with similar sensitivity (68% to 80%). These antibodies can be detected several years before the development of clinical RA (and before RF), and they are associated with severe RA outcomes, including radiographic joint damage and a poor prognosis. Because of their higher specificity for RA, anti-CCP antibodies are useful in differentiating RA from other conditions positive for RF, including Sjögren syndrome, infection, and hepatitis.

Acute phase reactants, such as the erythrocyte sedimentation rate and C-reactive protein, are usually elevated in active inflammation but are not sensitive or specific for the diagnosis of RA. They are useful for differentiating RA from noninflammatory conditions such as osteoarthritis or fibromyalgia. Even when there is clinical evidence of joint inflammation, the values for acute phase reactants may be normal. Inflammation in RA often leads to anemia of chronic disease and thrombocytosis.

Synovial fluid analysis is usually not necessary when the diagnosis is already established, but arthrocentesis should be performed to rule out infection or crystalline arthropathy if only one joint is involved. Synovial fluid analysis is nonspecific but indicates inflammation. Radiographs, although not part of the 2010 RA classification criteria, may show characteristic periarticular osteopenia, marginal erosions, and uniform joint space narrowing in a symmetrical distribution.

 For a deeper discussion of these topics, please see Chapter 257, "Laboratory Testing in Rheumatoid Arthritis," Chapter 258, "Imaging Studies in the Rheumatic Diseases," Chapter 263, "Bursitis, Tendinitis, and Other Periarticular Disorders and Sports Medicine," and Chapter 264, "Rheumatoid Arthritis," in Goldman-Cecil Medicine, 25th Edition.

TREATMENT

The ultimate goals of RA management are to reduce pain and discomfort, prevent deformities and loss of normal joint function, and maintain normal physical and social function. Although there is no cure for RA, remission can be maintained in a subset of patients. Treatment begins with effective communication between the physician and patient regarding the nature of the disease and the goals of treatment.

Nonpharmacologic therapeutic options include reduction of joint stress and physical and occupational therapy. Local rest of an inflamed joint can reduce joint stress, as can weight reduction, splinting, and the use of walking aids. Vigorous activity should be avoided during disease flares. Full range of motion of joints, however, should be maintained by a graded exercise program to prevent contractures and muscle atrophy. Physical therapy improves muscle strength and conditioning and maintains joint mobility. Occupational therapy can provide various appliances to protect joints and make daily activities easier.

Pharmacologic Approach

Studies have revealed that disease-modifying antirheumatic drug (DMARD) therapy early in the course of RA slows disease progression more effectively than delayed therapy.

Effective treatment can improve signs, symptoms, and radiographic progression, even in long-standing disease. The inflammation of RA should be controlled as completely as possible, as soon as possible, and for as long as possible. Conventional DMARDs and biologic DMARDs prevent disease progression and disability.

Symptomatic Control and Bridging Therapy

DMARDs require 1 to 6 months to work. Consequently, nonsteroidal anti-inflammatory drugs (NSAIDs), which are not disease modifying, are frequently used early in the disease process for symptomatic control. NSAIDs have significant side effects, including renal failure and increased risk of gastrointestinal bleeding, and should be used with caution in patients with multiple medical comorbidities.

Glucocorticoids remain important in the treatment of RA, especially for acute exacerbations of disease. These agents are used sparingly in low to medium doses. Although glucocorticoids are useful for brief exacerbations and decrease bone erosions, the long-term side effects of glucocorticoids can be substantial. They should be used primarily as bridging therapy for further DMARD effects. Side effects include osteoporosis, avascular necrosis of bone, obesity, hypertension, and glucose intolerance. Screening, prevention, and treatment for osteoporosis should be considered for all patients who receive long-term glucocorticoid therapy for prevention of glucocorticoid-induced osteoporosis. Intra-articular glucocorticoids are extremely effective treatment for exacerbations involving only a few joints.

 For a deeper discussion of these topics, please see Chapter 243, "Osteoporosis," in Goldman-Cecil Medicine, 25th Edition.

Conventional and Biologic Disease-Modifying Antirheumatic Drugs

Many DMARDs are available for treating RA. All conventional DMARDs have a slow onset, taking 1 to 6 months to become fully effective, and they need close monitoring for toxicity.

Methotrexate is universally used as the initial DMARD in patients with moderate to severe RA because of its established efficacy and known toxicity profile (level A evidence, multiple randomized controlled trials). It can be administered once weekly by the oral or parenteral route. Known side effects include oral ulcers, nausea, hepatotoxicity, and pneumonitis.

After methotrexate failure, the subsequent choice of conventional and biologic DMARDs is not standardized and is instead based on the preferences of patients and physicians. For patients with mild RA, hydroxychloroquine or sulfasalazine, or both, may be used as first-line drugs (level B evidence). Triple therapy, the combination of methotrexate, hydroxychloroquine, and sulfasalazine, was shown in two randomized, controlled trials to be noninferior to biologic TNF- α inhibitors (level A). Tofacitinib is an oral Janus kinase inhibitor and the first kinase inhibitor of its class that reduces cytokine levels.

Biologic DMARDs are targeted, immune-based therapies that were introduced in the 1990s with the initiation of cytokine-directed TNF- α inhibitors. TNF- α inhibitors were the first of nine biologic DMARDs approved by the U.S. Food and Drug

TABLE 77-3 DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

CONVENTIONAL AGENTS	TOXICITIES
Hydroxychloroquine	Retinal toxicity, requires ophthalmologic monitoring
Sulfasalazine	Nausea, bone marrow suppression
Methotrexate	Oral ulcers, nausea, bone marrow suppression, pneumonitis; contraindicated in pregnancy and coexistent lung disease
Leflunomide	Bone marrow and hepatic toxicity; cholestyramine washout if toxic; contraindicated in pregnancy
Tofacitinib (oral DMARD)	Infection rate similar to biologic DMARDs; bone marrow and hepatic toxicity, hyperlipidemia
BIOLOGIC AGENTS	MECHANISMS
Adalimumab, certolizumab, etanercept, golimumab, infliximab	Cytokine directed, anti-TNF- α
Tocilizumab	Cytokine directed, anti-IL-6
Anakinra	Cytokine directed, anti-IL-1
Abatacept	T-cell directed, inhibits costimulation
Rituximab	B-cell directed, anti-CD20

DMARDs, Disease-modifying antirheumatic drugs; IL, interleukin; TNF, tumor necrosis factor.

Administration (FDA) for the treatment of RA (Table 77-3). Five TNF- α -directed therapies are available. The TNF- α inhibitors are the most widely used biologic agents because of the rapid improvement they produce in patients resistant to methotrexate therapy. They are recommended in addition to methotrexate after methotrexate failure (level A evidence).

Most biologic DMARDs are given by intravenous or subcutaneous injection and are quite expensive. Some have an increased risk of infection, including risk of reactivation of tuberculosis. Other cytokine-directed therapies include the IL-6 receptor antagonist tocilizumab and the IL-1 receptor antagonist anakinra. Biologic DMARDs also include an inhibitor of T-cell costimulation, abatacept; and a B-cell-depleting agent, rituximab

 For a deeper discussion of these topics, please see Chapter 36, "Biologic Agents," in Goldman-Cecil Medicine, 25th Edition.

Medical Care Specialized for Rheumatoid Arthritis

RA is a chronic disease that requires focused care for comorbidities. DMARDs themselves require frequent laboratory monitoring for toxicities, including bone marrow suppression, hepatotoxicity, and renal dysfunction. Opportunistic infections can occur in patients receiving biologic therapies and DMARDs. In the setting of acute infection, DMARDs and biologic therapies should be withheld. Prophylactically, all RA patients should be vaccinated for pneumococcal, influenza, and hepatitis B infection. Herpes zoster vaccine to prevent shingles should be given prior to biological agents because the vaccine is live.

RA itself is a risk factor for osteoporosis, and combined with glucocorticoid use, it can lead to severe osteoporosis and

subsequent morbidity. In every RA patient, bone health should be addressed to prevent development of osteoporosis. RA is also a risk factor for cardiovascular disease due to chronic inflammation and should be aggressively monitored.

Caution should be taken preoperatively when the RA patient is being anesthetized to avoid C1-C2 subluxation and spinal cord compression. Joint replacement surgery plays an important role for patients who have had severe, destructive joint disease, particularly in the knees and hips.

PROGNOSIS

Although the underlying cause of RA is unknown, advances in cell biology, immunology, and molecular biology have led to dramatic therapeutic advancements for this disease. Conventional and biologic DMARDs improve short- and long-term outcomes. Bone erosions occur within 1 to 2 years of disease onset, and early initiation of DMARDs is essential to prevent further morbidity.

RF positivity, CCP positivity, and extra-articular features are characteristic of severe disease. The incidence of lymphoma and other malignancies is increased among patients with RA, and the overall mortality rate is increased by coexisting cardiovascular disease and infection.

Although up to 15% of patients can go into drug-free remission, long-term disability is significant. Fifty percent of patients with RA are not working after 10 years, approximately 10 times the rate in the normal population. Most patients fall between these extremes with various levels of disability. Some have a waxing and waning course over a period of years, with acute episodes of single- or multiple-joint exacerbations.

Future developments will include guidelines about when to institute biologic DMARDs, novel targeted biologic agents, and personalized approaches based on an understanding of individual disease pathogenesis.

Spondyloarthritis

Douglas W. Lienesch

DEFINITION

Spondyloarthritis, formerly called *seronegative arthritis* or *spondyloarthropathy*, is the name of a group of related inflammatory disorders that share certain clinical features unique among rheumatic diseases. The six types of spondyloarthritis in adults are ankylosing spondylitis, reactive arthritis, arthritis of inflammatory bowel disease (i.e., Crohn's disease and ulcerative colitis), psoriatic arthritis, and undifferentiated spondyloarthropathy. The juvenile form of spondyloarthropathy is similar to ankylosing spondylitis and usually persists into adulthood.

The cardinal clinical feature of spondyloarthritis is inflammation of the sacroiliac joints (i.e., sacroiliitis) and the spine (i.e., spondylitis). Inflammation of tendon insertion sites (i.e., enthesitis), inflammation of entire digits (i.e., dactylitis), and inflammation of one to four lower extremity joints (i.e., oligoarthritis) are typical extraspinal skeletal findings. A positive family history, eye inflammation (i.e., anterior uveitis or conjunctivitis), and the absence of rheumatoid factor and subcutaneous nodules are common.

Further classification of these disorders is based on the finding of psoriatic skin or nail changes, inflammatory bowel disease, or a history of preceding gastrointestinal or genitourinary infection. Alternatively, patients with spondyloarthritis can be classified based on the distribution pattern of joint involvement. Cases with dominant spinal disease are classified as *axial spondyloarthritis* (i.e., prototypically ankylosing spondylitis), and those without spinal disease are classified as predominantly *peripheral spondyloarthritis*.

Spondyloarthritis is strongly associated with human leukocyte antigen B27 (HLA-B27), a specific allele of the B locus of the HLA-encoding class I major histocompatibility complex genes. The frequency of HLA-B27 among whites is approximately 8%. However, up to 90% of white patients with ankylosing spondylitis and 80% of white patients with reactive arthritis or juvenile spondyloarthritis are HLA-B27 positive, and these percentages are even higher among patients with uveitis. The rate of HLA-B27 positivity among patients with inflammatory bowel disease or psoriasis with peripheral arthritis is not markedly increased unless they have spondylitis, in which case the frequency of HLA-B27 is 50%. The frequency of HLA-B27 varies widely among other ethnic groups and accounts for the broad variation of the prevalence of ankylosing spondylitis in different populations.

Ankylosing spondylitis is much more common among adolescent boys and young men, but this finding may reflect

underdiagnosis in women, in whom disease manifestations may be milder than they are in men. Reactive arthritis is more common among men when it follows genitourinary *Chlamydia trachomatis* infection, but the sex distribution is even among patients after dysentery. Inflammatory arthritis including spondylitis affects approximately 5% to 8% of patients with psoriasis and 10% to 25% of patients with ulcerative colitis or Crohn's disease. Men and women are affected equally. The prevalence of spondyloarthritis, particularly psoriatic and reactive arthritis, is increased in populations with high human immunodeficiency virus (HIV) infection rates.

PATHOLOGY

Although the strong association of HLA-B27 with spondyloarthritis is well established, a specific role in the pathogenesis of these disorders has not been elucidated. Animal models in which rodents transgenic for HLA-B27 develop inflammatory abnormalities strikingly similar to those seen in HLA-B27-associated human diseases provide compelling indirect evidence for a pathogenic role. When raised in a germ-free environment, these animals remain disease free, suggesting a key additional environmental factor.

In addition to the strong genetic links for the risk of spondyloarthritis, important associations exist between specific bacterial agents and disease pathogenesis. Genitourinary infection with *C. trachomatis* or diarrheal illness with *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia* species can induce reactive arthritis. Several additional infectious agents are less commonly implicated. They appear to trigger an inflammatory response, possibly as a result of persistence of bacterial antigens, or cause an aberrant immunologic response to infection that results in misfolding of HLA-B27 molecules in antigen-presenting cells, generating a persistent inflammatory reaction.

No one theory of pathogenesis of spondyloarthritis explains the clinical spectrum of these disorders, and more research is clearly needed to solidify an understanding of their origin. The complex role of the immune system in the spondyloarthritis is highlighted by the observation that patients infected with HIV appear more likely to have severe disease, especially psoriatic arthritis. When HIV infection is treated with antiviral agents, the incidence of spondyloarthritis declines.

Although many of the cellular and molecular mechanisms of inflammatory joint disease have been elucidated, the pathophysiology of spondyloarthritis remains incompletely understood. Inflammation of the sacroiliac joints, spine, and entheses is a unique feature of these disorders. Pathophysiologic studies show

that the inflammation originates at the interface of bone and cartilage in the sacroiliac joint and bone and fibrocartilage in the entheses. Macrophages and CD4⁺ and CD8⁺ T cells are present, and the proinflammatory cytokines tumor necrosis factor- α (TNF- α) and interleukin-23 (IL-23) are abundant.

Synovial tissue becomes inflamed, and osteoclasts are activated, leading to bone resorption, reminiscent of rheumatoid arthritis joint inflammation. Unlike in rheumatoid arthritis, early bone resorption is followed by a secondary phase during which osteoblast activity predominates, leading to new bone formation in periarticular bone (i.e., hyperostosis) and around joints (i.e., osteophytosis) or vertebral bodies (i.e., syndesmophytes). Ultimately, bony fusion of joints (ankylosis) occurs. The relationship between these paradoxical phases of bone resorption and proliferation is an area of active investigation.

CLINICAL PRESENTATION

Common Clinical Features of Spondyloarthritis

All forms of spondyloarthritis have considerable clinical overlap with one another and are most easily considered as a group of related disorders. Table 78-1 outlines the clinical features of these disorders. The cardinal clinical features common to all of them are inflammatory spine pain and an asymmetrical, predominantly lower extremity inflammatory joint or tendon disease. Inflammatory spine pain should be suspected in young patients (<40 years) who have an insidious onset of chronic low back pain or buttock pain associated with prolonged morning stiffness and relieved by exercise.

The characteristic peripheral joint disease involves one to four joints, usually in the lower extremities, and may be associated with tendon insertion inflammation (i.e., enthesitis) or sausage digits (i.e., dactylitis). Symmetrical polyarthropathy involving the upper extremities and clinically similar to rheumatoid arthritis is seen in some forms of psoriatic or inflammatory bowel disease-related spondyloarthritis. Anterior uveitis, enthesitis, dactylitis, psoriatic skin or nail changes, inflammatory bowel disease, a family history of spondyloarthritis, or a history of preceding gastrointestinal or genitourinary infection suggests spondyloarthritis. Subcutaneous nodules, rheumatoid factor, and antinuclear antibodies are usually absent.

In a given patient, the clinical features of these disorders may accumulate over a prolonged period. Some patients do not initially demonstrate the typical findings of a specific disorder. They are considered to have undifferentiated spondyloarthritis. Early disease can be subcategorized as predominately axial spondyloarthritis or predominately peripheral spondyloarthritis, depending on the site of the dominant symptoms. Many patients later have clinical findings consistent with a specific subtype of spondyloarthritis.

Inflammatory spine pain is the cardinal feature of axial disease and results from inflammation in the sacroiliac joints and spinal elements. Uncontrolled disease may lead to ankylosis (i.e., bony fusion) at sacroiliac joints and throughout the vertebral column, culminating in loss of spinal and costovertebral motion, deformity, and restrictive extrapulmonary physiology.

Enthesitis can occur in many different anatomic locations. They include spinous processes, costosternal junctions, ischial tuberosities, plantar aponeuroses, and Achilles tendons.

When peripheral arthritis of spondyloarthritis occurs, it frequently begins as an episodic, asymmetrical, oligoarticular process that often involves the lower extremities. The arthritis can progress and may become chronic and disabling. A unique feature of spondyloarthritis is the appearance of fusiform swelling of an entire finger or toe, referred to as *dactylitis* or *sausage digits*.

Anterior uveitis, or inflammation of the anterior chamber of the eye, is a common extra-articular manifestation of spondyloarthritis, especially among HLA-B27-positive patients. Acute bouts of uveitis are usually monocular, painful, and accompanied by eye redness and blurred vision. Recurrent attacks are common and can lead to blindness. Scleritis, episcleritis, and conjunctivitis are less commonly associated phenomena.

Spondyloarthritis may occasionally involve other organ systems and may cause significant morbidity and mortality. Aortitis, especially occurring in the ascending segment, can result in aortic insufficiency from aortic root dilation, aortic dissection, and cardiac conduction system abnormalities. Pulmonary fibrosis of the apical regions can occur, often in an insidious fashion. Spinal cord compression can result from atlantoaxial joint subluxation, cauda equina syndrome, or vertebral fractures. In rare cases, long-standing spondyloarthritis is associated with secondary amyloidosis.

TABLE 78-1 COMPARISON OF THE SPONDYLOARTHRITIS

Specific Clinical Features of Spondyloarthritis

Ankylosing Spondylitis

The cardinal clinical feature of ankylosing spondylitis is inflammatory spine pain. Over time, spine involvement ascends from the sacroiliac joints to involve all levels of the spine. Progressive loss of motion results from ankylosis of the vertebral column and apophyseal joints. Costovertebral involvement leads to decreased chest expansion and restrictive lung physiology.

Loss of mobility and secondary osteoporosis of the vertebral bodies increase the risk of traumatic spine fracture. Axial involvement of the shoulders and hips is common and associated with a worse prognosis. Peripheral oligoarthritis, enthesitis, and dactylitis are more common in females. Diagnosis requires demonstration of radiographic sacroiliitis (i.e., sacroiliac joint erosions, sclerosis, and ankylosis). Anterior uveitis is common. Aortitis, upper lobe pulmonary fibrosis, cauda equina syndrome, and amyloidosis are less common and seen in late disease.

Reactive Arthritis

Among the unique clinical features of reactive arthritis are urethritis, conjunctivitis, and certain dermatologic problems (Fig. 78-1). The urethritis may result from the chlamydial infection that triggers the disease, or it may be a sterile inflammatory discharge seen in diarrhea-associated disease. Conjunctivitis may be mild in reactive arthritis and is distinct from uveitis.

Keratoderma blennorrhagicum is a distinct papulosquamous rash usually found on the palms or soles. Circinate balanitis is a rash that may appear on the penile glans or shaft of men with reactive arthritis. Nonpitting nail thickening and oral ulcers may also occur in patients with reactive arthritis. These lesions can be confused with similar findings in patients with psoriasis and inflammatory bowel disease, respectively.

Most cases are self-limited. Chronic or relapsing arthritis and chronic spondylitis are associated with HLA-B27 and *Chlamydia* infection.

Psoriatic Arthritis

Five identifiable clinical patterns of psoriatic arthritis are recognized: distal interphalangeal joint involvement with nail pitting;

asymmetrical oligoarthritis of large and small joints; arthritis mutilans, a severe, destructive arthritis; symmetrical polyarthritis, which is identical to rheumatoid arthritis; and predominately axial disease. These patterns are not exclusive, and clinical overlap is significant.

Spondylitis or sacroiliitis may occur along with any of the other patterns. The prevalence of HLA-B27 is increased among the patients with spondylitis or sacroiliitis but not among patients with the other patterns. Psoriatic skin or nail disease predates arthritis in most cases, but both may occur concomitantly, or joint disease may precede skin involvement. Rarely, joint disease indistinguishable from psoriatic arthritis, which can occur in patients with a family history but no personal history of psoriatic skin disease.

Enteropathic Arthritis: Inflammatory Bowel Disease

Crohn's disease and ulcerative colitis (see Chapter 38) are frequently associated with inflammatory spine disease and peripheral arthritis. The peripheral arthritis is typically nonerosive, oligoarticular, and episodic, and the degree of joint involvement fluctuates with gut activity. A more chronic, symmetrical polyarthritis may occur in patients with Crohn's disease.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of spondylarthritis remains a clinical diagnosis made by identifying typical history and physical examination phenomena, analyzing selected laboratory tests, and using musculoskeletal imaging. The diagnosis is suggested by inflammatory spine pain or chronic lower extremity asymmetric inflammatory oligoarthritis in two to four joints. In this setting, features that increase the probability of spondyloarthritis include uveitis, psoriasis, enthesitis, dactylitis, inflammatory bowel disease, family history of spondylarthropathy, elevated C-reactive protein (CRP) level, HLA-B27, preceding gastrointestinal or genitourinary infection, and sacroiliitis on radiography, computed tomography (CT), or magnetic resonance imaging (MRI).

Differentiating spondyloarthritis from other inflammatory or degenerative joint or spine diseases can be challenging. Crystalline arthropathies can manifest with peripheral oligoarthritis, often in the lower extremities. However, the spine is rarely

FIGURE 78-1 Reactive arthritis. **A**, Keratoderma blennorrhagicum. Red to brown papules, vesicles, and pustules with central erosion show characteristic crusting and peripheral scaling on the dorsolateral and plantar foot. **B**, Balanitis circinata. Moist, well-demarcated erosions with a slightly raised micropustular circinate border on the glans penis. **C**, Bilateral conjunctivitis associated with anterior uveitis. (From Fitzpatrick TB, Johnson RA, Wolff K, et al: Color atlas and synopsis of clinical dermatology, ed 3, New York, 1983, McGraw-Hill, pp 393, 395.)

involved, and intracellular crystals can be demonstrated in the synovial fluid. Rheumatoid arthritis and other systemic autoimmune diseases usually manifest with symmetrical polyarthritis of the upper and lower extremities associated with abnormal serologies such as rheumatoid factors, anti-cyclic citrullinated peptide (CCP) antibodies, or antinuclear antibodies. Predominately axial spondyloarthritis must be differentiated from indolent infections of the sacroiliac joints, vertebrae, or intravertebral disks; degenerative disease of the spine and disks (i.e., spondylosis); and diffuse idiopathic skeletal hyperostosis (DISH).

The radiographic features of the spondyloarthritis are highly specific and, in the correct clinical setting, greatly increase the certainty of the diagnosis. Sacroiliitis is usually the earliest radiographic sign of spine disease and results in sclerosis and erosions of the sacroiliac joints with eventual bony fusion (Fig. 78-2A). Many radiographic changes result from chronic spondylitis, including ossification of the annulus fibrosus, calcification of spinal ligaments, bony sclerosis and squaring of vertebral bodies, and ankylosis of apophyseal joints. These changes can lead to vertebral fusion and a bamboo spine appearance (see Fig. 78-2B).

Radiographic findings progress over many years of illness and may not be apparent in early disease. However, during this pre-radiographic period, MRI demonstrates bone inflammation (i.e., osteitis) and erosion at the sacroiliac joints and vertebral bodies, and CT shows bony sclerosis and joint erosions.

Bone erosions, sclerosis, and new bone formation may occur at sites of enthesitis. Erosions at bone-cartilage interface (i.e., subchondral erosions), sclerosis, and bone proliferation are hallmarks of spondyloarthritis involving peripheral joints. In severe cases such as the arthritis mutilans form of psoriatic arthritis, total or subtotal bone resorption (i.e., osteolysis) of a phalange may occur.

TREATMENT

No cure has been found for any form of spondyloarthritis, but effective treatment for many of the manifestations is available. Patient education regarding the disease is essential and allows identification of affected family members and early detection of urgent clinical features such as uveitis. Physical therapy, including a daily stretching program, postural adjustments, and strengthening, helps to maintain proper bony alignment, reduce deformities, and maximize function, particularly for those with axial disease. Selective use of orthopedic surgery may be highly effective in correcting significant spinal deformities or instability.

Nonsteroidal anti-inflammatory drugs (NSAIDs) can provide significant relief of spinal pain and stiffness, and many patients take these drugs continually for years (Centre for Evidence Based Medicine; level 1 evidence). No clear evidence indicates that systemic glucocorticoids benefit patients with spondyloarthritis, and these agents are usually avoided. Intra-articular glucocorticoid injection into the sacroiliac or other involved joints may provide temporary relief. Similarly, the role and efficacy of older immunosuppressive agents in the treatment of axial spondyloarthritis have not been established. In contrast, clinical trials have shown that the peripheral manifestations of spondyloarthritis improve with sulfasalazine and methotrexate (level 2).

TNF- α blockers (i.e., infliximab, etanercept, adalimumab, and golimumab) represent a substantial breakthrough in the treatment of spondyloarthritis. The efficacy of these agents is well established, and they have rapidly become the treatment of choice for patients with axial inflammation who do not satisfactorily or fully respond to NSAIDs and physical therapy (level 1 evidence). TNF- α blockers can significantly reduce pain, improve function, and improve quality of life. They may also prevent or

FIGURE 78-2 **A**, Bilaterally symmetrical sacroiliitis in ankylosing spondylitis. **B**, Lumbar spondylitis in ankylosing spondylitis with symmetrical, marginal bridging syndesmophytes and calcification of the spinal ligament. (From Cush JJ, Lipsky PE: The spondyloarthropathies. In Goldman L, Bennett JC, editors: Cecil textbook of medicine, ed 21, Philadelphia, 2000, Saunders, pp 1499–1507.)

slow disease progression and structural damage. The drugs are effective in psoriatic arthritis, suppress the skin and nail disease of psoriasis, and retard radiographic progression in the peripheral joints. Infliximab and adalimumab reduce gut inflammation in ulcerative colitis and Crohn's disease, with concomitant reduction in symptoms of joint and spine inflammation. Ustekinumab, an inhibitor of IL-23, has demonstrated efficacy in psoriasis and psoriatic arthritis (level 1).

Flares of uveitis require care by an ophthalmologist experienced in treating inflammatory eye diseases. Topical or intraocular glucocorticoids may suffice, but systemic therapy with glucocorticoids or immunosuppressive medications may be necessary to control the inflammation and prevent permanent visual loss. Methotrexate and TNF- α inhibitors are frequently employed (level 2 evidence).

Reactive arthritis is usually self-limited, and joint symptoms are managed with NSAIDs or intra-articular corticosteroid injections. When chronic arthritis or spondylitis develops, interventions are similar to those employed for other forms of spondyloarthritis. Evaluation and treatment of *C. trachomatis* and associated sexually transmitted diseases in patients with reactive arthritis and their sex partners are essential. Early treatment reduces the frequency of reactive arthritis. Long-term antibiotics are ineffective for gastroenteritis-associated reactive arthritis. Clinical trials of long-term antibiotics for reactive arthritis after *C. trachomatis* infection have had mixed results, and this practice requires further study before it can be adopted.

SUMMARY

Disability due to spondyloarthritis varies according to the subtype and severity of the specific syndrome. Historically, patients with spondyloarthritis usually experienced a lesser degree of disability compared with those with rheumatoid arthritis. Some patients with reactive arthritis experience self-limited disease with no long-term sequelae. Alternatively, those with more severe disease can have deformation and destruction of the axial and peripheral joints, leading to severe disability. Serious and potentially fatal extraskeletal manifestations can manifest.

With the advent of effective immunosuppressant medications such as methotrexate in psoriatic disease and biologic agents (i.e., TNF- α and IL-23 inhibitors), patients with more severe manifestations have markedly improved symptom control and quality of life.

Systemic Lupus Erythematosus

Amy H. Kao and Susan Manzi

DEFINITION AND EPIDEMIOLOGY

Systemic lupus erythematosus (SLE) is the classic systemic autoimmune disease. The cause is unknown. SLE predominantly affects young women of childbearing age but can also afflict young men and older individuals of either sex.

The clinical manifestations are protean, ranging from mild symptoms of fatigue and oral ulcerations to life-threatening renal and neurologic disease. Typically, the disease fluctuates with periods of flares and clinical quiescence. However, recurrent disease flares and their treatment may ultimately lead to irreversible organ damage.

SLE is diagnosed by a thorough history, physical examination, and laboratory testing. A single diagnostic laboratory test for SLE is not available, and the diagnosis is often difficult, requiring many patient visits to numerous doctors.

Although there is no cure for SLE, patients are treated for the many chronic medical conditions associated with the disease with a variety of medications, primarily immunosuppressants. Unique consideration must be given to SLE patients regarding pregnancy, bone health, cardiovascular disease (CVD), and malignancy.

The reported incidence and prevalence of SLE vary greatly, reflecting the heterogeneity of the disease. The incidence of SLE worldwide is estimated at 1.8 to 7.6 cases per 100,000 persons per year and appears to have increased over time. Prevalence rates range from 14.6 to 149.5 cases per 100,000 persons.

During the childbearing years, the female-to-male ratio of SLE prevalence is 10:1 to 15:1. This gender discrepancy also exists but is less distinct (2:1) in young children and older patients. SLE also has a predilection for nonwhite ethnic populations, with greater prevalence rates for African Americans (three times), Afro-Caribbeans (five times), Asians (two times), and Hispanics than for whites. These patients also tend to have more severe SLE disease and worse overall prognoses than those who are white.

PATHOLOGY

Although SLE pathogenesis remains poorly understood, individuals who develop SLE likely have a genetic predisposition in the setting of immune system dysregulation, environmental triggers, and altered hormonal milieu. The genetic contribution to SLE is emphasized by the high concordance rate for monozygotic twins (>20%) and a lower concordance rate among other siblings (<5%). The search for genes involved in SLE pathogenesis is an active area of research. Genes coding for certain human leukocyte antigens, complement system components, immuno-

globulin receptors, and various other proteins are being considered as candidate genes for SLE.

The many immune abnormalities in SLE implicate dysregulation of the humoral and cellular immune systems in the pathogenesis of the disease. Dysregulation leads to loss of self-tolerance and autoimmune destruction of healthy tissues, hallmarked by the production of autoantibodies and immune complexes.

Various environmental triggers, including microorganisms and ultraviolet light exposure, may influence the development of SLE and lupus activity. The striking differences in SLE prevalence between genders and the effect of pregnancy on disease activity suggest a role for hormones in SLE pathogenesis.

CLINICAL PRESENTATION

Virtually any organ system may be involved in SLE. [Table 79-1](#) outlines some of the many clinical manifestations of SLE.

Constitutional Manifestations

Fatigue, fever, lymphadenopathy, and generalized arthralgias and myalgias are common in SLE patients. The most common symptom, fatigue (>90%), can also be the most debilitating. Other reasons for fatigue, including anemia, hypothyroidism, and fibromyalgia, should be excluded when attempting to diagnose SLE.

Mucocutaneous Manifestations

Oral ulcerations may be painful or painless and are classically located on the tongue or palate. Skin manifestations of SLE are common and include the classic malar (butterfly) rash, discoid lesions (i.e., permanent scarring and disfigurement), alopecia, and photosensitivity. Subacute cutaneous SLE can manifest with a psoriasiform rash or annular lesions mimicking tinea corporis. Frequently, acne rosacea is mistaken for a malar rash. A key distinguishing feature is that erythema in lupus malar rash does not cross the nasolabial folds.

Musculoskeletal Manifestations

Arthralgias and inflammatory arthritis are common manifestations in SLE (>75%). Lupus arthritis is usually nonerosive (unlike rheumatoid arthritis), but 10% of patients have Jaccoud's arthropathy with reversible hand deformities due to inflammation and joint tendon laxity.

Cardiopulmonary Manifestations

More than 60% of SLE patients have pericarditis and pleuritis during their disease course. Subsequent pericardial or pleural effusions are typically exudative. Valvular thickening and

noninfective Libman-Sacks endocarditis are frequently observed on echocardiography and autopsy studies. Myocarditis should be suspected in patients with cardiopulmonary symptoms and fever.

Renal Manifestations

Nephritis, which manifests with hematuria and proteinuria, is a major cause of morbidity and mortality for SLE patients. The International Society of Nephrology/Renal Pathology Society (ISN/RPS) revisited the 1982 World Health Organization classification of lupus nephritis (classes I through VI). ISN/RPS class IV (i.e., diffuse, proliferative) lupus nephritis is the most common form and has the worst prognosis, but it is also the most amenable to aggressive immunosuppressive therapy.

Neuropsychiatric Manifestations

Neuropsychiatric symptoms are broad, including sensorimotor neuropathy, headache, cognitive dysfunction, mood disorders, psychosis, life-threatening ischemic stroke, cerebritis, and transverse myelitis. In 2010, the European League Against Rheumatism task force recognized that “mild or moderate cognitive dysfunction is common in SLE” and recommended the “management of SLE and non-SLE-associated factors, as well as psycho-educational support to prevent further deterioration of cognitive function.”

Hematologic Manifestations

Leukopenia, primarily lymphopenia, anemia, and thrombocytopenia are common in SLE. Anemia is typically results from hemolysis or chronic disease. Antiphospholipid antibodies (APAs) are detected in approximately 33% of SLE patients and are associated with recurrent thromboses, thrombocytopenia, and recurrent spontaneous miscarriages.

Vascular Manifestations

More than 40% of SLE patients have Raynaud's phenomenon. Venous clots (e.g., pulmonary emboli, deep vein thromboses) and arterial clots typically result from APAs. Leg ulcers, gangrene, thrombophlebitis, nail fold infarcts, cutaneous necrosis, and necrotizing purpura may also be seen. Small vessel vasculopathy or vasculitis can occur in any organ system and can be a life-threatening manifestation.

Ocular Manifestations

Keratoconjunctivitis sicca from secondary Sjögren's syndrome (see Chapter 85) is the most common ocular manifestation of SLE. Episcleritis, scleritis, and retinal vasculitis can occur but are less common.

 For a deeper discussion of these topics, please see Chapter 266, “Systemic Lupus Erythematosus” in Goldman-Cecil Medicine, 25th Edition.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

SLE is a clinical diagnosis; no single test or feature is definitively diagnostic of the disease. The clinical disease of most patients evolves over time, and, in most situations, only after several years (and several different physicians' visits) are patients recognized as having SLE.

Classification

Classification criteria for SLE were established for conducting more uniform SLE research. The commonly used American College of Rheumatology classification criteria for SLE (Table 79-2) was updated in 1997. Using this system, meeting 4 of 11 criteria classifies a patient as having definite SLE.

In 2012, the Systemic Lupus International Collaborating Clinics (SLICC) further revised the classification criteria (Table 79-3) to improve clinical relevance and incorporate new knowledge into the definition of SLE immunopathogenesis. Based on the SLICC system, a patient is classified as having SLE if she has at least four of the criteria (including at least one clinical criterion and one immunologic criterion) listed in Table 79-3 or has biopsy-proven lupus nephritis (i.e., stand-alone criterion) in the setting of antinuclear antibodies (ANAs) or anti-double-stranded DNA (anti-dsDNA) antibodies. Although these classification criteria are not used for diagnostic purposes, practicing clinicians can use them along with a comprehensive examination to support the diagnosis.

Various autoantibodies are found in patients with SLE, and the prevalence of autoantibodies varies across different SLE patient cohorts and ethnic groups (Table 79-4). These autoantibodies often can be detected before the onset of SLE clinical

manifestations. More than 95% of patients with SLE test positive for ANAs with titers of 1:160 or higher.

ANAs are evaluated by the indirect immunofluorescence antibody test, and results are reported in titers and patterns. The most common pattern in SLE is homogenous (i.e., diffuse). Antibodies to dsDNA and Smith antigen are highly specific for SLE, whereas antibodies to SSA/Ro and SSB/La antigens are also commonly found in patients with Sjögren's syndrome and rheumatoid arthritis. Certain antibodies are associated with specific clinical manifestations, particularly anti-dsDNA antibodies with lupus nephritis and anti-U1-RNP antibodies with overlapping features of systemic sclerosis or myositis. Autoantibodies alone are not diagnostic for any autoimmune disease and must be interpreted in the context of the patient's clinical presentation.

Overlap Syndrome

Some patients with clinical and laboratory features of two or more autoimmune diseases have an overlap syndrome. Mixed connective tissue disease is characterized by overlaps among SLE, scleroderma, and myositis with a high titer of anti-U1-RNP antibody levels. For patients who have multiple autoimmune manifestations but do not meet the criteria of a specific autoimmune disease, the term *undifferentiated connective tissue disease* is

TABLE 79-2 1997 AMERICAN COLLEGE OF RHEUMATOLOGY CRITERIA FOR CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS*

CRITERIA	DEFINITIONS
1. Malar rash	Fixed, flat or raised erythema is observed over the malar eminences, tending to spare the nasolabial folds.
2. Discoid rash	Erythematous, raised patches develop with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions.
3. Photosensitivity	Rash occurs as a result of unusual reaction to sunlight, determined by patient history or physician observation.
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, is observed by the physician.
5. Arthritis	Nonerosive arthritis involves two or more peripheral joints, characterized by tenderness, swelling, or effusion.
6. Serositis	a. Pleuritis: convincing history of pleuritic pain exists or rub is heard by a physician or pleural effusion is in evidence. or b. Pericarditis: documented by electrocardiogram or rub or evidence of pericardial effusion.
7. Renal disorder	a. Persistent proteinuria is >0.5 g/day or scored >3+ if quantitation is not performed. or b. Cellular casts: may be red cell, hemoglobin, granular, tubular, or mixed.
8. Neurologic disorder	a. Seizures: occurs in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance). or b. Psychosis: occurs in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance)
9. Hematologic disorder	a. Hemolytic anemia: develops with reticulocytosis. or b. Leukopenia: <4000/mm ³ is documented on two or more occasions. or c. Lymphopenia: <1500/mm ³ is documented on two or more occasions. or d. Thrombocytopenia: <100,000/mm ³ develops in the absence of offending drugs.
10. Immunologic disorder	a. Anti-double-stranded DNA: antibody to native DNA in abnormal titer. or b. Anti-Smith: presence of antibody to Smith nuclear antigen. or c. Positive finding of antiphospholipid antibodies is based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test.
11. ANA	An abnormal titer of antinuclear antibody is documented by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome.

Data from Tan EM, Cohen AS, Fries, et al: The 1982 revised criteria of the classification of systemic lupus erythematosus, *Arthritis Rheum* 25:1271, 1982; Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus, *Arthritis Rheum* 40:1725, 1997.

*This classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a patient is classified as having definite SLE if any 4 or more of the 11 criteria are present (cumulative) during any interval of observation.

TABLE 79-3 SYSTEMIC LUPUS INTERNATIONAL COLLABORATING CLINICS (SLICC) CLASSIFICATION CRITERIA OF SYSTEMIC LUPUS ERYTHEMATOSUS

CLINICAL CRITERIA*	EXAMPLES
1. Acute cutaneous lupus	Bullous lupus Lupus malar rash (not malar discoid) Maculopapular lupus rash Photosensitive lupus rash (in the absence of dermatomyositis) Subacute cutaneous lupus Toxic epidermal necrolysis variant of SLE
2. Chronic cutaneous lupus	Classic discoid rash Localized (above the neck) Generalized (above and below the neck) Chilblains lupus Discoid lupus/lichen planus overlap Hypertrophic (verrucous) lupus Lupus erythematosus tumidus Lupus panniculitis (profundus) Mucosal lupus
3. Oral ulcers	Palate, buccal, tongue, <i>or</i> nasal ulcers (in the absence of other causes: vasculitis, Behçet's disease, infection, inflammatory bowel disease, reactive arthritis, and acidic foods)
4. Nonscarring alopecia	Diffuse thinning <i>or</i> hair fragility with visible broken hairs (in the absence of other causes: alopecia areata, drugs, iron deficiency, and androgenic alopecia)
5. Synovitis (≥2 joints)	Characterized by swelling <i>or</i> effusion <i>or</i> tenderness with ≥30 minutes of morning stiffness
6. Serositis	Typical pleurisy for >1 day <i>or</i> pleural effusions <i>or</i> pleural rub Typical pericardial pain for >1 day <i>or</i> pericardial effusion <i>or</i> pericardial rub <i>or</i> pericarditis by ECG (in the absence of other causes: infection, uremia, and Dressler's pericarditis)
7. Renal	Urine protein/creatinine (<i>or</i> 24-hr protein) ≥500 mg of protein/24 hr <i>or</i> red blood cell casts
8. Neurologic	Acute confusional state (in the absence of other causes: toxic-metabolic, uremia, and drugs) Mononeuritis multiplex (in the absence of other known causes: primary vasculitis) Myelitis Peripheral <i>or</i> cranial neuropathy (in the absence of other known causes: primary vasculitis, infection, and diabetes mellitus) Psychosis Seizure
9. Hemolytic anemia	
10. Leukopenia	<4000 cells/mm ³ detected at least once (in the absence of other known causes: Felty's syndrome, drugs, and portal hypertension)
<i>or</i> Lymphopenia	<1000 cells/mm ³ detected at least once (in the absence of other known causes: corticosteroids, drugs, and infection)
11. Thrombocytopenia	<100,000 cells/mm ³ detected at least once (in the absence of other known causes: drugs, portal hypertension, and thrombotic thrombocytopenic purpura)
IMMUNOLOGIC CRITERIA	
1. ANAs	Above laboratory reference range
2. Anti-double stranded DNA	Above laboratory reference range, except ELISA: two times greater than laboratory reference range
3. Anti-Smith	
4. Antiphospholipid	Any of the following: lupus anticoagulant, false-positive RPR, medium- or high-titer anticardiolipin (IgA, IgG, or IgM), or anti-β ₂ glycoprotein I (IgA, IgG, or IgM)
5. Low complement	Low C3 Low C4 Low CH50
6. Direct Coombs test	In the absence of hemolytic anemia

Modified from Petri M, Orbai AM, Alarcón GS, et al: Derivation and validation of Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus, *Arthritis Rheum* 64:2677–2686, 2012.

ANAs, Antinuclear antibodies; ECG, electrocardiogram; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; RPR, rapid plasma reagin; SLE, systemic lupus erythematosus.

*Criteria are cumulative. A patient is classified as having SLE using lupus nephritis as a stand-alone criterion (in the setting of ANAs or anti-dsDNA antibodies) *or* four criteria (with at least one of the clinical criteria and one of the immunologic criteria).

TABLE 79-4 PREVALENCE OF AUTOANTIBODIES IN SYSTEMIC LUPUS ERYTHEMATOSUS

TARGET AUTOANTIGEN	POSITIVE (%)
Nuclear antigens	>95
Double-stranded DNA	30-60
Smith	10-44
Ribonucleoprotein (U1-RNP)	25-40
SSA/Ro	30-40
SSB/La	38
Phospholipids	16-60
Ribosomal P	5-10
Histone	21-90

used. These patients typically are early in their disease course and eventually develop a specific autoimmune disease.

TREATMENT

No cure for SLE has been identified, and treatment is aimed at educating patients, reducing inflammation, suppressing the immune system, and closely monitoring patients to identify disease manifestations as early as possible. Treatment with glucocorticoids and immunosuppressive agents has reduced the morbidity and mortality of patients with SLE, although the treatments themselves are associated with extensive toxicity. Physicians caring for SLE patients must carefully weigh the benefits of therapy against the known risks of treatment.

Patient education and prophylactic measures to prevent disease flares are crucial in the care of patients with SLE. Sunscreens (SPF ≥ 50) and ultraviolet radiation-protective clothing are effective in preventing photosensitivity skin rashes and systemic flares. Low-dose aspirin is frequently prescribed for patients with positive APA assays to prevent thrombotic events. Other treatments for antiphospholipid antibody syndrome (APS) are discussed later. Routine immunizations (e.g., influenza, pneumococcus) with nonlive vaccines are recommended for all patients. Psychological support is essential for patients with SLE because the disease may lead to depression and feelings of being overwhelmed.

Nonsteroidal anti-inflammatory medications may be used for mild arthralgias, but glucocorticoids remain the primary anti-inflammatory agent and one of the most effective medications for SLE. Glucocorticoids are used for almost all manifestations of SLE in regimens ranging from low, alternate-day doses to large, intravenous doses. Given the chronic nature of the disease, glucocorticoids are often used over many years, and the cumulative exposure may lead to extensive toxicity, including obesity, diabetes mellitus, accelerated atherosclerosis, osteoporosis, avascular necrosis, cataracts, and increased risk of infections. To avoid these toxicities, steroid-sparing immunomodulating or immunosuppressant agents are used.

Antimalarial medications (primarily hydroxychloroquine) are effective in SLE and are considered standard care. Antimalarials are especially beneficial for the fatigue, mild arthritis, and mucocutaneous manifestations of SLE. These medications are often used chronically and are safe to use in pregnancy. The most serious side effect is retinal toxicity, although it is uncommon. Patients taking antimalarials should have a baseline and annual ophthalmologic examination with visual field testing.

Azathioprine and methotrexate are immunosuppressive agents prescribed for SLE when glucocorticoids alone are not fully effective or to allow for a reduction in glucocorticoid dose. Toxicities of azathioprine include cytopenias, increased infection risk, and potential malignant hematologic disease. Azathioprine may be used during pregnancy for severe internal organ lupus, especially nephritis. Methotrexate is particularly effective in treating inflammatory arthritis associated with SLE. In addition to cytopenias and infections, liver function abnormalities, alopecia, nausea, and pneumonitis are potential side effects of methotrexate. Because it is teratogenic, methotrexate should be stopped 3 to 6 months before pregnancy. Azathioprine and methotrexate require regular laboratory monitoring.

Mycophenolate mofetil (MMF) is increasingly used to treat patients with internal organ involvement, particularly nephritis. Mycophenolic acid, the active metabolite of MMF, can be used in place of MMF because it may have fewer gastrointestinal side effects for some patients. Clinical trials have shown that MMF is as efficacious as intravenous cyclophosphamide for inducing remission of active lupus nephritis. MMF also has a category D rating in pregnancy, and toxicities include gastrointestinal disturbance and leukopenia.

Patients with neurologic lupus, rapidly progressive nephritis, or vasculitis of internal organs are often treated with cyclophosphamide, the most potent immunosuppressive agent used to treat SLE. Because of potential toxicities, this drug is usually reserved

for the most severe manifestations of SLE. Acute toxicities of cyclophosphamide include pancytopenia, alopecia, mucositis, and hemorrhagic cystitis. Long-term use of cyclophosphamide may lead to transitional cell carcinoma, malignant hematologic disease, sterility, premature menopause, and opportunistic infections.

Great potential and optimism exist for biologic immunomodulating agents that focus on various aspects of the immune system, including B cells, interactions between B and T cells, and cytokines. The most promising agents are those that target B cells, which produce autoantibodies. Belimumab, a monoclonal antibody that inhibits B-lymphocyte stimulator, is the first therapeutic agent approved for the treatment of SLE in more than 50 years.

 For a deeper discussion of these topics, please see Chapter 35, "Immunosuppressing Drugs including Corticosteroids" in Goldman-Cecil Medicine, 25th Edition.

SPECIAL ISSUES IN THE CARE OF PATIENTS WITH SLE

Pregnancy

Pregnant women with SLE have higher rates of pregnancy loss (i.e., miscarriage and stillbirths) and preterm delivery (i.e., premature rupture of membranes, preeclampsia, and intrauterine growth restriction) than their healthy counterparts. Lupus activity preceding conception, especially nephritis, hypertension, and APS, are risk factors for pregnancy complications in SLE. Pregnancy itself may place women with SLE at a greater risk of a flare, particularly if the disease was active before conception.

Neonatal lupus is a rare disorder in which maternal anti-SSA/Ro or SSB/La antibodies, or both, cross the placenta and affect the fetus. Mothers with these autoantibodies have a 2% risk of having a child with congenital heart block. These mothers are screened with fetal heart tones and fetal echocardiography beginning at 16 weeks' gestation. Treatment with a fluorinated corticosteroid (i.e., dexamethasone or betamethasone) may be beneficial, but many children with congenital heart block do not survive (30%) or have morbidities, with more than 60% requiring pacemakers.

More common manifestations of neonatal SLE are rashes, cytopenias, and hepatosplenomegaly, all of which typically resolve in 6 to 8 months after maternal antibodies are removed from the child's circulation. Mothers of children with neonatal SLE do not necessarily have SLE themselves.

With careful prenatal screening and planning, women with SLE can successfully have a healthy child. Prenatal monitoring of anti-SSA/Ro and anti-SSB/La antibodies and APAs and pre-pregnancy consultation with obstetricians caring for high-risk pregnancies are critical. Ideally, women with SLE should have clinical quiescence for 6 months before considering a planned pregnancy.

Hormone Therapy

Hormones were thought to play a role in the development of SLE because of its female predominance. Rheumatologists have historically been hesitant to prescribe estrogen therapy for fear of

inducing a flare. Randomized, placebo-controlled clinical trials have helped to guide hormonal therapy in women with SLE.

A multicenter, randomized trial revealed that oral contraceptive therapy does not increase the risk of SLE flares in women with mild or stable SLE disease activity. However, this is not generalizable to all SLE women, particularly those whose disease is active or severe and those with prior thrombotic events or APAs. An effective form of birth control is necessary for young, sexually active women with SLE, especially those on teratogenic medications. Physicians must carefully discuss the risks and benefits of birth control with SLE patients.

Hormonal therapy is a controversial topic regardless of SLE status. However, it is of particular interest in SLE because some women reach menopause prematurely. In a clinical trial of hormonal therapy in SLE patients with mild or stable disease with no prior thrombotic events, APAs, or gynecologic or breast cancers, no SLE patients had severe clinical flares, but 20% did have mild to moderate flares. These findings suggest that brief (1-year) hormonal therapy may be considered for alleviating menopausal symptoms in a subset of SLE women.

Bone Health

SLE patients have higher rates of low bone mineral density, osteoporosis, and fractures than do healthy age-matched subjects. The increased risk is accounted for by traditional risk factors, such as female sex, white or Asian race, older age, and low body weight, and by SLE-associated factors. Fatigue and articular symptoms due to SLE may limit physical activity, leading to loss of bone strength.

Therapies commonly used for SLE contribute to overall loss of bone health. Corticosteroids reduce bone mass and are an independent risk factor for fractures in women with SLE. Cyclophosphamide use can lead to premature ovarian failure, another risk factor for osteoporosis. Lupus disease damage, regardless of steroid use, leads to low bone mineral density. SLE patients are advised to avoid sun exposure, which can lead to low 25-hydroxyvitamin D levels and insufficient absorption of calcium.

Because of SLE-specific risk factors for low bone mineral density, prevention of osteoporosis is extremely important (see [Chapter 75](#)). Although osteoporosis screening guidelines for SLE patients are the same as for the general population, bone density scans should be considered for patients with premature menopause and those who are or will be on chronic (>3 months) corticosteroids.

Cardiovascular Disease

As survival and therapies for SLE have improved and patients are living longer, CVD has emerged as a leading cause of morbidity and mortality. SLE patients are 5 to 10 times more likely than healthy individuals to have a coronary event. More striking, premenopausal women between 35 and 44 years of age are more than 50 times as likely as healthy women to have a myocardial infarction.

Autopsy series reveal atherosclerotic heart disease as the underlying mechanism of CVD in SLE. The cause of premature atherosclerosis in SLE is multifactorial and includes inflammatory mediators, SLE-related factors (e.g., premature menopause,

corticosteroid therapy, disease activity), and traditional cardiovascular risk factors.

Although no firm cardiovascular management guidelines exist for SLE patients, the 2011 updated guidelines from the American Heart Association for prevention of CVD in women included (for the first time) autoimmune diseases (i.e., SLE and rheumatoid arthritis) in the increased-risk category. Physicians should consider premature atherosclerotic CVD and aggressively evaluate SLE patients with typical and atypical cardiac symptoms, regardless of age and sex.

Secondary Antiphospholipid Syndrome

APS is a disorder characterized by recurrent vascular thrombosis or recurrent pregnancy loss, or both, in the setting of APAs ([Table 79-5](#)). Lupus anticoagulant is part of the antiphospholipid laboratory panel and is paradoxically associated with thrombosis and recurrent pregnancy loss. The term *lupus anticoagulant* is a misnomer because the in vitro anticoagulant effect reflects the prolonged activated partial thromboplastin time (aPTT), but the term does not indicate a diagnosis of SLE or an increased risk of bleeding.

Diverse proteins binding to APAs have been recognized. APS is considered primary if it occurs in isolation and secondary if it occurs in conjunction with other autoimmune diseases. There are no major differences in severity or clinical consequences between primary and secondary APS. The reported prevalence of various APAs in SLE ranges from 16% to 55%. SLE patients with APAs have an increased risk of thromboembolism and pregnancy complications and have a higher prevalence of pulmonary hypertension, Libman-Sacks endocarditis, and neurologic complications. The term *catastrophic APS* has been coined to describe patients who exhibit multiple microthromboses, are positive for APAs, and often have a life-threatening illness resulting in multiorgan failure that can be clinically indistinguishable from sepsis or thrombotic thrombocytopenic purpura.

Treatment for APS is tailored to the patient and the clinical manifestations. For patients with vascular thrombosis, indefinite anticoagulation is usually prescribed as prophylaxis against recurrence. Warfarin is the usual drug of choice for long-term therapy, with a target of an international normalized ratio (INR) between 2 and 3. Higher INR levels (3 to 4) are not more effective and are associated with bleeding complications. Unfractionated and low-molecular-weight heparin is also an effective anticoagulant for APS and is used for patients who suffer recurrent events while on warfarin therapy or patients who are or plan to become pregnant.

Malignancy

A multicenter international cohort (SLICC) of more than 16,000 SLE patients reported an increased risk of malignancy among them compared with the general population. Most striking was a fourfold increased risk of non-Hodgkin's lymphoma. Other hematologic, vulvar, lung, and thyroid cancers were described with increased frequency, whereas breast and endometrial cancers were observed less than expected in SLE patients compared with the general population. Malignancy risk appears to be highest early in the disease course, but risk remains elevated throughout a patient's lifespan. Although lymph node

TABLE 79-5 REVISED CLASSIFICATION CRITERIA OF ANTIPHOSPHOLIPID SYNDROME

CLASSIFICATION CRITERIA*	DEFINITION
CLINICAL CRITERIA	
1. Vascular thrombosis	One or more clinical episodes of arterial, venous, or small vessel thrombosis in any tissue or organ. Thrombosis must be confirmed by objective validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. Pregnancy morbidity	a. One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks' gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus or b. One or more premature births of a morphologically normal neonate before 34 weeks' gestation because of (i) eclampsia or severe pre-eclampsia or (ii) recognized features of placental insufficiency or c. Three or more unexplained consecutive spontaneous abortions before 10 weeks' gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded
LABORATORY CRITERIA	
1. Lupus anticoagulant	LAC detected in plasma on two or more occasions at least 12 wk apart
2. Anticardiolipin antibody	The ACA antibody of IgG and/or IgM isotype in serum or plasma in medium or high titer (i.e., >40 GPL units, or >the 99th percentile) on two or more occasions at least 12 weeks apart, measured by a standardized ELISA
3. Anti- β_2 glycoprotein I antibody	B2GPI antibody of IgG and/or IgM isotype in serum or plasma (in titer >the 99th percentile), detected on two or more occasions at least 12 weeks apart, measured by a standardized ELISA

Modified from Miyakis S, Lockshin MD, Atsumi T, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS), *J Thromb Haemost* 4:295–306, 2006.

ACA, Anticardiolipin antibody; ELISA, enzyme-linked immunosorbent assay; B2GPI, anti- β_2 glycoprotein I antibody; Ig, immunoglobulin; LAC, lupus anticoagulant.

*Antiphospholipid antibody syndrome is diagnosed if at least one clinical criterion and one laboratory criterion are met.

enlargement is a common manifestation of SLE, physicians must consider malignancy if the lymphadenopathy does not resolve with SLE treatment, is nontender or nonmobile, or if it occurs without other lupus symptoms.

PROGNOSIS

In 1955, patients with SLE had a 5-year survival rate of only 50%. Advances in early diagnosis and treatment of lupus patients have led to the current 5- and 10-year survival rates of more than 90% and approximately 90%, respectively, in developed countries.

A bimodal pattern of mortality is seen in SLE. Early deaths (<5 years from diagnosis) are attributed to active SLE disease and infections, whereas later deaths (>5 years from diagnosis) result from chronic SLE complications and medications, atherosclerotic CVD, and infections. Data suggest that malignancy-associated morbidity and mortality are lifelong risks, but rates are the greatest early in the disease. With recent and ongoing improvements in the treatment of SLE and increasing survival rates of patients with SLE, we need to pay additional attention to comorbid conditions associated with SLE and its treatment, specifically premature atherosclerotic heart disease, malignancy, bone health, and psychosocial well-being.

Systemic Sclerosis

Robyn T. Domsic

INTRODUCTION

Systemic sclerosis (SSc) is a connective tissue disease that is characterized by cutaneous and visceral fibrosis. The more common term for the disease, *scleroderma*, reflects its derivation from the Greek *scleros*, which means thick, and *derma*, which means skin.

The disorder can range from a relatively benign condition to a rapidly progressive disease leading to significant morbidity or death. Although cutaneous manifestations are the most obvious features, visceral involvement can be severe and disabling. Monitoring for potential organ complications is essential in caring for SSc patients, because early detection and treatment may minimize morbidity and mortality.

EPIDEMIOLOGY

The annual U.S. incidence of SSc is approximately 20 cases per million persons. Because patients with SSc often live for many years, the prevalence is 240 cases per million persons. Incidence and prevalence vary somewhat throughout the world, and they typically are lower in Europe and Asia. SSc more commonly affects women, with a 3 : 1 female-to-male ratio. It occurs in individuals of all ages, from childhood to the elderly, but it most frequently affects those between the ages of 40 and 60 years.

A familial pattern of inheritance is not as evident in SSc as in other connective tissue diseases. Twin studies have demonstrated only a 5% rate of concordance in monozygotic and dizygotic twins, implying that there are significant environmental contributions to its occurrence. Many patients with SSc, however, have family histories of other autoimmune diseases (e.g., thyroid disease, rheumatoid arthritis, systemic lupus erythematosus [SLE]). Genome-wide association studies have revealed a handful of genes associated with SSc that are shared with other diseases such as rheumatoid arthritis and SLE (e.g., major histocompatibility complex class I and II genes *STAT4* and *IRF5*). These findings suggest a shared genetic predisposition to autoimmune conditions.

PATHOLOGY

The pathogenesis of SSc has not been fully elucidated. There are three clearly identified components: endothelial and vascular injury with associated vasculopathy, immune system activation, and fibrosis with overproduction of collagen and other connective tissue matrix proteins (Fig. 80-1). Involvement of these systems initially became evident from autopsy studies. Vascular changes include endothelial cell injury and subintimal thickening leading to luminal narrowing with occasional vascular occlusion

FIGURE 80-1 Pathogenic processes in systemic sclerosis. Vascular injury leads to intimal proliferation of endothelial cells (red) and smooth muscle cells (blue). Fibroblasts are activated to deposit increased amounts of interstitial matrix. IL, Interleukin; PDGF, platelet-derived growth factor; TGF- β , transforming growth factor- β .

and periadventitial fibrosis. Vascular changes are seen in the skin and may occur in the pulmonary, cardiac, and renal blood vessels, affecting arteries, arterioles, and capillaries. True vasculitis is conspicuously absent.

Cutaneous inflammatory infiltrates consist of activated mononuclear cells, T lymphocytes, and monocytes in the dermis, often occurring in a perivascular distribution. Dermal thickening is accompanied by excessive deposition of collagen fibrils and fibrous replacement of subcutaneous fat and secondary skin appendages such as hair follicles and sebaceous glands.

The interplay between the vascular, immunologic, and connective tissue changes is complex. Most hypotheses focus on interactions between early vascular and immunologic events leading to activation of fibroblasts, which are thought to be the effector cells in this disease. Fibroblasts are found in increased numbers in the skin and other tissues, and they develop an SSc phenotype when grown *in vitro*, producing an overabundance of collagen and living longer in tissue culture. Fibroblast persistence in culture suggests a perpetuated abnormality not requiring continued immune stimulation.

Other factors that may contribute to fibrosis include hypoxia and local cytokine changes. Early vascular involvement consists of an imbalance between vasodilatory and vasoconstrictive factors, endothelial cell activation with resultant leukocyte migration, smooth muscle cell proliferation, and defective vasculogenesis. Vascular activation can induce fibrosis by interleukin-mediated mechanisms.

Immune system activation is evident in several respects. First, serum levels of inflammatory markers (based on the sedimentation rate) and circulating cytokines are increased. Second, serum autoantibodies are detected in more than 95% of patients with SSc. One of nine autoantibodies is relatively specific for the disease. All of the antibodies are directed against distinct nuclear antigens. They are helpful in classifying patients, but their pathogenic role has not been elucidated. Third, there is evidence of T-cell activation, with a T_H2-predominant cytokine profile. Elevated levels of interleukins (i.e., IL-1, IL-2, IL-2R, IL-4, IL-8, IL-13, and IL-17) and interferon have been reported. The role of T_H17 cells is not understood, but studies suggest that dysregulation of these proinflammatory T cells contributes to disease pathogenesis. Fourth, there is increasing evidence of innate immune dysregulation in the setting of activated macrophages and altered expression and function of toll-like receptors.

CLINICAL PRESENTATION

Patients with SSc can have several clinical presentations, although Raynaud's phenomenon is the most common symptom. Distinctive phenotypes may manifest differently. SSc can have many internal organ manifestations, producing various clinical presentations and requiring tailored work-up protocols.

Classification by Cutaneous Features

Historically, SSc has been separated into two major clinical subsets defined by the degree and extent of skin involvement: limited cutaneous (lc) and diffuse cutaneous (dc) disease. Patients with lcSSc experience skin thickening limited to the distal extremities (i.e., below the elbows and knees). The dcSSc patients have similar distal changes in addition to involvement of

the upper arms, thighs, or trunk at some time during the disease course. Few patients (<1%) have no skin thickening but have one or more typical SSc visceral manifestation.

The term *scleroderma sine scleroderma* has been used to describe dcSSc patients whose clinical course resembles that of individuals with lcSSc. The distinct cutaneous patterns are important, because patients with dcSSc are more likely to develop internal organ complications (e.g., renal crisis, cardiac involvement) early in their illness, whereas those with lcSSc can develop internal organ involvement throughout their disease, even decades after the initial symptoms (Table 80-1). Some patients with lcSSc or dcSSc may have typical features of another connective tissue disease (most commonly polymyositis, SLE, or rheumatoid arthritis-like features), and they are considered to have SSc *in overlap*.

Serologic Classification

Serologic classification refers to SSc-associated serum autoantibodies. Patients with the same autoantibody tend to have a similar cutaneous pattern, natural history of disease, and risk of internal organ involvement.

TABLE 80-1 MANIFESTATIONS OF SYSTEMIC SCLEROSIS BY CLINICAL CLASSIFICATION

MANIFESTATIONS	DIFFUSE (N = 1434)	LIMITED (N = 1718)
CUTANEOUS		
Puffy fingers	82%	78%
Skin induration, thickening	Widespread: trunk, face, extremities	Face, below the elbow and knee
Telangiectasias	58%	70%
Calcinosis	14%	22%
PERIPHERAL VASCULAR		
Raynaud's phenomenon	95%	97%
Digital ulcerations	42%	39%
PULMONARY		
Interstitial lung disease	37%	34%
Pulmonary arterial hypertension	5%	16%
CARDIAC		
Arrhythmias	16%	14%
Diastolic dysfunction	4%	5%
Myocarditis	6%	2%
Pericarditis	4%	3%
RENAL		
Renal crisis	18%	2%
GASTROINTESTINAL		
Esophageal hypomotility, reflux	79%	77%
Small intestine dysmotility	18%	13%
Malabsorption	11%	9%
Incontinence	2%	2%
JOINT AND MUSCULOSKELETAL		
Tendon friction rubs	53%	5%
Joint contractures	88%	38%
Myositis	10%	6%
Bland myopathy	2%	1%

Data from the University of Pittsburgh Scleroderma Databank, 1980-2012.

Serologic classification can augment the clinical classification described previously. For example, 95% of patients with anticentromere antibody have lcSSc and are at increased risk for pulmonary hypertension during the follow-up period. Individuals with anti–topoisomerase I (i.e., anti-SCL70) or anti–RNA polymerase III antibody are more likely to have dcSSc. Those with anti–RNA polymerase III antibody have an increased risk of renal crisis, and those with anti-SCL70 have a higher frequency of interstitial lung disease.

The primary internal organ risks and cutaneous associations are depicted in [Figure 80-2](#), which illustrates the combined clinical-serologic classification of SSc. It is uncommon for patients to have more than one SSc autoantibody.

Raynaud’s Phenomenon and Peripheral Vascular Involvement

Most patients with SSc experience Raynaud’s phenomenon during their disease course. Raynaud’s phenomenon is a triphasic vasospastic response to cold consisting of pallor (i.e., blanching) with or without cyanosis (i.e., bluish discoloration followed by reactive hyperemia (i.e., erythema) with a characteristic distinct line of demarcation on the digits separating the affected from unaffected areas.

The onset of Raynaud’s phenomenon can precede the development of skin changes by years in some patients. Severe involvement may result in ischemia with loss of digital tip tissue, including digital pitting scars, ulcers, and gangrene (rare). Digital tip ulcers are more frequent in patients who are anticentromere or anti–topoisomerase I autoantibody positive. Lower extremity ulcerations in SSc patients have been increasingly reported in recent years.

Interstitial Lung Disease

Interstitial lung disease (ILD) can be one of the most serious complications of SSc and should be monitored for routinely (see [Chapter 17](#)). The initial presentation is often a nonproductive

cough and a gradual onset of dyspnea on exertion over several months to years. However, the onset can be abrupt.

High-resolution chest computed tomography (CT) typically shows bibasilar fibrotic changes, which can be progressive. Pulmonary function tests reveal reduced forced vital capacity (FVC). On pathologic examination, the most frequently seen pattern is nonspecific interstitial pneumonitis. Patients with anti-SCL70 autoantibody are at the highest risk for ILD.

Pulmonary Hypertension

SSc patients can develop pulmonary hypertension of three World Health Organization (WHO) classifications (see [Chapter 18](#)). Pulmonary arterial hypertension (PAH, group 1) is the most common, with an estimated 10% to 15% of patients in cohort studies developing PAH. It occurs most commonly in those with lcSSc. The clinical presentation includes rapidly progressive dyspnea occurring over several months. Pulmonary function tests reveal a reduced diffusion capacity for carbon monoxide (DLCO) out of proportion to any concomitant reduction in the FVC.

Less frequently, SSc patients develop pulmonary hypertension associated with ILD (group 3) or pulmonary hypertension associated with left ventricular diastolic dysfunction from myocardial fibrosis or non-SSc-associated left ventricular disorders (group 2). Screening for all types of pulmonary hypertension is performed by echocardiogram, and results should be confirmed by right heart cardiac catheterization.

Scleroderma Renal Crisis

Scleroderma renal crisis (SRC) manifests as the abrupt onset of accelerated arterial hypertension accompanied by a rise in serum creatinine levels and by microscopic hematuria and proteinuria on urinalysis. Microangiopathic hemolytic anemia and thrombocytopenia are common. Although once the major cause of mortality in SSc, SRC is now managed by aggressive blood pressure control with an angiotensin-converting enzyme (ACE) inhibitor.

FIGURE 80-2 Clinical-serologic classification of systemic sclerosis and antibody-associated internal organ manifestations. *Bold text* indicates an antibody; clinical manifestations listed below are associated with that antibody. DU, Digital ulcers; ILD, interstitial lung disease; Ku, 70/80-kD protein (XRCC6/XRCC5); PH, pulmonary hypertension; PM, polymyositis; RNP, ribonucleoprotein; Sci, sclerosis; SRC, scleroderma renal crisis.

The typical setting for SRC is early dcSSc with a recent increase in skin thickening, palpable tendon friction rubs, and anti-RNA polymerase III antibody. During active, early dcSSc, patients should check their blood pressure once weekly and report a rise in systolic blood pressure of more than 20 mm Hg from baseline. Prednisone given at a dose of 15 mg daily or higher has been associated with the development of SRC and should be avoided in at-risk patients.

Cardiac Manifestations

Patients with SSc have three primary types of cardiac involvement: pericarditis, myocarditis, and myocardial fibrosis. The latter can lead to congestive heart failure and arrhythmias due to fibrosis of the conduction system. These complications can be asymptomatic and underrecognized in SSc patients, but pathologic changes have been found in most patients in older autopsy series. Later studies using cardiac magnetic resonance imaging (MRI) have confirmed the autopsy findings.

Diastolic dysfunction is becoming increasingly recognized as a complication of fibrosis and can be evaluated by echocardiogram during pulmonary hypertension screening. Many SSc deaths occur suddenly, possibly due to ventricular arrhythmias. It is prudent to obtain a resting electrocardiogram early in the disease course. Palpitations noticed by the patient should be addressed with a formal cardiac arrhythmia evaluation.

Gastrointestinal Tract Manifestations

At least one gastrointestinal manifestation will affect 80% or more of SSc patients, and all areas of the gastrointestinal tract may be affected. Gastrointestinal involvement is a significant cause of morbidity.

When the esophagus is affected, patients experience heartburn due to relaxation of the esophageal sphincter and distal dysphagia for solid foods due to esophageal dysmotility. Neuropathic changes and fibrosis of the muscularis of the small intestine can lead to motor dysfunction and symptoms of postprandial abdominal distention. Small intestinal hypomotility may lead to bacterial overgrowth, causing bloating and diarrhea.

When severe atony of the small intestine develops, patients occasionally develop a functional ileus or intestinal pseudo-obstruction. Parenteral nutrition may be necessary for severe malabsorption with accompanying weight loss and steatorrhea. Similar to the small bowel, the colon may develop impaired motor function leading to constipation and occasionally overflow diarrhea. Wide-mouthed diverticula on the antimesenteric border of the colon can be seen. The internal anal sphincter may become fibrotic, resulting in fecal incontinence.

Musculoskeletal Manifestations

Musculoskeletal manifestations are common. Tendons can become inflamed and fibrotic, particularly in early, diffuse disease. Palpable tendon or bursal friction rubs are virtually pathognomonic of SSc and often are a harbinger of progression to dcSSc before widespread skin thickening has occurred. Finger joint flexion contractures develop frequently within the first 2 years of diffuse SSc. True arthritis with palpable synovitis should raise the question of overlap with rheumatoid arthritis.

Some patients develop a bland myopathy with nonprogressive, mild proximal muscle weakness and wasting. A few, particularly with features that overlap with other connective tissue diseases, can develop true myositis, which can result in morbidity and disability.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Raynaud's disease (i.e., primary Raynaud's phenomenon) is prominent in the differential diagnosis for SSc. Features that identify Raynaud's patients who have or may later develop SSc or another connective tissue disease are abnormal nail fold capillaries (i.e., capillary dilation, megacapillaries, and avascular areas), tissue loss at the tips of the fingers, and a positive antinuclear antibody (ANA) test result. None of these features is found in Raynaud's disease.

Mixed connective tissue disease (MCTD) is also on the differential for SSc. MCTD patients have features of two or more autoimmune diseases. This most frequently includes SSc, polymyositis, and SLE. Patients are positive for anti-U1-RNP antibody, a serologic marker for MCTD. Patients with MCTD can develop any or all of the following SSc manifestations: Raynaud's phenomenon, puffy fingers, limited or diffuse skin thickening, myositis, ILD, PAH, and esophageal dysmotility.

Scleroderma mimics are sometimes difficult to distinguish from SSc (Table 80-2). They include eosinophilic fasciitis, the localized forms of scleroderma such as linear scleroderma (more frequently seen in children), and plaque or generalized morphea.

Nephrogenic systemic fibrosis is a complication of gadolinium administration for radiographic studies that occurs in the setting of renal failure. Nephrogenic systemic fibrosis manifests as symmetrical, bilateral, fibrotic, indurated papules, plaques, or subcutaneous nodules, which can be erythematous and occur on the lower legs or hands. The lesions are often preceded by edema and may initially be misdiagnosed as cellulitis. This diagnosis should be considered in patients being evaluated for a fibrotic disorder who have renal failure, regardless of the cause of renal disease.

Scleromyxedema and scleredema are cutaneous fibrotic disorders in which excessive mucin accumulation is found on skin biopsy. Scleromyxedema can mimic dcSSc on the physical examination or can manifest with multiple, firm, nodular skin lesions (i.e., papular mucinosis). A frequent association is a monoclonal gammopathy (i.e., immunoglobulin [IgG] paraprotein). Scleredema typically involves the nape of the neck and shoulders, sparing the distal extremities. All SSc mimics lack Raynaud's phenomenon, characteristic SSc internal organ involvement, and SSc-associated serum antibodies.

TREATMENT

Because no single therapy exists for SSc, patients must be appropriately monitored for visceral involvement to allow early identification and therapy targeted at specific organ complications. Consultation with a rheumatologist is helpful in this respect, and referral of severely affected patients to a dedicated scleroderma center should be the rule.

All patients should undergo screening evaluation for ILD and pulmonary hypertension throughout the course of their disease. Current expert recommendations suggest that patients with early, diffuse disease should be monitored at least yearly for these

TABLE 80-2 SCLERODERMA MIMICS

DISORDER	DISTINGUISHING FEATURES
OTHER DISEASES	
Morphea	One or more discrete lesions; patchy or linear in distribution
Eosinophilic fasciitis	Finger flexures without sclerodactyly; characteristic groove sign when the arms are raised; puckering or dimpling of the upper arm and thigh skin; peripheral blood eosinophilia; fascia and deep subcutaneous fibrosis
Scleredema (Buschke's disease)	Prominent involvement of neck, shoulders, and upper arms; hands spared; associated with diabetes
Scleromyxedema	Association with gammopathy; skin lichenoid and thickened but not tethered; may have Raynaud's phenomenon
Graft-versus-host disease	Skin changes similar to scleroderma; vasculopathy
Nephrogenic fibrosing dermopathy	Indurated plaques or nodules on the legs or arms, sparing the face; administration of gadolinium in the setting of renal dysfunction; often preceded by edema
REACTIONS TO ENVIRONMENTAL AGENTS AND DRUGS	
Bleomycin	Skin and lung fibrosis similar to scleroderma
L-Tryptophan (1980s)	Eosinophilia-myalgia syndrome from L-tryptophan contaminant or metabolite (first described in the 1980s); fever, eosinophilia, neurologic manifestations
Organic solvents (e.g., trichloroethylene)	Clinically indistinguishable from idiopathic systemic sclerosis
Pendazocine	Localized lesions at injection sites
Toxic oil syndrome	Contaminated rapeseed oil (Spanish epidemic in 1981); similar to eosinophilia myalgia syndrome
Vinyl chloride	Vascular lesions, acro-osteolysis, sclerodactyly, no visceral disease
Gadolinium	Nephrogenic fibrosing dermopathy

complications. Patients with active dcSSc should undergo weekly monitoring of blood pressure because the abrupt appearance of hypertension suggests SRC. Early dcSSc patients should also have skin thickness scores assessed for progression or regression of cutaneous disease. For dcSSc and lcSSc, initial esophageal motility studies should be performed, and further objective studies should be ordered on the basis of symptoms.

Education of patients and family members regarding the disease and the patient's classification (i.e., early or late, diffuse or limited disease) can help to alleviate patients' anxiety. An excellent publication, *The Scleroderma Book: A Guide for Patients and Families*, is available.

Raynaud's Phenomenon

Calcium-channel blockers have been widely used for decades, and they are generally well tolerated by patients. Long-acting nifedipine is effective in more than one half of patients, and newer agents such as amlodipine are frequently prescribed (level 1B evidence). The angiotensin-receptor blocker losartan reduced the severity and frequency of Raynaud's phenomenon attacks in a placebo-controlled trial. ACE inhibitors have not proved effective in several controlled trials. Phosphodiesterase-5 (PDE-5) inhibitors have been shown to improve Raynaud phenomenon (level 1A evidence).

In patients with digital ulcerations, more aggressive therapy may be warranted. PDE-5 inhibitors have been helpful (level 1B

evidence) has been helpful. Topical nitroglycerin as a paste, gel, or patch placed at the base of the fingers may be a useful adjunct. In randomized, placebo-controlled trials, bosentan prevented the formation of new digital ulcerations in patients with SSc and Raynaud's phenomenon, although it has not been approved by the U.S. Food and Drug Administration (FDA) for this indication (level 1B evidence). Iloprost, an intravenous prostacyclin, has also been shown to reduce digital ulcerations and is frequently used in Europe, but also it is not FDA approved in the United States (level A evidence).

For patients with digital ulcers involving adjacent fingers, assessment of the ulnar and radial artery should be performed with arterial Doppler or angiography because larger arteries can become severely narrowed. Surgical interventions include sympathectomy of the digital, radial, or ulnar artery and venous bypass for ulnar or radial artery occlusion. In SSc patients with recurrent digital ulcers or other thrombotic events, evaluation for a hypercoagulable state, particularly for lupus anticoagulant, should be performed. In this circumstance, aspirin or other anti-coagulants are indicated.

Cutaneous Disease

No therapeutic agent has been found to improve skin thickening in a randomized, placebo-controlled trial for patients with dcSSc. Several methodologic issues have contributed to the negative findings, including the drugs chosen, patient populations, and trial designs. In the past, considerable attention was given to methotrexate and D-penicillamine, but no convincing data support the use of either drug.

Case series with historical controls and comparisons with clinical trials have suggested a benefit for mycophenolate mofetil, although it has not been studied in a randomized setting (level B evidence).

Several reports on the benefit of autologous stem cell transplantation have been published. In an ILD study, cyclophosphamide use showed significant improvement in skin thickening in treated patients compared with placebo. Unless there is a serious internal organ complication, this potent therapy cannot be recommended because of the concern about life-threatening adverse effects, including malignancy.

Scleroderma Renal Crisis

Early diagnosis and prompt initiation of ACE inhibitors are the keys to improved survival and outcomes of SRC. ACE inhibitors should be titrated to maintain a normal blood pressure (level 3 evidence), preferably less than 125/75 mm Hg. β -Blockers are relatively contraindicated.

Even if patients with SRC become dialysis dependent initially, some may experience a slow reversal of renal vascular damage if ACE inhibitor therapy is maintained. Because up to 50% of SRC patients can spontaneously come off dialysis, transplantation evaluation should be delayed until at least 2 years after SRC onset.

Interstitial Lung Disease

Early recognition of inflammatory ILD is important if treatment is to prevent progression to distortion of lung architecture and irreversible fibrosis. A recent large, randomized,

placebo-controlled trial demonstrated statistically significant but modest FVC improvement with oral cyclophosphamide at 1 year. However, after an additional year off therapy, cyclophosphamide-treated patients lost their benefit, suggesting that other treatment options are needed.

Case series with and without historical controls support the potential benefit of mycophenolate mofetil, and this drug is the subject of an ongoing randomized controlled trial. Lung transplantation can be considered for end-stage ILD.

Pulmonary Hypertension

Several agents have been approved for the treatment of PAH (see [Chapter 18](#)). Subset analyses of several placebo-controlled drug trials have shown improvement in established SSc or connective tissue disease–related PAH. They have included phosphodiesterase-5 inhibitors (e.g., sildenafil, tadalafil), endothelial receptor antagonists (e.g., bosentan, ambrisentan), and prostacyclin analogues (e.g., treprostinil, epoprostenol) (level A evidence).

Theoretically, treatment of patients with early, less severe disease should improve outcomes, but studies are only beginning to be reported. Because patients with SSc-related PAH have a worse prognosis than those with idiopathic PAH, SSc patients with PAH should be recommended to a tertiary care facility with a dedicated pulmonary hypertension clinic.

Cardiac Manifestations

Combined corticosteroids and immunosuppression can be used for myocarditis. Conventional treatment is recommended for symptomatic pericarditis (see [Chapter 10](#)), arrhythmias (see [Chapter 9](#)), and congestive heart failure (see [Chapter 5](#)).

Gastrointestinal Manifestations

Gastroesophageal reflux, which occurs in most SSc patients, can be treated with proton pump inhibitors and conservative measures, including elevation of the head of the bed and avoidance of alcohol and caffeine. If untreated, reflux esophagitis can progress to distal esophageal stricture formation.

Patients with severe esophageal, gastric, or small bowel dysmotility may improve with the use of prokinetic drugs such as metoclopramide, erythromycin, or octreotide. Rotating antibiotics may be of assistance for bacterial overgrowth. For advanced small bowel involvement with malabsorption, supplementation of iron, calcium, and fat-soluble vitamins may be required. Occasionally, total parental nutrition is necessary. Unexplained iron-deficiency anemia in SSc patients suggests the possibility of gastric antral vascular ectasias (i.e., watermelon stomach), which are treated with laser photocoagulation.

Skeletal Muscle, Joint, and Tendon Manifestations

Bland myopathy usually is nonprogressive and is treated with physical therapy. If there is evidence of myositis with elevated serum levels of muscle enzymes or abnormal electromyography or muscle biopsy, corticosteroids and immunosuppressive therapy (e.g., methotrexate, azathioprine) may be helpful.

Patients with lcSSc or dcSSc can develop contractures of the hands due to tendon involvement. Physical therapy with daily stretching exercises directed at the finger joints should be instituted as soon as possible to prevent further loss of finger motion.

 For a deeper discussion of these topics, please see [Chapter 267, "Systemic Sclerosis \(Scleroderma\),"](#) in *Goldman-Cecil Medicine, 25th Edition*.

Systemic Vasculitis

Kimberly P. Liang

DEFINITION AND EPIDEMIOLOGY

The primary systemic vasculitides are inflammatory disorders of blood vessels that are characterized by immune-mediated injury leading to vessel necrosis, thrombosis, stenosis, or some combination of these. Vessels in any organ may be affected, but each vasculitis is characterized by different preferential vessel size or territory and tissue targeting. Although these disorders are rare, they may be organ- or life-threatening, so prompt diagnosis and treatment are necessary. The vasculitides are defined according to the 1990 American College of Rheumatology (ACR) classification criteria and the 1994 Chapel Hill Consensus Conference (CHCC) based on generally affected vessel size (small, medium, or large). Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides (AAVs) have known associations with characteristic autoantibodies. **Figure 81-1** shows the major types of vasculitides. Although the ACR and CHCC definitions were not designed as diagnostic criteria, classification criteria such as these are important in clinical research study design, treatment, and prognosis. The ACR and the European League Against Rheumatism (EULAR) are currently in the process of refining diagnostic and classification criteria for primary vasculitides.

Determining the incidence and prevalence of each of the vasculitides is challenging given the rarity of the disorders, imperfect

classification criteria and definitions for epidemiologic purposes, and some clinicopathologic overlaps that occur between certain types (e.g., AAVs).

Small Vessel Vasculitis

ANCA-Associated Vasculitides

Granulomatosis with polyangiitis (GPA; previously known as Wegener's granulomatosis), microscopic polyangiitis (MPA), eosinophilic granulomatosis with polyangiitis (EGPA; previously known as Churg-Strauss syndrome), and renal-limited vasculitis (RLV) affect small and medium-sized blood vessels and may be associated with ANCA. Various studies have shown AAVs to have an incidence of approximately 10 to 20 per million. The peak age at onset is 65 to 74 years, with a female-to-male ratio of 1.5 : 1. EGPA is the least common of the AAVs, with an incidence of approximately 1.0 to 3.0 per million, and it also has a weaker association with ANCA than GPA and MPA do.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) is a small vessel vasculitis that occurs most frequently in young children, with a peak age at onset of 4 to 6 years, but can also occur in adults. HSP accounts for almost half of all cases of childhood vasculitis. In children

FIGURE 81-1 The vascular spectrum of the vasculitides. (From Jennette JC, Falk RJ, Andrassy K, et al.: Nomenclature of systemic vasculitides: proposal of an international consensus conference, *Arthritis Rheum* 37:187–192, 1994.)

younger than 17 years of age, the annual incidence of HSP is approximately 20 per 100,000. Males are more commonly affected than females (approximately 2 : 1), and HSP occurs more frequently during the winter and spring months.

Medium Vessel Vasculitis

Polyarteritis nodosa (PAN) is a medium vessel vasculitis that is characterized by arterial aneurysmal and stenotic lesions of muscular arteries, often located at segmental and branch points. In contrast to small vessel vasculitis, renal involvement in PAN is not characterized by glomerulonephritis but rather by aneurysms and stenoses of renal arteries that may result in hypertension or renal dysfunction or both. PAN may occur either as a primary vasculitis or secondary to viral infections, mainly hepatitis B or C, or human immunodeficiency virus (HIV). Determining the incidence of this vasculitis is difficult, because PAN and MPA were not differentiated until 1994.

Kawasaki disease is a medium vessel vasculitis most often seen in boys younger than 5 years of age. It is the second most common vasculitis in childhood after HSP, accounting for about 23% of all childhood vasculitis cases. In the United States, the annual incidence in children younger than 5 years old is 20 per 100,000.

Large Vessel Vasculitis

Giant cell arteritis (GCA), also known as temporal arteritis, is the most common form of vasculitis in adults. It is a large vessel vasculitis that typically affects patients of Eastern European descent, with a mean age at onset of 70 to 75 years. It affects women more commonly than men (3 : 1). About 40% of patients with GCA have the related condition, polymyalgia rheumatica (PMR), which is characterized by subacute onset of aching and stiffness in the muscles of the neck, shoulder girdle, and hip girdle. However, only 10% to 25% of patients with PMR have or will develop GCA.

Takayasu's arteritis (TAK), or "pulseless disease," is a rare large vessel vasculitis that was initially identified in young women from East Asia in the 1800s but is now described worldwide. In adults, the female-to-male ratio is about 8 : 1, with an average age at diagnosis in the mid-20s.

PATHOLOGY

For most of the systemic vasculitides, the etiology and pathogenesis of disease are largely unknown. It has been proposed that a number of diverse mechanisms contribute to the development of vascular inflammation and subsequent injury on the background of genetic susceptibility (Fig. 81-2). Proposed triggers of disease include infection and environmental exposures (e.g., chemicals, pollutants). For most vasculitides, these associations remain speculative.

Humoral and cellular immune responses, cytokine release, chemokine activation, and immune complex deposition are important in disease pathogenesis. Normal protective and repair processes in the vessel can also contribute to injury and ischemia. For example, after injury, cellular migration and proliferation occurring as part of vessel repair can result in intimal hyperplasia, and the procoagulant milieu that is protective against hemorrhage may lead to thrombosis and vessel occlusion. Impairment of blood flow in injured vessels results in tissue ischemia and

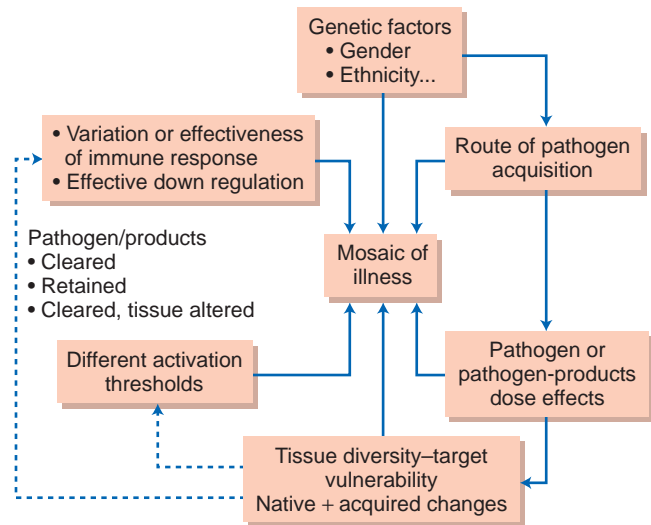

FIGURE 81-2 Factors affecting disease vulnerability and expression.

damage. The degree of blood flow impairment varies along a broad spectrum of severity and may depend on the type of vasculitis as well as the size and location of the vessels involved.

Among the AAVs, the pathology of GPA is typically characterized by necrotizing granulomatous inflammation of small blood vessels supplying the upper and lower respiratory tract. In both GPA and MPA, renal pathology shows a pauci-immune necrotizing crescentic glomerulonephritis. In EGPA, there is a strong association with allergic and atopic disorders, including allergic rhinitis, nasal polyposis, and asthma. Approximately 70% of patients with EGPA have elevated levels of immunoglobulin E (IgE) and eosinophilia of peripheral blood and tissue. Small vessel histopathology typically reveals transmural eosinophilic infiltrates with scattered plasma cells and lymphocytes and extravascular granulomas.

The pathology of HSP is characterized by a leukocytoclastic vasculitis of small vessels with IgA deposition seen on immunofluorescence. Various infectious agents, including bacteria and viruses, have been reported as triggers for HSP.

The pathology of GCA and TAK are very similar histologically. In both, large vessels demonstrate a lymphoplasmacytic inflammatory infiltrate. Giant cells and granulomas may be seen in the media, and lumen-occlusive arteritis may occur from exuberant intimal hyperplasia. Additional pathologic features include proliferation of vascular smooth muscle cells and fragmentation of the internal elastic lamina.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical manifestations of the systemic vasculitides are diverse and differ not only among disorders but also among patients. Typical clinical manifestations associated with the size of the affected vessel are detailed in Table 81-1.

Small Vessel Vasculitis

ANCA-Associated Vasculitides

GPA most commonly affects the sinuses and upper airway, the lungs, and the kidneys, although almost any organ system may be affected. Chronic refractory sinusitis, nasal crusting and ulcers,

TABLE 81-1 TYPICAL CLINICAL FEATURES* BASED ON VESSEL SIZE

LARGE	MEDIUM	SMALL
Limb claudication	Cutaneous nodules	Purpura
Asymmetrical blood pressures	Ulcers	Vesiculobullous lesions
Absence of pulses	Livedo reticularis	Alveolar hemorrhage
Bruits	Digital gangrene	Glomerulonephritis
Aortic dilatation	Mononeuritis multiplex	Mononeuritis multiplex
Aortic primary branch stenoses and/or aneurysms	Microaneurysms of mesenteric and/or renal branch arteries	Cutaneous extravascular necrotizing granulomas
		Splinter hemorrhages
		Scleritis, episcleritis, uveitis

*Constitutional symptoms in all types are fever, weight loss, malaise, anorexia, arthralgias, and myalgias.

epistaxis, septal perforations, and otitis media are common presenting manifestations. Chronic nasal cartilaginous inflammation and destruction may lead to the characteristic “saddle nose” deformity. Lung involvement in GPA or MPA can include pulmonary nodules (often cavitary in GPA), infiltrates, or diffuse alveolar hemorrhage due to capillaritis. Importantly, life-threatening pulmonary hemorrhage may manifest simply as progressive acute dyspnea with hypoxia or respiratory failure, and not necessarily hemoptysis. Laryngotracheal disease may manifest as hoarseness or subglottic stenosis; orbital pseudotumors can also occur from GPA, and they may cause optic nerve compression, proptosis, and/or extraocular muscle palsies.

The renal manifestations in GPA, MPA, or RLV are those of acute renal failure. Renal biopsy reveals pauci-immune necrotizing crescentic glomerulonephritis. Additional organ manifestations that may occur in either GPA or MPA include neurologic, cutaneous, musculoskeletal, cardiovascular, and constitutional signs and symptoms. Patients may have subacute symptoms (weeks to months of sinusitis, arthralgias, and fatigue) or may exhibit acute “pulmonary-renal syndrome” with rapidly progressive glomerulonephritis and life-threatening alveolar hemorrhage with respiratory failure.

In EGPA, the clinical features comprise severe asthma, eosinophilia (>1500 cells/mL), and vasculitis involving two or more organs. Additional organ involvement in EGPA may include the nervous system, kidneys, skin, heart, and gastrointestinal tract. Sinus involvement in EGPA is typically not destructive as in GPA, and pulmonary infiltrates may be fleeting.

The diagnosis of any of the AAVs is most frequently established by tissue biopsy (e.g., kidney, lung, skin, sinus, nerve). ANCA testing plays an important diagnostic role in suspected small vessel vasculitis and is helpful in differentiating between GPA and MPA. Almost 90% of patients with renal disease have positive ANCA on testing. Most GPA patients have the cytoplasmic (cANCA) antiproteinase 3 (anti-PR3) type, whereas most MPA patients have the perinuclear (pANCA) antityeloperoxidase (anti-MPO) type. The differential diagnosis for positive ANCA testing includes drug-induced effects, infections, and other autoimmune conditions. EGPA can be distinguished from other AAVs on the basis of a prior history of adult-onset asthma or allergic rhinitis and blood or tissue eosinophilia.

FIGURE 81-3 Palpable purpura on the lower extremities of a patient with small vessel vasculitis affecting the skin. These lesions are “palpable” because they are slightly raised (i.e., palpable even with the eyes closed), and they are typically nonblanching when palpated. (Modified from Molyneux ID, Moon T, Webb AK, Morice AH: Treatment of cystic fibrosis associated cutaneous vasculitis with chloroquine, *J Cystic Fibrosis* 9:439–441, 2010. Copyright 2010 European Cystic Fibrosis Society.)

The differential diagnosis for any small vessel vasculitis includes infection, disorders of coagulation, drug toxicity, atherosclerotic and embolic disease, malignancy, and secondary vasculitides associated with other autoimmune diseases.

Henoch-Schönlein Purpura

Patients with HSP have lower extremity purpura, arthritis (typically of the large joints), abdominal pain, and renal disease at presentation (Fig. 81-3). In children, arthritis and abdominal pain affect about 75% of patients; the gastrointestinal manifestations may precede the purpura by up to 2 weeks and include hematochezia. The most common renal manifestation is microscopic hematuria with or without proteinuria.

The diagnosis of HSP is most often based on clinical and laboratory evidence, although skin or renal biopsy revealing IgA deposition may be helpful in solidifying the diagnosis. By classification criteria from the EULAR, patients with HSP must have purpura or petechiae with lower limb predominance and at least one of the following: arthritis or arthralgias; abdominal pain; histopathology demonstrating IgA deposition; and renal involvement. The differential for HSP includes other causes of abdominal pain, other causes of purpura in childhood, and hypersensitivity vasculitis. Hypersensitivity vasculitis is also a small vessel vasculitis that may occur in both children and adults and may be idiopathic or triggered by infections or drug exposures. It typically manifests as an isolated cutaneous leukocytoclastic vasculitis that is self-limited with treatment of the underlying cause (e.g., treatment of infection, discontinuation of drug culprit).

Medium Vessel Vasculitis

Polyarteritis Nodosa

The most common organ systems affected in PAN are the gastrointestinal, renal, and nervous systems. Mesenteric aneurysms or stenoses resulting in gut ischemia lead to symptoms of abdominal pain or “intestinal angina” (pain after eating). Renal

artery aneurysms or stenoses result in hypertension or renal dysfunction, rather than glomerulonephritis as in MPA. Neurologic involvement may manifest as mononeuritis multiplex. Orchitis may be seen, manifesting as acute testicular pain. Anemia, elevated erythrocyte sedimentation rate or C-reactive protein or both, and hypertension (if renal artery involvement is present) are common. As in all vasculitides, constitutional symptoms may also be present.

The diagnosis of PAN is made based on angiographic or biopsy findings in the appropriate clinical setting. ANCA typically are absent in PAN. A work-up for infection, including tests for hepatitis B and C and HIV, is warranted, given their known associations with PAN. The differential diagnosis includes MPA and mixed cryoglobulinemic vasculitis. The latter vasculitis shares many clinical features with PAN, including peripheral neuropathy, arthralgias, myalgias, purpura, and association with hepatitis C.

Kawasaki Disease

The clinical presentation of Kawasaki disease includes fever lasting longer than 5 days, conjunctival injection, oropharyngeal changes (strawberry tongue, mucous membrane desquamation), peripheral extremity changes (cutaneous desquamation), polymorphous rash, and cervical lymphadenopathy. Arthralgias, abdominal pain, hepatitis, aseptic meningitis, and uveitis have also been reported. Coronary artery aneurysms, one of the most serious complications of this vasculitis, appear within the first 4 weeks after onset of disease and are often detectable with echocardiography. Although areas of ectasia and small aneurysms may regress, larger aneurysms often persist and can result in coronary ischemia at any time after development, even into adulthood. Kawasaki disease is a triphasic disease, consisting of an acute febrile period lasting up to 14 days, a subacute phase of 2 to 4 weeks, and a convalescent phase that can last months to years. In the acute phase, the fever is persistent and high ($>38.5^{\circ}\text{C}$) and is minimally responsive to antipyretics.

The differential diagnosis is wide and includes viral infections, toxin-mediated illnesses (e.g., toxic shock syndrome, scarlet fever), systemic juvenile idiopathic arthritis, hypersensitivity reactions, and drug reactions (e.g., Stevens-Johnson syndrome).

Large Vessel Vasculitis

Giant Cell Arteritis or Temporal Arteritis

At presentation, patients with GCA most commonly have new continuous headache, jaw claudication, visual disturbances (e.g., amaurosis fugax, diplopia), fatigue, and arthralgias. They are usually older than 50 years of age, have tender or thickened temporal arteries, and have an elevated erythrocyte sedimentation rate (>50 mm/hour by the Westergren method). Disease onset may be insidious or acute. Blindness due to anterior ischemic optic neuropathy occurs in 10% to 15% of patients with GCA and can occur at disease onset. Given the association between GCA and PMR, patients with PMR should be educated regarding signs and symptoms of GCA, and patients with GCA should be monitored for symptoms of PMR.

The diagnosis of GCA is often made by a biopsy of the superficial temporal artery. It is important to obtain a sufficient

length of tissue (2 to 3 cm) because the vasculitis can have “skip lesions.”

Takayasu's Arteritis

The typical clinical manifestations of TAK include a systolic blood pressure difference of greater than 10 mm Hg between the arms, decreased brachial or radial artery pulses, bruits auscultated over the subclavian arteries or aorta, claudication of extremities, neck or jaw pain, headache, dizziness, hypertension, constitutional symptoms, arthralgias, and myalgias.

The diagnosis of TAK is often based on vascular imaging studies that demonstrate long, tapering stenotic lesions or aneurysmal lesions in the aorta and primary branches. The differential diagnosis includes syphilis, spondyloarthropathies, rheumatoid arthritis, inflammatory bowel disease, and connective tissue disorders. Vascular imaging studies including computed tomographic angiography and magnetic resonance angiography are typically performed for both diagnosis and disease surveillance.

TREATMENT AND PROGNOSIS

Small Vessel Vasculitis

ANCA-Associated Vasculitides

Glucocorticoids, often with other agents, are uniformly used to induce and maintain remission in AAV. They are typically initiated at a prednisone equivalent dose of 1 mg/kg/day with or without pulse methylprednisolone (1 g IV daily \times 3 days), followed by a gradual taper over approximately 6 to 12 months. In addition, the standard. In addition, the standard of care in both GPA and MPA has traditionally been cyclophosphamide, either oral or intravenous, for 3 to 6 months. This has been reported to yield remission rates varying from 30% to 93% in GPA and from 75% to 89% in MPA.

Rituximab, an anti-CD20 chimeric monoclonal antibody that depletes B cells, was shown to be noninferior to cyclophosphamide in remission induction for AAV in several randomized controlled trials (RITUXVAS and RAVE trials).

Plasmapheresis, or plasma exchange therapy, is often used in combination with remission induction therapy in patients with life-threatening disease such as alveolar hemorrhage, or rapidly progressive glomerulonephritis (pulmonary-renal syndrome). The MEPEX study was a randomized controlled trial comparing plasmapheresis with high-dose methylprednisolone for severe renal vasculitis. Plasmapheresis was shown to be superior to methylprednisolone in reducing the number of patients remaining dependent on dialysis.

For limited (early) GPA, such as disease confined to the upper respiratory tract, methotrexate may be used for remission induction, rather than cyclophosphamide; this conclusion was supported by level I evidence in the NORAM trial. Trimethoprim-sulfamethoxazole was shown in two randomized controlled trials to be helpful in preventing relapses after remission induction in GPA.

Remission maintenance therapies in AAV (level I evidence) include methotrexate, azathioprine, or mycophenolate mofetil. Because there are known risks of bladder cancer, hemorrhagic cystitis, and bone marrow suppression with cumulative use of

cyclophosphamide, it no longer has a role in remission maintenance in AAV.

Although AAVs were once considered diseases with considerable mortality (80% at 2 years if left untreated), the prognosis has improved significantly over the last 30 years because of improved treatments. Patient survival is now reported to be as high as 45% to 91% at 5 years. Among AAV patients with renal involvement at presentation, 20% develop end-stage renal disease within 5 years.

Henoch-Schönlein Purpura

In mild cases, the therapy for HSP is simply supportive care (i.e., hydration and analgesics). However, glucocorticoids are commonly used to hasten the resolution of symptoms; early use of glucocorticoids has been associated with improved outcomes, especially when there is severe gastrointestinal involvement. In life-threatening cases and in severe acute renal failure, additional immunosuppressive agents or plasmapheresis may be considered. The prognosis of HSP is generally good, with fewer than 1% of patients developing end-stage renal disease.

Medium Vessel Vasculitis

Polyarteritis Nodosa

Treatment of PAN includes glucocorticoids or nonsteroidal anti-inflammatory drugs (NSAIDs) or both. If disease is severe and persistent or relapsing, additional immunosuppressive agents are used, such as cyclophosphamide (especially for gastrointestinal or cardiac involvement), methotrexate, colchicine, or intravenous immunoglobulin (IVIG). In cases of PAN associated with hepatitis B or C, antiviral therapy is required not only for attaining control of the viral infection but also for treatment of the associated vasculitis itself. Corticosteroids and cyclophosphamide have improved patient outcomes, and the 1-year survival rate is now 85%. Prognosis is typically worse with more systemic complications such as renal or neurologic involvement.

Kawasaki Disease

Treatment of Kawasaki disease includes high-dose aspirin (80 to 100 mg/kg/day) for the first 48 hours, then 3 to 5 mg/kg/day. IVIG is standard therapy and has significantly decreased the incidence of coronary artery aneurysm complications in this disease. The initial IVIG dose is 2 g/kg within the first 10 days after presentation, with at least one repeat dose typically given if the first IVIG dose fails to improve the child's condition. The prognosis of Kawasaki disease, if promptly treated, is good; however, approximately 15% to 25% of patients develop coronary artery aneurysms that increase morbidity and mortality.

Large Vessel Vasculitis

Giant Cell Arteritis or Temporal Arteritis

Glucocorticoids are the cornerstone of therapy in GCA. To prevent vision loss, treatment should be instituted immediately (within 24 hours) if clinical suspicion for GCA is high or if visual disturbances are present. The initial dose of glucocorticoids is typically 1 mg/kg/day with a gradual taper. Most patients require a glucocorticoid treatment duration of 1 to 2

years, but it may be longer, especially in those with symptoms of PMR. In PMR without GCA, lower doses of glucocorticoids (10 to 20 mg/day of prednisone equivalent) are effective and provide prompt clinical response.

If patients experience relapse with glucocorticoid tapering, other immunosuppressive agents may be used. Methotrexate was shown in a meta-analysis of three randomized controlled trials to be a beneficial adjunctive agent in reducing risks of first and second relapses in GCA, with a significant decrease in the cumulative dose of glucocorticoids. Low-dose aspirin is an important adjunctive therapy in protecting against cranial ischemic events (level II evidence from two large retrospective studies). Biologic agents in GCA are still under investigation.

Takayasu's Arteritis

Glucocorticoids are also the cornerstone of therapy for TAK; they are typically initiated at a dose of 0.5 to 1 mg/kg/day. Although most patients respond to the initial dose, relapses occur in more than 50% of patients during glucocorticoid tapering. Hence, steroid-sparing agents are often used to aid in maintaining disease remission. The most commonly used steroid-sparing agents are methotrexate and azathioprine. In TAK, unlike in GCA and PMR, the tumor necrosis factor (TNF) inhibitors have shown promise in treating refractory disease. As in GCA, low-dose aspirin is believed to play a beneficial adjunctive role in preventing ischemic complications.

Revascularization interventions are often indicated in patients with TAK whose presenting symptoms include cerebrovascular disease, coronary artery disease, moderate to severe aortic regurgitation, renovascular hypertension, progressive limb claudication, or progressive aneurysm enlargement. Elective intervention should be performed when the disease is quiescent.

In both GCA and TAK, aortitis—a common manifestation of large vessel involvement—can lead to an increased risk of aortic aneurysm and subsequent dissection and rupture. In both GCA and TAK, disease flares occur in most patients, rendering them chronic, progressive and relapsing conditions.

ADDITIONAL CONSIDERATIONS IN TREATMENT

Immunosuppressive therapy is associated with an increased risk of infection. Patients receiving combination therapy with moderate- to high-dose glucocorticoid (>20 mg/day of prednisone equivalents) and another immunosuppressive agent should also receive prophylaxis for *Pneumocystis jiroveci* pneumonia (previously known as PCP). Furthermore, infections can often mimic or result in flares of systemic vasculitis. Glucocorticoid therapy should never be discontinued abruptly, even in the setting of infection, because of the risk of adrenal crisis or disease relapse or both. In most cases, other immunosuppressive agents should be discontinued if infection is suspected or diagnosed.

Glucocorticoid therapy is a common cause of bone loss (osteopenia, osteoporosis). Because significant bone loss can occur even within the first 6 months of therapy, calcium and vitamin D supplementation should be initiated, and a baseline bone density study should be obtained. Consideration should be given to additional bone protection therapies (e.g., bisphosphonates). Methotrexate and cyclophosphamide are teratogenic, and cyclophosphamide may result in premature ovarian failure. These

factors must be considered when choosing therapies for women of child-bearing age. Immunosuppressive agents also can be associated with bone marrow suppression and with additional long-term risks such as malignancy.

Crystal Arthropathies

Ghaith Noaiseh

Gout

INTRODUCTION

The term *gout* refers to a heterogeneous group of diseases that result from deposition of monosodium urate (MSU) crystals in joints and soft tissue. Gout typically begins as an intermittent monoarthritis in the lower extremities; it may progress over time into a chronic, deforming and debilitating arthritis affecting almost any peripheral joint.

Gout is associated with hyperuricemia, which is defined as a serum urate level greater than 6.8 mg/dL. Above that concentration, urate can form uric acid crystals in normal physiologic conditions.

EPIDEMIOLOGY

More than 6 million adults in the United States have had gout attacks. The incidence and prevalence are markedly increasing. This is thought to be related to the aging of the population, increased use of certain medications such as diuretics, and increasing prevalence of comorbidities such as obesity, hypertension, renal disease, cardiovascular disease, and metabolic syndrome.

The incidence and prevalence are proportional to age and the degree and duration of serum urate elevation. Men are three to six times more likely to have gout than women, but the sex disparity decreases with aging, in part due to the declining levels of estrogen in postmenopausal women. Estrogen has a uricosuric effect, and this also explains why gout is uncommon in premenopausal women.

PATHOGENESIS

Pathophysiology of Hyperuricemia

Uric acid is the end product of purine metabolism in humans. Unlike many other species, humans lack the enzyme uricase, which catalyzes the conversion of uric acid into allantoin, a very soluble metabolite. Most individuals maintain uric acid levels between 4 and 6.8 mg/dL and a total body uric acid pool of approximately 1000 mg. However, accumulation of uric acid can occur and may lead to supersaturation of urate in blood. Serum uric acid levels greater than 6.8 mg/dL under normal pH and temperature may result in the precipitation of MSU crystals in joints, soft tissues, and other organs. Urate crystallization is a critical step in the progression from asymptomatic hyperuricemia to clinical gout. Unlike soluble urate molecules, MSU crystals are a potent promoter of acute inflammation.

Only about 20% of hyperuricemic patients develop gout during their lifetime. Additional factors, which are still poorly defined, are required for crystal formation.

The total body uric acid pool is closely related to the net purine accumulation, which comes from three sources: dietary purine intake, nucleic acid release from ongoing cell degradation, and de novo synthesis (endogenous purine biosynthesis). About two thirds of the daily excretion of uric acid occurs in the kidneys; the rest is eliminated by the gut. The balance between these mechanisms determines total uric acid body stores.

Hyperuricemia is caused by an imbalance between synthesis and elimination. Renal underexcretion is the cause for approximately 90% of hyperuricemia cases (Table 82-1). In the remaining 10%, hyperuricemia is caused by uric acid overproduction (>1000 mg of uric acid in a 24-hour urine collection while on a standard Western diet) or by a combination of overproduction with renal underexcretion.

Figure 82-1 summarizes the de novo biosynthesis and salvage pathways of purine metabolism. Abnormalities in the activities of key enzymes can lead to increased serum uric acid levels and development of gout. Overall, enzymatic deficiencies account for a small fraction of uric acid overproduction; most cases of uric

TABLE 82-1 CAUSES OF HYPERURICEMIA

URATE OVERPRODUCTION	URATE UNDEREXCRETION
METABOLIC DISORDERS	Renal insufficiency
HGPRT deficiency (homozygous or heterozygous)	Volume depletion
PRPP synthetase hyperactivity	Metabolic acidosis (lactic acidosis and ketoacidosis)
G6PD deficiency	Obesity
Glycogen storage diseases	Ethanol
OTHERS	Medications: low dose salicylate, diuretics (thiazides, loop diuretics), cyclosporine, tacrolimus, L-dopa, ethambutol
Myeloproliferative and lymphoproliferative disorders	Familial juvenile hyperuricemic nephropathy
Erythropoietic disorders (hemolytic anemia, megaloblastic anemia, sickle cell disease, thalassemia, other hemoglobinopathies)	Medullary cystic kidney disease
Solid tumors	Lead nephropathy
Diffuse psoriasis	
Ethanol (particularly beer)	
Medications: cytotoxic agents, nicotinic acid	
Shellfish, organ meat, red meat	
Fructose	
Obesity	

HGPRT, Hypoxanthine-guanine phosphoribosyltransferase; PRPP, 5'-phosphoribosyl 1-phosphosphate; G6PD, glucose-6-phosphate dehydrogenase.

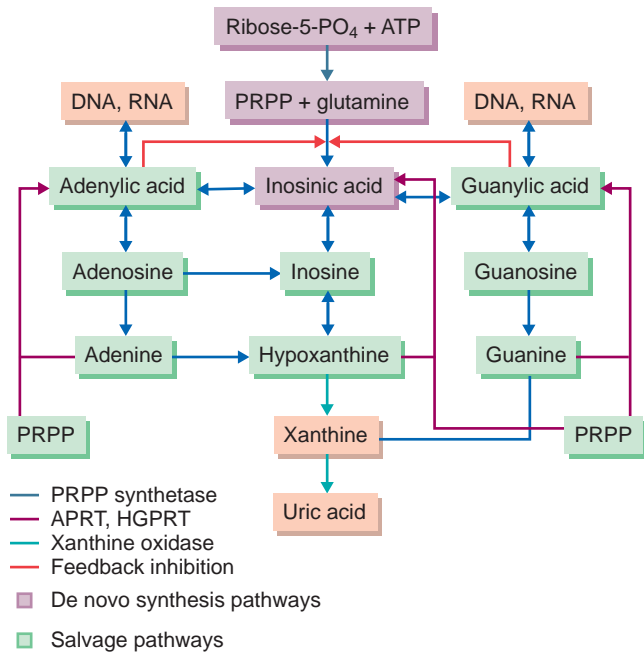

FIGURE 82-1 Biochemical pathways of purine synthesis, interconversion, and degradation. APRT, Adenine phosphoribosyl transferase; ATP, adenosine triphosphate; HGPRT, hypoxanthine-guanine phosphoribosyltransferase; PRPP, 5'-phosphoribosyl 1-pyrophosphate.

acid overproduction result from increased reutilization of purine bases through salvage pathways (see Fig. 82-1). The de novo synthesis of purine is driven by the enzyme 5'-phosphoribosyl 1-pyrophosphate (PRPP) synthetase. In PRPP synthetase overactivity, overproduction of PRPP increases purine production. In salvage pathways, tissue-derived intermediate purine products (hypoxanthine, guanine, and adenine) are reutilized rather than undergoing further degradation to xanthine and uric acid. Deficiencies of hypoxanthine-guanine phosphoribosyltransferase (HGPRT) activity result in impaired purine salvage and increased substrate for uric acid generation (Lysch-Nyhan syndrome and Kelley-Seegmiller syndrome).

Diseases associated with increased cell turnover (e.g., hemolysis, ineffective hematopoiesis, psoriasis) or with other causes of enhanced purine nucleotide breakdown (ethanol or fructose ingestion) can lead to hyperuricemia. Purine-rich foods comprise a significant portion of the daily purine load and can worsen hyperuricemia. On the other hand, consumption of low-fat dairy products is associated with reduced serum urate levels and may decrease the risk of gout.

A very small proportion of serum urate is bound to plasma proteins; therefore, urate is almost completely filtered in the glomeruli. Subsequent reabsorption and secretion occur through various organic acid transporters located on the luminal side of the proximal convoluted tubule epithelium. Only about 10% of the total filtered uric acid is excreted in the urine.

In addition to the bidirectional transport of uric acid, organic acid transporters are also responsible for eliminating other organic acids and certain medications. The function of these transporters is affected by certain medications, including thiazides, low-dose aspirin, and cyclosporine, leading to decreased uric acid excretion and hyperuricemia. Conversely, medications such as probenecid and losartan, when excreted in the tubular lumen, exert their uricosuric effect by displacing uric acid from

the transporter and increasing uric acid excretion. Certain genetic mutations affecting these transporters may lead to uric acid underexcretion. Renal insufficiency can cause hyperuricemia though decreased uric acid filtration.

Pathophysiology of Acute Gouty Attack

In some patients with prolonged hyperuricemia, tissue deposits of MSU crystals, called *microtophi*, form in the synovium and on the surface of cartilage. During an acute attack, microtophi break apart, shedding a large number of MSU crystals into the joint space and activating synovial macrophages and fibroblasts that phagocytize the crystals. This, in turn, leads to the activation of a cytosolic multiprotein complex, the NALP3 (NACHT, LRR, and PYD domains-containing protein 3) inflammasome, which generates interleukin-1 β . Interleukin-1 β production activates bloodstream neutrophils and endothelial cells, allowing neutrophils to cross the capillary endothelium into the joint space. Inflammation is propagated by further activation of the newly recruited neutrophils, which leads to the clinical signs of inflammation characteristic of the acute gouty attack.

MSU crystals undergo clearance by inflammatory cells that then undergo apoptosis. This, along with other mechanisms, eventually leads to resolution of the acute inflammatory process, typically after 10 to 14 days. Even after complete resolution of symptoms, a low-grade level of inflammation (intercritical inflammation) can persist in the otherwise asymptomatic joint. This inflammation may become clinically apparent in long-standing gout, and it contributes to chronic synovitis, cartilage loss, and bony erosions.

CLINICAL FEATURES

Gout has three stages: asymptomatic hyperuricemia, acute intermittent gout, and chronic gout.

Acute Gouty Attacks

The classic picture of acute gout is rapid development of an inflammatory arthritis involving one (or occasionally two) joints. Severe pain, erythema, swelling and exquisite tenderness typically occur. The most commonly involved joints are the first metatarsophalangeal joint (podagra), followed by the joints of the ankle, midfoot, and knee. The pain intensifies over 8 to 24 hours. Acute attacks usually resolve, even without therapy, within 5 to 14 days. The clinical resolution is complete, and the patient is asymptomatic between attacks. This clinical picture can be easily confused with that of septic arthritis or cellulitis, because many patients can mount an intense systemic inflammatory response with fever, chills, and elevated inflammatory markers.

Attack-provoking factors include use of diuretics, alcohol, surgery, trauma, and consumption of foods containing high purine levels. Each of these can cause fluctuation in serum urate levels. Initiation of urate-lowering therapy can trigger attacks in the early phase by the same mechanism.

Subsequently, involvement of the upper extremities can occur, affecting the small joints of the hands, wrists, and elbows.

Chronic Gout

Transition to the chronic phase can occur if hyperuricemia is inadequately treated. This phase, called *chronic gout* (also referred

to as *chronic tophaceous gout* or *chronic advanced gout*), typically develops 10 or more years after the onset of acute attacks. This phase is characterized by less severe attacks compared with the early flares and incomplete resolution of symptoms between flares as the patient continues to experience some baseline joint pain.

The characteristic lesion of chronic gout is the *tophus*, a palpable collection of MSU crystals in soft tissue or joints. It is detected in about 75% of patients who have had gout for more than 20 years. The severity and duration of hyperuricemia determine the likelihood of tophus development. Although the ears, fingers, wrist, and olecranon bursa are the typical locations, tophi can occur anywhere in the body.

DIAGNOSIS

The typical presentation of acute gouty arthritis in a characteristic joint distribution is strongly suggestive of the diagnosis, particularly if there is a history of similar attacks that completely resolved. Nevertheless, the diagnosis should be confirmed by aspiration of the involved joint. This is a critical step to rule out septic arthritis and other crystalline arthropathies such as CPPD deposition disease, which is caused by deposits of calcium pyrophosphate dihydrate (CPPD) crystals in the cartilage (see later discussion). During acute attacks, intracellular, strongly negative birefringent, needle-shaped MSU crystals are typically identified by polarized compensated microscopy. MSU crystals can also be demonstrated in tophus aspiration (Fig. 82-2A).

Bacterial infection can coexist with urate crystals in the synovial fluid; Gram stain and culture should be performed. Aspirated fluid appears cloudy, and synovial fluid analysis shows inflammatory fluid (>2000 white blood cells per microliter) with as many as 50,000 to 100,000 cells/ μL or even more). Serum uric acid is not a diagnostically reliable test during acute flares because the serum urate level may be normal or even low. Laboratory testing may reveal leukocytosis and elevated inflammatory markers, both of which are nonspecific. Between attacks, MSU crystals can often be demonstrated in previously inflamed joints. This can provide support for a diagnosis of gout when the patient is asymptomatic.

Radiologic Features

During an acute attack, a plain radiograph may only show soft tissue swelling. After many years of the disease and during the chronic phase, well defined, “punched out” juxtaarticular erosions with overhanging bony edges and sclerotic margins may be seen. The joint space is preserved until late in the course of the disease. Soft tissue masses may be detected in patients with tophi. Periarticular osteopenia is absent. Ultrasound can be a promising tool in the diagnosis and management of gout.

Gout in Transplantation Patients

Hyperuricemia occurs much more frequently in transplantation patients using cyclosporine than in the normal population. Compared to patients with classic gout, these patients exhibit a significantly shorter period of asymptomatic hyperuricemia (0.5 to 4 years versus 20 to 30 years), a shorter stage of acute intermittent gout (1 to 4 years versus 10 to 15 years), and rapid development of tophi as early as 1 year after transplantation. Gouty attacks can be atypical and less severe, in part because of the concomitant use of prednisone.

DIFFERENTIAL DIAGNOSIS

Acute gouty arthropathy should be distinguished from septic arthritis and other crystal-induced arthropathies such as CPPD deposition disease. The onset of acute CPPD arthropathy is usually less abrupt, and attacks tend to last longer, up to 1 month or more. Attacks occur more often in large joints such as the knee and wrist. Forms of spondyloarthritis including reactive arthritis, psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel related arthritis can also manifest with monoarticular arthritis. In these disorders, synovial fluid is inflammatory, with a leukocyte count usually in the range of 10,000 to 50,000/ μL , but crystals are absent and fluid culture is negative.

In its chronic phase, gout can be confused with rheumatoid arthritis and tophi can be confused with rheumatoid nodules. Aspiration of chronically inflamed joints or a tophus can help in distinguishing the two entities.

TREATMENT

Management of Acute Gouty Attack

The goal of management is to quickly control the inflammation and pain. Affected joints should be rested. Application of ice to the joint is usually helpful in reducing symptoms, but it is rarely sufficient to adequately control symptoms.

Nonsteroidal anti-inflammatory drugs (NSAIDs) including ibuprofen, naproxen, indomethacin, and diclofenac are typically used, and all seem to be equally effective. Full doses of NSAIDs should be initiated immediately, and a treatment duration of 7 to 10 days may be necessary for complete resolution of symptoms. NSAIDs are inappropriate in patients with peptic ulcer disease, inflammatory bowel disease, or renal insufficiency, and they must be used with caution in patients who are at risk for cardiovascular events.

Oral colchicine can be effective if it is used early in an acute attack (i.e., within the first 24 to 48 hours). A commonly prescribed dose is 1.2 mg, followed by 0.6 mg 4 hours later for the first day, followed by dose tapering until the attack is resolved. The drug should be stopped if nausea or loose stool occurs. Use of intravenous colchicine is discouraged because of the unacceptable risk of bone marrow suppression. Intraarticular corticosteroid injection is a very effective therapy for patients with monoarticular or oligoarticular disease in whom other systemic therapies need to be avoided. Enteral or parenteral glucocorticosteroids are effective in patients with renal insufficiency, intolerance to NSAIDs or colchicine, or treatment resistance. This approach is usually reserved for polyarticular flares when intraarticular injection is not practical (i.e., too many involved joints). A common starting corticosteroid dose is prednisone, 30 to 50 mg daily.

Urate-lowering therapy (ULT) should *not* be interrupted during acute attacks. Patients with established disease should be encouraged to maintain a supply of their medication for acute attacks and to start it promptly at the onset of typical symptoms; this may shorten the duration of attacks.

Management of Intercritical and Chronic Gout

Urate-Lowering Therapy

The aim of chronic treatment is to prevent recurrent attacks and to minimize joint damage by depleting tophaceous deposits in joints and soft tissue. This is achieved by lowering the uric acid level to less than 6 mg/dL. A target serum uric acid concentration of less than 5 mg/dL should be considered in patients with chronic tophaceous gout because it can result in a faster, more effective reduction in tophus size and flare frequency. Indications for ULT in patients with gout include two or more attacks in a single year, recurrent nephrolithiasis, and presence of tophi or chronic gouty arthritis.

ULT agents are divided into three categories: those that decrease uric acid production (uricostatic), those that increase renal excretion (uricosuric), and those that metabolize uric acid (uricolytic). The optimal duration of ULT is not known, and lifelong therapy is usually recommended. ULT is typically started after resolution of an acute attack.

Uricostatic Therapy

Allopurinol and febuxostat are xanthine oxidase inhibitors that prevent urate formation. They are effective in both overproducers and undersecretors of uric acid.

Allopurinol remains the first-line and most commonly used ULT agent, particularly in patients with chronic renal insufficiency, uric acid stones, or uric acid overproduction. If renal function is normal, a starting dose of 100 mg daily is recommended because higher doses may increase the risk of allopurinol hypersensitivity, a potentially lethal complication. The risk of early flares may also be increased with higher doses. It is recommended that the allopurinol dose be titrated up by 100 mg increments every 2 to 5 weeks until the uric acid goal is reached. The maximal dose is 800 mg/day. Adverse events include rash (2%), hepatitis, vasculitis, eosinophilia, and bone-marrow suppression.

Allopurinol hypersensitivity reaction can be fatal, and the risk may be higher with concomitant use of thiazides and in patients with penicillin allergy. Fever, severe exfoliative dermatitis, eosinophilia, and hepatic and renal failure can occur. If the uric acid goal is not achieved with allopurinol titration, or if side effects occur, then febuxostat may be used.

If the target uric acid level is not achieved with monotherapy, combination therapy with a uricosuric agent and a xanthine oxidase inhibitor may be considered.

Uricosuric Therapy

In the United States, probenecid is the only available uricosuric agent. It may be used as a first-line ULT in uric acid undersecretors (<600 mg in a 24-hour urine collection), but it is ineffective in patients with renal insufficiency (glomerular filtration rate <50 mL/minute) and is contraindicated in patients with nephrolithiasis. Patients should maintain high urine volume by drinking at least 1.5 L of fluid daily.

Uricolytic Therapy

Pegloticase (pegylated recombinant uricase), administered intravenously every 2 weeks, is considered for patients whose gout is refractory to conventional ULT.

Rasburicase, another recombinant uricase, is used to prevent tumor lysis syndrome but has no role in the management of gout.

Non-Urate-Lowering Prophylactic Therapy

Anti-inflammatory prophylaxis using low-dose colchicine or NSAIDs is usually recommended in conjunction with ULT to decrease the risk of flares that often accompany initiation of ULT. Prophylactic treatment is usually continued for 6 months after the serum uric acid goal is achieved.

Lifestyle Modifications and Education

A patient newly diagnosed with gout should be evaluated for potentially modifiable risk factors and associated illnesses such as obesity, hypertension, and hyperlipidemia. Decreased consumption of high-purine foods (e.g., shellfish, liver, sweetbreads) and fructose-containing beverages, as well as reduced alcohol intake, should be recommended. Diuretics should be avoided if possible.

Treatment of Hyperuricemia in Patients Without Gout

Allopurinol and rasburicase have been used for prevention and treatment of tumor lysis syndrome associated with hyperuricemia occurring after chemotherapy. Apart from this indication, there is no evidence to support their use for the routine treatment of asymptomatic hyperuricemia.

CALCIUM PYROPHOSPHATE DIHYDRATE DEPOSITION DISEASE

Calcium pyrophosphate dihydrate (CPPD) deposition disease is a clinically heterogeneous disorder that is characterized by the presence of intraarticular CPPD crystals. These crystals are deposited primarily in the cartilage, in the normally unmineralized pericellular matrix of hyaline and fibrocartilage. Calcification of the cartilage is promoted by alterations in the metabolism of inorganic pyrophosphate (PPi) and extracellular matrix leading to extracellular accumulation of PPi, which is necessary to the formation of CPPD crystals. Crystals are phagocytized by resident synovial macrophages, activating the intracellular NALP3 inflammasome complex and leading to recruitment and influx of neutrophils into the joint space.

CPPD deposition disease typically affects the elderly population. Up to 50% of individuals older than 85 years of age have radiographic evidence of CPPD crystal accumulation in cartilage (chondrocalcinosis), but most are asymptomatic. The most commonly involved joints are the knee menisci and the triangular fibrocartilage of the wrist.

The clinical course of CPPD deposition disease may be asymptomatic, acute, subacute, or chronic. The most common clinical manifestation, occurring in more than 50% of patients, is a peculiar type of osteoarthritis called pseudo-osteoarthritis; it is a non-inflammatory arthritis involving joints not typically affected by osteoarthritis, such as the wrist, shoulder, ankle, and metacarpophalangeal joints. Asymptomatic disease may be an incidental finding on radiographs showing chondrocalcinosis. Pseudogout is an acute monoarthritis similar in presentation to the acute gouty attack. A chronic symmetric polyarticular arthritis pattern resembling rheumatoid arthritis and a severe destructive arthropathy that mimics neuropathic arthritis on radiographs may be seen.

It is uncommon for CPPD deposition disease to affect patients younger than 50 years of age, unless the disease is familial or related to a metabolic abnormality (e.g., hyperparathyroidism). Acute pseudogout attacks may be precipitated by trauma, surgery (particularly parathyroidectomy for hyperparathyroidism), or severe medical illness. Administration of intraarticular viscosupplementation may also trigger a CPPD flare. Attacks are usually monoarticular or oligoarticular; if left untreated, they may last from a few days to a few months. Involved joints are swollen, with variable erythema and warmth. Fever, elevated erythrocyte sedimentation rate, and leukocytosis can occur.

The diagnosis is confirmed by demonstration in synovial fluid of intracellular rod- or rhomboid-shaped crystals with weak positive birefringence when examined by compensated polarized light microscopy (see Fig. 82-2B). These crystals can be difficult

to detect in some patients and are frequently missed in clinical specimens.

The presence of chondrocalcinosis (radiodense deposits on radiographs) is highly suggestive of the diagnosis in the appropriate clinical context. Joint aspiration should always be performed to rule out the possibility of infection. Importantly, joint infection can cause crystal shedding, leading to a concomitant crystal-related inflammation. Synovial fluid is inflammatory (>2000 white blood cells per microliter), with an average of 24,000 cells/ μ L.

Therapy for CPPD deposition disease is indicated for symptomatic patients. There is no effective treatment to remove CPPD deposits from synovium or cartilage. Treatment options include intraarticular glucocorticoid injection of the affected joint or joints. NSAIDs are effective, but their potential toxicity in elderly patients may limit their utility. Severe polyarticular attacks may require short courses of systemic corticosteroids. In patients with frequent pseudogout attacks, prophylactic daily low-dose colchicine may decrease the frequency.

APATITE-ASSOCIATED ARTHROPATHY

Abnormal accumulation of apatite (basic calcium phosphate, or BCP) may occur in hypercalcemic states and other illnesses. Unlike MSU or CPPD crystals, individual BCP crystals are not identifiable by polarized microscopy and can be seen only by electron microscopy. The most common apatite-associated condition is calcific periarthritis, which typically occurs in the shoulder.

Milwaukee shoulder is an extremely destructive BCP-associated arthropathy that occurs more commonly in elderly women. It is characterized by a large noninflammatory effusion (i.e. <2000 white blood cells per microliter) and results in destruction of the rotator cuff with subsequent marked instability and destruction of glenohumeral cartilage.

Other manifestations include acute reversible inflammatory arthropathies that resemble gout, referred to as *pseudo-pseudogout*, and ossifications along the anterolateral aspect of spinal vertebrae, termed *diffuse idiopathic skeletal hyperostosis* (DISH). Acute attacks of arthritis or bursitis may be self-limited. Intraarticular or periarticular injection of corticosteroids or the use of NSAIDs may shorten the duration and intensity of symptoms.

CALCIUM OXALATE DEPOSITION DISEASE

In calcium oxalate deposition disease, or oxalosis, calcium oxalate crystals are deposited in tissue. In primary oxalosis, a hereditary metabolic disorder, this deposition leads to nephrocalcinosis, renal failure, and early mortality. Secondary oxalosis complicates long-term hemodialysis or peritoneal dialysis; crystals are deposited in bone, cartilage, synovium, and periarticular tissue. Crystal shedding into the joint space may result in inflammatory arthritis of peripheral joints. Chondrocalcinosis or soft tissue calcifications can be seen on plain radiographs. The presence of strongly birefringent bipyramidal crystals is characteristic. Treatment with NSAIDs, intraarticular corticosteroids, or colchicine usually results in moderate improvement.

Osteoarthritis

C. Kent Kwoh

DEFINITION AND EPIDEMIOLOGY

Osteoarthritis, also known as degenerative joint disease, is the most common type of arthritis and musculoskeletal disease. It is a disease of synovial joints that encompasses the pathophysiologic changes that result from alterations in joint structure due to failed repair of joint damage and the individual's experience of illness, which is most often characterized by pain.

More than 26.9 million Americans older than 25 years have some form of osteoarthritis, and the prevalence increases with age. The radiographic prevalence varies by the joint involved. Twenty-seven percent of adults and more than 80% of those older than 65 years have evidence of hand osteoarthritis, and 37% of those older than 60 years have radiographic evidence of knee disease. The prevalence of symptomatic osteoarthritis is lower, with 7% of adults having symptomatic hand disease and 17% of those older than 45 years having symptomatic knee involvement.

Hand and knee osteoarthritis is more common among women, especially after 50 years of age, and it is more common among African Americans. Nodal osteoarthritis, involving the distal and proximal interphalangeal joints, is significantly more common in women and among female first-degree relatives.

Osteoarthritis is associated with major morbidity and is the leading cause of long-term disability in the United States. Lower extremity osteoarthritis is the most common cause of difficulty with walking or climbing stairs, preventing an estimated 100,000 elderly Americans from independently walking from their bed to the bathroom.

Osteoarthritis has a large economic impact because of direct medical costs (e.g., physician visits, laboratory tests, medications, surgery) and indirect costs (e.g., lost wages, home care). With the aging of the U.S. population, the burden of osteoarthritis is expected to increase in the coming years.

 For a deeper discussion of these topics, please see Chapter 262, "Osteoarthritis," in Goldman-Cecil Medicine, 25th Edition.

PATHOLOGIC FACTORS

The causes of osteoarthritis are complex and heterogeneous, and its pathophysiology is not well understood. The cardinal feature is progressive loss of articular cartilage with associated remodeling of subchondral bone. In normal cartilage, there is continuous extracellular matrix turnover with a balance between synthesis and degradation. In osteoarthritis, there is an imbalance of these two processes, with an excess of matrix degradation that exceeds

ongoing matrix synthesis. Excess degradation results from overproduction of catabolic factors such as proinflammatory cytokines and reactive oxygen species.

Osteoarthritis is best defined as joint failure, a disease process that involves the total joint, including the subchondral bone, ligaments, joint capsule, synovial membrane, periarticular muscles, and articular cartilage. After bone trauma or repetitive injury, joint failure may result from joint instability caused by muscle weakness and ligamentous laxity; nerve injury and neuronal sensitization or hyperexcitability, or both. Also contributing are low-grade systemic inflammation caused by subacute metabolic syndrome and local inflammation resulting from synovitis. Identifiable risk factors for osteoarthritis include biomechanical, metabolic, and inflammatory processes; congenital or developmental deformities of the joint that alter its shape; and genetic factors. Age, sex, and race are prominent risk factors for osteoarthritis.

Biomechanical contributors include repetitive or isolated joint trauma related to certain occupations or physical activities that involve repeated joint stress and predispose to early osteoarthritis. Altered joint shape may contribute to osteoarthritis through biomechanical factors. Obesity may contribute biomechanically or systemically through subacute or overt metabolic syndromes, both of which are associated with low-grade systemic inflammation.

Metabolic disorders such as hemochromatosis, ochronosis, Wilson's disease, and Gaucher's disease are associated with osteoarthritis. High bone mineral density is associated with hip and knee involvement. Estrogen deficiency may be a risk factor for hip or knee disease. Candidate gene studies and genome-wide scans have identified several potential genetic markers. Patients often have a family history of osteoarthritis or joint replacement.

Inflammatory joint diseases such as rheumatoid arthritis may result in cartilage degradation and biomechanical effects that lead to secondary osteoarthritis. The destruction of the joint, including articular cartilage damage, osteophyte formation, and subchondral bone remodeling, is best viewed as joint failure and the final product of a variety of etiologic factors.

The earliest finding is fibrillation of the most superficial layer of the articular cartilage. Over time, disruption of the articular surface becomes deeper, with fibrillations extending to subchondral bone, fragmentation of cartilage with release into the joint, matrix degradation, and eventually, complete loss of cartilage, leaving only exposed bone.

Early in the process, the cartilage matrix demonstrates increased water and decreased proteoglycan content, unlike the

dehydration of cartilage that occurs with aging. The tidemark zone, separating the calcified cartilage from the radial zone, is invaded by capillaries. Chondrocytes initially are metabolically active and release a variety of cytokines and metalloproteinases, contributing to matrix degradation. In the later stages, this results in the penetration of fissures to the subchondral bone and the release of fibrillated cartilage into the joint space.

An imbalance between tissue inhibitors of metalloproteinases and the production of metalloproteinases may be operative in osteoarthritis. Subchondral bone remodels and increases in density. Cystlike bone cavities containing myxoid, fibrous, or cartilaginous tissue may form. Osteophytes or bony proliferations at the margin of joints at the site of the bone-cartilage interface may form at capsule insertions. Osteophytes contribute to joint motion restriction and are thought to be the result of new bone formation in response to the degeneration of articular cartilage, but the precise mechanism for their production remains unknown.

Several crystals have been identified in synovial fluid and other tissues from osteoarthritic joints, most notably calcium pyrophosphate dehydrate and hydroxyapatite. Although these crystals have potent inflammatory potential, their role in the pathogenesis of osteoarthritis remains unclear. Frequently, the crystals are asymptomatic and do not correlate with extent or severity of disease.

The diversity of risk factors predisposing to osteoarthritis suggests that many insults to the joints, including biomechanical trauma, chronic articular inflammation, and genetic and metabolic errors, can contribute to or trigger the cascade of events that results in the characteristic pathologic features described earlier. At some point, the cartilage degradative process becomes irreversible. With progressive changes in articular cartilage, joint mechanics become altered, perpetuating the degradative process.

CLINICAL PRESENTATION

Pain is the characteristic feature of osteoarthritis and the most common presenting symptom. Pain is usually worse with activity or weight bearing and better with rest. In later stages, pain may also occur at rest. Early in the disease course, pain tends to be transient, intermittent, and unpredictable. The pain may be characterized as severe, and its unpredictable nature is an extremely bothersome feature that limits activity and affects quality of life. With disease progression, pain tends to become constant but is reported to be less severe and have an aching quality. Other prominent symptoms, such as stiffness, gelling, fatigue, and sleep disturbance, often lead to functional limitation and disability.

Pain tends to be localized to the specific joint involved, but it may be referred to a more distant site. The cause of pain is unclear but is likely to be heterogeneous. Pain may result from interactions among structural pathology; the motor, sensory, and autonomic innervation of the joint; and pain signal processing at the spinal and cortical levels. Specific individual and environmental factors also may be important. A subset of patients may have neuropathic pain.

Patient-specific factors may modify pain reception and pain reporting. Patients' affective status, such as depression, anxiety, and anger, may influence the level of pain reported.

Their cognitive status, including pain beliefs, expectations, and memories of past pain, and their communication skills may determine how pain is perceived and reported. Studies have shown that demographic factors such as age, sex, socioeconomic status, race or ethnicity, and cultural background may affect pain reporting.

Patients may have stiffness, particularly after prolonged inactivity, but it is not a major feature of osteoarthritis and usually lasts for less than 30 minutes. Patients do not report systemic features such as fever.

Examination of an involved joint may reveal tenderness and bony enlargement. Joint effusion and soft tissue swelling may occur with knee involvement, but they tend to be intermittent. Persistent inflammation with joint warmth, erythema, effusion, and soft tissue swelling is usually not seen. Crepitus with movement, limitation of joint motion, and joint deformity, malalignment, and joint laxity or instability may be detected on evaluation. Joint deformity as manifested by lateral subluxation is fixed and not reducible. Muscle weakness and gait abnormalities may be seen.

Several subtypes of osteoarthritis have been identified. The nodal form involves the distal interphalangeal joints (DIPs), also known as Heberden's nodes, and the proximal interphalangeal joints (PIPs), also known as Bouchard's nodes. It is most common in middle-aged women, typically those with a strong family history among first-degree relatives. Erosive, inflammatory osteoarthritis is associated with prominent destructive changes, especially in the finger joints, and it is often quite symptomatic. Generalized osteoarthritis is characterized by involvement of the DIP, PIP, and first carpal-metacarpal joints, as well as the knees, feet, and hips.

For a deeper discussion of these topics, please see Chapter 256, "Approach to the Patient with Rheumatic Disease," and Chapter 262, "Osteoarthritis," in Goldman-Cecil Medicine, 25th Edition.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of osteoarthritis is based on the signs and symptoms previously outlined. Although there are characteristic radiographic features, they are not necessary to make the clinical diagnosis. Imaging may be used to confirm the diagnosis and exclude other diseases, but radiographs are insensitive and may not show findings early in the disease course. Despite radiographic findings of osteoarthritis, pain may have other sources, such as bursitis, tendonitis, or referred pain. For example, hip disease may manifest as knee pain.

Osteoarthritis must be distinguished from inflammatory joint diseases such as rheumatoid arthritis and the spondyloarthropathies. This is accomplished by identifying the characteristic pattern of joint involvement and the nature of the individual joint deformity. Joints commonly involved in osteoarthritis include the DIPs, PIPs, first carpal-metacarpal, cervical and lumbar spine facet joints, hips, knees, and first metatarsophalangeal joints. Involvement of the metacarpal phalangeal joints (MCPs), wrist, elbows, shoulders, and ankles is uncommon, except in the case of trauma, congenital disease, or coexisting endocrine or metabolic disease.

The characteristic radiographic features of osteoarthritis include joint space narrowing as a surrogate for cartilage loss; osteophytes and subchondral sclerosis as an indicator of new bone formation, which is characteristic of osteoarthritis; and subchondral cysts as a manifestation of myxoid or fibrous degeneration of subchondral bone. Bone attrition and subchondral bone remodeling may result in changes in bone shape. Magnetic resonance imaging (MRI) can demonstrate additional morphologic abnormalities, such as bone marrow lesions in subchondral bone, meniscal degeneration, and synovitis.

The pain and swelling of erosive hand osteoarthritis may suggest rheumatoid arthritis, although systemic inflammatory signs and other typical features of rheumatoid arthritis are absent. The prevalence of false-positive findings of rheumatoid factor and antinuclear antibody, sometimes in significant titers, is higher with increasing age. Osteoarthritis more commonly affects the distal small joints in the hands (DIPs > PIPs > MCPs and wrists), whereas rheumatoid arthritis more commonly affects proximal small joints in the hands (MCPs and wrists > PIPs > DIPs).

 For a deeper discussion of these topics, please see Chapter 258, "Imaging Studies in the Rheumatic Diseases," Chapter 264, "Rheumatoid Arthritis," and Chapter 265, "The Spondyloarthropathies," in Goldman-Cecil Medicine, 25th Edition.

TREATMENT

The natural history of osteoarthritis includes periods of relative stability interspersed with rapid deterioration. Management should be individually tailored and may include a combination of nonpharmacologic, pharmacologic, and surgical approaches. The primary goal of treatment is to improve pain and function and reduce disability.

Patients should be educated regarding the objectives of treatment and the importance of lifestyle changes, exercise, pacing of activities, and other measures to unload the damaged joints. The initial focus should be on self-help and patient-driven treatments rather than on passive therapies. Patients should be encouraged to adhere to nonpharmacologic and pharmacologic therapies. Physical therapists may be helpful in providing instruction in appropriate exercises to reduce pain and preserve functional capacity. For knee and hip osteoarthritis, assistive devices such as walking aids may be useful. Graded regular aerobic, muscle-strengthening, and range-of-motion exercises are beneficial. Tai chi may also be useful.

Overweight patients should be encouraged to lose weight. A knee brace can reduce pain, improve stability, and diminish the risk of falling for patients with knee osteoarthritis and mild or moderate varus or valgus instability. Advice concerning appropriate footwear is also important. Spinal orthoses may provide benefit to patients with significant cervical or lumbar involvement. Local applications of heat, ultrasound, or transcutaneous electrical nerve stimulation (TENS) may provide short-term benefit. Acupuncture may also offer symptomatic benefit for these patients.

Pharmacologic therapy provides symptomatic relief but does not alter the course of the disease. Pharmacologic therapy should therefore be selected based on its relative efficacy and safety. The

use of concomitant medications in the setting of comorbidities should be taken into account.

Acetaminophen (up to 3 g/day with caution) may be an effective initial oral analgesic for mild to moderate pain. In patients with symptomatic osteoarthritis, nonsteroidal anti-inflammatory drugs (NSAIDs) should be used at the lowest effective dose, although their long-term use should be avoided if possible. If patients are at risk for increased gastrointestinal toxicity, a cyclooxygenase-2 (COX2)-selective agent or a nonselective NSAID with co-prescription of a proton pump inhibitor or misoprostol for gastroprotection should be considered. All NSAIDs, including nonselective and COX2-selective agents, should be used with caution in patients with cardiovascular risk factors. Topical NSAIDs and capsaicin may be effective alternatives to oral analgesic or anti-inflammatory agents in knee and hand osteoarthritis and may be used as adjunctive agents, particularly in elderly patients.

Meta-analyses have shown that oral glucosamine and chondroitin sulfate have limited benefit in patients with knee osteoarthritis. If other interventions have been ineffective or are contraindicated, weak opioids and narcotic analgesics may be considered for the treatment of refractory pain. Stronger opioids should be used for the management of severe pain only in exceptional circumstances. Occasional injection of intra-articular corticosteroids (no more than once every 4 months) may provide modest short-term symptomatic benefit with minimal toxicity, especially in the knee. Patients with moderate to severe pain and effusion or other local signs of inflammation may be more responsive. Intra-articular hyaluronate appears to have little or no benefit based on current evidence.

Surgical management includes total joint replacement, which is extremely effective in relieving pain, decreasing disability, and improving function. With improvements in surgical technique and technology, the indications for total joint replacement have expanded to include younger and older age groups. Other surgical options include osteotomy and unicompartmental knee replacement. Arthroscopy is not recommended for the management of knee osteoarthritis.

PROGNOSIS

Given the obesity epidemic and the marked contact loads that increased weight places on the knee, obesity is likely the most important modifiable risk factor for the development and progression of knee osteoarthritis. One kilogram of weight loss decreases the load on the knee by 4 kg. Varus and valgus malalignments have also been identified as important risk factors for the progression of knee osteoarthritis.

 For a deeper discussion of these topics, please see Chapter 262, "Osteoarthritis," in Goldman-Cecil Medicine, 25th Edition.

Nonarticular Soft Tissue Disorders

Niveditha Mohan

INTRODUCTION

The nonarticular soft tissue disorders account for most musculoskeletal complaints in the general population. These disorders include a large number of anatomically localized conditions (e.g., bursitis, tendinitis) and fibromyalgia syndrome, a generalized pain disorder. For most nonarticular soft tissue conditions, the etiologic factors and pathogenesis are poorly understood.

The nonarticular soft tissue syndromes can be classified according to the anatomic region involved, such as shoulder pain. After the region is defined, an attempt is made to identify the structure at fault, such as the supraspinatus tendon, bicipital tendon, or subacromial bursa. In the case of back pain, precise anatomic delineation of the structure involved (e.g., intervertebral disk, facet joint, ligament, paraspinal muscle) is frequently impossible.

EPIDEMIOLOGY

Precise data for prevalence or incidence of most nonarticular soft tissue syndromes are not available, but these conditions account for up to 30% of all outpatient visits. Fibromyalgia is considered to be the most common cause of generalized musculoskeletal pain in women between the ages of 20 and 55 years. The global mean prevalence is 2.7%.

ETIOLOGIC FACTORS AND PATHOGENESIS

The precise pathophysiology of most nonarticular soft tissue disorders remains unknown, although predisposing factors, such as overuse or repetitive activities (e.g., tennis elbow, lateral epicondylitis) or biomechanical factors (e.g., leg-length discrepancy in trochanteric bursitis), can be identified in many cases.

The term *tendinitis* implies tendon sheath inflammation, but small tendon tears, periostitis, and nerve entrapment have been proposed as potential mechanisms. Similarly, although the term *bursitis* implies bursal inflammation, demonstrable inflammation is difficult to find. In some cases (e.g., acute bursitis of the olecranon or prepatellar bursa), the mechanism is an acute inflammatory response to sodium urate crystals deposited in the soft tissue, an extra-articular manifestation of gout. The favorable response of tendinitis and bursitis to anti-inflammatory agents, including corticosteroids, supports the view that at least one component of these syndromes is the result of an inflammatory process.

In myofascial pain syndrome, the causes are even more obscure. Frequently, overuse and trauma are cited as etiologic factors, but many cases lack antedating mechanical considerations.

Investigators have examined diverse mechanisms for fibromyalgia syndrome, including studies of muscle, sleep physiologic processes, neurohormonal function, and psychological status. Although the pathophysiologic mechanisms remain unknown, an increasing body of literature points to central (central nervous system) rather than peripheral (muscle) mechanisms. Muscle tissue has been a focus of investigation for many years. Initial studies, including histologic and histochemical studies, suggested a possible metabolic myopathy; however, carefully controlled studies indicated that these abnormalities were the result of deconditioning.

Sleep studies suggested that disruption of deep sleep (stage IV) by so-called alpha-wave intrusion (i.e., normal awake electroencephalographic pattern) may play a causal role, but this finding was later observed in other disorders and more likely indicates an effect than a cause.

In some cases, musculoskeletal injury has been implicated as a trigger for fibromyalgia, but social and legal issues cloud its causative role. Several studies have suggested that subtle hypothalamic-pituitary-adrenal axis hypofunction may occur in fibromyalgia syndrome, although it remains uncertain whether these changes are constitutive or are the result of fibromyalgia. A prevailing theory of pathogenesis is dysregulation of pain pathways leading to central sensitization and marked by neurotransmitter, neurohormone, and sleep physiology irregularities.

Fibromyalgia has long been linked to psychological disturbance. Most studies have confirmed high lifetime rates of major depression, which range from 34% to 71%, associated with fibromyalgia syndrome. High lifetime rates of migraine, irritable bowel syndrome, and panic disorder have also been associated with fibromyalgia syndrome, suggesting that fibromyalgia may be part of an affective spectrum group of disorders.

CLINICAL PRESENTATION

Many of the soft tissue rheumatic syndromes involve bursae, tendons, ligaments, and muscles. Bursae are closed sacs lined with mesenchymal cells that are similar to synovial cells; the sacs are strategically located to facilitate tissue gliding. Subcutaneous bursae (e.g., olecranon, prepatellar) form after birth in response to normal external friction. Deep bursae (e.g., subacromial bursa) usually form before birth in response to movement between muscles and bones and may or may not communicate with adjacent joint cavities. Adventitious bursae (e.g., over the first metatarsal head) form in response to abnormal shearing stresses and are not uniformly found. Although most forms of bursitis involve

isolated, local conditions, some may be the result of systemic conditions such as gout.

Tendinitis, bursitis, and myofascial disorders should be distinguished from articular disorders. In most cases, this can be accomplished by a careful examination of the involved structure (Table 84-1). General principles of the musculoskeletal examination are as follows:

1. Observation: If deformity or soft tissue swelling is detected, is it fusiform (i.e., surrounding the entire joint in a symmetrical fashion) or is it localized? Local rather than fusiform deformity distinguishes nonarticular disorders from articular disorders.
2. Palpation: Is tenderness localized or in a fusiform distribution? Is there an effusion? Local (not fusiform or joint line) tenderness distinguishes nonarticular disorders from articular disorders. An effusion typically indicates an articular disorder.
3. Assessing range of motion: The musculoskeletal examination includes the assessment of active range of motion (i.e., patient attempts to move the symptomatic structure) and passive range of motion (i.e., examiner moves the symptomatic structure). Articular disorders usually are characterized by equal impairment in active and passive movements as a result of the mechanical limitation of joint motion resulting from proliferation of the synovial membrane, an effusion, or derangement of intra-articular structures. Impairment of active movement characterizes nonarticular disorders to a much greater degree than passive movement.

Clinical symptoms include pain, warmth, and swelling over the site of the bursa that are worse with activity and better with rest. Bursitis can be distinguished from tendinitis by the pain during active and passive range of movement; in tendinitis, pain is elicited only during active range of movement. However, for many patients these patterns often occur simultaneously.

Muscle sprains or strains are typically diagnosed based on a history of preceding activity causing the symptom along with pain and limitation of movement when the muscle is contracted against resistance. The clinical signs and symptoms of chronic myofascial pain are more nonspecific and characterized by a dis-

tribution that is frequently nonanatomic and associated with hyperalgesia in the involved area.

Fibromyalgia syndrome is characterized by widespread pain and a host of other symptoms, including insomnia, cognitive dysfunction, depression, anxiety, recurrent headaches, dizziness, fatigue, morning stiffness, extremity dysesthesia, irritable bowel syndrome, and irritable bladder syndrome.

DIAGNOSIS AND TREATMENT

Septic Bursitis

Superficial forms of bursitis, particularly olecranon bursitis and prepatellar and occasionally infrapatellar bursitis, are more frequently infected or involved with crystal deposition than are deep forms of bursitis, presumably due to direct extension of organisms through subcutaneous tissues. Most commonly, *Staphylococcus aureus* is isolated from infected superficial bursae. Septic bursitis should be suspected when there is cellulitis, erythema, fever, and peripheral leukocytosis.

Definitive diagnosis and exclusion of infection of subcutaneous bursae usually require aspiration of the distended bursa. The bursal fluid should be assessed for cell count, Gram stain, and culture and examined for crystals.

Nonseptic Bursitis

Nonseptic bursitis frequently appears as an overuse condition associated with sudden or unaccustomed repetitive activity of the associated extremity. The two most common types of bursitis are subacromial and trochanteric bursitis (Table 84-2).

Subacromial bursitis is the most common overall cause of shoulder pain over the lateral upper arm or deltoid muscle that is exacerbated with abduction of the arm. Subacromial bursitis is the result of compression of the inflamed rotator cuff tendon between the acromion and humeral head. Because the rotator cuff forms the floor of the subacromial bursa, bursitis in this location often results from tendinitis of the rotator cuff. Occasionally,

TABLE 84-1 DIFFERENTIATING NONARTICULAR SOFT TISSUE DISORDERS FROM ARTICULAR DISEASE

MANIFESTATION	NONARTICULAR SOFT TISSUE DISORDERS	ARTICULAR DISEASE
Limitation of motion	Active > passive	Active = passive
Crepitus of articular surfaces (structural damage)	0	+ / 0
Tenderness		
Synovial (fusiform pattern)	0	+
Local	+	0
Swelling		
Synovial (fusiform pattern)	0	+
Local	+ / 0	0

+, Present; 0, absent.

TABLE 84-2 BURSITIS SYNDROMES

LOCATION	SYMPTOM	FINDING
Subacromial	Shoulder pain	Tender subacromial space
Olecranon	Elbow pain	Tender olecranon swelling
Iliopectineal	Groin pain	Tender inguinal region
Trochanteric	Lateral hip pain	Tender at greater trochanter
Prepatellar	Anterior knee pain	Tender swelling over patella
Infrapatellar	Anterior knee pain	Tender swelling lateral or medial to patellar tendon
Anserine	Medial knee pain	Tender medioproximal tibia (below joint line of knee)
Ischiogluteal	Buttock pain	Tender ischial spine (at gluteal fold)
Retrocalcaneal	Heel pain	Tender swelling between Achilles tendon insertion and calcaneus
Calcaneal	Heel pain	Tender central heel pad

subacromial bursitis or rotator cuff tendinitis results from osteophyte compression of the rotator cuff tendon originating from the acromioclavicular joint. The differential diagnosis includes tears of the rotator cuff, intra-articular pathologic mechanisms of the glenohumeral joint, bicipital tendinitis, cervical radiculopathy, and referred pain from the chest.

Trochanteric bursitis is the result of inflammation at the insertion of the gluteal muscles at the greater trochanter. It produces lateral thigh pain, which is often worse when the patient lies on the affected side. Women seem to be more prone to develop this condition, perhaps because of increased traction of the gluteal muscles as a result of the relatively broader female pelvis. Other potential risk factors include weight gain, local trauma, overuse activities such as jogging, and leg-length discrepancies (primarily on the side with the longer leg). These factors are thought to lead to increased tension of the gluteus maximus on the iliotibial band, producing bursal inflammation. The differential diagnosis of trochanteric bursitis includes lumbar radiculopathy (particularly of the L1 and L2 nerve roots), meralgia paresthetica (i.e., entrapment of the lateral cutaneous nerve of the thigh as it passes under the inguinal ligament), true hip joint disease, and intra-abdominal pathologic processes. Other bursitis syndromes are less common and listed in [Table 84-2](#).

Septic bursitis is treated with a combination of serial aspirations of the infected bursa and antibiotics, initially directed against *S. aureus* and then adjusted depending on the results of bursal fluid cultures. Recurrent septic bursitis may need surgical excision of the bursa. The approach to nonseptic bursitis should include rest, local heat, and unless contraindicated by peptic ulcer disease, renal disease, or advanced age, nonsteroidal anti-inflammatory drugs (NSAIDs).

The most effective approach usually is local injection of a corticosteroid. Superficial bursae with obvious swelling should be aspirated before the corticosteroid is injected. For deep bursae, such as the subacromial or trochanteric bursae, aspiration yields little or no fluid, and direct injection of a corticosteroid without attempted aspiration is reasonable. Caution is advised in attempted aspiration or injection of the iliopsoas bursa, the ischiogluteal bursa, and the gastrocnemius-semimembranosus bursa (i.e., Baker's cyst). These bursae lie close to important neural and vascular structures, and aspiration under ultrasound guidance is recommended.

Tendinitis

Most tendinitis syndromes are the result of inflammation in the tendon sheath. Overuse with microscopic tearing of the tendon is the most common risk factor for tendinitis. Tendon compression by an osteophyte may occur, such as in the rotator cuff tendon compressed by an osteophyte originating from the acromioclavicular joint.

A common form of tendinitis is lateral epicondylitis, also known as *tennis elbow* ([Table 84-3](#)). This is a common overuse syndrome among tennis players, but it can be seen in many other settings requiring repetitive extension of the forearm (e.g., painting overhead). The diagnosis is confirmed by exclusion of elbow joint pathology and the finding of local tenderness at the lateral epicondyle, which is typically exacerbated by forearm extension against resistance. Enthesopathies such as Achilles tendinitis and

TABLE 84-3 TENDINITIS SYNDROMES

LOCATION	SYMPTOM	FINDING
Extensor pollicis brevis and abductor pollicis longus (de Quervain tenosynovitis)	Wrist pain	Pain on ulnar deviation of the wrist, with the thumb grasped by the remaining four fingers (i.e., Finkelstein test)
Flexor tendons of fingers	Triggering or locking of fingers in flexion	Tender nodule on flexor tendon on palm over metacarpal joint
Medial epicondyle	Elbow pain	Tenderness of medial epicondyle
Lateral epicondyle	Elbow pain	Tenderness of lateral epicondyle
Bicipital tendon	Shoulder pain	Tenderness along bicipital groove
Patella	Knee pain	Tenderness at insertion of patellar tendon
Achilles Tibialis posterior	Heel pain Medial ankle pain	Tender Achilles tendon Tenderness under medial malleolus with resisted inversion of ankle
Peroneal	Lateral midfoot or ankle pain	Tenderness under lateral malleolus with passive inversion

peroneal and posterior tibial tendinitis may occur in the setting of an underlying seronegative arthropathy such as Reiter's disease or psoriatic arthritis. A history and clinical evaluation for these disorders should be pursued for the appropriate patient.

Therapy for tendinitis—NSAIDs, local heat, and corticosteroid injection—is similar to that for bursitis. Rest, physical therapy, occupational therapy, and occasionally ergonomic modification are useful adjuncts. The goal of corticosteroid injection in tendinitis is to infiltrate the tendon sheath rather than the tendon itself because direct injection into a tendon may result in rupture of the tendon. Corticosteroid injection of the Achilles tendon should be avoided because of the propensity of this tendon to rupture. Surgical management of tendinitis is indicated only after failure of conservative treatment. For example, chronic impingement of the supraspinatus tendon that is refractory to conservative treatment may require subacromial decompression.

Fibromyalgia Syndrome

Descriptions of fibromyalgia syndrome exist far back in the medical literature, but it remains a diagnosis of exclusion due to the lack of objective diagnostic or pathologic findings. Fibromyalgia syndrome as defined by the American College of Rheumatology (ACR) 1990 definition for use in clinical trials is a chronic, widespread pain condition with characteristic tender points on physical examination, often associated with a constellation of symptoms such as fatigue, sleep disturbance, headache, irritable bowel syndrome, and mood disorders. In 2010, the ACR developed preliminary diagnostic criteria based only on symptoms because of well-documented issues with the tender point examination ([Table 84-4](#)). These criteria do not require a tender point examination, but they provide a scale for measuring the severity of symptoms that are characteristic of fibromyalgia and show good correlation with the 1990 ACR criteria.

TABLE 84-4 2010 AMERICAN COLLEGE OF RHEUMATOLOGY FIBROMYALGIA DIAGNOSTIC CRITERIA

CRITERIA

1. Widespread pain index (WPI) ≥ 7 , symptom severity (SS) scale score ≥ 5 , or WPI of 3-6 and SS scale score ≥ 9
2. Symptoms manifest at a similar level for at least 3 months
3. Exclusion of other explanation for the pain

ASCERTAINMENT

1. WPI score
The number of areas where the patient has had pain over the past week is assessed from 19 possible sites: left shoulder girdle, right shoulder girdle, left upper arm, right upper arm, left lower arm, right lower arm, left hip, right hip, left upper leg, right upper leg, left lower leg, right lower leg, left jaw, right jaw, chest, abdomen, upper back, lower back, and neck.
2. SS scale score
For fatigue, waking unrefreshed, cognitive symptoms, and somatic symptoms,* the level of severity during the past week is assessed as follows: 0 = no symptoms; 1 = few symptoms; 2 = moderate number of symptoms; 3 = many symptoms.
The SS scale score is the sum of the severity of the first three symptoms plus the severity of somatic symptoms in general. The final score is between 0 and 12.

*Somatic symptoms may include muscle pain or weakness, irritable bowel syndrome, fatigue or tiredness, cognitive or memory problems, headache, numbness or tingling, dizziness, insomnia, depression, nervousness, seizures, abdominal pain or cramps (especially upper abdomen), constipation, diarrhea, nausea, vomiting, fever, dry mouth, itching, chest pain, wheezing, Raynaud's phenomenon, hives or welts, tinnitus, hearing difficulties, heartburn, oral ulcers, loss of or change in taste, dry eyes, blurred vision, shortness of breath, loss of appetite, rash, sun sensitivity, easy bruising, hair loss, frequent or painful urination, and bladder spasms.

The clinical presentation of fibromyalgia syndrome is an insidious onset of chronic, diffuse, poorly localized musculoskeletal pain, typically accompanied by fatigue and sleep disturbance. The physical examination reveals a normal musculoskeletal system, with no deformity or synovitis. However, widespread tenderness occurs, especially at tendon insertion sites, indicating a general reduction in the pain threshold.

Approximately one third of the patients identify antecedent trauma as a precipitant for their symptoms, one third of patients describe a viral prodrome, and one third have no clear precipitant. A variety of less typical presentations has been described, including a predominantly neuropathic presentation with paresthesias (i.e., numbness and tingling) in a nondermatomal distribution, an arthralgic rather than myalgic presentation, and an axial skeletal manifestation resembling degenerative disk disease. Many patients may have undergone invasive diagnostic tests and,

in some cases, inappropriate procedures such as carpal tunnel release or cervical or lumbar laminectomies.

Conditions that should be considered in the differential diagnosis of fibromyalgia syndrome include polymyalgia rheumatica (in older patients), hypothyroidism, polymyositis, and early systemic lupus erythematosus or rheumatoid arthritis. However, symptoms are exhibited for many months or years without evidence of other signs or symptoms of an underlying connective tissue disease, making other possible diagnoses unlikely.

Results of laboratory and radiographic studies are usually normal for patients with fibromyalgia syndrome. Exclusion of other conditions, such as osteoarthritis, rheumatoid arthritis, and systemic lupus erythematosus, by radiography, erythrocyte sedimentation rate, assays for rheumatoid factor or antinuclear antibody, and other tests is no longer considered necessary for the diagnosis of fibromyalgia syndrome. Fibromyalgia should be diagnosed on the basis of positive criteria.

The treatment of fibromyalgia includes reassurance that the condition is not a progressive, crippling, or life-threatening entity. A combination of treatment options, including medication and physical measures, is helpful for most patients. Medications found to be helpful in short-term, double-blind, placebo-controlled trials include amitriptyline and cyclobenzaprine. Low doses of these medications (e.g., 10 to 30 mg of amitriptyline, 10 to 30 mg of cyclobenzaprine) are moderately effective and generally well tolerated. Studies have shown that newer antidepressants of the serotonin-norepinephrine reuptake inhibitor group (e.g., duloxetine, venlafaxine, bupropion) and $\alpha_2\delta$ ligands (e.g., gabapentin, pregabalin) are also effective, particularly in combination with low doses of tricyclic antidepressants.

Patients should be encouraged to take an active role in the management of their condition. If possible, they should begin a progressive, low-level aerobic exercise program to improve muscular fitness and provide a sense of well-being. A combination approach is effective for most patients in alleviating symptoms, although a small minority of patients requires more intensive treatment strategies, such as psychiatric treatment or referral to a pain center.

Rheumatic Manifestations of Systemic Disorders; Sjögren's Syndrome

Yong Gil Hwang

INTRODUCTION

Rheumatologic manifestations may herald a variety of systemic conditions, including malignancy, endocrinopathy, and sarcoidosis (Tables 85-1 and 85-2). Musculoskeletal symptoms can precede or follow the diagnosis of these diseases. Patients may complain of joint pain, muscle weakness and pain, or reduced range of motion. Other chapters in this textbook provide detailed reviews of these systemic diseases, including rheumatologic manifestations.

RHEUMATIC SYNDROMES ASSOCIATED WITH MALIGNANCY

Paraneoplastic rheumatologic manifestations include hypertrophic osteoarthropathy (HOA), arthritis (i.e., inflammatory arthritis and carcinomatous polyarthritis), myositis, vasculitis, systemic lupus erythematosus (SLE)-like symptoms, and scleroderma. The pathophysiologic mechanisms of musculoskeletal symptoms in a patient with cancer are often unknown and remain speculative. The association is presumed if there is a close temporal relationship between the diagnosis of a malignancy and the onset of musculoskeletal symptoms or the rheumatic syndrome resolves after successful treatment of the malignancy. In many cases, however, the association may be coincidental.

Cancer may directly invade articular or periarticular structures and mimic rheumatic syndromes, as in chondrosarcoma, giant cell tumor, and osteogenic sarcoma. Musculoskeletal symptoms can occur as paraneoplastic phenomena without direct involve-

ment by the tumor, as in dermatomyositis in patients with ovarian cancer.

The incidence of malignancy with rheumatic manifestations is unclear, but musculoskeletal symptoms occur more frequently with hematologic malignancies than with solid tumors. No single laboratory test can confirm the diagnosis of a rheumatic illness in a patient with cancer. All patients with rheumatologic syndromes should be evaluated with a thorough history, physical examination, and age-appropriate malignancy screening.

Hypertrophic Osteoarthropathy

HOA is characterized by digital clubbing, periostitis of the long bones, and arthritis. Arthritis is most prominent in large joints, and periostitis develops mostly at the distal ends of the femur,

tibia, and radius. The primary form of HOA (i.e., primary pachydermoperiostosis) is usually a self-limited disease of childhood. The secondary form may be generalized or localized and is mainly associated with lung cancer and suppurative lung disease.

HOA is also associated with cardiovascular disease (e.g., cyanotic congenital heart disease, infective endocarditis), hepatobiliary disorders (e.g., liver cirrhosis, primary biliary cirrhosis), and gastrointestinal disease (e.g., inflammatory bowel disease, celiac disease). Periostitis without digital clubbing can be seen in thyroid acropathy, hypervitaminosis A, fluorosis, venous stasis, hyperphosphatemia, and sarcoidosis. Isolated chronic digital clubbing, which is mainly associated with pleuropulmonary disease, does not seem to cause HOA.

The pathogenesis of HOA remains unknown, although several possible mechanisms have been proposed. HOA is usually accompanied by bone and joint pain associated with periarticular periostitis. The pain is usually exacerbated by dependency and relieved with limb elevation. Typical signs of periostitis include periosteal new bone along the distal ends of long bones, which can be seen on plain radiographs. When periostitis is not obvious on plain radiography, a bone scan is useful to demonstrate early evidence of disease. When HOA is clinically suspected, radiologic evaluation of the thorax is important because of the association between HOA and lung neoplasms.

In many cases, symptomatic management with nonsteroidal anti-inflammatory drugs or other analgesics while treating the underlying disorder provides significant relief of symptoms. In refractory cases, bisphosphonates such as pamidronate and zoledronic acid have been reported to be effective.

Rheumatoid Arthritis–Like Syndrome

Inflammatory rheumatoid arthritis–like syndrome has been associated with solid neoplasms and hematologic malignancies. Clinical characteristics associated with this paraneoplastic syndrome include acute onset or late onset, asymmetrical disease frequently involving the lower extremities, nonspecific synovitis in large joints that spares the wrists and hands without bony erosion, negative results for rheumatoid factor and cyclic citrullinated peptide antibody. However, these features are not specific and may be confused with elder-onset rheumatoid arthritis, seronegative rheumatoid arthritis, spondyloarthropathy, remitting seronegative symmetrical synovitis with pitting edema (RS3PE), or polymyalgia rheumatica (PMR).

RS3PE manifests with sudden onset of polyarthritides, pitting edema, and prominent constitutional symptoms. More than one half of RS3PE cases are associated with malignancy. Lymphoproliferative disorders such as leukemia and lymphoma may simulate various rheumatic syndromes from direct invasion of the synovium, articular tissues, or juxta-articular bone, producing synovitis or bone pain.

Lupus-Like Syndrome

Antinuclear antibodies (ANAs) can be seen in patients with solid neoplasms (e.g., gastric, cervical, and breast carcinomas, testicular seminoma), lymphomas, or myelodysplastic disorders, but the significance of these autoantibodies is not well understood. The association between SLE and occult malignancy is uncertain.

It is not necessary to search for underlying malignancy in a patient with typical manifestations of SLE. However, lupus-like autoantibodies and unexplained Coombs–positive hemolytic anemia or thrombocytopenia without clinical signs of rheumatic disease warrant further investigation for an occult neoplasm.

Raynaud’s Phenomenon and Scleroderma-Like Syndrome

The sudden onset of Raynaud’s phenomenon and scleroderma-like syndrome can herald an underlying tumor such as hematologic malignancies and carcinomas of the liver, ovary, testis, bladder, breast, or stomach. Scleroderma-like skin changes may also occur in patients with osteosclerotic myeloma with polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin abnormalities (i.e., POEMS syndrome) and in those with carcinoid tumors.

Characteristics that suggest secondary Raynaud’s phenomenon include age at onset older than 50 years, symptom asymmetry, symptoms that persist year round, and rapid digital ulceration and necrosis. Secondary Raynaud’s is also suggested by scleroderma-like syndromes in patients older than 50 years, rapid progression of skin sclerosis, or a poor response to therapy. The lack of Raynaud’s phenomenon can be another distinguishing characteristic of paraneoplastic scleroderma-like syndrome because Raynaud’s phenomenon occurs in approximately 95% of cases of systemic sclerosis.

Polymyalgia Rheumatica

Clinical symptoms and signs of PMR include shoulder and pelvic girdle pain and morning stiffness, a high erythrocyte sedimentation rate (ESR), and anemia of chronic disease. Although the association between PMR and cancer is controversial, several features are atypical for PMR and may suggest an occult malignancy: disease onset before the age of 50 years, asymmetrical or localized involvement of typical sites, an ESR less than 40 or higher than 100 mm/hr, and a poor response to low doses of glucocorticoids.

Myelodysplastic syndromes and myeloproliferative syndromes are frequently associated with PMR. Myelodysplastic syndromes also are associated with a variety of musculoskeletal symptoms and signs, including cutaneous vasculitis, monoarticular or polyarticular arthritis, lupus-like conditions, Raynaud’s phenomenon, polychondritis, and pyoderma gangrenosum.

Vasculitides

Vasculitis is rarely associated with malignancy and is most commonly seen in patients with lymphoproliferative disorders and myelodysplastic syndrome. Cutaneous leukocytoclastic vasculitis is the most common manifestation of vasculitic paraneoplastic. Although clinical presentations of paraneoplastic vasculitides are indistinguishable from those of the idiopathic condition, a chronic, relapsing disease with cytopenias and poor response to conventional treatment suggest a hidden malignancy.

Inflammatory Myopathies

The association between inflammatory myopathies and malignancies has been well established.

For a deeper discussion of these topics, please see Chapter 269, "Inflammatory Myopathies," in Goldman-Cecil Medicine, 25th Edition.

Miscellaneous Conditions

Other rheumatologic syndromes that may be harbingers of neoplasia include eosinophilic fasciitis, palmar fasciitis, reflex sympathetic dystrophy, erythromelalgia, Sweet's syndrome, and osteomalacia. Up to 15% cases of Sweet's syndrome (i.e., acute neutrophilic dermatosis) are associated with malignancy, and it can manifest as an acute, self-limited polyarthritis or vasculitis. Knee pain or shoulder pain with normal physical examination findings can be a referred pain from various neoplasms.

HEMATOLOGIC DISORDERS WITH RHEUMATIC MANIFESTATIONS

Hemophilia

Acute, painful hemophilic arthropathy of the knees, elbows, and ankles is the most common manifestation of hemophilia. Repeated episodes of hemarthrosis result in synovial proliferation and chronic inflammation, causing chronic hemophilic arthropathy.

Chronic hemophilic arthropathy is characterized by joint deformity, fibrous ankylosis, and osteophyte overgrowth. Radiography typically shows degenerative arthritis. Besides prompt administration of factor concentrate replacement, acute hemarthrosis must be treated conservatively with cold applications and joint immobilization followed by a structured physical therapy program. Aspiration (after factor replacement) is needed only if concomitant sepsis is suspected or the joint is very tense.

Sickle Cell Disease

Musculoskeletal complications of sickle cell disease include painful crises, arthropathy, dactylitis, osteonecrosis, and osteomyelitis. Sickle cell crisis is the most common musculoskeletal feature, and it can produce painful arthritis of the large joints and noninflammatory joint effusions adjacent to areas of bony crisis. Osteonecrosis of the femoral head, shoulder, and tibial plateau may result from repeated local bone ischemia or infarct.

Dactylitis manifesting as bilateral, painful, swollen hands or feet (i.e., hand-foot syndrome) may be the first manifestation of the disease in infants and young children. It usually resolves spontaneously in a few weeks. Increased risk of septic arthritis and osteomyelitis, most often due to *Salmonella* species, has been associated with hemoglobinopathies.

Multiple Myeloma

Rheumatologic manifestations of multiple myeloma include bone pain resulting from lytic bone lesions, pathologic fractures, and osteoporosis. Thoracolumbar pain in the setting of hypercalcemia, renal insufficiency, and anemia suggests the possibility of multiple myeloma. Multiple myeloma can manifest atypically and mimic specific autoimmune disorders such as Sjögren's syndrome (SS) and SLE.

Amyloidosis

Amyloidosis is a disorder of protein folding in which insoluble fibrillar proteins are deposited in the extracellular space in one or more organs, disrupting tissue structure and function. The clinical manifestations and prevalence depend on the type of amyloidosis.

Myeloma-associated amyloidosis (i.e., amyloid light-chain [AL] amyloidosis) is one of the most common forms of systemic amyloidosis. Amyloid proteins derived from monoclonal light chains can involve the synovium and the articular cartilage, producing rheumatoid arthritis–like polyarthritis. Joint stiffness is more pronounced in amyloid arthropathy, and deposition of amyloid protein at the glenohumeral joint produces enlargement of the anterior shoulder, called the *shoulder pad sign*. Other rheumatic manifestations of AL amyloidosis include muscle weakness, pseudohypertrophy of muscles, and pathologic fracture from osteolytic lesions, jaw claudication that mimics giant cell arteritis, and sicca syndrome due to exocrine gland infiltration.

The amyloid protein can be identified as apple green birefringence on Congo red staining of an abdominal fat pad aspiration or rectal mucosal biopsy specimen. The other principal systemic forms of amyloidosis are secondary amyloidosis (i.e., deposition of amyloid A [AA] protein), hereditary amyloidosis, and β_2 -microglobulin–associated amyloidosis.

Endocrine Disorders

Endocrine diseases usually manifest with diffuse, poorly defined musculoskeletal symptoms and joint pain that is more often periarticular than articular. Clinical suspicion of endocrinopathy is by far the most important diagnostic step. Routine clinical laboratory tests such as ESR, ANA, rheumatoid factor, uric acid level, and an antistreptolysin O (ASO) titer are usually not helpful, and radiographs often first suggest the possibility of endocrinopathy.

Diabetes

One of the most common musculoskeletal complications of diabetes is diabetic cheiroarthropathy (i.e., diabetic hand syndrome). It is characterized by insidious development of waxy thickening of the skin of the fingers and hands and by flexion contractures of the metacarpophalangeal joints and interphalangeal joints. Patients cannot press the palms together completely without a gap with the wrists fully flexed (i.e., prayer sign). Although this syndrome is associated with the duration of diabetes and the control of blood sugar, it may develop before the onset of overt diabetes and mimic sclerodactyly.

Dupuytren contracture and stenosing flexor tenosynovitis (i.e., trigger finger) may be identified. People with diabetes are more prone to develop a carpal tunnel syndrome. Diabetic peri-arthritis of the shoulders (i.e., adhesive capsulitis or frozen shoulder) is more common in patients with diabetes, especially in women with a long history of diabetes. Capsulitis is characterized by staged progression of pain and restriction of shoulder motion, and bilateral involvement occurs in about one half of patients.

Patients with long-standing, poorly controlled diabetes may develop a painless, swollen, deformed joint known as a Charcot

joint or neuropathic arthropathy. Tarsal, metatarsophalangeal, and tarsometatarsal joints are most commonly involved, and it can be confused with osteomyelitis on radiographs.

Diffuse idiopathic skeletal hyperostosis (DISH) is seen in up to 20% of diabetic patients, who are typically obese and older than 50 years. It is associated with neck and back stiffness rather than pain. Lateral radiographic views of the spine show four or more contiguously fused vertebrae as a result of flowing ossification of the anterior longitudinal ligament without involvement of apophyseal (facet) joints.

Diabetic amyotrophy (i.e., diabetic lumbosacral radiculoplexus neuropathy) is remarkable for acute or subacute onset of severe hip, buttock, or thigh pain followed by progressive weakness of the affected extremity. It occurs typically in older male patients who have relatively well-controlled diabetes, and there are often preceding anorexia, weight loss, and unsteady gait.

Hypothyroidism

Almost one third of patients with hypothyroidism have musculoskeletal symptoms. Arthritis of hypothyroidism can resemble early rheumatoid arthritis, affecting small joints of the hands and wrists, but it is not erosive or deforming. In contrast, myxedematous arthropathy classically involves large joints such as knees.

Many hypothyroid patients experience carpal tunnel syndrome, trigger finger, Raynaud phenomenon, and pseudogout. Acute pseudogout can be a presenting feature of hypothyroidism.

Hypothyroidism can also cause a broad spectrum of muscular diseases. Hypothyroid patients may have asymptomatic elevation of muscle enzymes, but a few patients develop proximal muscle weakness or polymyositis-like syndrome. Patients may complain of fatigue, malaise, and fibromyalgia-like generalized muscle pain. Rarely, hypothyroid myopathy manifests with muscle enlargement, stiffness, and muscle cramps (i.e., Hoffmann's syndrome).

Hyperthyroidism

Common rheumatic symptoms of hyperthyroidism include proximal myopathy, periartthritis of the shoulder, thyroid acropachy (i.e., thickened skin with periosteal new bone formation), and osteoporosis. Proximal muscle weakness is more frequently observed in elderly patients with apathetic or masked hyperthyroidism. Asking a patient to stand from a squat position can reveal the proximal muscle weakness.

Hyperparathyroidism

Musculoskeletal symptoms, often widespread and nonspecific, are common in hyperparathyroidism and can be the clinical presentation for many patients. The musculoskeletal manifestations of hyperparathyroidism include osteitis fibrosa cystica (i.e., bone pain, osteopenia, and bony cysts), subperiosteal resorption, pseudogout, rheumatoid arthritis-like disorder, diffuse osteopenia, spinal compression fracture, and proximal myopathy. Secondary hyperparathyroidism is the leading cause of renal osteodystrophy in chronic kidney disease.

Acromegaly

Acromegalic arthropathy commonly develops in the large joints and is seen in approximately 70% of the patients with acromegaly. Overgrowth of cartilage initially produces joint space widening,

but it may eventually lead to severe osteoarthritis with pain, limited range of motion, and deformity.

GASTROINTESTINAL DISEASES WITH RHEUMATIC MANIFESTATIONS

Whipple's Disease

Whipple's disease is a rare, multisystemic disease that most often affects the gastrointestinal tract. It is caused by infection with *Tropheryma whippelii*. Musculoskeletal symptoms of Whipple's disease are the most common prodrome, and they may exist for years before the diagnosis. Intermittent migratory oligoarthritis of large joints is typical, but some patients may have a florid polyarthritis. Synovial fluid is usually inflammatory with predominant mononuclear cells. Radiographs are often normal.

Hemochromatosis

Hemochromatosis is one of the most common genetic diseases among people with northern European ancestry, and it is frequently associated with osteoarthritis-like arthropathy, chondrocalcinosis, and osteoporosis. The second and third metacarpophalangeal joints of both hands are typically involved, and hooklike osteophytes on the radial side of the metacarpal are characteristic in radiographs. Chondrocalcinosis of the wrist and knee is very common in patients with hemochromatosis. Acute attacks of pseudogout can be a predominant clinical manifestation. Treatment with regular phlebotomies and iron chelation has little effect on the arthropathy.

Primary Biliary Cirrhosis

Primary biliary cirrhosis is frequently associated with other autoimmune diseases, such as limited scleroderma, rheumatoid arthritis, SS, and autoimmune thyroid disease. Vitamin D deficiency is highly prevalent among patients with primary biliary cirrhosis, and the risk of developing osteoporosis is markedly increased in women with this disease.

OTHER SYSTEMIC ILLNESSES WITH RHEUMATIC MANIFESTATIONS

Human Immunodeficiency Virus Infection

Patients with human immunodeficiency virus (HIV) disease may have osteomyelitis, osteonecrosis, reactive arthritis, or psoriatic arthritis.

Sarcoidosis

Clinical features of sarcoidosis can mimic those of many acute and chronic rheumatic diseases. Acute sarcoidosis or Löfgren's syndrome manifests with fever, erythema nodosum, hilar lymphadenopathy, and acute polyarthritis, almost invariably involving the ankles and knees. The arthritis is usually self-limited and tends to be nondeforming and nonerosive.

Chronic sarcoid arthritis is less common and usually associated with active multisystemic disease. Osseous involvement can be a focal or generalized and occurs in about 5% of patients with sarcoidosis. Bone cysts are usually asymptomatic, but they can manifest in the phalanges with sausage-like fingers or

pseudoclubbing. Focal osteolytic changes can lead to pathologic fractures. Sarcoid muscle involvement is often asymptomatic, but it may manifest with proximal pain, progressive weakness, or atrophy.

SJÖGREN'S SYNDROME

Definition and Epidemiology

SS is a chronic autoimmune disorder characterized by infiltration of exocrine glands by predominantly CD4⁺ T lymphocytes, resulting in dry eyes (i.e., keratoconjunctivitis sicca) and dry mouth (i.e., xerostomia). SS can occur as a primary disorder or can be associated with other autoimmune diseases (i.e., secondary SS) such as rheumatoid arthritis and SLE.

SS is the second most common rheumatic disease, with a community prevalence of primary SS ranging from 0.1% to 0.6% in different studies. However, many patients remain undiagnosed, and little is known about the prevalence of SS in the general population. The disease is diagnosed nine times more often in women than in men and tends to manifest in patients older than 40 years, although it may be seen among people of all ages.

Pathogenesis and Pathology

The pathogenesis of SS is not fully understood, although accumulating evidence shows that chronic immune system stimulation in genetically predisposed individuals (HLA-DR3) is important. Upregulation of type 1 interferon-regulated genes (i.e., interferon signature) and abnormal expression of B-cell activating factor (BAFF) and its receptors appear to play an important role in the development of SS.

Exocrine gland involvement is characterized by a focal lymphocytic sialadenitis and hyperplasia of salivary ductal epithelium seen on minor salivary gland biopsy. Parenchymal atrophy fibrosis or fatty infiltration, or both, are common in the elderly and should not be confused with SS.

Clinical Presentation

The clinical features of SS can be divided into exocrine gland dysfunction and extraglandular manifestations. Subjective symptoms of dry eyes and mouth are the most common problems for most affected patients. Many years can elapse before the diagnosis is established because of nonspecific initial manifestations. Patients with keratoconjunctivitis sicca complain of chronic gritty or sandy eye irritation rather than describing dryness. They may also report itching, photophobia, and the accumulation of thick mucous filaments at the inner canthus. Severe dry eyes can result in vision impairment and punctate keratopathy, which can be detected by fluorescein, lissamine green, or rose bengal staining.

Decreased saliva production can lead to dental caries, gingival recession, oral candidiasis, chronic esophagitis, weight loss due to difficulty chewing and swallowing, and nocturia. Other exocrine gland dysfunction includes recurrent nonallergic rhinitis and sinusitis, vaginal dryness with associated dyspareunia in women with SS and dry cough due to laryngeal, tracheal, and bronchial involvement. SS is a systemic disease and one third of patients with primary SS have various extraglandular features (Table 85-3).

TABLE 85-3 EXTRAGLANDULAR CLINICAL FEATURES OF SJÖGREN'S SYNDROME

SKIN AND MUCOUS MEMBRANES	CENTRAL NERVOUS SYSTEM
Lower extremity purpura associated with hyperglobulinemia and/or leukocytoclastic vasculitis on biopsy	Focal defects including multiple sclerosis, stroke
Photosensitive lesions indistinguishable from those of subacute cutaneous lupus erythematosus	Diffuse deficits including dementia, cognitive dysfunction
	Spinal cord involvement including transverse myelitis
PULMONARY SYSTEM	PERIPHERAL NERVOUS SYSTEM
Chronic bronchitis due to dryness of the tracheobronchial tree	Peripheral sensorimotor neuropathy
Lymphocytic interstitial pneumonitis, interstitial pulmonary fibrosis, chronic obstructive lung disease, cryptogenic organizing pneumonia, pseudolymphoma with intrapulmonary nodules	Trigeminal sensory neuropathy, optic nerve
MUSCULOSKELETAL SYSTEM	RETICULOENDOTHELIAL SYSTEM
Polymyositis	Splenomegaly
Polyarthralgia, polyarthritis	Lymphadenopathy and development of pseudolymphoma
RENAL SYSTEM	HEPATOBIILIARY SYSTEM
Tubulointerstitial nephritis	Hepatomegaly
Type 1 renal tubular acidosis	Primary biliary cirrhosis
VASCULAR SYSTEM	ENDOCRINE SYSTEM
Raynaud's phenomenon	Hypothyroidism caused by Hashimoto's thyroiditis
Small vessel vasculitis, with a mononuclear perivascular infiltrate or leukocytoclastic changes on biopsy	Other autoimmune endocrinopathies

Skin

The major cutaneous manifestations of SS include dry, scaly skin, itchy annular erythema, cutaneous vasculitis, and Raynaud's phenomenon. Cutaneous vasculitis occurs in approximately 10% of patients with SS. It typically involves small and medium-sized vessels, leading to palpable purpura, urticaria, or skin ulceration. Raynaud's phenomenon can precede other features by many years, and it does not cause digital ulceration or infarcts.

Pulmonary Disease

Lung manifestations of SS include asymptomatic interstitial lung disease, pulmonary function abnormalities, and cryptogenic organizing pneumonia by lymphocytic infiltration around bronchioles. Lymph node enlargement of the lung and pulmonary lymphoproliferative disease typically is seen only in patients with primary SS.

Joints

About one half of primary SS patients are affected by joint pain, with or without evident synovitis. It usually involves the hands and knees symmetrically. Arthropathy is typically nonerosive and nondeforming. Identification of rheumatoid factor is associated with a higher prevalence of articular symptoms.

Renal Disease

Urine acidification abnormalities of the distal renal tubule leading to complete or incomplete distal renal tubular acidosis are the most common manifestation of renal involvement, but overt renal disease is less common. Glomerular diseases such as membranoproliferative glomerulonephritis and membranous nephropathy can occur in patients with SS and SLE overlap or those with cryoglobulinemia and hypocomplementemia.

Cardiovascular System

Although pericardial effusion can be seen on the echocardiogram, primary SS patients rarely have acute pericarditis. Placental transmission of maternal anti-Ro/SSA and anti-La/SSB antibodies can cause neonatal lupus and fatal fetal congenital heart block. In women with these antibodies, there is 5% risk of their first child being born with heart block. This risk rises to 15% with subsequent pregnancies. Fetal heart rate monitoring in the antenatal period is essential.

Neuromuscular Disease

Peripheral neuropathy occurs in about 10% of patients with SS and can precede sicca symptoms. Diagnosis of small fiber neuropathy may require quantitative sudomotor autonomic reflex testing or measurement of epidermal nerve density by biopsy. Cranial nerves, particularly the trigeminal and optic nerves, can be involved as a consequence of vasculitis. Although the frequency of central nervous system involvement remains controversial, focal or diffuse brain lesions and multiple sclerosis–like syndromes have been reported. Myalgia is very common, but symptomatic inflammatory myopathy is rare.

Lymphoproliferative Disease

Patients with SS are predisposed to develop lymphoma (primarily B cell in origin). Risk factors include cutaneous vasculitis, peripheral neuropathy, rheumatoid factor, cryoglobulinemia, and hypocomplementemia. Development of new masses with constitutional symptoms or persistent lymph node enlargement should raise concern for malignancy.

Gastrointestinal and Hepatobiliary Disease

Dysphagia commonly results from dryness of the pharynx and esophagus. Lymphocytic infiltration, predominantly by CD4⁺ T cells, may cause chronic atrophic gastritis, achlorhydria, and pernicious anemia. Although liver involvement in primary SS patients is rare, histologic features show a clear association between SS and hepatic abnormalities. However, other causes of abnormal liver function test results in SS, particularly hepatitis C infection and drug toxicity, should be considered.

Diagnosis and Differential Diagnosis

Although there are no established diagnostic criteria for SS, classification criteria were developed for use in research. The American-European Consensus Group (AECG) classification is most widely accepted, and it requires demonstration of the following:

1. Signs and symptoms of inadequate tear production and decreased salivary gland function

2. Detection of autoantibodies (anti-Ro/SSA or anti-La/SSB, or both)
3. Exclusion of underlying diseases that may mimic SS, including head and neck irradiation, hepatitis C, acquired immune deficiency syndrome, preexisting lymphoma, sarcoidosis, graft-versus-host disease, and anticholinergic drug use.

A provisional classification was proposed by American College of Rheumatology and the Sjögren International Collaborative Clinical Alliance investigators (ACR-SICCA), but it has not been validated completely. The MAIN differences between the AECG and ACR-SICCA criteria are that ocular or oral dryness symptoms are not required in the latter and the ACR criteria do not distinguish between primary and secondary forms of SS.

The diagnosis of SS is made on the basis of compatible clinical and laboratory features and after the exclusion of other causes of sicca symptoms. Various tests are used to evaluate the objective glandular component of the disease. To confirm keratoconjunctivitis sicca, the Schirmer test, the rose bengal test, and tear breakup time can be used. Salivary gland scintigraphy with uptake of technetium-99m, parotid sialography, and measurement of unstimulated production of saliva (i.e., Saxon test) may provide objective evidence of xerostomia. A labial salivary gland biopsy is often essential in evaluating patients with suspected SS, particularly when the patients lack anti-Ro/SSA or anti-La/SSB antibodies. Rheumatoid factor and ANAs are commonly detected, and patients may be erroneously diagnosed with rheumatoid arthritis. Common laboratory findings include anemia, thrombocytopenia, leukopenia, raised ESR, monoclonal gammopathy, and hypergammaglobulinemia.

Other conditions can produce keratoconjunctivitis sicca symptoms, xerostomia, or lacrimal and salivary gland enlargement. The differential diagnosis of SS must consider infectious diseases such as diffuse infiltrative lymphadenopathy syndrome associated with HIV, hepatitis B and C, human T-cell lymphotropic virus infection, syphilis, and infection with mycobacteria, and it must take into account infiltrative diseases such as sarcoidosis and amyloidosis. Anticholinergic side effects from many drugs, including over-the-counter products, should be considered during assessment of dry eyes and dry mouth. Sicca symptoms may result from overlap syndromes, which may have features of SS and SLE or of SS and scleroderma.

Treatment

No cure for SS is available. Because of the diverse symptoms of SS, several medications are used to ameliorate the symptoms outlined in [Table 85-4](#). Patients with moderate to severe involvement may require systemic medical therapy, including the use of immunosuppressive and biologic agents. There is no evidence that azathioprine, low-dose steroids, cyclosporine, infliximab, or methotrexate are useful. Hydroxychloroquine normalizes the ESR and immunoglobulin levels, but it does not increase the salivary flow rate significantly. Many clinicians use it to treat rash, fatigue, myalgia, and arthralgia. B-cell and anticytokine or antichemokine-directed therapies are active areas of research.

Prognosis

Primary and secondary forms of SS are characterized by chronic courses and different rates of progression. Systemic involvement

TABLE 85-4 TREATMENT OPTIONS FOR SJÖGREN'S SYNDROME**LOCAL TREATMENT OF EXOCRINE DYSFUNCTION****Keratoconjunctivitis Sicca**

Artificial tears, preservative free
 Eyeglasses and/or goggles
 Punctal occlusion (plugs or electrocautery)
 Topical cyclosporine drops

Xerostomia

Artificial saliva
 Salivary stimulators, mechanical or electrical
 Fluoride treatments and/or fastidious dental care
 Sugar-free lozenges, lemon drops

Dyspareunia

Vaginal lubricants or propionic acid gels
 Rigorous treatment of infection

SYSTEMIC TREATMENT OF EXOCRINE DYSFUNCTION

Pilocarpine or cevimeline
 When possible, avoid or discontinue medications with anticholinergic effects

TREATMENT OF SYSTEMIC MANIFESTATIONS

Salivary gland infection: tetracycline and nonsteroidal anti-inflammatory drugs
 Arthralgia: hydroxychloroquine or chloroquine
 Systemic vasculitis and glomerulonephritis: glucocorticoids and/or cyclophosphamide
 Leukocytoclastic vasculitis: no specific therapy
 Interstitial lung disease: glucocorticoid, cyclophosphamide

of lungs, kidneys, nervous system, and skin may develop, and the risk of developing lymphoma is increased among patients with primary SS, particularly those with the previously described risk factors. The overall mortality rate for SS is not higher than that of the general population.

For a deeper discussion of these topics, please see Chapter 268, "Sjögren's Syndrome," in Goldman-Cecil Medicine, 25th Edition.

Host Defenses Against Infection

Bharat Ramratnam and Edward J. Wing

HOST VERSUS PATHOGEN: VICTORY, DEATH, OR COEXISTENCE

Many factors determine whether we live successfully in symbiosis with our normal microbial flora, whether we can resist exposure to outside pathogens, and whether we live or die in an environment filled with an incredibly wide spectrum of microbes. Factors include age, nutrition, underlying medical conditions (e.g., diabetes mellitus, chronic lung disease), and the nature of the exposure (e.g., microbial virulence, inoculum). The outcome is determined by our host defenses, including barriers (e.g., skin), innate immunity (e.g., phagocytes), and specific responses that include antibodies and T cell-mediated events.

The human host has developed a multilayered host defense system to counter infectious organisms, and the resulting duel between pathogen and human can lead to one of four outcomes: death of the human host, elimination of the pathogen, peaceful coexistence of both in a symbiotic relationship, or an association whose latent nature changes with time and under additional biologic pressures. For example, pneumococcal pneumonia may kill the individual, or the host's defenses may eliminate the organism. *Escherichia coli* and *Bacteroides fragilis* in the gut survive and help to protect the host in a symbiotic relationship. Most individuals exposed to *Mycobacterium tuberculosis* are asymptomatic and latently infected with an inactive nonreplicating organism. Almost one third of the world's population is latently infected, but only about 10% progress to active disease. Immunologic impairment (e.g., human immunodeficiency virus [HIV] infection) and factors such as age increase the risk of progressing from latent to active disease.

The asymptomatic nature of an infection should not automatically be equated with latency or dormancy of the pathogen. For example, chronic HIV-1 infection was incorrectly characterized as having a prolonged latent or silent stage before the host developed immunodeficiency and opportunistic infections. However, most untreated HIV-1-infected individuals harbor actively replicating virus that kill CD4⁺ T lymphocytes on a daily basis, although the aggregate effects are not appreciated until CD4⁺ T lymphocyte levels are reduced to below 200 cells/mL after 8 to 10 years of infection. Infected individuals are infectious despite their relatively asymptomatic state, and in resource-rich countries, treatment is recommended regardless of CD4⁺ T lymphocyte levels. Treatment halts viral immune destruction, reduces viral burden in genital secretions, and decreases an infected individual's risk of transmitting HIV-1.

CATEGORIES OF HOST DEFENSES AND RISKS OF INFECTION

The relative importance of the innate and adaptive defenses is best illustrated by hosts who are deficient in a particular component. For example, chemotherapy leading to the depletion of immune cells such as neutrophils renders the host more susceptible to bacterial and fungal infections. Congenital deficiency of immunoglobulins increases the risk of infections that are usually thwarted by antibody responses such as those associated with *Streptococcus pneumoniae* and *Haemophilus influenzae*. Pharmacologic inhibition of tumor necrosis factor- α (TNF- α) increases the risk of developing active tuberculosis among those with latent infection. Astute clinicians, recognizing the increased incidence of atypical infections such as those caused by *Pneumocystis jirovecii* among young men, sounded the alarm that a novel immunodeficiency syndrome had appeared that was later ascribed to HIV-1.

Host defenses to infection can be classified as nonimmunologic host defenses, innate immunity, and specific or adaptive immunity. Immune host defenses against microbial pathogens are composed of cells and molecules located in peripheral sites, such as the skin and submucosal regions, and in secondary lymphoid tissues, such as the lymph nodes, tonsils, spleen, and Peyer's patches.

 For a deeper discussion of these topics, please see Chapters 45 through 50 in Section VII, "Principles of Immunology and Inflammation," in Goldman-Cecil Medicine, 25th Edition.

Nonimmunologic Host Defenses

Nonimmunologic host defenses include epidermal and mucosal barriers that physically prevent the entry of pathogens into the body. The respiratory tract defenses depend on mucus that entraps pathogens and on ciliary action and cough that continuously clear the mucus and organisms from the lungs and upper airways. Respiratory viruses, including influenza, may inhibit ciliary action or denude the mucous membrane completely, allowing bacteria to colonize and cause infection. Stroke, medications, or other causes of reduced cough reflex may lead to poor clearance of secretions, mucus, and pathogens and cause lung infection. Smoking and industrial exposure to toxins such as silica may similarly reduce lung host defenses, such as reducing ciliary action that leads to infection. In addition to mucus and ciliary action, alveolar macrophages located in the lung

parenchyma play an essential role in initial clearance and killing of pathogens.

Gastrointestinal defenses include gastric acidity, which kills many organisms, and vomiting and diarrhea, which help to clear pathogens from the gut. Bacteria vary greatly in their susceptibility to gastrointestinal host defenses. For example, as few as 10 *Shigella* organisms can cause infection, whereas 10⁵ to 10⁸ *Vibrio cholera* organisms are required for infection.

The urinary tract is protected physically by regular urine flow, the acidity of the urine, and antibacterial proteins. Conditions that interfere with these factors (e.g., prostatic hypertrophy, renal stones) may lead to stasis and infection. Mechanical injection of bacteria through the urethra into the bladder, as occurs in women during sexual intercourse, can lead to colonization of the bladder and infection. Injuries or devices that damage or bypass anatomic barriers frequently lead to infection. Examples include burns, intravenous catheters, intubation, urinary tract catheters, surgery, and trauma.

The normal microbiologic flora on the skin and in the respiratory and gastrointestinal tracks is an important component of host defenses. Normal floras compete with pathogens for nutrients and have antimicrobial activity of their own. Disruption of the normal flora by antibiotics allows superinfecting organisms such as *Candida* species and *Clostridium difficile* in the gut to colonize and then cause infection.

Organs that clear organisms from the bloodstream and lymph, including the liver, spleen, and lymph nodes, play an essential role after a pathogen has breached the primary anatomic barriers. Lack of a spleen increases a person's susceptibility to overwhelming sepsis caused by encapsulated bacteria including *S. pneumoniae*, *Neisseria meningitidis*, and *H. influenzae*. Cirrhosis of the liver allows portal vein blood to bypass the liver, increasing susceptibility to infection by gut flora.

Innate Immunity

Innate immunity refers to cells, molecules, and cellular receptors that recognize pathogens and promote inflammation nonspecifically at the site of infection. Table 86-1 compares innate and adaptive immunity. The response of innate immunity is relatively nonspecific, invariant, rapid, and without memory. Adaptive immunity is highly specific, slow during primary infection, and

can be recalled after primary infection with a more rapid, robust response.

The molecules involved in innate and acquired immunity include cytokines, chemokines, and integrins. Cytokines are soluble proteins that have numerous functions, including promoting cellular growth and activation as well as regulating the adaptive immune response (Table 86-2). Their functions range from stimulating the production of and activating inflammatory cells, including neutrophils, macrophages, and eosinophils, to the direct antiviral action of interferons. Some activate endothelial cells and cause fever, whereas others are regulatory and down-regulate the inflammatory response.

Concentration gradients of chemokines in tissue attract leukocytes to areas of inflammation. Integrins on the surface of leukocytes allow adhesion to receptors on other types of cells such as vascular endothelium. This is the first step in attracting and localizing leukocytes to areas of inflammation.

Relatively nonspecific pathogen recognition receptors on phagocytes include toll-like receptors (TLRs), which were originally described in the fruit fly, *Drosophila*; oligomerization domain-like receptors (often abbreviated as Nod-like receptors); C-type lectin-like receptors; and intracellular receptors that detect double-stranded RNA. TLRs have been studied extensively (Table 86-3). TLRs are located on several cell types, including macrophages and dendritic cells. When a pathogen is detected by its adherence to a TLR on the surface of a cell, activation of nuclear transcription factors, including nuclear factor- κ B, occurs. This stimulates the production of numerous cytokines important in the inflammatory response, including interleukin-1 (IL-1), IL-6, IL-10, IL-15, TNF- α , and growth factors (see Table 86-2). These cytokines amplify the inflammatory response by activating effector cells and by stimulating the production of many other inflammatory factors, including IL-2, interferons, C-reactive protein, complement components, and growth factors.

Complement factors are soluble proteins and enzymes that are produced in the liver. Complement activation occurs through several pathways that are involved in the innate and acquired host defense system as shown in Figure 86-1. Complement activation can occur as a result of antigen-antibody immune complex binding of C1, the mannose-binding lectin pathway, or the alternative pathway, which can be activated by bacterial cell wall components.

The complement cascade results in C3 convertase, a protein that cleaves C3. Cleavage of C3 leads to the production of multiple proteins (C3a, C4a, and C5a) that stimulate histamine release from mast cells leading to vasodilatation, increased endothelial permeability, and attraction of activated neutrophils. A second cleavage product of C3, C3b, in conjunction with immunoglobulin G (IgG) stimulates phagocytosis of pathogens. Activation of C5-9 results in bacterial lysis. Patients deficient in the complement components C5-9 appear to be particularly susceptible to organisms such as *N. meningitidis* and *Neisseria gonorrhoeae*. Complement activation is regulated by several regulatory proteins, such as C1 esterase inhibitor that inhibits the inappropriate activation of the classic complement activation pathway.

The inflammatory response results in the clinical signs of inflammation, including erythema, tenderness, warmth, and swelling. It can be initiated by microorganisms in tissue, tissue

TABLE 86-1 FEATURES OF THE INNATE AND ADAPTIVE IMMUNE RESPONSES

INNATE RESPONSE	ADAPTIVE RESPONSE
No memory: quality and intensity of response invariant	Memory: response adapts with each exposure
Recognizes limited number of nonvarying, generic molecular patterns on or made by pathogens	Recognizes vast array of specific antigens* on or made by pathogens
Pattern recognition mediated by a limited array of receptors	Antigen recognition mediated by a vast array of antigen-specific receptors
Response immediate on first encounter	Response on first encounter takes 1-2 weeks; on second encounter, 3-7 days

From Kumar P, Clark M, editors: Kumar and Clark's clinical medicine, ed 8, London, 2012, Elsevier.

*Antigen is a molecular structure (e.g., protein, peptide, lipid, carbohydrate) that generates an immune response.

**TABLE 86-2** CYTOKINES

CYTOKINE	CELLULAR SOURCE	TARGETS	FUNCTION	RECEPTOR
IL-1 α	Epi, fibroblasts, damaged or dying cells	Wide variety	“Dual function” cytokine involved in initiating inflammatory response and modifying gene expression	CD121a or CD121b
IL-1 β	M, B	T, B, M, End, other	Leukocyte activation, increases endothelium adhesion	CD121a or CD121b
IL-2	T	TB, NK, M, oligo	T cell proliferation, regulation	CD122/CD25
IL-3	T,* Mas, Eos, NK, End	Ery, G	Proliferation and differentiation of hematopoietic precursors	CD123/CDw131
IL-4	Mas, T, M	B, T, End	Differentiation of T _H 2 and B cells	CD124/CD132
IL-5	Mas, T, Eos	Eos, B	Growth differentiation of B cells and eosinophils	CD125/CDw131
IL-6	T, B, M, astrocytes, End	T, B, others	Hematopoiesis, differentiation, inflammation	CD126/CD130
IL-7	Bone marrow and thymic stroma	pB, pT	Pre/pro-B proliferation, T, upregulation of proinflammatory cytokines	CD127/CD132
IL-8	M, L, others	PMN, Bas, L	Chemoattractant	CD128
IL-9	T _H 2*	T, B	Potentiates production of IgM, IgG, IgE	
IL-10	CD8 ⁺ T,* T _H 2, (B), [†] M	T, B, Mas, M	Inhibits IFN- γ /TNF- β , IL-2 by T _H 1 cells, DTH, stimulates T _H 2	CD210
IL-11		Bone marrow stroma	Osteoclast formation	
IL-12	DC, B, T	T, NK	Potentiates IFN- γ and TNF- α production by T and NK, downregulates IL-10	CD212
IL-13	T _H 2,* Mas, NK	T _H 2, B, M	T _H 2 modulator, downregulated IL-1, IL-6, IL-8, IL-10, IL-12	
IL-14	T	B*	Stimulates proliferation, inhibits Ig secretion	
IL-15	M, Epi	T, B*	Proliferation	
IL-16	Eos, CD8 ⁺ T*	CD4 ⁺ T*	CD4* chemoattractant	
IL-17	(T)	Epi, End, others	Osteoclastogenesis, angiogenesis	
IL-18	M	T _H 1, NK	Induces IFN- γ production, enhances NK activity	
IL-32	Tn, NK, Epi	Wide variety	Proinflammatory	
TGF- β	Eos, others	Many cell types	Anti-inflammatory, promotes wound healing	
TNF- α	M,* PMN, T, B, NK	M, PMN, T, End, others	Mediator of inflammatory reactions	CD120a and CD120b
TNF- β	L	Wide variety	Mediator of inflammatory reactions	CD120a and CD120b
IFN- α	L, Epi, fibroblasts	Wide variety	Upregulates MHC class I, inhibits viral proliferation	
IFN- β	Epi, fibroblasts	Wide variety	Upregulates MHC class I, inhibits viral proliferation	
IFN- γ	CD8 ⁺ ,* (CD4 ⁺)*, NK	T, B, M, NK, End	Antiviral, antiparasitic, inhibits proliferation, enhances MHC class I and II expression	CD119
M-CSF	L, M, G, End, Epi, others	M	Growth and differentiation of Ms	CD115
G-CSF	T,* M, End	G	Growth and differentiation of Gs	
GM-CSF	T, M, End, Mas	pG, pMye	Stimulates growth and differentiation of Gs and Mye lineage cells	CD116
MIF	M	M	Antiapoptotic activity for macrophages, promotes M survival

injury, or dysfunctional adaptive immunity (e.g., autoantibodies). The response includes inflammatory molecules as previously described and tissue and migrating leukocytes. Neutrophils are central to the clinical manifestations of inflammation in tissue, and patients with neutropenia often lack the signs of inflammation at the site of serious infection.

Neutrophils are bone marrow–derived phagocytes whose production is greatly stimulated by infection through the action of macrophage-produced growth factors, including granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). Neutrophils circulate in blood, are attracted to sites of inflammation, and are activated

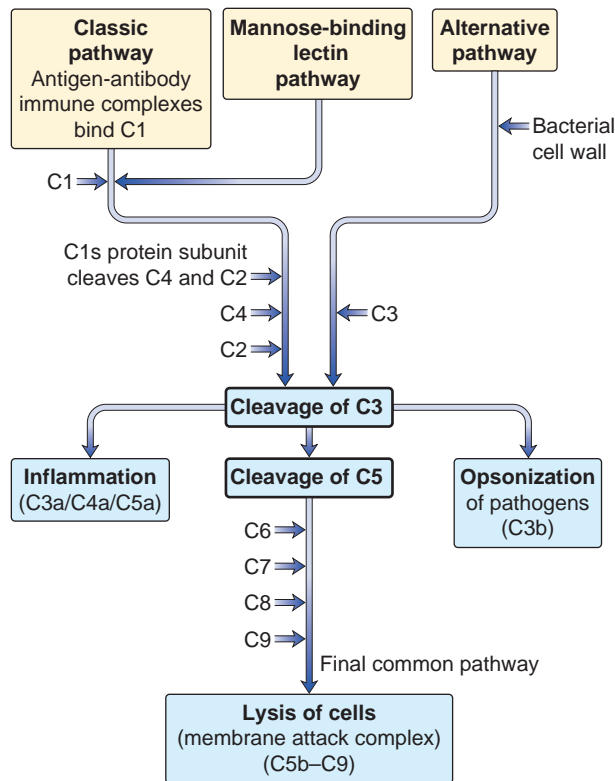

FIGURE 86-1 The complement pathway and other effector functions. (From Kumar P, Clark M, editors: Kumar and Clark's clinical medicine, ed 8, London, 2012, Elsevier.)

by chemotactic factors, including formyl peptides derived from bacteria, complement C3a and C5a, IL-8, interferon, and leukotrienes, particularly leukotriene B₄. Neutrophils migrate from the endovascular space into inflammatory tissue through a complicated integrin-regulated process that includes receptors on neutrophils and endothelial cells. Activated neutrophils then migrate down a chemoattractive (i.e., chemokine) gradient toward the site of inflammation.

Neutrophils are killing machines containing granules that have up to 100 different antimicrobial molecules. The contents of granules are released intracellularly into phagosomes after phagocytosis of a pathogen or released extracellularly in the vicinity of pathogens. Phagocytosis is greatly enhanced by opsonization (i.e., antibody and complement binding) of pathogens. The major microbicidal mechanism of neutrophils is the superoxide burst (i.e., production of superoxide anion catalyzed by NADPH oxidase) and then the dismutation to hydrogen peroxide. Many other granule molecules, such as cathepsins, elastases, defensins, and collagenase contribute to the killing process. Similar mechanisms exist in other phagocytes such as macrophages.

Eosinophils, which are found more in tissue than the circulation, are primarily important in host defenses against multicellular parasites such as parasitic worms. Growth and differentiation of eosinophils is promoted by IL-5. Eosinophils are activated and recruited by a variety of mediators, including complement factors and leukotrienes. Eosinophil granules contain specific cationic proteins that are toxic to parasites. Eosinophils also play key roles in the pathogenesis of allergic reactions and diseases such as asthma.

Basophils in blood and mast cells in tissue contain granules with histamine. They can be activated by complement factors and antigen-IgE binding on the surface of mast cells. Histamine is a short-acting, low-molecular-weight amine that acts through four different histamine receptors. Its actions include bronchoconstriction and bronchial smooth muscle contraction, itching, pain, vasodilation, and increased vascular permeability. Histamine also plays a role in gastric acid secretion, motion sickness, and sleep suppression. Commonly used antihistamines counter these effects.

Blood monocytes are produced in the bone marrow and circulate for several days in the blood. They then migrate into tissues, where they phagocytize pathogens and debris and kill microorganisms when activated by bacterial products such as lipopolysaccharide (LPS), interferon- γ , and other cytokines.

The properties and function of macrophages depend on the tissue. Alveolar macrophages in the lung are continuously exposed to airborne particles and pathogens, whereas microglia in the brain have a very different environment and function. Macrophages clear cellular debris after acute inflammation, and thus are the janitors of peripheral tissue. Macrophages produce a variety of cytokines important in the inflammatory process, including IL-1, TNF- α , IL-6, IL-15, and leukocyte growth factors.

Fever during inflammation and infection results from cytokines such as IL-1 and TNF- α that are released by macrophages into the circulation. These molecules increase the level of prostaglandins in the hypothalamus, which elevates the normal temperature set point. This stimulates thermoregulatory mechanisms to elevate the core body temperature.

Macrophages play a central role in granuloma formation. For example, macrophages are critical in controlling difficult-to-kill acid-fast mycobacteria such as *M. tuberculosis* or fungi by walling off viable organisms in granulomas. Macrophages also present antigen derived from microbial pathogens to T cells, helping to initiate the adoptive immune response. Cells of the myeloid lineage can control the immune response and are known as myeloid-derived suppressor cells.

Dendritic cells are derived from myeloid or lymphocytic precursors. Dendritic cells are found primarily in tissues where pathogens are likely to enter the body, such as the skin, gastrointestinal tract, spleen, and respiratory tract. These cells have branchlike cytoplasmic extensions (for which they are named), and they phagocytize pathogens in a manner similar to macrophages. They are the major antigen-presenting cells (APCs) in the body.

Natural killer (NK) cells are T lymphocytes that kill abnormal cells, including virus-infected cells and certain tumor cells. They do not require antigen sensitization for the production of perforin, a pore-forming protein with lethal effects. They are part of the first line of defense against viral infections while adaptive immunity is developing.

Adaptive Immunity

The adaptive immune response produces exquisitely specific, protective mechanisms against microbial pathogens (see Table 86-1). The specific response can be recalled rapidly by memory B and T cells years after infection if the particular

pathogen is encountered again. The capacity of the adaptive immune system to protect against different pathogens is truly astounding. It has been estimated that B cells can produce 10^{14} different immunoglobulin molecules, and that T cells can have up to 10^{18} different T-cell receptors (TCRs) for specific antigens.

B Lymphocytes

Antibodies are glycoproteins produced by B cells that recognize specific structural motifs (i.e., epitopes) on microbial pathogens. In antimicrobial defense, binding of an antibody to a pathogen may inhibit the ability of the pathogen to infect a cell or the ability of a toxin to be effective (i.e., neutralization); prompt phagocytosis by phagocytic cells such as neutrophils and macrophages (i.e., opsonization); activate the complement cascade; or kill an infected cell through the process of antibody-dependent cellular cytotoxicity (ADCC).

Antibody-mediated host defense occurs mainly in the extracellular space. T cell-mediated host defenses act primarily on intracellular organisms (i.e., those that enter cells and survive intracellularly). The five major classes (i.e., isotypes) of antibodies are summarized in Table 86-4. Complement fixation is accomplished by IgM and IgG molecules, whereas opsonization is effected by IgG and IgA molecules. IgG antibodies cross the placenta, providing protective immunity to newborns for months. IgA molecules are secretory antibodies that act at mucosal surfaces and are the predominant antibody in external secretions such as mucus. IgE is responsible for allergic responses and host defenses against parasites. IgD acts as an immunomodulatory molecule with the capacity to trigger innate immune responses.

Structurally, antibodies are composed of two large heavy chains and two small light chains (Fig. 86-2). Each heavy and light chain has a constant and a variable region. Each of the five isotypes of heavy chains designates a specific antibody class (i.e., IgM, IgG, IgA, IgE, and IgD) and two types of light chains (i.e., κ and λ). The antigen-binding site of each molecule is composed of the variable region of a heavy chain and the variable region of a light chain. There are two such binding sites for each molecule. The B-cell receptor is composed of the specific immunoglobulin associated with that B cell. Unstimulated B cells express single IgM molecules on their cell surfaces. When stimulated, B cells may initially produce IgM antibodies. Later, a B cell may switch the type of immunoglobulin produced (e.g., from IgM to IgG)

and become a plasma cell producing large amounts of antibody or become a long-term memory cell. B cells do not change their antigen specificity.

The constant region of the two heavy chains comprises the Fc portion, which after immunoglobulin has bound to antigen, can then bind to Fc receptors on the cell surface of neutrophils, macrophages, and dendritic cells. This interaction binds antigen-antibody complexes to phagocytic cells and allows opsonization and phagocytosis or activation of the classic complement pathway, depending on the isotype.

Humans can generate billions of different antibodies, and this diversity results from organization of the genes that encode the variable regions of antibodies. The two major genetic strategies that allow humans to produce antibody specific to virtually any microorganism are somatic hypermutation and recombination of the variable (V), diversity (D), and joining (J) gene segments of the immunoglobulin light and heavy chains. The variable region of the heavy chain is encoded by V, D, and J genes. The variable region of the light chain is encoded by V and J genes.

There are more than 1000 different V, D, and J genes. During B-cell differentiation, somatic translocations randomly select the V, D, and J heavy chain genes and the V and J light chain genes. In this manner, an enormously diverse set of variable chains is assembled. Further genetic variation arises from somatic mutations in B cells as they encounter antigen in lymphoid tissues. B cells have specific Ig antibodies on their surface, with specificity produced by V(D)J recombinations that recognize three-dimensional structures. These molecular structures are on the surface of pathogens or are toxins produced by pathogens.

The adaptive immune cell response begins with recognition of antigen by specific B cells in lymph node follicles. IgM antibodies are produced by B cells whose Ig surface receptors have affinity for the antigen. Interaction with complementary T cells in lymph nodes may result in class switching (e.g., from IgM to IgG classes or others). The switch is called an *isotype switch* and is driven by specific cytokines, such as IL-4, IL-10, IL-5, and others produced by T cells. The isotype switch allows the host to take advantage of the different functions of different isotypes specific for the same antigen (e.g., complement fixation for IgM, opsonic activity for IgG). T-cell interaction through surface coreceptors and stimulatory soluble molecules results in B-cell division and increased

TABLE 86-4 PROPERTIES OF HUMAN IMMUNOGLOBULINS

PROPERTY	IgG	IgA	IgM	IgD	IgE

FIGURE 86-2 Structure of antibodies. Antibody molecules are composed of two heavy chains (red lines) and two light chains (blue lines) held together by disulfide bonds. The two heavy chains join to form a tail (Fc end), which can interact with receptors (FcR) on a variety of cells. The heavy and light chains contribute to the Fab end. At the 5' or amino-terminal end, these chains form two identical antigen-binding sites, much like two lobster claws. Near the hinge region of the antibody, there is a binding site for C1q, the first component of the complement cascade. (From Birdsall H: Adaptive immunity: antibodies and immunodeficiencies. In Bennett JE, Dolin R, Blaser M, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 8, Philadelphia, 2015, Saunders.)

antibody production. B cells may also differentiate into plasma cells that do not contain surface antibody but secrete large amounts of a single specific isotype immunoglobulin.

B cells may also undergo somatic hypermutation. In this process, cells producing antibody develop point source mutations in the immunoglobulin DNA that may increase the affinity to antigen. This may stimulate increased production of the higher-affinity antibody, thus fine tuning the B-cell response. Driven by T-cell interaction, a portion of the B cells are formed for life, and these *memory cells* have the capacity to secrete antibodies rapidly on antigen reexposure that have extremely high avidity for a particular antigen.

B cells can be activated by two routes. Some antigens can stimulate B cells to proliferate and produce antibody directly without the presence of helper CD4⁺ T cells. They include microbial-derived molecules such as LPS, which have broad stimulatory properties. Others, such as microbial-derived repetitive motifs on polysaccharides, stimulate mature B cells more specifically. More commonly, B cells are stimulated through synergistic action with CD4⁺ T cells. Specific antigen is bound to the surface immunoglobulin of the B cell, which triggers endocytosis, degradation of the antigen, and presentation of peptide fragments in association with MHC class II molecules on the cell surface. CD4⁺ T cells with TCR specificity for the antigen interacts with the B cell through adhesion molecules and costimulatory activation molecules such as CD28 and CD80/86. CD4⁺ T cells then produce cytokines such as IL-4 that drive antibody production by the B cells.

T Lymphocytes

T cells are produced in the bone marrow and then are processed and selected in the thymus. T lymphocytes have CD4 or CD8 molecules on their surface along with a TCR that has exquisite antigen specificity. During development, the TCR is produced in a process involving gene rearrangement and selection of V, D, and J clusters similar to B-cell antibody differentiation. The potential number of epitopes that T cells can respond to is greater than those that induce B cells.

As maturation takes place in the thymus, T cells whose TCRs have too high an affinity for self-molecules are eliminated. Naïve T cells, usually in regional lymph nodes or similar tissues such as

Peyer's patches in the gut, are sensitized by interaction with an APC such as the dendritic cell. The APC processes a microbial peptide antigen and then presents the antigen to the associated T cell. Presentation of antigen occurs in association with human leukocyte antigen (HLA) class II molecules for CD4⁺ cells or HLA class I molecules for CD8⁺ cells. CD4⁺ cells are called helper T cells and develop into T_{H1}, T_{H2}, and T_{H17} subsets. CD8⁺ cells are cytotoxic T cells (Fig. 86-3).

CD4⁺ T cells are key enhancing cells that are permissive and amplify the response of B lymphocytes, other CD4⁺ T cells, and CD8⁺ T cells. They also can activate cells such as phagocytes. CD4⁺ T cells orchestrate host defenses against pathogens that are initially recognized by phagocytic cells during phagocytosis or pinocytosis. Dendritic cells, for example, incorporate external pathogens or antigens by phagocytosis or pinocytosis and then degrade them within phagosomes.

Short-chain peptide antigens, which are produced by proteolytic degradation, attach to a groove in the MHC class II molecules. The complex is then transported to the surface for presentation to naïve T lymphocytes expressing CD4 molecules on their surface. CD4⁺ T lymphocytes with specificity for the antigen then adhere to the MHC class II/antigen complex on the surface of the APC. Accessory molecules, such as the adhesion molecule lymphocyte function-associated antigen 1 (LFA-1) on T cells, which interacts with intercellular adhesion molecule 1 (ICAM-1) on the APC, are necessary to stabilize the interaction. Activating adhesion complexes such as CD28 (on T cells) and CD80/86 (on APCs) are necessary for sensitization, proliferation, and activation of T cells. Activation and proliferation is also driven by IL-2.

Activated CD4⁺ T cells (initially called T_{H0} cells) can be driven by IL-12 and other cytokines to become T_{H1} cells or by IL-4 and IL-10 to become T_{H2} cells. T_{H17} cell differentiation is driven by transforming growth factor-β (TGF-β), IL-6, and IL-23. T_{H1} cells mediate host defenses against intracellular pathogens such as *M. tuberculosis* or *Toxoplasma gondii*. They do so by producing γ-interferon that activates APCs such as macrophages that then destroy the invading intracellular pathogen. T_{H1} cells also produce IL-12, IL-2, and TNF-α, which can enhance the immune response. They also activate cytotoxic T lymphocytes to lyse infected cells.

FIGURE 86-3 Overview of T-cell activation. The dendritic cell (DC) initiates the interaction with a $CD4^+$ or $CD8^+$ T cell through a major histocompatibility complex (MHC)–peptide interaction with the T cell receptor. The DC provides an 11-amino-acid peptide on the class II MHC, B7 coreceptor, and cytokines to activate $CD4^+$ T cells. The $CD8^+$ T cell is activated through the class I MHC and 8- to 9-amino-acid peptide plus the B7 coreceptor and cytokines. Presentation of antigen to $CD4^+$ T cells and cross-presentation to $CD8^+$ T cells is shown. The cytokines produced by the DCs determine the type of helper T (T_H) cell. Activated $CD8^+$ T cells can interact with and lyse target cells through T-cell receptor recognition of peptide in class I MHC molecules on target cells. APC, Antigen-presenting cell; CTL, cytotoxic T lymphocyte; Ig, immunoglobulin; TGF- β , transforming growth factor- β . (From Rosenthal KS, Tan MJ, editors: Rapid review microbiology and immunology, ed 3, Philadelphia, 2011, Mosby.)

Alternatively, $CD4^+$ T cells can become T_H2 cells that drive processes such as antiparasitic activity. T_H2 cells stimulate B cells to produce antibodies against extracellular pathogens through the production of IL-4, and they stimulate proliferation of eosinophils for activity against parasites (e.g., worms) through the production of IL-5.

T_H17 cells are stimulated by IL-23 and produce IL-17, which plays an important role in amplifying the inflammatory response by attracting neutrophils to sites of infection caused by extracellular bacteria and possibly fungi. The complexity of these $CD4^+$ T-cell subsets is still being explored.

$CD8^+$ T cells respond to pathogens that initially enter phagocytic cells directly, such as viruses. Upon intracellular replication, viral proteins are marked for destruction by covalent binding to the protein ubiquitin. The tagged molecules are then degraded by a proteasome, which is a cytoplasmic enzyme complex. Resulting peptide chains of 6 to 24 amino acids then associate with MHC class I molecules in a complex intracellular process in the APC and are presented on the surface of the APC. Naïve $CD8^+$ cells that are specific for the presented antigen adhere to the presented MHC class I/antigen complex and express IL-2 receptors. $CD4^+$ T_H1 antigen-specific cells also interact with the APC, which stimulates the production of IL-2 by the $CD4^+$ cell and increases CD80/86 expression by the APC. CD28 on the $CD8^+$ T cell interacts with the CD80/86 on the APC to stimulate the $CD8^+$ T cell to proliferate and differentiate into cytotoxic T lymphocytes. The cytotoxic T cells can lyse target cells expressing the appropriate MHC class I/antigen complex. Several signals,

including MHC class I/antigen recognition, IL-2 stimulation, and CD28 and CD80/86 adherence, combine to optimally initiate $CD8^+$ cytotoxic T cells to attack virus-infected cells.

$CD4^+$ and $CD8^+$ T cells help to regulate the immune response. $CD4^+$ regulatory T cells (Tregs) express CD4 and CD25 and help to regulate immune responses, particularly those related to autoimmune diseases but also some infectious diseases. $CD8^+$ suppressor T cells inhibit some autoimmune inflammatory processes.

HOST DEFENSE RESPONSE TO PATHOGENS

Humans are constantly threatened by microbial pathogens. Organisms such as *S. pneumoniae*, group A streptococci, and respiratory viruses colonize the respiratory tract. *S. aureus*, fungi, and many other organisms live on the skin. Every type of pathogen lives in the gastrointestinal tract; some are benign, and some are dangerous.

Host defenses need to react continuously and appropriately to breaches in nonimmunologic host defenses as described earlier. For example, if a person suffers a cut on the hand, the skin barrier is breached, and pathogens may be inoculated into the subcutaneous tissues. This stimulates an immediate nonimmunologic host defense response that includes phagocytosis by cells such as macrophages, which produce cytokines such as IL-1 and TNF- α . Cytokines stimulate the expression of adhesion molecules on vascular endothelium. Neutrophils then bind to the endothelium, move into tissues, and are attracted by a chemokine gradient to the site of invasion.

A second process that breaches nonimmune host defenses results from infection by respiratory viruses. Influenza virus may damage upper and lower respiratory host defenses by destroying the respiratory epithelium, inhibiting ciliary action and mucus production. Bacterial pathogens, most commonly *S. pneumoniae*, that colonize the respiratory tract in normal hosts may then colonize and invade the lower respiratory tract, leading to pneumonia. Organisms such as *M. tuberculosis*, an intracellular pathogen, may evade upper respiratory and lower respiratory defenses and lodge in alveolar macrophages in the lung, where they can survive and multiply. Interference with alveolar macrophage function (e.g., silica exposure) may increase susceptibility to tuberculosis.

The innate immune system is critical during the early phases of infection. The response is rapid, although nonspecific, and eliminates the pathogen or holds the infection in check until the more powerful, highly specific adaptive immune system has time to respond. Phagocytes such as tissue macrophages patrol the periphery and detect pathogens through receptors such as TLRs. This activates the phagocyte, induces phagocytosis and killing, and stimulates the phagocyte to produce cytokines and chemokines that initiate the inflammatory response.

Complement may be activated through the alternative pathway and produce products to attract neutrophils, opsonize pathogens, and lyse pathogens. Vasodilation results from histamine release, and circulating neutrophils are localized to the vascular endothelium nearest the site of invasion by integrins, pass through the vascular wall, and move down a chemokine gradient to the site of infection. Opsonization helps neutrophils and other immune cells ingest and kill the pathogen. These immediate inflammatory and innate immune responses are initiated immediately and increase over hours to days. Although they are effective, these responses are temporizing measures while more specific and more effective host responses of the adaptive immune system are developing.

Immature dendritic cells in peripheral tissues are watchman for foreign molecules. Through pinocytosis and phagocytosis initiated by TLRs and other receptors, they detect pathogens; when identified, dendritic cells migrate to regional lymph nodes. There

the dendritic cells mature, stop phagocytosis, and process antigen for presentation to T cells, initiating the specific adoptive immune response. The type of response depends on the type of pathogen. Intracellular pathogens such as *M. tuberculosis* stimulate a T cell–mediated response, whereas *S. pneumoniae* stimulates primarily a B-cell, antibody-mediated (humoral) response. Most infections produce components of cellular and humoral host responses in various degrees that often act in concert. For example, influenza virus induces a B-cell and T-cell response.

Humoral Response

Early in infection, complement and preexisting circulating or tissue antibodies react to pathogens directly and can initiate direct lysis, opsonization, and neutralization of pathogens. B cells may be activated by T cell–independent antigens or through interaction with CD4⁺ T cells and T cell–dependent antigens. B-cell populations proliferate and produce IgM antibodies initially and then with isotype switching produce other types of antibodies, including IgG and IgA. Antibodies acting in the extracellular space bind to pathogens or their products, potentially leading to neutralization, opsonization, complement fixation, and ADCC.

Cell-Mediated Response

Naïve T cells with specificity for the invading pathogen are activated, proliferate, and produce cytokines. CD4⁺ T cells produce cytokines that stimulate other T cells, enhance the overall inflammatory response, activate phagocytes for killing, and stimulate antibody production. Previously sensitized T cells may react rapidly with activation and proliferation on exposure to a previously recognized intracellular pathogen.

Laboratory Diagnosis of Infectious Diseases

Kimberle Chapin

INTRODUCTION

The ability to diagnose a greater number of infectious diseases rapidly and accurately represents a significant recent advance in medicine. Diagnosis has become readily available with point-of-care (POC) testing that is automated, molecularly based, and technologically advanced. At the same time, specimen acquisition, test selection, test performance parameters, and result interpretation have become more complex.

Up to 70% of individual patient medical diagnoses are made with the aid of a laboratory test result. Implementation of the right diagnostic technology can affect patient safety, morbidity, mortality, and health care costs. Examples of how test results can optimize patient care have been published for *Clostridium difficile* toxin molecular testing and infection control practices; algorithms for identification and treatment of sepsis to reduce morbidity and mortality; screening for colonization with methicillin-resistant *Staphylococcus aureus* (MRSA) and *S. aureus*, allowing decontamination and targeted antibiotic therapy in high-risk surgical procedures; and use of rapid molecular testing to aid in successful anti-infective intervention and stewardship programs.

This chapter highlights significant components of testing for infectious diseases and the trends in the laboratory and diagnostic technology that affect patient care. More information is available in the 2013 American Society for Microbiology (ASM) and Infectious Disease Society of America (IDSA) guideline on use of the microbiology laboratory for the diagnosis of infectious diseases. This excellent resource summarizes laboratory diagnosis of infectious diseases by basic disease categories (e.g., respiratory, genital) and contains numerous tables for rapid access of information. The document is well referenced and is updated on a regular basis; it is now available as part of the Sanford Guide—Lab Diagnosis of Infectious Diseases (<http://www.sanfordguide.com/>).

SPECIMEN COLLECTION AND PROCESSING

Collection of the specimen and its preservation during transportation are components of infectious disease diagnosis that are often overlooked. As part of their accreditation and inspection process, laboratories have collection procedures and criteria for rejection of specimens that are deemed inappropriate to process. These evidenced-based protocols ensure that results can reliably be used to treat patients. Examples include rejection of a sputum specimen after initial smear evaluation shows the specimen is contaminated with squamous epithelial cells and indicates

normal mouth flora rather than a deep respiratory specimen. Another example is rejection of a hard stool for *C. difficile* toxin testing because it is inconsistent for a person with *C. difficile* infection, which produces watery diarrhea.

All personnel (e.g., physicians, nurses, phlebotomists) collecting specimens should be familiar with the appropriate collection devices, recommended collection techniques, and requirements for transportation to the laboratory to ensure optimal identification of the pathogen. If the practitioner requests a microbiology test not typically performed, such as for anaerobic organisms from a cerebral spinal fluid (CSF) specimen, a call should be made to the laboratory to clarify the order.

RAPID DIAGNOSTIC METHODS

Rapid or *STAT* is no longer a term foreign to direct testing for infectious diseases and the microbiology laboratory. All major areas of diagnostic testing, including direct visualization of specimens; detection of organism-specific antigens, proteins, and nucleic acids; and cell counts and biomarkers can be performed in 1 to 4 hours. Test results are often available during the time a practitioner is involved with the patient.

Table 87-1 lists the most common U.S. Food and Drug Administration (FDA)–cleared direct testing methods used in laboratories for primary specimens. Examples include Gram stain for bacteria and yeast, fluorescent calcofluor staining for fungi, *Legionella* urinary antigen for legionnaires disease, and polymerase chain reaction (PCR) for enterovirus in CSF.

Direct and *rapid* do not necessarily equate to high predictive values for a true positive or negative test result. As a result, tests commonly used in the past (e.g., bacterial antigen and India ink in CSF) are no longer routinely recommended because false-positive results are common.

DIRECT SMEAR INTERPRETATION

A direct smear interpretation can be exceedingly helpful in confirming a suspected cause (e.g., Gram stain of sputum for pneumococcal pneumonia) and can be performed usually in a few minutes to hours from receipt in the laboratory. High sensitivity and specificity, however, depend on specimens being collected appropriately (e.g., obtained before antibiotic administration) and sometimes on knowing the immune status of the patient.

Fluorescent staining with calcofluor (Fig. 87-1) and auramine have increased sensitivity for direct detection of fungal elements and acid-fast bacilli (AFB), respectively. Direct fluorescent antibody staining for parasites, viruses, or *Pneumocystis jirovecii* is specific and rapid compared with staining of histologic tissue

TABLE 87-1 FDA-CLEARED METHODS OF DIRECT TESTING FROM SPECIMENS

TEST METHODS*	DIAGNOSTIC METHOD	ANALYTE DETECTED
Smear stain preparations	Gram stain	Bacteria, yeast
	Fluorescence	DFA: <i>Pneumocystis jirovecii</i> , viruses [†] Auramine: mycobacteria Calcofluor: fungi
	Special: acid-fast (Kinyoun), partial acid-fast (PAF), India Ink [‡]	Smear use determined by laboratory and based on primary stained specimen [§]
	Wright stain	Leukocyte differentiation and count
Antigen-antibody	Latex agglutination	<i>Legionella</i> or <i>Streptococcus pneumoniae</i> urinary antigen Cryptococcal antigen in serum and CSF
	Lateral flow antibody/antigen	GAS, RSV, influenza A or B
	Serology for IgG, IgM, Western blot	Multiple analytes; detection and/or confirmation of immune status and acute disease
	Biomarker	Procalcitonin, C-reactive protein
Molecular [¶]	Hybridization and signal amplification	HPV, bacterial vaginosis or vaginitis, GAS
	Amplification of RNA or DNA or both	Small bundle with ≤5 targets: sexually transmitted pathogens (GC, CT, TV) Multiplex amplification with ≥10 targets: blood sepsis, respiratory, gastrointestinal pathogens Chip array: multiple targets, HCV genotyping
	Amplification with quantification of nucleic acids	HIV, HCV, HBV

CSF, Cerebrospinal fluid; CT, *Chlamydia trachomatis*; DFA, direct fluorescent antibody; DNA, deoxyribonucleic acid; FDA, U.S. Food and Drug Administration; GAS, group A streptococci; GC, *Neisseria gonorrhoeae*; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; Ig, immunoglobulin; RNA, ribonucleic acid; RSV, respiratory syncytial virus; TV, *Trichomonas vaginalis*

*One-hour, same-day testing.

[†]Because the direct fluorescent antibody (DFA) is organism specific (e.g., *P. jirovecii*, varicella zoster, herpes simplex 1 or 2, cytomegalovirus), these smears are better than histologic stains (e.g., silver stain) and Tzanck preparations (e.g., nucleated giant cells), which can yield similar appearances for many infectious causes.

[‡]Cryptococcal antigen from cerebrospinal fluid (CSF) or serum is the recommended test. India ink often yields false-positive results and is used by the laboratory for confirmation of suspected yeast in a Gram stain of CSF.

[§]For example; partial acid fast testing is performed if the Gram stain shows branching of gram-positive rods and *Nocardia* is suspected; acid fast testing is performed if the auramine-stained sample is positive.

^{||}Procalcitonin is a better marker for identification of bacterial sepsis than C-reactive protein.

[¶]Common examples of pathogens are listed for each group, but many more analytes are available.

preparations, which may take days. However, because adequate specimens are often difficult to obtain, sensitivity may be lacking with smear and culture, and alternative methods such as molecular and empirical therapy are still warranted in specific cases.

POINT-OF-CARE OR NEAR-PATIENT TESTING

POC or near-patient testing offers rapid results, typically while the patient is still in the clinical care setting, and it allows directed treatment. However, most tests done in practitioners' offices or on-site laboratories are rapid antigen tests. The predictive values

FIGURE 87-1 Calcofluor fluorescent stain depicts fungal hyphae from a wound specimen.

of these tests depend on the specimen type collected (e.g., nasopharyngeal swab is better than a throat swab for influenza A or B testing), the test analyte (e.g., group A streptococci performance is more reliable than influenza A or B), and the prevalence of disease at the time of testing.

False-positive results for rapid antigen tests are unusual, and the patient can be treated based on a positive result. In contrast, a negative test result can be quite misleading. For example, data from the novel H1N1 influenza outbreak demonstrated very poor sensitivity for rapid antigen tests (about 50%) compared with molecular tests. When a multiplex viral panel was used, other viral pathogens were identified as the cause of influenza-like illness in more than 50% of patients admitted to hospitals (Fig. 87-2). Molecular detection of influenza is recommended for hospitalized patients with influenza-like illness if a rapid antigen test result is negative. Many manufacturers have submitted amplified testing assays for influenza, seeking Clinical Laboratory Improvement Amendment (CLIA)-waived status for rapid influenza detection tests that can be performed in the laboratories of physicians' offices or urgent care centers.

Molecular Assays

Molecular identification of infectious diseases has intensified in the past 10 years. The basic categories are shown in Table 87-1.

FDA-cleared direct molecular tests include hybridization and amplification methods. The main difference between these methods is that with hybridization methods, the nucleic acid is not multiplied beyond what is already in the sample. For assays that target DNA, the sensitivity is limited because DNA exists as a single copy. For assays that target proteins or RNA, detection sensitivity is somewhat increased because these components are naturally amplified in the microbe. Familiar hybridization assays include fluorescent in situ hybridization (FISH) for targets in tissue and the protein nucleic acid (PNA) smear (Fig. 87-3). Hybridization assay systems can increase their sensitivity by pairing with signal amplification, such as for human papillomavirus (i.e., Qiagen/Digene HPV test).

In contrast, amplification assays increase the original nucleic acid copy number through a variety of processes, including PCR, transcription-mediated amplification (TMA), and isothermal loop amplification (LAMP). Real-time PCR refers to

FIGURE 87-2 The graph represents the respiratory viruses detected from hospitalized patients who had influenza-like illness over a period of two respiratory seasons. Viral epidemiology was determined using a multiplex respiratory viral assay for 14 viral pathogens. The viral epidemiology provides helpful information for decreasing antibiotic use and discussing the likely cause of illness with patients.

FIGURE 87-3 A protein nucleic acid (PNA) hybridization probe can be used to identify yeast from a positive blood culture. The Yeast Traffic Light PNA FISH assay identified *Candida albicans* and/or *Candida parapsilosis* (green), *Candida tropicalis* (yellow), and *Candida glabrata* and/or *Candida krusei* (red).

amplification and detection occurring simultaneously, enabling the analyte to be detected more quickly. Amplification assays can detect a single analyte (e.g., enterovirus from CSF) or a group of pathogens for a disease entity from a single specimen, such as sexually transmitted infections (e.g., *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Trichomonas vaginalis*).

These assays can detect numerous pathogens from a single specimen in a multiplex amplification testing format (i.e., FDA-cleared multiplex assays for 14 to 24 targets exist for respiratory or acute gastroenteritis pathogens). They also allow

quantification of the viral load for purposes of long-term treatment and assessment of clearance (i.e., human immunodeficiency virus, hepatitis B virus, and hepatitis C viral loads).

Culture

Despite advances in rapid direct and molecular diagnostics, culture is still a mainstay for infectious disease diagnosis of most specimen types, but techniques for rapid identification of cultures have been enhanced with updated technology. Blood and AFB specimens are incubated in continuously monitoring incubator cabinets that signal when a specimen is positive based on algorithmic growth curves. A positive specimen can be identified at any time of day, pulled and stained immediately after signaling positive, and tested for definitive identification and susceptibility.

Table 87-2 lists the most common identification methods used from positive broth cultures (e.g., blood) and from colony growth on a culture plate. They include several molecular hybridization methods that have become standard practice for many laboratories (see Fig. 87-3).

Although most laboratories still rely on biochemical and enzymatic phenotypic methods for identification, 16s and 18s sequencing of microbial genomes has demonstrated that the biochemical methods lack specificity. In addition, they require growth for reactions to take place, resulting in further delay of organism identification. The increased use of matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) represents a significant methodologic change. This technique relies on the protein spectral analysis of the organism for identification and takes only minutes rather than days. The technique is described in Figure 87-4.

Susceptibility testing typically requires growth of an organism in the presence of the antibiotics that are appropriate for treatment of the organism. Molecular technology has improved

TABLE 87-2 RAPID IDENTIFICATION METHODS FOR A POSITIVE CULTURE BROTH OR COLONY

METHOD*	ORGANISMS DETECTED	TIME	COST	TECHNICAL EXPERTISE
PNA fluorescent smear	Bacteria, fungi (yeast)	1-2 hr	\$\$	+
MALDI-TOF	Bacteria, fungi, mycobacteria	Minutes	\$	+
Hybridization probes	Bacteria, dimorphic fungi, mycobacteria	1-4 hr	\$\$	++
Amplification [†]	Bacteria, viruses, mycobacteria	1-4 hr	\$\$\$	++
16s/18s sequencing	Bacteria, fungi	1-12 hr	\$\$\$	+++
HPLC	Mycobacteria	24 hr	\$\$\$	+++

MALDI-TOF, Matrix-assisted laser desorption ionization–time of flight mass spectrometry; PLC, high-pressure liquid chromatography; PNA, peptide nucleic acid; \$, relative cost; +, relative level of required expertise.

*Rapid methods require 2 to 24 hours. Methods presented are U.S. Food and Drug Administration cleared or have had test performance validated in the clinical laboratory. Due to required technical expertise and cost, some of these assays may not be available in the routine laboratory, and providers should inquire about availability.

[†]Includes many different technologies, such as polymerase chain reaction (PCR), transcription-mediated amplification (TMA), and isothermal loop amplification (LAMP).

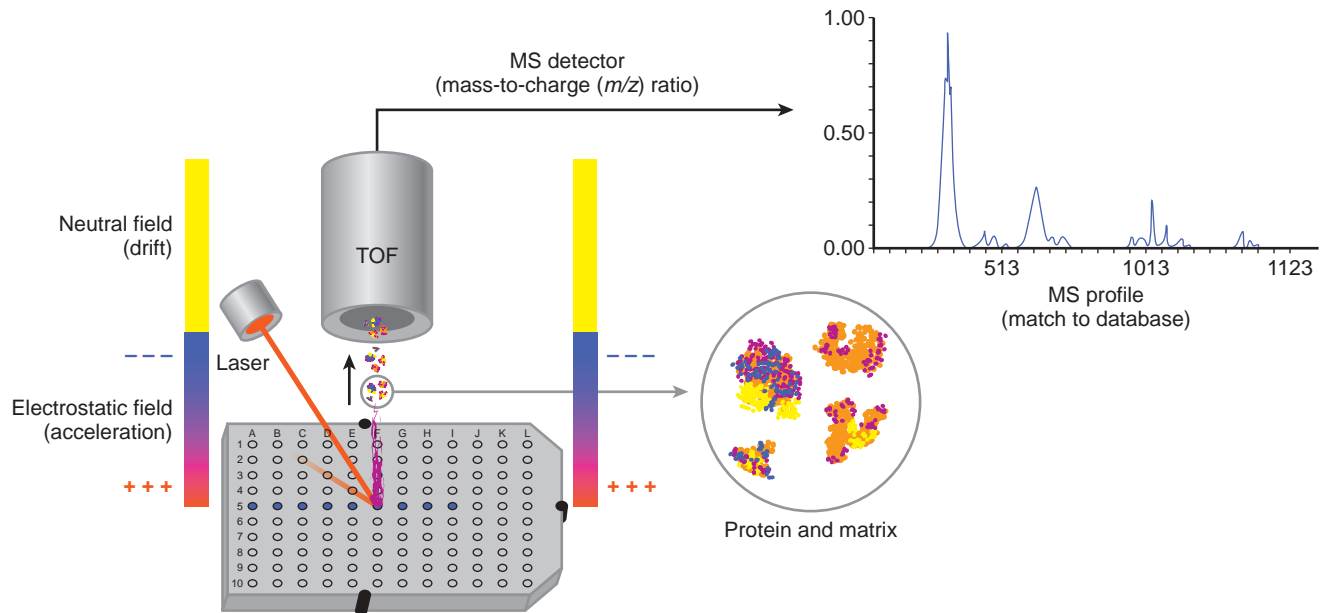

FIGURE 87-4 Matrix-assisted laser desorption–time of flight mass spectrometry (MALDI-TOF MS). Bacterial or fungal growth is selected from a culture plate and applied directly onto a MALDI slide. Samples are overlaid with a matrix and dried. Samples are then bombarded by a laser, which results in sublimation and ionization of the sample and the matrix. The ions are separated based on their mass-to-charge ratio in a tube that measures the time it takes the ions to travel. A spectral representation of these ions is generated and analyzed by software that generates a profile that is subsequently compared with a database of reference MS spectra and matched, generating identification. The process takes only minutes. Although the instrumentation is expensive, the technology is U.S. Food and Drug Administration cleared, and it yields rapid, robust, and reliable identification.

traditional screening tests for the detection of MRSA, vancomycin-resistant enterococci (VRE), carbapenem-resistant organisms, and rifampin-resistant *Mycobacterium tuberculosis*. However, the medical implications of detecting a resistance gene sequence and its expression are not fully understood.

TRENDS IN THE DIAGNOSIS OF INFECTIOUS DISEASES

Evidence-based guidelines exist for specimen work-ups in an effort to standardize reporting and interpretation of microbiologic results. They are especially useful for specimens submitted from sites potentially contaminated with normal commensal flora (e.g., urine, surface wounds, respiratory sources).

There are limitations on which microbes and how many different microbes should have full identification and susceptibility testing according to the specimen type submitted. For instance, a clean catch urine specimen is called *mixed* if three or more organisms are present in equal amounts (even if they are potential

pathogens) because the significance of any one organism cannot be determined. The specimen must be recollected. Likewise for other specimen types, listing every organism present is not considered helpful.

Other trends include limiting test ordering and the use of algorithms that may be disease or health care system based; continued efforts between microbiologists, pharmacists, and practitioners to optimize the stewardship of anti-infectives; use of multiplex testing to streamline the diagnosis of complex entities such as acute gastroenteritis; developing data on the relevance of a positive molecular result; and the increasing use of metagenomics and sequencing data to perform direct testing (e.g., blood, orthopedic specimens) and to identify infectious disease outbreaks.

Fever and Febrile Syndromes

Ekta Gupta and Maria D. Mileno

INTRODUCTION

Fever is one of the most common problems requiring medical evaluation. Fever is an elevation in core body temperature greater than normal daily variation, which is $36.8^{\circ}\text{C} \pm 0.4^{\circ}\text{C}$ ($98.2^{\circ}\text{F} \pm 0.7^{\circ}\text{F}$). Documentation of true fever can be important evidence of infectious processes that warrant investigation. Although fever is characteristic of most infections, it also occurs in noninfectious conditions such as autoimmune and inflammatory diseases, malignancy, and trauma.

This chapter reviews the pathogenesis of the febrile response, the approach to the acutely ill patient with fever, and fever of unknown origin. Fever can be associated with infections, such as those from animal exposures, or with common clinical scenarios in which it may occur as the sole complaint, manifest with rash, or develop with lymphadenopathy. A word of caution about the difference between true and factitious fever is offered at the end of the chapter.

PATHOGENESIS

Thermoregulation of core body temperature is one of the most important mechanisms in mammalian and human physiology. The hypothalamic heat-regulating set point shifts in response to infection or inflammation mediated primarily by the host's monocytes and macrophages, which are activated as they encounter exogenous bacterial substances, toxins, or the cellular products of trauma.

Monocytes and macrophages produce small proteins called *cytokines*, such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF). They are collectively known as *endogenous pyrogens* because they actively increase body temperature by increasing the hypothalamic set point, which is the normal temperature for the body that is controlled by the hypothalamus. IL-1 and other endogenous pyrogens are released by macrophages at the site of infection and travel through the bloodstream to the hypothalamus, where they elevate levels of prostaglandin E_2 (PGE_2). Elevated PGE_2 levels increase the set point, and thermoregulatory mechanisms raise the body's core temperature. IL-1 also induces production of PGE_2 in peripheral tissues, which causes the non-specific myalgias and arthralgias that often accompany fever. Prostaglandin inhibitors such as aspirin or acetaminophen block prostaglandin synthesis and reduce elevated temperatures.

Thermoregulatory control is initiated through sensory neurons in the skin, abdomen, and spinal cord. Central nervous system (CNS) thermoreceptors sense and integrate temperature information. After the hypothalamic set point is raised, the firing rates of neurons in the vasomotor center are altered, causing peripheral

vasoconstriction and producing a noticeable cold sensation in the hands and feet. Blood is shunted away from the periphery to the internal organs, and this process is sufficient to raise core body temperature by 1° to 2°C .

Other signaling mechanisms have roles in thermoregulation. The adipocyte-derived hormone leptin actively controls energy homeostasis, and thermogenesis in fat tissue contributes to increasing core temperature. Thermogenesis is important in fighting infection and in responding to cold-induced heat production. Fever has direct antimicrobial effects in some infections such as neurosyphilis and salmonellosis, and elevated temperature augments humoral and cellular immune responses. IL-1 acts independently on two physiologic systems: thermoregulation and iron metabolism. IL-1 can stimulate a wide range of host defenses to conduct a synergistic response to infection.

Fever also can have deleterious effects. It may lead to disorientation and confusion in persons with underlying brain disease and in healthy older individuals. Tachycardia can increase cardiopulmonary work, precipitating congestive heart failure or myocardial infarction in persons with significant cardiopulmonary disease. Fever should be controlled with antipyretics for comfort and to avoid compromising individuals with multiple medical problems. Acetaminophen is preferred for control of fever in children because of the risk of Reye's syndrome with salicylate use.

The terms *fever*, *hyperthermia*, and *hyperpyrexia* are not synonymous. Although most patients with elevated temperature have fever ($>38.3^{\circ}\text{C}$ or 100.9°F), some conditions can increase the body temperature by overriding or bypassing the normal homeostatic mechanism and may even produce body temperatures in excess of 41°C or 105.8°F (i.e., hyperthermia), which can be rapidly fatal and does not respond to antipyretics. Rapid cooling is critical to the patient's survival in hyperthermic conditions such as heat stroke. Even in otherwise healthy individuals, heat stroke can occur after vigorous exercise and prolonged exposure to high environmental temperatures and humidity. Heat stroke is marked by temperatures greater than 40.6°C (105.1°F), altered sensorium or coma, and cessation of sweating. Treatment includes covering the patient with wet compresses followed by intravenous infusion of fluids appropriate to correct fluid and electrolyte losses.

Severe hyperthermia may be a heritable reaction to anesthetics (i.e., malignant hyperthermia) or a response to phenothiazines (i.e., neuroleptic malignant syndrome). Serotonin syndrome, which often includes fever, is classically associated with the simultaneous administration of two serotonergic agents. It can also occur after initiation of a single serotonergic drug that increases the serotonin level of individuals who are particularly sensitive to

serotonin. Occasionally, persons with CNS disorders such as paraplegia and persons with severe dermatologic conditions are unable to dissipate heat and can experience hyperthermia.

Hyperpyrexia is the term for extraordinarily high fever (>41.5° C or 106.7° F), which can occur in patients with severe infections but is most commonly observed in persons with CNS hemorrhages.

DIAGNOSTIC APPROACH TO THE ACUTELY ILL PATIENT WITH FEVER

Patterns of fever should be considered when assessing acutely ill, febrile persons. Evaluation includes determining the normal diurnal variation in body temperature, which often persists when patients have fever. Normally, body temperature peaks in the late afternoon or early evening.

Rigors (i.e., bed-shaking chills) often mark the onset of bacterial infection, typically bacteremia, although they may occur in other clinical situations, such as drug-induced fever or transfusion reactions. Wide swings in temperature may indicate an abscess. Malaria should be considered for anyone with fever who has visited or lived in malarious regions or who has relapsing fever accompanied by episodes of shaking chills and high fever separated by 1 to 3 days of normal body temperature and relative well-being. The timing of administration of anti-inflammatory drugs should be assessed because they may alter or blunt the febrile response. Most infectious diseases manifest with fever as an early finding and with subclinical and eventual clinical involvement of specific organ systems.

If fever occurs as the sole complaint or is associated with localized symptoms and signs, the diagnostic approach includes taking a thorough history, including an extensive review of systems, medical and surgical histories, and immunizations, including those from childhood. Antipyretics may be withheld to allow assessment of the fever trajectory. Elderly individuals, persons taking corticosteroids, and patients with chronic liver or renal disease may be less likely to mount a fever. All likely sources of disease, including travel, exposure to *Mycobacterium tuberculosis*, and occupational, hobby, animal, insect, and sexual contacts, should be assessed. Previous itineraries and activities, geographic risks of diseases, and the seasonality and incubation periods of possible disease exposures should be considered in returning travelers (Table 88-1).

Viral Infection

Acute febrile illnesses in young healthy adults usually are caused by viral infections, which do not require precise diagnosis because they are self-limited and seldom have therapeutic options. Upper respiratory tract symptoms of rhinorrhea, sore throat, cough, and hoarseness most often result from rhinovirus, coronavirus, parainfluenza virus, and adenoviruses. Adenovirus outbreaks occur among persons living in close quarters such as military barracks or college dormitories. Respiratory syncytial virus, human metapneumovirus, and human bocavirus infections occur in similar conditions and sometimes manifest with pneumonia.

A coronavirus causes the potentially fatal upper respiratory viral infection called *Middle East respiratory syndrome* (MERS).

TABLE 88-1 COMMON INFECTIONS IN TRAVELERS BY INCUBATION PERIOD

DISEASE	USUAL INCUBATION PERIOD (RANGE)	DISTRIBUTION
INCUBATION <14 DAYS		
Malaria, <i>Plasmodium falciparum</i>	6-30 days	Tropics, subtropics
Dengue	4-8 days (3-14 days)	Tropics, subtropics
Chikungunya	2-4 days (1-14 days)	Tropics, subtropics (Eastern Hemisphere)
Spotted fever, rickettsiae	Few days to 2-3 weeks	Causative species vary by region
Leptospirosis	7-12 days (2-26 days)	Widespread; most common in tropical areas
Enteric fever	7-18 days (3-60 days)	Especially in Indian subcontinent
Malaria, <i>Plasmodium vivax</i>	8-30 days (often >1 month to 1 year)	Widespread in tropics/subtropics
Influenza	1-3 days	Worldwide; can also be acquired en route
Acute human immunodeficiency virus (HIV) infection	10-28 days (10 days to 6 weeks)	Worldwide
Legionellosis	5-6 days (2-10 days)	Widespread
Encephalitis, arboviral (e.g., Japanese encephalitis, tick-borne encephalitis, West Nile virus)	3-14 days (1-20 days)	Specific agents vary by region
INCUBATION 14 DAYS TO 6 WEEKS		
Malaria, enteric fever, leptospirosis	See earlier incubation periods for relevant diseases	See earlier distribution for relevant diseases
Hepatitis A	28-30 days (15-50 days)	Most common in developing countries
Hepatitis E	26-42 days (2-9 weeks)	Widespread
Acute schistosomiasis (Katayama syndrome)	4-8 weeks	Most common after travel to sub-Saharan Africa
Amebic liver abscess	Weeks to months	Most common in developing countries
INCUBATION >6 WEEKS		
Malaria, amebic liver abscess, hepatitis E, hepatitis B	See earlier incubation periods for relevant diseases	See earlier distribution for relevant diseases
Tuberculosis	Primary, weeks; reactivation, years	Global distribution; rates and levels of resistance vary widely
Leishmaniasis, visceral	2-10 months (10 days to years)	Asia, Africa, South America

Modified from Centers for Disease Control and Prevention: CDC health information for international travel, 2012, New York, 2012, Oxford University Press.

It has caused pneumonia with acute respiratory distress syndrome (ARDS) and death in one half of infected individuals, and it is highly contagious.

Meningitis symptoms occur predominantly from enterovirus infections during summer months, although the symptom complex warrants urgent treatment of bacterial causes while the diagnostic process occurs. Febrile syndromes without meningitis are more common manifestations of enteroviral infections.

Arthropod-borne viruses such as California encephalitis virus; eastern, western, and Venezuelan equine encephalitis viruses; St. Louis encephalitis virus; and West Nile virus can produce self-limited febrile illnesses and encephalitis. Colorado tick fever is a biphasic illness seen after northwestern and southwestern tick exposures. It is characterized by high fevers and leukopenia. In New York State, a deer tick virus has been associated with numerous cases of fever and confusion.

Influenza causes sore throat, cough, myalgias, arthralgias, and headache in addition to fever, and it most often manifests in an epidemic pattern during winter months. It is unusual for fever to persist beyond 5 days in uncomplicated influenza. Prolonged fever in persons with diagnosed influenza warrants investigation and treatment of bacterial superinfection.

Early recognition of fever and dry cough led to the discovery and containment of the outbreak of severe acute respiratory syndrome (SARS). The epidemics of avian influenza and H1N1 pandemic strains in recent years are sobering reminders that influenza viruses have a remarkable ability to mutate, producing new immune-resistant strains on a regular basis. Preventive yearly influenza vaccination is important.

Mononucleosis syndromes of fever with detectable lymph node enlargement typify infections with Epstein-Barr virus (EBV), cytomegalovirus (CMV), primary human immunodeficiency virus (HIV), and *Toxoplasma gondii* (i.e., toxoplasmosis). Other manifestations of these infections include abnormal liver function test results, respiratory tract symptoms, and neurologic symptoms. Diagnosis of acute HIV infection, which can produce a mononucleosis-like syndrome, is an urgent issue.

Bacterial Infections

Pathogenic bacteria can infect all body parts and can cause a spectrum of localized illness warranting antibiotic therapy. For example, *Staphylococcus aureus* may cause skin abscesses or cellulitis. Highly pathogenic organisms may colonize individuals who have had contact with the health care system. Most concerning is the event of bacteria entering the bloodstream. Obtaining timely blood cultures before administering the antibiotics indicated for presumed bacterial infections in persons with common clinical syndromes can help to identify bloodstream pathogens and define the required course of treatment.

Fever may be the predominant clinical manifestation of *S. aureus* illness. This organism and the methicillin-resistant form (i.e., MRSA) frequently cause sepsis without an obvious primary site of infection. It should be considered in patients undergoing intravenous therapy or hemodialysis and in those who use intravenous drugs or who have severe chronic dermatitis. Bacteremia with staphylococci may cause hematogenous seeding of bones leading to osteomyelitis and heart valves leading to endocarditis in individuals; the bacteremia may also reflect these underlying

processes. Other common causes of bacteremia and their sources include *Streptococcus pneumoniae* (i.e., pneumonia), *Escherichia coli* (i.e., urinary tract and gastrointestinal sources), streptococci (i.e., skin), and anaerobes (i.e., gastrointestinal tract).

Listeria monocytogenes bacteremia is seen predominantly in persons with depressed cell-mediated immunity. It is the most common manifestation of listeriosis in these hosts. Many with listeriosis may have meningitis and warrant lumbar puncture for cerebrospinal fluid culture.

Typhoid and paratyphoid fever (i.e., enteric fever) are common in many low-income countries. Patients may have fever alone as the primary clinical manifestation. Travelers to six countries account for 80% of U.S. cases: India, Mexico, Philippines, Pakistan, El Salvador, and Haiti. Fever with headache and an insidious onset with an unremarkable physical examination is common, although a faint and transient rash (i.e., rose spots) may appear by the second week of illness. Symptoms may include diarrhea, constipation, vague abdominal discomfort, and sometimes dry cough. Diagnosis depends on the culture of blood or stool.

Fever with Localized Symptoms and Signs

Localized bacterial infection can be apparent, as in cases of abscess, cellulitis, or otitis media, or clinically occult. It can develop as an undifferentiated febrile syndrome. Careful inspection of mucous membranes and conjunctiva may reveal petechiae, which are clues to meningococcemia or infective endocarditis. Finding heart murmurs in the setting of fever may suggest endocarditis and warrant additional blood cultures. Pulmonary signs in pneumonia include rales and evidence of consolidation, but persons with cryptococcosis, coccidioidomycosis, histoplasmosis, psittacosis, legionellosis, or pneumocystis pneumonia may show few signs.

These infections should be suspected based on exposure history and the host's immune status. It is important to assess the size of the liver, spleen, and lymph nodes, particularly in cases of viral infection. A swollen joint may indicate septic arthritis. A complete neurologic examination, including cranial nerves and testing for meningeal signs, may indicate CNS infection.

Malaria, bacterial sepsis, and bacterial infections of the lung, urinary tract, CNS, and intestines with resultant bacteremia warrant urgent initiation of empirical treatment while awaiting final identification and sensitivities. For febrile patients with features suggesting a bacterial infection, evaluation should include complete blood counts with differential and platelet counts, blood smears for those at risk for malaria or babesiosis, urinalysis, throat and blood cultures, and a chest radiograph.

Fevers with rash as a prominent feature warrant exclusion of life-threatening infectious diseases, including meningococcemia, toxic shock syndrome (TSS), and Rocky Mountain spotted fever (RMSF). Characterization of the rash can help. Clues to some of the common infections exhibiting fever as the sole feature and those causing fever with rash are provided in [Tables 88-2, 88-3, and 88-4](#). [Tables 88-5 and 88-6](#) list common syndromes associated with imported fevers when assessing travelers.

FEVER OF UNKNOWN ORIGIN

Most febrile conditions resolve or are readily diagnosed and treated, but some fevers can persist and remain unexplained.

**TABLE 88-2** INFECTIONS EXHIBITING FEVER AS THE SOLE OR DOMINANT FEATURE

INFECTIOUS AGENT OR SOURCE	EPIDEMIOLOGIC EXPOSURE AND HISTORY	DISTINCTIVE CLINICAL AND LABORATORY FINDINGS
VIRUSES		
Rhinovirus, adenovirus, parainfluenza	None (adenovirus in epidemics)	Often URI symptoms; throat and rectal cultures; rapid viral antigen testing
Middle East respiratory syndrome (MERS)	Travel to Arabian Peninsula or contact from Middle East	Pneumonia with ARDS; viral antigen testing of sputum; PCR of normally sterile sites (CDC)
Enteroviruses (nonpolioviruses: coxsackieviruses, echovirus)	Summer, epidemic	Occasionally aseptic meningitis, rash, pleurodynia, herpangina; serologic or nucleic acid testing (PCR)
Influenza	Winter, epidemic	Headache, myalgias, arthralgias; nasopharyngeal culture, rapid viral antigen testing
EBV, CMV	Close personal contact; blood or tissue exposure; occupational or perinatal exposure	Monospot test, EBV specific antibodies; EBV PCR in immunocompromised; CMV IgM shell vial assay; CMV antigenemia assay; CMV DNA of CSF; culture and histopathology of tissues
Colorado tick fever	Southwest and northwest regions, tick exposure	Biphasic illness, leukopenia; blood, CSF cultures, serologic or PCR
Deer tick virus (Powassan virus)	New York State tick exposure	Altered mentation or encephalitis; serum and CSF IgM (CDC)
BACTERIA		
<i>Staphylococcus aureus</i>	IV drug users, IV catheters, hemodialysis, dermatitis	Must exclude endocarditis; blood cultures
<i>Listeria monocytogenes</i>	Depressed cell-mediated immunity	Meningitis may also be present; blood, CSF cultures
<i>Salmonella typhi</i> , <i>Salmonella paratyphi</i>	Food or water contaminated by carrier or patient	Headache, myalgias, diarrhea, or constipation, transient rose spots; blood, marrow, or stool cultures
Streptococci	Valvular heart disease	Low-grade fever, fatigue; blood cultures
ANIMAL EXPOSURE		
<i>Coxiella burnetii</i> (Q fever)	Exposure to infected livestock, parturient animals	Headache, occasionally pneumonitis, hepatitis, culture-negative endocarditis; serologic testing
<i>Leptospira interrogans</i>	Water contaminated by urine From dogs, cats, rodents, small mammals	Headache, myalgias, conjunctival suffusion, biphasic illness, aseptic meningitis; serologic testing

ARDS, Acute respiratory disease syndrome; CDC, Centers for Disease Control and Prevention case definition; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; IgM, immunoglobulin M; IV, intravenous; PCR, polymerase chain reaction; URI, upper respiratory infection.

TABLE 88-3 DIFFERENTIAL DIAGNOSIS OF INFECTIOUS AGENTS PRODUCING FEVER AND RASH

MACULOPAPULAR, ERYTHEMATOUS LESIONS	DIFFUSE ERYTHRODERMA
Enterovirus	Group A streptococci (scarlet fever, toxic shock syndrome)
EBV, CMV, <i>Toxoplasma gondii</i>	<i>Staphylococcus aureus</i> (toxic shock syndrome)
Acute HIV infection	DISTINCTIVE RASH
Colorado tick fever virus	Ecthyma gangrenosum: <i>Pseudomonas aeruginosa</i>
<i>Salmonella typhi</i>	Erythema migrans: Lyme disease
<i>Leptospira interrogans</i>	MUCOUS MEMBRANE LESIONS
Measles virus	Vesicular pharyngitis: coxsackievirus A
Rubella virus	Palatal petechiae: rubella, EBV, scarlet fever (group A streptococci)
Hepatitis B virus	Erythema: toxic shock syndrome (<i>Staphylococcus aureus</i> and group A streptococci)
<i>Treponema pallidum</i>	Oral ulceronodular lesion: <i>Histoplasma capsulatum</i>
Parvovirus B19	Koplik's spots: measles virus
Human herpesvirus 6	
VESICULAR LESIONS	
Varicella-zoster virus	
Herpes simplex virus	
Coxsackievirus A	
<i>Vibrio vulnificus</i>	
CUTANEOUS PETECHIAE	
<i>Neisseria gonorrhoeae</i>	
<i>Neisseria meningitidis</i>	
<i>Rickettsia rickettsii</i> (Rocky Mountain spotted fever)	
<i>Rickettsia typhi</i> (murine typhus)	
<i>Ehrlichia chaffeensis</i>	
Echoviruses	
<i>Streptococcus viridans</i> (endocarditis)	

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus.

**TABLE 88-4** FEVER AND RASH IN VIRAL INFECTION

VIRUS	DISEASE FEATURES	INCUBATION AND EARLY SYMPTOMS
Coxsackie, ECHO virus	Maculopapular rubelliform, 1-3 mm, faint pink, begins on face, spreading to chest and extremities Herpetiform vesicular stomatitis with peripheral exanthema (papules and clear vesicles on an erythematous base), including palms and soles (hand, foot, and mouth disease)	Summertime No itching or lymphadenopathy Multiple cases in household or community-wide epidemic Mostly diseases of children
Measles	Erythematous, maculopapular rash begins on upper face and spreads down to involve extremities, including palms and soles. Koplik's spots are blue-gray specks on a red base found on buccal mucosa near second molars. Atypical measles occurs in individuals who received killed vaccine and then are exposed to measles. The rash begins peripherally and is urticarial, vascular, or hemorrhagic.	Incubation period 10-14 days First, severe upper respiratory symptoms, coryza, cough, and conjunctivitis; then Koplik's spots, then rash
Rubella	Maculopapular rash beginning on face and moving down; petechiae on soft palate	Incubation 12-23 days Adenopathy; posterior auricular, posterior cervical, and suboccipital
Varicella	Generalized vesicular eruption; pruritic lesions in different stages from erythematous macules to vesicles to crusted; spread from trunk centrifugally; zoster lesions are painful and often dermatomal	Incubation 14-15 days; late winter, early spring Herpes zoster is a reactivation, occurs any season
Herpes simplex virus	Oral primary: small vesicles on pharynx, oral mucosa that ulcerates; painful and tender Recurrent: vermilion border, one or few lesions, genital; may be asymptomatic or appear similar to oral lesions on genital mucosa	Incubation 2-12 days
Hepatitis B and C virus	Prodrome in one fifth; erythematous, maculopapular rash, urticaria Leukocytoclastic vasculitis occurs in hepatitis C	Arthralgias, arthritis; abnormal liver function test results; hepatitis B antigenemia
Epstein-Barr virus	Erythematous, maculopapular rash on trunk and proximal extremities Occasionally urticarial or hemorrhagic	Transiently occurs in 5-10% of patients during first week of illness
Human immunodeficiency virus	Maculopapular truncal rash may occur as early manifestation of infection	Associated fever, sore throat, and lymph node enlargement may persist for 2 or more weeks

TABLE 88-5 COMMON SYNDROMES AND DISEASES ASSOCIATED WITH FEVER IN RETURNED TRAVELERS

SORE THROAT	COUGH	ABDOMINAL PAIN	ARTHRALGIA OR MYALGIA	DIARRHEA
Bacterial pharyngitis	Amebiasis (hepatic)	Amebiasis (intestinal)	Arboviruses	Amebiasis (intestinal)
Diphtheria	Anthrax	Anthrax	Dengue	Anthrax
Infectious mononucleosis	Bacterial pneumonia	<i>Campylobacter enteritis</i>	Yellow fever	<i>Campylobacter enteritis</i>
HIV seroconversion	Filarial fever	Legionnaires disease	Babesiosis	HIV seroconversion
Lyme disease	TPE	Malaria	Bartonellosis	Legionnaires disease
Poliomyelitis	Histoplasmosis	Measles	Brucellosis	Malaria melioidosis
Psittacosis	Legionnaires' disease	Melioidosis	Erythema nodosum leprosum	Plague
Tularemia	Leishmaniasis (visceral)	Plague	Hepatitis (viral)	Relapsing fever
Viral hemorrhagic fever (Lassa)	Loeffler syndrome	Relapsing fevers	Histoplasmosis	Salmonellosis
Nonspecific viral URTI	Malaria	Salmonellosis	HIV seroconversion	Schistosomiasis (acute)
	Measles	Schistosomiasis (acute)	Legionnaires disease	Shigellosis
	Melioidosis	Shigellosis	Leptospirosis	Typhoid in children
	Plague	Typhoid fever	Lyme disease	Viral hemorrhagic fevers
	Q fever	Viral hemorrhagic fevers	Malaria	Yersiniosis
	Relapsing fever	Yersiniosis	Plague	
	Schistosomiasis (acute)		Poliomyelitis	
	Toxocariasis		Q fever	
	Trichinosis		Relapsing fevers	
	Tuberculosis		Secondary syphilis	
	Tularemia		Toxoplasmosis	
	Typhoid and paratyphoid		Trichinosis	
	Typhus		Trypanosomiasis (African)	
	Viral hemorrhagic fevers		Tularemia	
	Nonspecific viral URTIs		Typhoid and paratyphoid	
			Typhus	
			Viral hemorrhagic fevers	

From Beeching N, Fletcher T, Wijaya L: Returned travelers. In Zuckerman JN, editor: Principles and practice of travel medicine, ed 2, Boston, 2013, Wiley-Blackwell, p 271.
HIV, Human immunodeficiency virus; TPE, tropical pulmonary eosinophilia; URTI, upper respiratory tract infection.

Table 88-7 shows the most common causes of unexplained fevers.

The term *fever of unknown origin* (FUO) identifies a pattern of fever with temperatures greater than 38.3° C (101° F) on several occasions over more than 3 weeks after an initial diagnostic

work-up for which the diagnosis remains uncertain. Verifying the presence or absence of fever is important; up to 35% of 347 patients admitted to the National Institutes of Health (NIH) for evaluation of prolonged fever were determined not to have significant fever or had fever of factitious origin. Cases of FUO are

TABLE 88-6 COMMON CLINICAL FINDINGS AND ASSOCIATED INFECTIONS

CLINICAL FINDINGS	INFECTIONS TO CONSIDER AFTER TROPICAL TRAVEL
Fever and rash	Dengue, chikungunya, rickettsial infections, enteric fever (skin lesions may be sparse or absent), acute HIV infection, measles, acute schistosomiasis
Fever and abdominal pain	Enteric fever, amebic liver abscess
Undifferentiated fever and normal or low white blood cell count	Dengue, malaria, rickettsial infection, enteric fever, chikungunya
Fever and hemorrhage	Viral hemorrhagic fevers (dengue and others), meningococemia, leptospirosis, rickettsial infections
Fever and eosinophilia	Acute schistosomiasis; drug hypersensitivity reaction; fascioliasis and other parasitic infections (rare)
Fever and pulmonary infiltrates	Common bacterial and viral pathogens; legionellosis, acute schistosomiasis, Q fever, melioidosis
Fever and altered mental status	Cerebral malaria, viral or bacterial meningoencephalitis, African trypanosomiasis
Mononucleosis syndrome	Epstein-Barr virus, cytomegalovirus, toxoplasmosis, acute HIV infection
Fever persisting >2 weeks	Malaria, enteric fever, Epstein-Barr virus, cytomegalovirus, toxoplasmosis, acute HIV, acute schistosomiasis, brucellosis, tuberculosis, Q fever, visceral leishmaniasis (rare)
Fever with onset >6 wk after travel	Vivax malaria, acute hepatitis (B, C, or E), tuberculosis, amebic liver abscess

Modified from Centers for Disease Control and Prevention: CDC health information for international travel 2012, New York, 2012, Oxford University Press.
HIV, Human immunodeficiency virus.

categorized as classic FUO, health care–associated FUO, neutropenic (immune-deficient) FUO, and HIV-related FUO. Each of these FUO subtypes can have unique causes.

Classic Fever of Unknown Origin

The most common causes of classic FUO are infections, malignancies, and noninfectious inflammatory disorders; miscellaneous causes and undiagnosed cases account for the remaining categories. Historically, infections have made up the largest category, representing 25% to 50% of cases. Abscesses, endocarditis, tuberculosis, complicated urinary tract infections, and biliary tract diseases have consistently been among the most important. Abscesses account for almost one third of infectious causes, and most are intra-abdominal or pelvic in origin. Perforation of a colonic diverticulum or appendicitis can sometimes lead to large, walled-off abdominal abscesses with few localizing signs.

During the past 50 years, the improvement of imaging studies and their greater accessibility have made abdominal or pelvic abscesses and malignancies more easily detected and less likely to be the cause of prolonged, undiagnosed fever. Malignant neoplasms can induce fever directly through the production and release of pyrogenic cytokines and indirectly by undergoing spontaneous or induced necrosis or creating conditions conducive to secondary infections. Endovascular infections are usually detectable by blood cultures, although slow-growing or fastidious organisms may make detection difficult.

TABLE 88-7 COMMON CAUSES OF FEVER OF UNKNOWN ORIGIN

INFECTIONS
Abscesses
Brucellosis
Catheter infections
Cytomegalovirus
Coccidioidomycosis
Histoplasmosis
Human immunodeficiency virus (HIV) infection
Infective endocarditis
Intra-abdominal, subdiaphragmatic, and pelvic disease
Liver and biliary tract disease
Lyme disease
<i>Mycobacterium tuberculosis</i>
Osteomyelitis
Sinusitis
Toxoplasmosis
Urinary tract infection
AUTOIMMUNE CONDITIONS
Adult Still's disease
Familial Mediterranean sarcoidosis
Rheumatoid arthritis
Systemic lupus erythematosus
Temporal arteritis
MALIGNANCY
Hepatocellular carcinoma
Leukemia
Metastatic cancers
Pancreatic cancer
Renal cell carcinoma
MISCELLANEOUS CAUSES
Deep vein thrombosis, pulmonary embolism
Hyperthyroidism
Kikuchi's disease
Periodic fever (tumor necrosis factor receptor associated)

Infections, including tuberculosis, typhoid fever, malaria, and amebic liver abscesses, remain the most frequent causes of FUO in developing countries. The incidence of some FUOs vary in incidence according to geographic location. Classic FUO may occur as familial Mediterranean fever among Ashkenazi Jews; in Kikuchi's disease, which is an unusual form of necrotizing lymphadenitis seen primarily in Japan; and as TNF receptor–associated periodic fever (TRAPS), formerly called familial Hibernian fever, which is an inherited periodic fever syndrome described originally in Ireland.

The proportion of FUOs due to noninfectious inflammatory diseases and undiagnosed conditions has risen. Of the connective tissue diseases, juvenile rheumatoid arthritis (i.e., Still's disease), other variants of rheumatoid arthritis, and systemic lupus erythematosus predominate among younger patients. Temporal arteritis and polymyalgia rheumatica syndromes are more common among elderly patients.

Fever may be blunted or absent in up to one third of elderly individuals with serious conditions. Older people may more often have atypical clinical presentations of common infectious and noninfectious diseases. For example, elderly persons may have tuberculosis without cough or fever, infective endocarditis with fatigue and weight loss but without fever, abdominal abscesses with little abdominal tenderness found on physical examination. Leukocytosis and increased band forms are more

likely to be associated with a serious infection. HIV should be considered as a possible cause of FUO in older patients, although it is not usually suspected early in the course of FUO.

Fever in returned travelers is most often caused by common infections, such as malaria and respiratory or urinary tract infections. However, fever caused by dengue, typhoid fever, or amebic liver abscess is increasingly identified, especially among international travelers returning from the tropics. Katayama fever is a febrile syndrome occurring after exposure to fresh water schistosomes in endemic areas. It may resolve spontaneously or may require treatment with antiparasitic agents to prevent sequelae that carry severe morbidity. A travel history should be obtained, and it may redirect the entire work-up.

Health Care–Associated Fever of Unknown Origin

Some FUOs are associated with health care practices, including surgical procedures, urinary and respiratory tract instrumentation, intravascular devices, drug therapy, and immobilization. Quality control measures are set up to minimize and avoid bloodstream infections and decubitus ulcers. Drug-related fever, septic thrombophlebitis, recurrent pulmonary emboli, and *Clostridium difficile* colitis must be considered in the work-up of hospitalized patients who develop fever greater than 38° C (100.4° F) for more than 3 days if it was not present on admission.

Immune Deficiency–Associated Fever of Unknown Origin

Immunosuppressed individuals have the highest incidence of FUO of any group of patients. Due to impaired immune responses, signs of inflammation other than fever are notoriously absent or diminished, producing atypical clinical manifestations and an absence of radiologic abnormalities for what otherwise would be readily diagnosed infections. In patients with impaired cell-mediated immunity, FUO often results from conditions other than pyogenic bacterial infections (e.g., fungi, CMV).

Neutropenia is a dangerous condition that can be considered a subclass of immunodeficiency. Persons with profound neutropenia are at high risk for bacterial and fungal infections. Episodes of fever are common in patients with neutropenia. Many episodes are short lived because they respond quickly to treatment or are manifestations of rapidly fatal infections.

Bacteremia and sepsis can cause rapid deterioration in neutropenic patients, and empirical, broad-spectrum antibiotics should be administered promptly without waiting for the results of cultures. However, only about 35% of prolonged episodes of febrile neutropenia respond to broad-spectrum antibiotic therapy. If fevers persist after 3 days of treatment with broad-spectrum antibiotics, diagnostic tests to explore fungal causes should be considered along with empirical antifungal treatment.

Human Immunodeficiency Virus–Related Fever of Unknown Origin

The primary phase of HIV infection is characterized by a mononucleosis-like illness in which fever is a prominent feature (see [Chapter 101](#)). After symptoms of the primary phase of HIV infection resolve, patients enter a long period of subclinical infection during which they are usually afebrile. In the later phases of

untreated HIV infection, episodes of fever become common, often signifying a superimposed illness. Many of these are potentially devastating opportunistic infections, which tend to manifest in atypical fashion because of the severe immunodeficiency. Patients with acquired immunodeficiency syndrome (AIDS) often have multiple infections simultaneously. After highly active antiretroviral therapy (HAART) has been started and the HIV viral load is effectively suppressed, the frequency of FUO in HIV-infected patients falls markedly.

Approach to the Patient with Fever of Unknown Origin

Evaluation of a patient with FUO typically includes verification that the patient has fever, consideration of the fever pattern, a comprehensive history, repeated physical examinations, appropriate laboratory investigations, key imaging studies, and invasive diagnostic procedures. The physical examination should scrutinize the patient more closely than usual because key physical abnormalities in patients with FUO are subtle and require repeated examinations to be appreciated.

Work-up of a patient with an FUO should focus on the history, physical examination, and initial laboratory data. In place of rational diagnostic thinking, there is a temptation to order multiple comprehensive laboratory and imaging studies. Rather than leading to a diagnosis, this shotgun approach may result in enormous expense, false-positive results, and unnecessary additional investigations that may obfuscate the true diagnosis.

A fundamental principle in the management of classic FUO is that therapy should be withheld, whenever possible, until the cause of the fever has been determined, so that treatment can be tailored to a specific diagnosis. The exception is in the setting of the immunocompromised host because rapid empirical treatment is most often needed.

SPECIFIC CONDITIONS AND EXPOSURES CAUSING FEVER

Fever after Animal Exposures

Q Fever

Q fever is a widespread zoonotic infection caused by the pathogen *Coxiella burnetii* that has acute and chronic manifestations. The primary source of infection is infected cattle, sheep, and goats. The organism can exist for months in soil and can become airborne. The onset of disease is typically abrupt, and high-grade fever (40° C or 104° F), fatigue, headache, and myalgias are the most common symptoms. Acute Q fever is usually a mild disease that resolves spontaneously within 2 weeks. Q fever endocarditis usually occurs in patients with previous valvular damage or immunocompromise, and it is often the predominant manifestation of chronic infection.

An immunofluorescence assay is the reference method for the serodiagnosis of Q fever. Consideration of doxycycline therapy is warranted only for patients who are symptomatic.

Leptospirosis

Leptospirosis is a zoonotic infection with protean manifestations caused by the spirochete *Leptospira interrogans*. It is distributed worldwide, but most clinical cases occur in the tropics. The

organism infects rodents, cattle, swine, dogs, horses, sheep, and goats, and it is shed in the urine. Humans most often become infected after exposure to environmental sources, such as contaminated water.

Leptospirosis may manifest as a subclinical illness followed by seroconversion, a self-limited systemic infection, or a severe, potentially fatal illness accompanied by multiorgan failure. Acute illness manifests with the abrupt onset of fever, rigors, myalgias, and headache in 75% to 100% of patients. Conjunctival suffusion in a patient with a nonspecific febrile illness accompanied by lymphadenopathy, hepatomegaly, and splenomegaly points to a diagnosis of leptospirosis.

During the second phase of illness, fever is less pronounced, but headache and myalgias can be severe, and aseptic meningitis is an important manifestation. In some patients with leptospirosis, the clinical course may be complicated by jaundice (although liver failure is rare), renal failure, uveitis, hemorrhage, ARDS, myocarditis, and rhabdomyolysis (i.e., Weil's syndrome).

Because the clinical features and routine laboratory findings of leptospirosis are not specific, a high index of suspicion must be maintained. The diagnosis is usually made by serologic testing for *L. interrogans*. Symptomatic individuals warrant treatment with doxycycline.

Brucellosis

Brucellosis is a zoonotic infection caused by *Brucella melitensis*. It is transmitted to humans by contact with fluids from infected animals (i.e., sheep, cattle, goats, pigs, or other animals) or derived food products such as unpasteurized milk and cheese.

Clinical manifestations of brucellosis include fever, night sweats, malaise, anorexia, arthralgias, fatigue, weight loss, and depression. Patients may have fever and a multitude of complaints but no other objective findings. The onset of symptoms may be abrupt or insidious, developing over several days to weeks. The musculoskeletal and genitourinary systems are the most common sites of involvement. Neurobrucellosis, endocarditis, and hepatic abscesses occur in 1% to 2% of cases.

The diagnosis of brucellosis should be considered for an individual with otherwise unexplained fever and nonspecific complaints who has had a possible exposure. Ideally, the diagnosis is made by culture of the organism from blood or other sites, such as bone marrow. Serologic tests include tube agglutination and enzyme-linked immunosorbent assay (ELISA). For adults with nonfocal disease, treatment with doxycycline and rifampin is suggested.

Fever and Rash

The most concerning diseases associated with fever and rash are meningococcemia, staphylococcal TSS, and RMSF.

Bacterial Meningitis

Neisseria meningitidis is the leading cause of bacterial meningitis in children and young adults in the United States. Recent experience in New York City identified HIV patients as being at increased risk for meningococcal disease.

Manifestations of meningococcal disease can range from transient fever and bacteremia to fulminant disease, with death ensuing within hours of the onset of clinical symptoms. Acute

systemic meningococcal disease may manifest as one of three syndromes: meningitis alone, meningitis with accompanying meningococcemia, and meningococcemia without clinical evidence of meningitis.

The typical initial symptoms of meningitis due to *N. meningitidis* consists of the sudden onset of fever, nausea, vomiting, headache, decreased ability to concentrate, and myalgias in an otherwise healthy patient. A petechial rash appears as discrete lesions 1 to 2 mm in diameter, most frequently occurring on the trunk and lower portions of the body. More than 50% of patients have petechiae at clinical presentation. Petechiae can coalesce into larger purpuric and ecchymotic lesions.

Staphylococcal Toxic Shock Syndrome

S. aureus strains produce exotoxins that cause three syndromes: food poisoning, caused by ingestion of *S. aureus* enterotoxin; scalded skin syndrome, caused by exfoliative toxin; and TSS, caused by toxic shock syndrome toxin 1 (TSST-1) and other enterotoxins. About one half of reported TSS cases are menstrual, associated with bacterial growth on highly absorbent tampons. Nonmenstrual TSS has been associated with surgical and postpartum wound infections, mastitis, septorhinoplasty, sinusitis, osteomyelitis, arthritis, burns, cutaneous and subcutaneous lesions (especially of the extremities, perianal area, and axillae), and respiratory infections after influenza. Some MRSA strains can produce TSST-1, and patients infected with these strains may develop TSS.

The Centers for Disease Control and Prevention (CDC) case definition for a confirmed case includes several criteria. Patients must have fever greater than 38.9° C, hypotension, diffuse erythroderma, desquamation (unless the patient dies before desquamation can occur), and involvement of at least three organ systems. Although 80% to 90% of TSS patients have *S. aureus* isolated from mucosal or wound sites, the isolation of *S. aureus* is not required for the diagnosis of staphylococcal TSS.

Rickettsial Infections

RMSF is a potentially lethal but usually curable tick-borne disease. Most cases of RMSF occur in the spring and early summer in endemic areas, particularly in the south central and southeastern states, when outdoor activity is most common. The etiologic agent, *Rickettsia rickettsii*, is a gram-negative, obligate intracellular bacterium that is usually transmitted through a tick bite. Up to one third of patients with proven RMSF do not recall a recent tick bite or recent tick contact.

In the early phases of illness, most patients have nonspecific signs and symptoms such as fever, headache, malaise, myalgias, arthralgias, and nausea with or without vomiting. Most patients with RMSF develop a rash between the third and fifth days of illness. The rash typically begins with pink, blanching macules that evolve to a deep red color and then become hemorrhagic. The lesions begin at the wrists, forearms, and ankles and then spread to the arms, thighs, trunk, and face.

The diagnosis of RMSF is based on a constellation of symptoms and signs in an appropriate epidemiologic setting (e.g., endemic area in the spring or early summer). In later illness, the diagnosis can be made by skin biopsy and confirmed serologically.

Murine typhus is a worldwide illness caused by *Rickettsia typhi* organisms that are transmitted by fleas. It produces a moderately severe illness characterized by fever, rash, and headache. Disease in the United States has been reported in Texas and Southern California.

Rickettsia africae, the cause of African tick-bite fever, occurs in travelers returning from East Africa. It produces a large eschar with a febrile syndrome similar to RMSF. Rickettsial infections respond to treatment with doxycycline and warrant rapid initiation of treatment.

Lyme Disease

Lyme disease is a tick-borne illness caused by pathogenic species of the spirochete *Borrelia burgdorferi* in the United States. Other species in Europe and Asia can cause more aggressive presentations. Localized disease includes erythema migrans in 80% of patients and nonspecific findings that resemble a viral syndrome. Erythema migrans is an expanding macule that forms an annular lesion with a clearing middle.

Early disseminated Lyme disease with acute neurologic or cardiac involvement usually occurs weeks to several months after the tick bite and may be the first manifestation of the disease. Nonspecific symptoms (e.g., headache, fatigue, arthralgias) may persist for months after treatment of Lyme disease. There is no evidence that these persistent subjective complaints represent ongoing active infection. Co-infection with *Babesia* and *Ehrlichia* is common, and these infections should be considered in persons diagnosed with Lyme disease.

Human Ehrlichiosis

The principal vector of *Ehrlichia chaffeensis*, the agent that causes human monocytic ehrlichiosis (HME), is the Lone Star tick (*Amblyomma americanum*). Patients typically have an acute illness that has an incubation period of 1 to 2 weeks. Most patients are febrile and have nonspecific symptoms such as malaise, myalgia, headache, and chills.

One feature that may distinguish HME from human granulocytic anaplasmosis (HGA), another tick-borne illness caused by *Anaplasma phagocytophilum*, is a rash (macular, maculopapular, or petechial). This rash occurs in about 30% of patients with HME but is rare in patients with HGA.

The preferred and most widely available diagnostic method for ehrlichiosis is the indirect fluorescent antibody test. The diagnosis should be considered in all patients with Lyme disease or babesiosis. Treatment with doxycycline should be initiated for all patients suspected of having ehrlichiosis or anaplasmosis.

Viral Infections Associated with Rash

The typical manifestations of viral infections associated with rash may unequivocally establish the cause of a febrile syndrome. For example, varicella-zoster virus infection manifests with distinctive lesions of chickenpox or herpes zoster (i.e., shingles). The resurgence of measles mandates the ability to recognize its rash.

Acute onset of high fever characterizes viral hemorrhagic fevers, along with bleeding complications and high mortality rates in some cases. Arthropods often transmit viral infections, including dengue, which is one of the most common causes of fever in returned travelers. The deer tick virus identified in New

York State causes a syndrome of fever and confusion with or without rash.

Fever with Lymphadenopathy

Generalized and localized lymphadenopathy can be major manifestations of some infectious diseases, such as in mononucleosis syndromes, tuberculosis, HIV infection, and pyogenic infections.

Infectious mononucleosis is characterized by a triad of fever, tonsillar pharyngitis, and lymphadenopathy. EBV is a widely disseminated herpesvirus that is spread by intimate contact between susceptible persons and EBV shedders. Lymph node involvement in infectious mononucleosis is typically symmetrical and more commonly involves the posterior cervical than the anterior chains. The posterior cervical nodes are deep beneath the sternocleidomastoid muscles and must be carefully palpated. The nodes may be large and moderately tender. Lymphadenopathy may also become more generalized including enlargement of the spleen, which distinguishes infectious mononucleosis from other causes of pharyngitis.

Lymphadenopathy peaks in the first week and then gradually subsides over 2 to 3 weeks. Splenomegaly is seen in 50% of patients with infectious mononucleosis and usually begins to recede by the third week of the illness.

Patients with a clinical picture of infectious mononucleosis should have a white blood cell count with differential and a heterophile (Monospot) test. If the heterophile test result is positive, no further testing is necessary when the clinical scenario is compatible with typical infectious mononucleosis. If the heterophile test result is negative but there is still a strong clinical suspicion of EBV infection, the Monospot test can be repeated because results can be negative early in clinical illness.

If the clinical syndrome is prolonged or the patient does not have a classic EBV syndrome, immunoglobulin M (IgM) and immunoglobulin G (IgG) viral capsid antigen (VCA) and Epstein-Barr nuclear antigen (EBNA) antibodies should be measured. IgG EBNA detected within 4 weeks of symptom onset excludes acute primary EBV infection as an explanation and should prompt consideration of EBV-negative causes of mononucleosis.

Cytomegalovirus

The spectrum of human illness caused by CMV is diverse and mostly depends on the host. CMV infection in the immunocompetent host usually is asymptomatic or may manifest as a mononucleosis-like syndrome. Transmission occurs through multiple routes.

The mononucleosis syndrome associated with CMV infection has been described as typhoidal because systemic symptoms and fever predominate, and signs of enlarged cervical nodes and splenomegaly are not as commonly seen as they are in EBV infection. Diarrhea, fever, fatigue, and abdominal pain are common symptoms. Immunocompromised patients, such as those who have received transplants, may have serious, life-threatening infections such as pneumonitis, hepatitis, colitis, and retinitis. Serology provides indirect evidence of recent CMV infection based on changes in antibody titers at different time points during the

clinical illness. Serologies are also helpful in determining past exposure to CMV. This information is particularly relevant for monitoring immunosuppressed hosts at risk for CMV reactivation syndromes.

Primary Human Immunodeficiency Virus Infection

Because a variety of symptoms and signs may be associated with acute, symptomatic HIV infection, all patients with mononucleosis syndromes should undergo HIV testing. Published series consistently report that the most common findings are fever, generalized lymphadenopathy, sore throat, rash, myalgia or arthralgia, and headache. The HIV plasma viral load should be assessed to detect acute infection because the ELISA result may not indicate positivity for HIV until months later.

Toxoplasmosis

Toxoplasmosis, an infection with a worldwide distribution, is caused by the intracellular protozoan parasite *T. gondii*. Humans can acquire *Toxoplasma* organisms through ingestion of contaminated meat, vertical transmission, blood transfusion, exposure to oocysts from cat feces, or organ transplantation.

Immunocompetent persons with primary infection are usually asymptomatic, but latent infection can persist for the life of the host. When symptomatic infection does occur, the most common manifestation is bilateral, symmetrical, nontender cervical adenopathy. Patients may have headache, fever, and fatigue. Symptoms usually resolve within several weeks. In AIDS patients or other immunocompromised hosts who have been previously infected, *T. gondii* infection may reactivate in the brain, causing abscesses and encephalitis.

Infections Causing Regional Lymphadenopathy

Scrofula (i.e., tuberculous cervical adenitis) develops in a subacute to chronic pattern. Low-grade fever is usually associated with a large mass of matted cervical lymph nodes. In children, *M. tuberculosis* is the etiologic agent, but in adults, *Mycobacterium avium* complex and *Mycobacterium scrofulaceum* are more commonly found. Surgical excision is the treatment of choice.

Cat-Scratch Disease

Cat-scratch disease, a condition caused by *Bartonella henselae*, is characterized by self-limited regional lymphadenopathy after a cat scratch or transmission from another vector. Other manifestations can include visceral organ, neurologic, and ocular involvement. In 85% to 90% of children, cat-scratch disease manifests as a localized cutaneous and lymph node disorder near the site of organism inoculation. In some individuals, the organisms disseminate and infect the liver, spleen, eye, bone, or CNS. Patients with localized disease usually have a self-limited illness, whereas those with disseminated disease can have life-threatening complications. *B. henselae* infection should be considered in the initial evaluation of FUO in children.

The diagnosis of cat-scratch disease is based on typical clinical findings (i.e., lymphadenopathy) associated with probable exposure to cats or fleas. Laboratory testing that supports the diagnosis includes a positive *B. henselae* antibody titer or biopsy of a

lymph node with a positive Warthin-Starry stain or polymerase chain reaction (PCR) analysis of tissue.

Pyogenic Infection

S. aureus and group A streptococcal (GAS) infections can produce acute, suppurative lymphadenitis. Enlarged and tender lymph nodes usually are found in the submandibular, cervical, axillary, or inguinal areas. Patients have fever and leukocytosis. Pyoderma, pharyngitis, and periodontal infections are usually the primary sites of infection. Management includes drainage and antibiotics.

Plague

Bubonic plague is a bacterial syndrome caused by *Yersinia pestis* that usually consists of fever, headache, and a large mat of inguinal, axillary, or cervical lymph nodes. Lymph nodes suppurate and drain spontaneously. The diagnosis should be considered for acutely ill patients in the southwestern United States with possible exposure to fleas and rodents. Gram-negative coccobacilli can be seen in lymph node aspirates. The characteristic safety-pin appearance of *Y. pestis* with dark blue staining of polar bodies is seen with Wayson stain.

Sexually Transmitted Diseases

Inguinal lymphadenopathy associated with sexually transmitted diseases can be unilateral or bilateral. In primary syphilis, enlarged nodes are discrete, firm and nontender. Tender lymphadenopathies with matting are seen in lymphogranuloma venereum. The lymphadenopathy of chancroid is most often unilateral and manifests with pain and fused lymph nodes. Primary genital herpes infection also causes tender inguinal lymphadenopathy.

FACTITIOUS FEVER AND SELF-INDUCED ILLNESS

In most case series, factitious fever or self-induced illness is a relatively uncommon cause of FUO, but it may occur more often than generally appreciated. Patients with these conditions are often young women, and 50% have had training in some aspect of health care. They are often well educated, cooperative, articulate, and manipulative of family and caregivers. Patients can no longer manipulate thermometers because electronic or infrared thermometry is used, and causing factitious fever is difficult. Clues to the factitious fever diagnosis include absence of a toxic appearance despite high temperature readings, lack of tachycardia, and absent diurnal variation. Patients may appear well between episodes of fever.

Genuine fever can be induced if an individual injects or ingests pyrogenic substances such as bacterial suspensions, urine, or feces. Although intermittent polymicrobial bacteremia may suggest a diagnosis of intra-abdominal abscess, it represents self-induced infection. The discovery of needles and substances for injection in the patient's belongings may help in the diagnosis.

In most cases, a psychogenic basis for the behavior is assumed. However, one study with detailed psychological patient analyses found no evidence of major psychiatric diagnoses among individuals with self-induced or simulated illnesses. Munchausen's syndrome and Munchausen by proxy are the most extreme forms of factitious fever. Patients often agree stoically to numerous highly invasive procedures to diagnose and treat themselves or their

children (i.e., proxy). All of these individuals require objective but complete, tactful, and compassionate assessments and considerable psychiatric care.

Bacteremia and Sepsis

Russell J. McCulloh and Steven M. Opal

DEFINITION

Sepsis is a leading cause of morbidity and death among hospitalized patients. The disease process results from a complex interplay of host immune responses and infectious microorganisms. As defined by the Surviving Sepsis Campaign, sepsis consists of proven or suspected infection combined with systemic manifestations of infection. Manifestations can include fever, altered mental status, and abnormalities in inflammation and coagulation. Severe cases can progress to multiple organ system dysfunction followed by organ failure and death.

Diagnostic criteria for sepsis are provided in [Table 89-1](#). Severe sepsis results from sepsis-induced tissue hypoperfusion and consequent organ dysfunction. Septic shock is a combination of severe sepsis and persistent hypotension despite adequate fluid resuscitation or the need to use vasopressors to maintain a mean arterial pressure (MAP) higher than 65 mm Hg. The continuum of disease manifestations from localized infection to multiorgan failure and refractory septic shock is depicted in [Figure 89-1](#).

Recently, a revised set of definitions was proposed. The term *sepsis* as currently used lacks specificity. Sepsis should imply a deleterious situation in which the infection-induced systemic inflammatory and coagulopathic responses have become injurious to the host. Sepsis is an infectious process characterized by tissue injury from hypoperfusion and immune dysregulation. Because sepsis always has severe ramifications for the patient, the term *sepsis* should be used instead of the current “severe sepsis.” *Severe infection* should be used to describe an infection that is accompanied by systemic inflammation but without evidence of organ dysfunction remote from the site of infection (i.e., the former definition of sepsis). Whether these revised definitions can resolve the current confusion in terminology remains to be seen.

Understanding the pathophysiology of sepsis syndrome has proved helpful in differentiating and treating severe inflammatory processes that manifest with symptoms similar to sepsis, including pancreatitis, severe trauma, thermal burns, and certain toxin or environmental exposures. These processes can produce a systemic inflammatory response syndrome (SIRS), but they lack the component of infection needed to establish a diagnosis of sepsis. The remarkable clinical similarity between these severe, “sterile” inflammations and septic shock reflects their molecular profiles. Identical signaling pathways for the immune response are activated by highly conserved pathogen-associated molecular patterns (PAMPs), which are molecular motifs recognized by cells of the host’s innate immune system. Damage-associated molecular patterns (DAMPs) are molecules released by injured host cells

that act as endogenous danger signals to promote the inflammatory response (see [Pathophysiology of Septic Shock](#)).

EPIDEMIOLOGY

The worldwide incidence of sepsis is difficult to assess due to limited data from developing countries. In industrialized countries, reported rates of sepsis range from 22 to 300 cases per 100,000 people. Sepsis may account for up to 6% of adult deaths. In the United States, more than 750,000 cases of sepsis and 200,000 sepsis-related deaths occur annually. The risk of mortality depends on the severity of illness and multiple host factors (discussed later). Overall, estimates of death from sepsis range

TABLE 89-1 DIAGNOSTIC CRITERIA FOR SEPSIS*

GENERAL VARIABLES

Fever ($>38.3^{\circ}\text{C}$)
 Hypothermia (core temperature $<36^{\circ}\text{C}$)
 Heart rate >90 beats/min or more than 2 SD above the normal value for age
 Tachypnea
 Altered mental status
 Significant edema or positive fluid balance (>20 mL/kg over 24 hr)
 Hyperglycemia (plasma glucose >140 mg/dL or 7.7 mmol/L) in the absence of diabetes

INFLAMMATORY VARIABLES

Leukocytosis (WBC count $>12,000$ mm³)
 Leukopenia (WBC count <4000 mm³)
 Normal WBC count with more than 10% immature forms
 Plasma C-reactive protein >2 SD above the normal value
 Plasma procalcitonin >2 SD above the normal value

HEMODYNAMIC VARIABLES

Arterial hypotension (SBP <90 mm Hg, MAP <70 mm Hg, or an SBP decrease [40 mm Hg in adults or <2 SD below normal for age])

ORGAN DYSFUNCTION VARIABLES

Arterial hypoxemia ($\text{Pao}_2/\text{Fio}_2 <300$)
 Acute oliguria (urine output <0.5 mL/kg/hr for at least 2 hr despite adequate fluid resuscitation)
 Creatinine increase (0.5 mg/dL or 44.2 $\mu\text{mol/L}$)
 Coagulation abnormalities (INR >1.5 or aPTT >60 sec)
 Ileus (absent bowel sounds)
 Thrombocytopenia (platelet count $<100,000/\text{mm}^3$)
 Hyperbilirubinemia (plasma total bilirubin, 4 mg/dL or 70 $\mu\text{mol/L}$)

TISSUE PERFUSION VARIABLES

Hyperlactatemia (1 mmol/L)
 Decreased capillary refill or mottling

From Dellinger RP, Levy MM, Rhodes A, et al: Surviving Sepsis Campaign: international guidelines for management of severe sepsis and septic shock, 2012, *Intensive Care Med* 39:165–228, 2013.

aPTT, Activated partial thromboplastin time; Fio₂, fraction of inspired oxygen; INR, international normalized ratio; MAP, mean arterial pressure; Pao₂, partial pressure of oxygen; SBP, systolic blood pressure; SD, standard deviations; WBC, white blood cell.

*The criteria include documented or suspected infection and some of the variables listed.

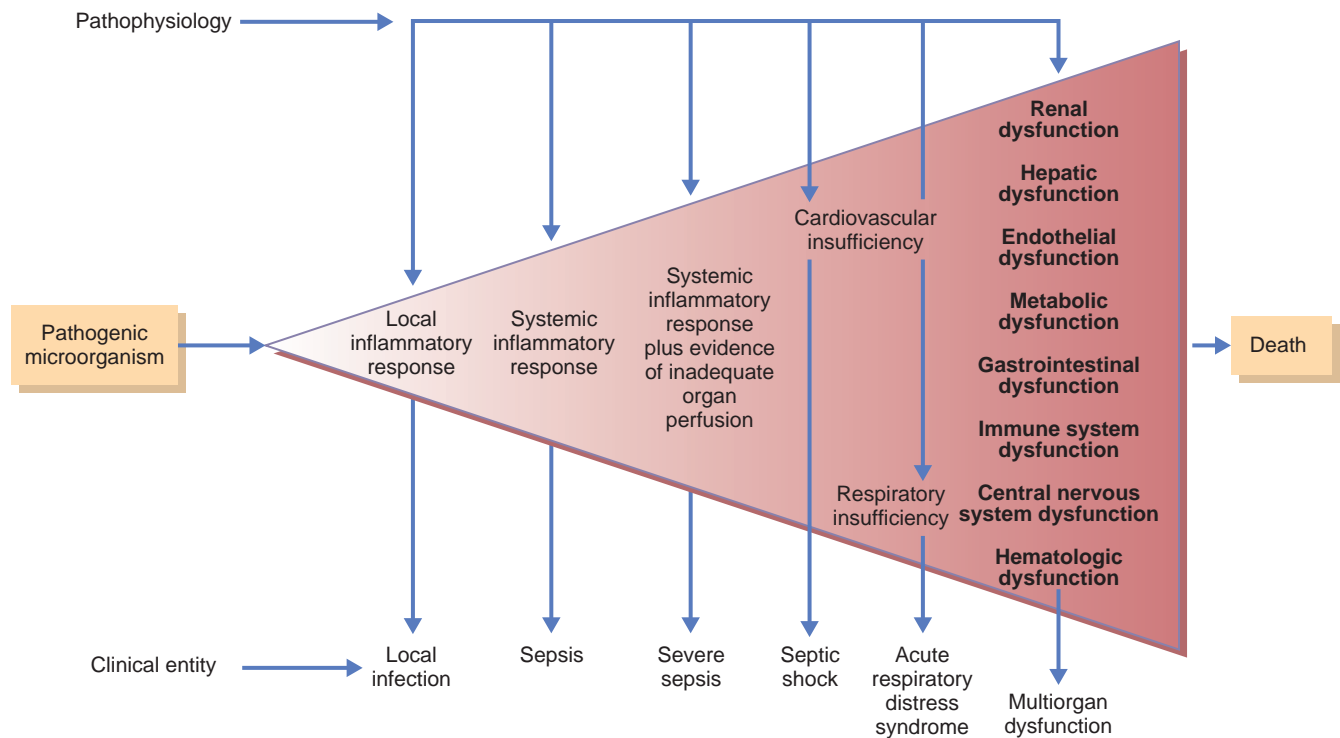

FIGURE 89-1 The spectrum of illness and nomenclature for sepsis pathophysiology.

TABLE 89-2 MICROORGANISMS COMMONLY IDENTIFIED IN SEPTIC PATIENTS BASED ON HOST FACTORS

HOST FACTOR	ORGANISMS TO CONSIDER
Asplenia	Encapsulated organisms, particularly <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i> , <i>Capnocytophaga canimorsus</i>
Cirrhosis	<i>Vibrio</i> , <i>Salmonella</i> , and <i>Yersinia</i> species; encapsulated organisms, other gram-negative rods
Alcohol abuse	<i>Klebsiella</i> species, <i>S. pneumoniae</i>
Diabetes	Mucormycosis, <i>Pseudomonas</i> species, <i>Escherichia coli</i> , group B streptococci
Neutropenia	Enteric gram-negative rods, <i>Pseudomonas</i> , <i>Aspergillus</i> , <i>Candida</i> , <i>Mucor</i> species, <i>Staphylococcus aureus</i> , streptococcal species
T-cell dysfunction	<i>Listeria</i> , <i>Salmonella</i> , and <i>Mycobacterium</i> species, herpesviruses (including herpes simplex, cytomegalovirus, varicella-zoster virus)
Acquired immunodeficiency syndrome	<i>Salmonella</i> species, <i>S. aureus</i> , <i>Mycobacterium avium</i> complex, <i>S. pneumoniae</i> , group B streptococci

from 20% of mild to moderate cases to more than 60% of patients with septic shock.

The financial impact of sepsis cases is immense. Each episode of sepsis costs approximately \$50,000 in health care expenditures, for a total of more than \$17 billion dollars annually in the United States alone.

Bacterial infections are the most common cause of sepsis. Bloodstream infections due to bacteria account for the largest proportion of hospitalizations. The rates are highest for premature infants, the advanced elderly (especially those older than 85 years of age), and patients with intravenous catheters, implanted devices, or severe medical morbidities such as severe burns or hematologic malignancies.

Pathogens most commonly identified in bloodstream infections include staphylococci (e.g., *Staphylococcus aureus*), group A streptococci, *Escherichia coli*, *Klebsiella* species, *Enterobacter* species, and *Pseudomonas aeruginosa*. Immunocompromised patients and patients with long-term intravascular catheters are at increased risk for fungal bloodstream infections from *Candida*

species, and some species may be resistant to commonly used antifungal medications. Given the broad variety of potential pathogens, clinicians face the dual challenges of an accurate and timely diagnosis and choice of appropriate empirical therapy.

Several epidemiologic factors can guide the clinician in cases of sepsis when a source has not been identified. Table 89-2 lists microorganisms that are associated with certain host factors that predispose a patient to infection and sepsis. Host factors associated with worse outcomes include extremes of age, use of immunomodulating or immunosuppressing medications, and concomitant chronic medical conditions.

Several diagnostic and treatment factors are associated with severity of illness and clinical outcome. Delay in effective antimicrobial therapy correlates with worse outcomes. Infection with multidrug-resistant organisms may cause a delay in effective therapy, and for some organisms, particularly gram-negative enteric rods, the delay may be independently related to worse outcomes. Certain organisms (e.g., *P. aeruginosa*) are more virulent. The primary infection site also is important; respiratory sites

are the most common, and the central nervous system often is the most lethal site of infection. The number of organ systems involved plays a role, with mortality increasing as the number of dysfunctional organ systems increase.

PATHOLOGY AND IMMUNOPATHOGENESIS

The pathologic findings of fatal septic shock are often rather bland on gross examination and even histologic examination of tissue samples. The most common finding is increased tissue edema in the interstitial spaces and excess lung fluid and pleural fluid. Signs of hyaline membrane formation and fibrin deposition in the alveoli are common and indicate the fibroproliferative stage of acute respiratory distress syndrome (ARDS). Occasionally, punctate or macroscopic evidence can be detected in the adrenal tissues, as can diffuse petechiae in tissues and mucosal surfaces that indicate disseminated intravascular coagulation (DIC).

The kidneys usually appear normal, and necrosis of kidney tissues is distinctly uncommon. The term *acute tubular necrosis* is a misnomer, and the term *acute kidney injury* (AKI) is more appropriate for describing the functional and usually reversible loss of kidney function found in septic shock without accompanying evidence of glomerular or tubular necrosis.

An important finding at autopsy is identification of the infectious focus that caused septic shock. The focal infection that precipitated sepsis is readily identifiable in most deceased patients despite days to weeks of seemingly appropriate antimicrobial therapy directed against the pathogens. If careful histochemical studies are performed shortly after a patient succumbs to sepsis,

excessive apoptosis (but not necrosis) of immune effector cells is identifiable in lung, spleen, lymph nodes, and hepatic tissues. Electron microscopy of tissues after death from sepsis often reveals loss of tight junctions along epithelial and endothelial surfaces. Electron microscopy also demonstrates diffuse mitochondrial swelling and degradation and clearance of intracellular organelles (i.e., autophagy).

PATHOPHYSIOLOGY OF SEPTIC SHOCK

The molecular mechanisms that underlie the basic pathophysiology of septic shock have been determined. Sepsis is triggered when a pathogen or cluster of pathogens breaches the epithelial barriers at a tissue site, evades clearance by humoral and cellular innate immune defenses, and causes an invasive infection. On entry into the host tissues, microbial pathogens are first sensed by myeloid cells of the innate immune system by pattern recognition receptors (e.g., toll-like receptors [TLRs]) on the cell surface and in endosomal compartments. TLRs detect highly conserved molecular motifs of microbes. Examples include lipopolysaccharide (LPS), the endotoxin produced by gram-negative bacteria; bacterial lipopeptides from gram-positive bacteria; β -glucans of the cell wall of fungi; viral RNA genomes and proteins; bacterial flagella; and DAMPs released from injured host cells, including intracellular structures such as histone proteins, mitochondrial DNA, and high-mobility group box 1 (Fig. 89-2).

TLRs and related intracellular pattern recognition receptors, including the inflammasome elements, retinoic acid-inducible gene 1 (*RIG1*)-like helicases, and cytoplasmic microbial TLR4, alert the host to infection. TLR4 is the long sought-after LPS

FIGURE 89-2 Immunopathogenesis of sepsis. Early recognition of bloodstream infection begins with sensing by pattern recognition receptors: toll-like receptor 4 (TLR4); cluster determinant 14 (CD14); myeloid differentiation factor 2 (MD2) for gram-negative bacterial lipopolysaccharide and TLR2 for lipoteichoic acid and other elements from gram-positive bacteria. Engagement of the TLRs by their ligands signals transcription of the acute phase response genes by the nuclear factor- κ light-chain enhancer of activated B cells (NF- κ B, which is a monocyte). Septic shock is initiated by systemic release of an array of vasoactive mediators, including nitric oxide (NO) produced by cytokine-inducible NO synthase (iNOS).

receptor of the human innate immune system. LPS is released from the cell membrane of gram-negative bacteria on their destruction. LPS is first bound to a carrier protein, LPS-binding protein, and the LPS monomer is then delivered to a membrane-associated, multiligand, pattern recognition receptor, CD14. LPS monomers are then passed to a soluble protein (i.e., myeloid differentiation factor 2 [MD2]) and bind to the ectodomain of TLR4. After this LPS/MD2/TLR4 complex is completed and dimerized, intracellular signaling alerts the host to the invasive infectious challenge. The pathway induces a series of phosphorylation events of adaptor proteins and signaling molecules that terminate in the activation and translocation of transcriptional activating factors such as nuclear factor- κ B (NF- κ B) into the nucleus. The transcription factors bind to promoter sites of the acute phase protein network, resulting in an acute outpouring of inflammatory, host defense, and coagulation components.

Other TLRs, such as TLR5 (i.e., bacterial flagella) and the TLR2/TLR1 and TLR2/TLR6 heterodimers (i.e., bacterial lipopeptides, lipoteichoic acid, and other elements of bacteria and fungi), are expressed on the cell surface of immune effector cells that recognize different molecular patterns. Nucleic acid recognition-specific TLRs reside in endosomal vacuoles, where they detect microbial DNA (TLR9), single-stranded RNA (TLR7 and TLR8), and double-stranded RNA (TLR3).

An array of complement elements, cytokines, chemokines, prostanoids (e.g., prostaglandins), vasoactive peptides, platelet-activating factor, and proteases are generated, resulting in activation of neutrophils, monocytes, macrophages, dendritic cells, lymphocytes, and endothelial cells in a combined effort to wall off the infectious process, clear the pathogens, and begin the process of tissue repair. This defense system efficiently clears pathogens from the host after local injury and the inevitable minor breaches of the epithelial barriers by microorganisms that occur over a lifetime.

If the inflammatory process is unchecked and accompanied by large numbers of pathogens or even a few highly virulent organisms (e.g., plague, tularemia, anthrax, hemorrhagic fever viruses) to which the host has no preexisting immunity, a generalized, inflammatory, and injurious process known as *sepsis* evolves over a short time, and it can be deleterious or lethal to the host. The same inflammatory response that can be lifesaving in localized infection can become life-threatening if it becomes sustained and generalized.

Endothelial membranes throughout the body are activated and become proadherent and procoagulant surfaces that promote neutrophil and platelet adherence. Neutrophils release proteases, cytokines, reactive oxygen radicals, and vasoactive prostanoids that damage endothelial cells and their function. Cytokine-inducible nitric oxide synthase is upregulated, resulting in massive generation of nitric oxide (NO). NO is a potent vasodilator, and in combination with other vasoactive peptides and phospholipid mediators, it promotes diffuse opening of capillary beds and increased permeability, with loss of intravascular fluids into the interstitial spaces. Reactive oxygen species combine with NO to generate highly injurious reactive nitrogen intermediates (e.g., peroxynitrite) that damage mitochondrial function and induce apoptosis. Systemic hypotension rapidly develops, and septic shock ensues. Immediate action by the clinician is mandatory to

correct the hemodynamic status and resolve the underlying infection.

CLINICAL PRESENTATION

Despite the vast improvements in understanding the pathophysiologic basis of sepsis, clinical diagnosis remains limited to the medical history, symptomatic assessment, and nonspecific laboratory and hemodynamic criteria. Compounding the problem is the need for prompt institution of appropriate antimicrobial therapy, making early recognition of sepsis critically important. Patients with general findings as outlined in [Table 89-1](#) should undergo thorough and prompt evaluation for a possible infectious cause, including bacterial cultures of blood and (when indicated) other body fluids. Localizing signs and symptoms should prompt a thorough physical examination and directed imaging to identify a nidus of infection. Defects of natural defensive barriers, such as transcutaneous devices or intravascular catheters, should be assessed for infection and removed if suspected to be the origin of the septic process.

Many patients have fever or chills, but older patients and those on immunomodulating medications may not mount a fever. Hypothermia portends a worse prognosis or more severe illness. Tachypnea may be an indicator of respiratory compensation for underlying metabolic acidosis or the early signs and symptoms of ARDS.

Mental status changes can result from metabolic derangements caused by sepsis, hypoglycemia, the underlying infectious process, or concomitant hypotension. This symptom can be difficult to identify in the elderly patient with dementia, and caution should be exercised in the evaluation and treatment of the otherwise stable elderly patient with possible mental status changes.

Skin findings (e.g., cellulitis, abscess) can provide clues to the cause of sepsis and may indicate the state of peripheral systemic perfusion. Several microorganisms can cause specific skin manifestations in systemic infection. *S. aureus* and streptococci can cause diffuse erythroderma, bullous lesions, or generalized desquamation. Bacteremia caused by several gram-negative organisms, including *P. aeruginosa* and enteric organisms, can result in ecthyma gangrenosum, particularly in immunocompromised patients. These lesions are round and 1 to 15 cm in diameter, and they have a central area of necrosis and peripheral erythema. Infection with *Neisseria meningitidis* can result initially in lower extremity petechiae progressing to diffuse purpura, which likely portends septic shock and a high risk of death. A similar clinical presentation can be observed in other unusual infectious diseases, such as overwhelming pneumococcal sepsis in the asplenic host or disseminated neisserial infections in patients with late complement deficiencies.

Hemodynamic instability, particularly hypotension with or without accompanying oliguria, is commonly associated with sepsis. Instability can result from poor cardiac output, intravascular fluid depletion, or low systemic vascular resistance. Hypotension can initially respond to intravenous fluid resuscitation, but in cases of severe sepsis and septic shock, it may require additional support with vasopressors. Intensive cardiac monitoring may be necessary to gauge the relative need for intravenous fluids or vasopressors after initial fluid resuscitation measures are attempted.

Patients in septic shock can be tachycardic and hypotensive. They may have relatively warm extremities (i.e., warm shock or distributive shock), or they may be peripherally vasoconstricted, with mottled and cool extremities (i.e., cold shock). Warm shock is the predominant finding in most adult patients at the onset of septic shock, with evidence of diffuse vasodilation, bounding pulses, and a compensatory high cardiac output despite evidence of diminished myocardial performance. Increased cardiac output is accomplished primarily by increased heart rate in an attempt to maintain blood pressure and perfuse vital organs. If shock is not promptly corrected, myocardial dysfunction ensues and cold shock evolves over the next several hours. Older patients with limited cardiac reserves tolerate shock poorly and are more likely to develop cold shock. Evidence of septic shock at presentation that is refractory to early resuscitation portends a poor prognosis, with mortality rates exceeding 70%.

Besides hypotension, oliguria can represent developing AKI. It can arise from a combination of the disease process, infecting organism, and medications. Inflammatory cytokines, microbial toxins, systemic hypotension, and iatrogenic renal injury from medications can result in AKI. Other causes of renal injury include interstitial injury from infection or medications and immune complex-mediated injury, as seen in cases of endocarditis.

Besides tachypnea, pulmonary symptoms seen in septic patients include marked hypoxia due to interstitial edema, inflammation, or hemodynamic instability. ARDS is defined as an arterial partial pressure of oxygen less than 50 mm Hg despite fractional inspired oxygen of greater than 50%, together with diffuse alveolar infiltrates and a pulmonary capillary wedge pressure of less than 18 mm Hg. ARDS occurs in up to 40% of septic patients. The diffuse pulmonary inflammation in ARDS results in increased pulmonary vascular permeability, which complicates fluid resuscitation efforts because excessive fluid can exacerbate pulmonary edema and hypoxia. Altered mental status and sepsis-related myopathy also result in airway compromise and weak respiratory effort, necessitating invasive ventilatory support.

Patients with sepsis can have marked hematologic changes. They may have neutrophilic leukocytosis, which is often accompanied by increased immature cell counts, or they can be markedly leukopenic (particularly lymphopenic), often in cases of severe septic shock. Transient neutropenia is often seen in the early phase of septic shock and results from activation and adherence of neutrophils along endothelial surfaces in the microcirculation. This is rapidly followed by prolonged neutrophilia as sepsis-induced inflammatory cytokines stimulate bone marrow synthesis of new white blood cells.

Thrombocytopenia and coagulopathy can occur, and patients have petechiae or purpura at presentation. Severe derangements in coagulation can produce DIC, which can lead to thrombin deposition throughout the microcirculation. Excessive activation and degradation of clotting factors can deplete coagulation factors, resulting in diffuse hemorrhage. Excessive mucosal bleeding around airway tubes and prolonged bleeding from venipuncture sites presage internal bleeding events. Massive gastrointestinal hemorrhage can occur, which can cause or exacerbate hypotension and shock.

Derangements in glucose homeostasis can be seen at presentation. This can take the form of hyperglycemia in diabetics receiving glucose-containing fluids or acute metabolic derangement due to infection. Hypoglycemia is more common in patients with underlying liver disease. Increased anaerobic metabolism due to poor tissue oxygenation and coupled with mitochondrial dysfunction and impaired hepatic clearance of lactic acid may result in increased serum lactate levels and metabolic acidosis.

DIAGNOSIS

Accurate diagnosis of sepsis relies on the history, physical examination, and general laboratory investigation. Diagnostic criteria for sepsis in adults based on the Surviving Sepsis Campaign guidelines are listed in [Table 89-1](#).

Accurate and timely identification of the underlying infectious cause is essential. For patients able to provide a history, an assessment of medical comorbidities, potential exposures, prior infections, and immune system abnormalities may help to guide empirical antimicrobial therapy and the laboratory investigation, particularly microbial cultures. Two sets of blood cultures drawn from a fresh venipuncture and from existing indwelling intravascular lines (before initiation of empirical antimicrobial therapy if possible) help to identify the causative organism in many cases. Symptomatic assessment and physical examination should suggest a location of focal infection that can help to guide radiologic studies and interventions to drain pus.

Beyond microbial cultures, several other laboratory studies can help to define the severity of illness and provide baseline data for monitoring the response to therapy. Basic laboratory testing, including a complete blood count with differential, chemistries, and creatinine and aminotransferase levels, can help to identify significant organ dysfunction. Oxygen saturation by pulse oximetry should be measured promptly to identify gas exchange capacity and the need for ventilatory support. Coagulation studies should be obtained, particularly for patients with evidence of DIC and those who are thrombocytopenic. For patients with altered mental status or marked respiratory difficulty, arterial blood gas sampling can help define the underlying derangement and physiologic compensation and can indirectly gauge the severity of illness.

Levels of inflammatory markers, including C-reactive protein and procalcitonin, usually are elevated. An elevated procalcitonin level can help to establish the diagnosis of severe sepsis and provide some prognostic data and a measure of response to therapy. In cases of sepsis due to pneumonia, serial measurement of procalcitonin can help to guide the duration of antibiotic therapy.

Other testing should be directed toward identifying the potential cause. Patients with severe diarrhea should undergo testing for antibiotic-associated *Clostridium difficile* infection. Imaging studies should focus on identifying infectious sources and facilitate drainage of fluid collections or abscesses. Computed tomography may be of use in such circumstances, although for the critically ill patient who is not stable for transport, bedside radiographic studies, especially ultrasound, should be considered.

Multiple tests of physiologic function and advanced microbiologic diagnostic tests are increasingly used in clinical practice. They include polymerase chain reaction (PCR)-based assays for

identifying bacteria and viruses and various assays of inflammatory cytokines and other biomarkers alone and in combination as potential diagnostic and prognostic aids.

TREATMENT

Septic shock is a medical emergency. Immediate attempts to reestablish physiologic hemodynamics, vital organ support, and oxygen delivery to tissues should accompany early diagnosis and treatment of infection. Patients should be transferred to the intensive care unit as soon as possible to receive optimal monitoring, hemodynamic support, and expert supportive care.

Early recognition, prompt resuscitation, and early institution of appropriate antimicrobial agents are the most important determinants of a successful outcome. If appropriate, draining infectious foci (i.e., source control) should be done as soon as possible. Key elements of the 2012 Surviving Sepsis Campaign guidelines are summarized in Table 89-3.

An essential element in the treatment of sepsis is early administration of antibiotics active against the causative pathogen. Treatment is best given within 1 hour of the onset of septic shock, and an empirical, broad-spectrum antimicrobial regimen is usually employed until the results of cultures of blood and the site of infection become available. A suggested initial treatment regimen is provided in Table 89-4. Failing to treat the causative pathogen until its identity and susceptibility profile become available days later is associated with adverse outcomes. After the pathogen is identified, de-escalation to the simplest monotherapy to which it is susceptible is important.

PROGNOSIS

Despite advances in clinical practice and treatment, sepsis mortality rates remain high, ranging from 20% to 30% among relatively healthy adults to more than 80% among the elderly, immunocompromised, and those with significant chronic medical comorbidities. Patients may experience significant weakness, wasting, and debilitation due to severe catabolism, poor

TABLE 89-3 RECOMMENDED INITIAL MANAGEMENT OF SEPSIS IN ADULTS

- Start resuscitation immediately in patients with hypotension or serum lactate level >4 mmol/L.
- Obtain appropriate cultures before starting antibiotics if doing so does not significantly delay therapy.
- Evaluate for a focus of infection amenable to source control (e.g., abscess drainage).
- Remove intravascular catheters if potentially infected.
- Begin broad-spectrum antibiotics within the first hour of severe sepsis and septic shock. Initial antibiotic regimen is based on likely source of sepsis, likely pathogens, and local antibiotic susceptibility patterns of common pathogens.
- Begin fluid resuscitation using crystalloids as the first choice. If colloids are used, avoid starches and consider albumin in selected patients who have hypoalbuminemia or require large-volume fluid resuscitation.
- Give fluid challenge of up to 30 mL/kg of crystalloids over 15-30 min in septic patients with suspected volume depletion; larger volumes of fluids may be needed in some patients. The goals for resuscitation should be a central venous pressure of 8-12 mm Hg, a mean arterial pressure (MAP) ≥ 65 mm Hg, and a superior vena cava oxygen saturation $\geq 70\%$ or mixed venous oxygen saturation $\geq 65\%$.
- Maintain targeted MAP of ≥ 65 mm Hg; if fluids are not effective in reestablishing adequate blood pressure, begin vasopressors. After hemodynamic parameters are stabilized, limit fluid therapy to prevent pulmonary fluid accumulation and exacerbation of hypoxemia.
- Use norepinephrine, centrally administered, as the vasopressor of choice. Epinephrine is the second choice, followed by vasopressin as salvage therapy. Dobutamine may be useful if an inotrope is needed. Avoid dopamine except for special situations (i.e., low risk of tachyarrhythmia and persistent bradycardia).
- Give red blood cells when the hemoglobin concentration decreases to <7 g/dL; target hemoglobin level is 7-9 g/dL.
- Target a tidal volume of 6 mL/kg in patients with acute respiratory distress syndrome.
- Give low-molecular-weight heparin or unfractionated heparin for deep vein thrombosis prophylaxis; use graduated pressure stockings or intermittent compression devices if heparin therapy is contraindicated.
- Provide stress ulcer prophylaxis using histamine H_2 -blockers or a proton pump inhibitor.
- Provide expert supportive care; provide low-dose nutrition for the first week; consider stress-dose steroids if refractory septic shock occurs; maintain blood glucose in the 110-180 mg/dL range.

Data from Dellinger RP, Levy MM, et al: Surviving Sepsis Campaign: international guidelines for the management of severe sepsis and septic shock, 2012, Crit Care Med 41:580-637, 2013.

TABLE 89-4 INITIAL ANTIBIOTIC RECOMMENDATIONS FOR ADULT PATIENTS WITH SEPSIS

INDICATION	RECOMMENDED DOSAGES*
Empirical coverage (source unknown)	Vancomycin 15 mg/kg q12h plus piperacillin-tazobactam [†] 3.375 g IV q6h or imipenem 0.5 g IV q6h or meropenem 1.0 g IV q8h with or without an aminoglycoside (e.g., tobramycin 5 mg/kg IV q24h). [‡]
Community-acquired pneumonia (CAP)	Ceftriaxone 1 g IV q24h plus azithromycin 500 mg IV q24h or a fluoroquinolone (e.g., moxifloxacin 400 mg IV q24h or levofloxacin 750 mg IV q24h). [§]
Community-acquired urosepsis	Piperacillin-tazobactam 3.375 g IV q6h or ciprofloxacin 400 mg IV q12h
Meningitis	Vancomycin 15 mg/kg IV q6h plus ceftriaxone 2 g IV q12h plus dexamethasone 0.15 mg/kg IV q6h \times 2-4 days, preferably before antibiotics; add ampicillin 2 g IV q4h if <i>Listeria</i> is suspected.
Nosocomial pneumonia	Vancomycin 15 mg/kg q12h plus piperacillin-tazobactam 4.5 g IV q6h or imipenem 0.5 g IV q6h or meropenem 1 g IV q8h or ceftazidime 2 g IV q8h plus an aminoglycoside (e.g., amikacin 15 mg/kg IV q24h or tobramycin 5-7 mg/kg IV q24h) or levofloxacin 750 mg IV q24h. Some authorities substitute linezolid 600 mg IV q12h for vancomycin if MRSA is a significant concern or known to be the cause.
Neutropenia	Ceftazidime 2 g IV q8h; add vancomycin 15 mg/kg IV q12h if a central line is present and infection is a concern. Add antifungal coverage with caspofungin 70 mg IV \times 1, then 50 mg IV q24h if fever persists ≥ 5 days. For suspected or proven invasive aspergillosis, voriconazole 6 mg/kg IV q12h \times 2, then 4 mg/kg IV q12h should be used.
Cellulitis and skin infections	Vancomycin 15 mg/kg IV q12h. Add piperacillin-tazobactam 3.375 g IV q6h in diabetics and immunocompromised patients. If necrotizing fasciitis is suspected, add clindamycin 900 mg IV; surgical débridement is crucial.

IV, Intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*.

*Assumes normal renal function; dose adjustments are required with impaired creatinine clearance.

[†]Substitute aztreonam 2 g IV q8h if patient is allergic to penicillin.

[‡]Monitor drug levels of aminoglycosides (i.e., peak and trough).

[§]Substitute Cefepime or a carbapenem and azithromycin \pm an aminoglycoside if the patient has severe CAP or health care-associated pneumonia.

nutrition, and prolonged hospitalization. Prolonged rehabilitation in a skilled facility after the initial hospitalization and additional home-based therapy may be required. Patients may have permanent disabilities, including impaired renal function or persistent debilitation from procedures required to treat the underlying infection.

Infections of the Central Nervous System

Allan R. Tunkel, Marjorie A. Janvier, and Avindra Nath

INTRODUCTION

Infections of the central nervous system (CNS) are associated with significant morbidity and mortality. This chapter focuses on meningitis, encephalitis, and brain abscesses in the parenchyma and parameningeal areas.

MENINGITIS AND ENCEPHALITIS

Contact with offending infectious agents such as viruses, bacteria, fungi, protozoa, and helminths can cause inflammation of the meninges covering the brain and spinal cord (i.e., meningitis) or lead to inflammation of the brain parenchyma (i.e., encephalitis). These infectious agents can penetrate the CNS by direct seeding or hematogenous spread and cause a constellation of symptoms. The clinician must rapidly initiate a diagnostic evaluation and begin appropriate management.

Meningitis

Definition

Meningitis is defined as inflammation of the leptomeninges that cover the brain and spinal cord. It is identified by an abnormal increase in the number of white blood cells in cerebrospinal fluid (CSF). Inflammation can be caused by many infectious agents (i.e., bacteria, viruses, fungi, and parasites) and also can occur as a result of noninfectious conditions, including tumors or cysts, medications (e.g., nonsteroidal anti-inflammatory drugs, antimicrobial agents), systemic illnesses (e.g., systemic lupus erythematosus, Behçet's disease, sarcoidosis), or neurologic procedures (e.g., neurosurgery, spinal anesthesia, intrathecal injections).

The clinical presentation can be acute, subacute, or chronic based on the virulence of the organism. Acute meningitis is a syndrome characterized by the onset of symptoms within hours to several days, whereas chronic meningitis characterized by clinical and CSF findings that remain abnormal for at least 4 weeks. Acute meningitis is most often caused by bacteria and viruses, whereas chronic meningitis is most often caused by spirochetes, mycobacteria, and fungi.

Epidemiology and Etiology

Bacterial Meningitis

In the United States, the epidemiology of bacterial meningitis has changed significantly over the past several decades with the introduction of conjugate vaccines against *Haemophilus influenzae* and *Streptococcus pneumoniae*. A surveillance study found that about 4000 cases of bacterial meningitis and 500 deaths

occurred annually between 2003 and 2007. The leading causes of bacterial meningitis were *S. pneumoniae* (58% of cases), *Streptococcus agalactiae* (18% of cases), *Neisseria meningitidis* (14% of cases), *H. influenzae* (7% of cases), and *Listeria monocytogenes* (3% of cases).

Specific etiologic agents may be more likely based on the patient's age and various risk factors (Table 90-1). In one study of 352 episodes of community-acquired pneumococcal meningitis, 70% of cases were associated with an underlying disorder. Conditions associated with pneumococcal meningitis include splenectomy or asplenic states, multiple myeloma, hypogammaglobulinemia, alcoholism, malnutrition, chronic liver or kidney disease, and diabetes mellitus. Patients often have contiguous or distant foci of infection such as pneumonia, otitis media, mastoiditis, sinusitis, endocarditis, and head trauma with a CSF leak.

The group B streptococcus (i.e., *S. agalactiae*) is a common etiologic agent of meningitis in neonates, with 52% of cases occurring during the first year of life. Risk factors for *S. agalactiae* meningitis in adults include age older than 60 years, pregnancy or the postpartum state, diabetes mellitus, and other chronic diseases and immunosuppressed states.

N. meningitidis usually causes meningitis in children and adults. Most cases in the United States are caused by serogroups B, C, and Y; serogroups A and W135 usually cause disease outside of the United States. Because of *N. meningitidis* in the upper

TABLE 90-1 COMMON BACTERIAL PATHOGENS AND FACTORS PREDISPOSING TO MENINGITIS

PREDISPOSING FACTOR	BACTERIAL PATHOGENS
Age	
<1 mo	<i>Streptococcus agalactiae</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i>
1-23 mo	<i>S. agalactiae</i> , <i>E. coli</i> , <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i>
2-50 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i>
>50 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli
Immunocompromised state	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli (including <i>Pseudomonas aeruginosa</i>)
Basilar skull fracture	<i>S. pneumoniae</i> , <i>H. influenzae</i> , group A β -hemolytic streptococci
Head trauma; post neurosurgery	<i>Staphylococcus aureus</i> , coagulase-negative staphylococci (especially <i>Staphylococcus epidermidis</i>), aerobic gram-negative bacilli (including <i>P. aeruginosa</i>)

From Tunkel AR, van de Beek D, Scheld WM: Acute meningitis. In Bennett JE, Dolin R, Blaser M, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 8, Philadelphia, 2015, Saunders.

respiratory tract, outbreaks of meningitis due to *N. meningitidis* may occur in persons living in close quarters, such as among household members, in daycare, in college dormitories, and among the incarcerated. One outbreak of serogroup C disease was reported in New York City among men who have sex with men, and outbreaks caused by serogroup B were reported on the campuses of Princeton University and University of California, Santa Barbara. Patients with deficiencies in the terminal complement components (C5-C8 and perhaps C9) and properdin are at increased risk for meningococcal infections.

The incidence of meningitis due to *H. influenzae* has declined more than 90% with the widespread use of routine vaccination with the *H. influenzae* type b conjugate vaccine. Isolation of this microorganism in older children and adults suggests certain underlying conditions, such as sinusitis, otitis media, epiglottitis, pneumonia, diabetes mellitus, alcoholism, splenectomy or asplenic states, head trauma with CSF leak, and immune deficiency.

Meningitis caused by *L. monocytogenes* is most common in neonates, adults older than 50 years, alcoholics, immunosuppressed adults, and in patients with chronic conditions such as diabetes mellitus and renal disease. Given the likely gastrointestinal portal of entry for this microorganism, outbreaks of listerial infection have been associated with ingestion of contaminated coleslaw, raw vegetables, milk, and cheese. Sporadic cases have been linked to contaminated turkey franks, alfalfa tablets, cantaloupe, diced celery, hog's head cheese, and processed meats.

Gram-negative meningitis is rare; it usually affects debilitated persons and those with a breach in the meninges as a result of trauma or neurosurgical procedures. *Staphylococcus aureus* meningitis is usually found in the early period after neurosurgery or trauma, in those with CSF shunts, or in patients with underlying conditions such as diabetes mellitus, alcoholism, chronic kidney disease requiring hemodialysis, injection-drug use, and malignancies. *Staphylococcus epidermidis* is the most common cause of meningitis in patients with CSF shunts.

Viral Meningitis

Enteroviruses are the leading identifiable cause of the *aseptic meningitis syndrome*, a term used to define any meningitis (particularly with lymphocytic pleocytosis) for which a cause is not apparent after initial evaluation, routine CSF stains, and cultures. The Centers for Disease Control and Prevention (CDC) estimate that 10 to 15 million symptomatic enteroviral infections occur annually in the United States; of these, 30,000 to 75,000 are meningitis cases.

Many other viruses can cause the aseptic meningitis syndrome, including mumps virus (in unimmunized populations), human immunodeficiency virus (HIV), several arboviruses (e.g., St. Louis encephalitis virus, the California encephalitis group of viruses, Colorado tick fever virus, West Nile virus), and herpesviruses. The syndrome of herpes simplex virus (HSV) meningitis is most commonly associated with primary genital infection. The DNA of HSV has been detected in the CSF of patients with the syndrome of recurrent benign lymphocytic meningitis (previously known as Mollaret's meningitis), with almost all cases caused by herpes simplex virus type 2 (HSV-2).

Spirochetal Meningitis

The most common spirochetes associated with meningitis are *Treponema pallidum* (the etiologic agent of syphilis) and *Borrelia burgdorferi* (the etiologic agent of Lyme disease). The incidence of syphilitic meningitis is greatest in the first 2 years after initial infection, occurring in 0.3% to 2.4% of untreated cases. The overall incidence of neurosyphilis has increased, with many cases reported in patients with HIV infection. The nervous system is involved in at least 10% to 20% of patients with Lyme disease while erythema migrans is apparent or 1 to 6 months later.

Tuberculous Meningitis

Tuberculous meningitis accounts for approximately 15% of cases of extrapulmonary tuberculosis in the United States. CNS disease is much more common in less developed areas of the world. Factors associated with reactivation of latent foci and progression to the syndrome of late generalized tuberculosis include advanced age, immunosuppressive drug therapy, gastrectomy, pregnancy, and chronic medical conditions. The epidemiology of tuberculosis has been influenced by the advent of HIV infection, in which extrapulmonary disease (including CNS disease) occurs in more than 70% of cases.

Fungal Meningitis

The incidence of fungal meningitis has increased dramatically in recent years because of the increased numbers of immunosuppressed patients. *Cryptococcus neoformans* is the most common fungal cause of clinically recognized meningitis, occurring most commonly in persons who are immunosuppressed or have chronic medical conditions. HIV-infected patients are in the highest-risk group. Cases have also been documented in apparently healthy individuals.

Coccidioides immitis is a thermal dimorphic fungus that is endemic in the semiarid regions of the Americas and desert areas of the southwestern United States (e.g., California, Arizona, New Mexico, Texas), where about one third of the population is infected. Less than 1% of patients develop disseminated infection, and one third to one half of those have meningeal involvement.

Other fungi less commonly cause CNS infection. *Histoplasma capsulatum* is endemic to fertile river valleys, principally the Mississippi and Ohio River basins. *Candida* meningitis is uncommon.

Clinical Presentation

Acute Meningitis

Adult patients with acute meningitis typically seek medical attention within hours to days of illness. Patients with bacterial meningitis classically exhibit fever, headache, meningismus, and signs of cerebral dysfunction (i.e., confusion, delirium, or a declining level of consciousness ranging from lethargy to coma). All signs may not be seen in a given patient. The meningismus may be subtle, marked, or accompanied by Kernig's sign or Brudzinski's sign, although the sensitivity of these signs is only 5% in adults. Cranial nerve palsies (especially involving cranial nerves III, IV, VI, and VII) and focal cerebral signs are seen in 10% to 20% of cases. Seizures occur in about 30% of patients. Older adult patients with bacterial meningitis, especially those with

underlying conditions (e.g., diabetes mellitus, cardiopulmonary disease), may have disease that manifests insidiously with lethargy or obtundation, no fever, and various signs of meningeal inflammation. Older adult patients may have an antecedent or concurrent bronchitis, pneumonia, or paranasal sinusitis.

Viral meningitis is typically a self-limited illness. The clinical manifestations of enteroviral meningitis depend on the host's age and immune status. In adolescents and adults, more than one half of the patients have nuchal rigidity. Adults usually have headache, which often is severe and frontal. Photophobia is also common in older patients. Nonspecific symptoms and signs include vomiting, anorexia, rash, diarrhea, cough, upper respiratory findings (especially pharyngitis), and myalgias. Other clues to the diagnosis of enteroviral disease are the time of year (more prevalent in summer and autumn months) and known epidemic disease in the community. The duration of illness of enteroviral meningitis is usually less than 1 week, and many patients report improvement after lumbar puncture, presumably from the reduction in intracranial pressure.

Meningitis associated with HSV-2 infections is usually characterized by stiff neck, headache, and fever. Patients with recurrent benign lymphocytic meningitis characteristically develop a few to 10 episodes of meningitis lasting 2 to 5 days, followed by spontaneous recovery. These patients have acute onset of headache, fever, photophobia, and meningism; about 50% of patients have transient neurologic manifestations, including seizures, hallucinations, diplopia, cranial nerve palsies, or altered consciousness.

Subacute or Chronic Meningitis

Subacute or chronic meningitis caused by spirochetes, mycobacteria, or fungi in the adult patient can linger for weeks to years before clinical presentation. The patient may initially have no overt symptoms, suffer from low-grade headaches and fever, or experience gradual mental status and other neurologic changes.

Syphilitic meningitis usually manifests in a manner similar to that of other forms of aseptic meningitis. Patients complain of headache, nausea, and vomiting. Other findings include stiff neck (60%), fever, seizures, cranial nerve palsies, and less commonly, other focal neurologic abnormalities.

Meningitis is the most important neurologic abnormality of acute disseminated Lyme disease, usually following erythema migrans by 2 to 10 weeks. Patients with Lyme meningitis have headache as the single most common symptom. Other findings include photophobia, nausea, vomiting, and stiff neck. About one half of patients with Lyme meningitis have mild cerebral symptoms consisting most commonly of somnolence, emotional lability, depression, impaired memory and concentration, and behavioral symptoms. Approximately 50% of patients also have cranial neuropathies, with facial nerve palsy occurring in 80% to 90% of cases.

In the usual patient with tuberculous meningitis, an insidious prodrome characterized by malaise, lassitude, low-grade fever, intermittent headache, and changing personality ensues. Within 2 to 3 weeks, the meningitic phase manifests as protracted headache, meningismus, vomiting, and confusion. In some adults, the initial prodromal stage may take the form of a slowly progressive

dementia, whereas others may have a rapidly progressive meningitis syndrome indistinguishable from pyogenic bacterial meningitis. Fever is an inconstant finding on physical examination (50% to 98% of cases). Meningismus and signs of meningeal irritation are not uniform findings (absent in 25% to 80% of children and adults). Focal neurologic signs frequently consist of unilateral or, less commonly, bilateral cranial nerve palsies; cranial nerve VI is most commonly affected.

The time course of fungal meningitis depends on the clinical setting. Cases may manifest acutely, subacutely, or chronically; some of the fungal meningitides may cause symptoms that persist for years in the absence of antifungal treatment. In contrast, the same organisms can produce severe symptoms and signs within a few days and without clinical signs of meningeal irritation in the immunocompromised patient. In patients without acquired immunodeficiency syndrome (AIDS), cryptococcal meningitis typically manifests as a subacute process after days to weeks of symptoms. Headache is the most frequent complaint. Fever, meningismus, and personality changes also may occur; confusion, irritability, and other personality changes reflecting meningoencephalitis occur in about one half of patients. Ocular abnormalities occur in about 40% of patients and include papilledema and cranial nerve palsies.

In AIDS patients, manifestation of cryptococcal meningitis can be subtle, with minimal or no symptoms. AIDS patients may have only headache and lethargy. Although fever is common, meningeal signs occur in a minority of these patients.

Patients with meningeal coccidioidomycosis usually complain of headache, low-grade fever, weight loss, and mental status changes. About one half of patients develop disorientation, lethargy, confusion, or memory loss. Meningeal signs are uncommon. The presenting symptoms of *Histoplasma* meningitis are nonspecific. Symptoms usually include headache and fever. Only about one half of patients have focal neurologic mental status symptoms. Candidal meningitis also manifests with nonspecific findings.

Diagnosis

Clinically suspected meningitis is diagnosed by analysis of CSF obtained by lumbar puncture (Table 90-2). Table 90-3 illustrates general findings for patients with meningitis based on cause, and the following sections detail specific methods for establishing an etiologic diagnosis.

Bacterial Meningitis

Gram stain examination of CSF permits rapid, accurate identification of the causative microorganism in 60% to 90% of patients with bacterial meningitis, and it has a specificity of nearly 100%. CSF culture is the gold standard in diagnosis and is positive in 80% to 90% of patients with community-acquired bacterial meningitis if CSF is obtained before the start of antimicrobial therapy. The probability of identifying the organism decreases for patients who have received prior antimicrobial therapy. It has been suggested that CSF sterilization may occur more rapidly after initiation of parenteral antimicrobial therapy than previously suggested, with complete sterilization of CSF containing meningococcus within 2 hours and the beginning of sterilization of pneumococcus by 4 hours into therapy.

Several rapid diagnostic tests have been developed to aid in the etiologic diagnosis of bacterial meningitis. Latex agglutination techniques detect the antigens of *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis*, *E. coli* K1, and the group B streptococci. However, because bacterial antigen testing does not appear to modify the decision to administer antimicrobial therapy and false-positive results have been reported, routine use of this modality for rapid determination of the bacterial cause of meningitis is not recommended. It can be considered for patients who have been pretreated with antimicrobial therapy and when CSF Gram stain and culture results are negative.

CSF, Cerebrospinal fluid; IgG, immunoglobulin G; IgM, immunoglobulin M; PCR, polymerase chain reaction; RBCs, red blood cells; WBCs, white blood cells.

*Check in the first and last tubes; in patients with a traumatic tap, there should be a decrease in the number of RBCs with continued flow of CSF. The following formula can be used for determining whether the numbers of CSF red blood cells and white blood cells are consistent with a traumatic tap (all units are number of cells/cubic mm):

$$\text{Adjusted WBCs in CSF} = \text{Actual WBCs in CSF} - \frac{\text{WBCs in blood} \times \text{RBCs in CSF}}{\text{RBCs in blood}}$$

[†]Compare with serum glucose concentration measured just before lumbar puncture.

[‡]Yield of viral culture may be low.

[§]May be useful for specific causes of meningitis and encephalitis.

^{||}Most useful for specific viral causes of encephalitis and causes of chronic meningitis.

[¶]In patients with suspected malignancy.

Nucleic acid amplification tests, such as polymerase chain reaction (PCR), have been used to amplify DNA from patients with meningitis caused by several meningeal pathogens. The test characteristics for broad-based bacterial PCR demonstrated a sensitivity of 100%, a specificity of 98.2%, a positive predictive value of 98.2%, and a negative predictive value of 100%.

Differentiation of Bacterial from Viral Meningitis

In patients without a positive CSF Gram stain or culture, the diagnosis of acute bacterial meningitis is often difficult to establish or reject. A combination of clinical features, with or without test results, has been assessed to develop models in an attempt to accurately predict the likelihood of bacterial meningitis compared with other potential causes (most often viruses). In a published meta-analysis of bacterial meningitis score validation studies in which 5312 patients were identified from eight studies, 4896 (92%) had sufficient clinical data to calculate the bacterial meningitis score, which identified children with CSF pleocytosis who were at very low risk for bacterial meningitis. Low-risk features were a negative CSF Gram stain, a CSF absolute neutrophil count less than 1000 cells/mm³, a CSF protein level less than 80 mg/dL, and a peripheral absolute neutrophil count less than 10,000 cells/mm³. Despite the positive results of this meta-analysis and other studies, clinical judgment should continue to be used in decisions about the need for administration of empirical therapy in patients with suspected bacterial meningitis.

Several proteins have been examined for their usefulness in the diagnosis of acute bacterial meningitis. C-reactive protein (CRP) detected in serum or CSF and serum procalcitonin concentrations have been elevated in patients with acute bacterial meningitis and may be useful in discriminating between bacterial and viral meningitis. In patients with meningitis in whom the CSF Gram stain result is negative and analysis of other parameters is inconclusive, serum concentrations of CRP or procalcitonin that are normal or below the limit of detection have a high negative predictive value in the diagnosis of bacterial meningitis.

PCR is the most promising alternative to viral culture for the diagnosis of enteroviral meningitis. Enteroviral reverse transcription PCR (RT-PCR) has been tested in clinical settings by numerous investigators and found to be more sensitive than culture for the detection of the enterovirus; the sensitivity has ranged from 86% to 100% and specificity from 92% to 100% for the diagnosis of enteroviral meningitis. For patients with HSV-2 meningitis, PCR appears promising for the diagnosis. In patients

TABLE 90-3 CEREBROSPINAL FLUID FINDINGS FOR PATIENTS WITH INFECTIOUS CAUSES OF MENINGITIS

CAUSE OF MENINGITIS	WHITE BLOOD CELL COUNT (cells/mm ³)	PRIMARY CELL TYPE	GLUCOSE (mg/dL)	PROTEIN (mg/dL)
Viral	50-1000	Mononuclear*	>45	<200
Bacterial	1000-5000 [†]	Neutrophilic [‡]	<40 [§]	100-500
Tuberculous	50-300	Mononuclear	<45	50-300
Cryptococcal	20-500 [¶]	Mononuclear	<40	>45

*May be neutrophilic early in presentation.

[†]May range from <100 to >10,000 neutrophils/mm³.

[‡]About 10% of patients have a cerebrospinal fluid (CSF) lymphocyte predominance.

[§]Should always be compared with a simultaneous serum glucose level; ratio of CSF to serum glucose is ≤0.4 in most cases.

^{||}A therapeutic paradox may exist in which a mononuclear predominance becomes neutrophilic during antituberculosis therapy.

[¶]More than 75% of patients with acquired immunodeficiency syndrome have <20 cells/mm³.

with recurrent benign lymphocytic meningitis, detection of HSV-2 has been strongly associated with typical cases in patients without symptoms or signs of genital infection.

Spirochetal Meningitis

For the diagnosis of CNS involvement in patients with syphilis, no single routine laboratory test is definitive. The specificity of the CSF Venereal Disease Research Laboratory (VDRL) test for the diagnosis of neurosyphilis is high, but the sensitivity is low (reactive tests in only 30% to 70% of patients). A reactive CSF VDRL test result in the absence of blood contamination is sufficient to diagnose neurosyphilis; a nonreactive result does not exclude the diagnosis. The diagnosis of neurosyphilis is based on elevated CSF concentrations of white blood cells or protein, or both, in the appropriate clinical and serologic setting.

The best currently available laboratory test for the diagnosis of Lyme disease is demonstration of specific serum antibody to *B. burgdorferi*, and this positive test result for a patient with a compatible neurologic abnormality is strong evidence for the diagnosis. However, these tests are not standardized, and marked variations are seen between laboratories.

Tuberculous Meningitis

The identification of tuberculous organisms in CSF by specific stains is difficult because of the small population of organisms. In many series, less than 25% of specimens were smear positive and less than 50% were culture positive. The technique of PCR for detecting fragments of mycobacterial DNA in CSF specimens appears to be a promising tool. The Gen-Probe technique is based on amplification of ribosomal RNA derived from *Mycobacterium tuberculosis* using a labeled DNA probe. A 5-year retrospective study of the performance of this test found a sensitivity and specificity of 94% and 99%, respectively, for patients with positive CSF cultures.

Fungal Meningitis

Conclusive proof that a fungal organism is causing the meningitis rests on identification of the fungus in CSF, although CSF cultures are not always positive in cases of fungal meningitis. The yield of CSF culture in cryptococcal meningitis is excellent for non-AIDS and AIDS patients. For patients with cryptococcal meningitis, CSF India ink examination remains a rapid, effective test that is positive in 50% to 75% of cases; the yield increases up to 88% among patients with AIDS. In contrast, only 25% to 50% of patients with other fungal meningitis have positive CSF cultures.

Because cultures may be negative or require long periods before yielding positive results for patients with fungal meningitis, adjunctive studies (particularly serologic tests) may be helpful for the diagnosis. The latex agglutination test for cryptococcal polysaccharide antigen is sensitive and specific for the diagnosis of cryptococcal meningitis. Cryptococcal polysaccharide antigen also can be found in the serum and CSF, usually in severely immunosuppressed patients such as those with AIDS. Serologic antibody tests (i.e., coccidioidal and histoplasma antigens) and antigen urine tests (i.e., histoplasma antigen) may be useful in other cases of fungal meningitis.

Treatment

Initial Treatment of the Patient with Acute Meningitis

Acute bacterial meningitis is a life-threatening illness, and early detection, work-up, and antimicrobial therapy are imperative to reduce morbidity and mortality. The initial management of a patient with presumed bacterial meningitis includes performance of a lumbar puncture to determine whether the CSF formula is consistent with that diagnosis (Fig. 90-1). If meningitis is purulent, institution of antimicrobial therapy should be based on the results of Gram staining (Table 90-4). However, if no etiologic agent can be identified by this means or performance of the lumbar puncture is delayed, institution of empirical antimicrobial therapy after obtaining blood cultures should be based on the patient's age and underlying disease status (Table 90-5).

It is reasonable to proceed with the lumbar puncture without computed tomography (CT) of the head if the patient does not meet any of the following criteria: new-onset seizures, an immunocompromised state, signs that are suspicious for space-occupying lesions (i.e., papilledema or focal neurologic signs, not including cranial nerve palsy), or moderate to severe impairment of consciousness. Patients at risk should undergo CT of the head before lumbar puncture to rule out brain shift (i.e., result of an intracranial mass lesion or generalized brain edema) because of

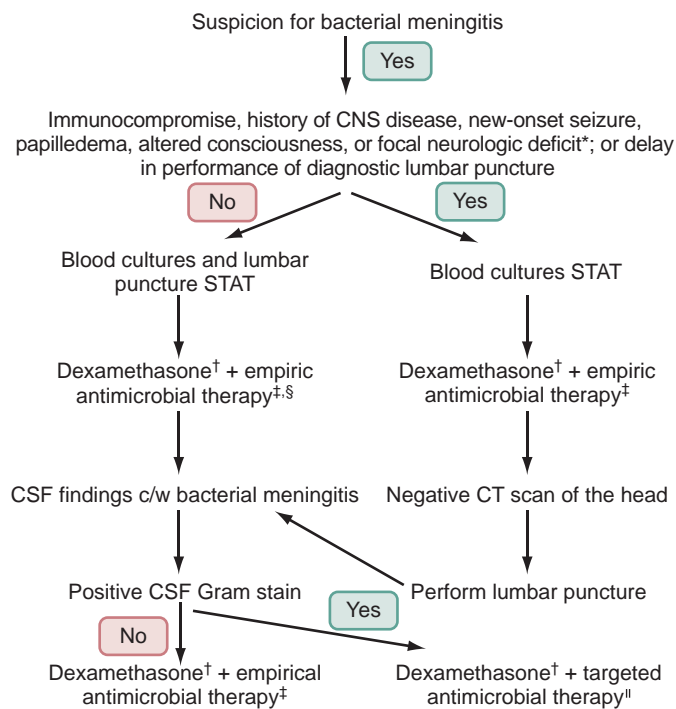

FIGURE 90-1 Management algorithm for adults with suspected bacterial meningitis. *Palsy of cranial nerve VI or VII is not an indication to delay lumbar puncture. †See text for recommendations for use of adjunctive dexamethasone in patients with bacterial meningitis. ‡See Table 90-5. §Dexamethasone and antimicrobial therapy should be administered immediately after CSF is obtained. ¶See Table 90-4. CNS, Central nervous system; CT, computed tomography; c/w, consistent with; STAT, intervention should be done emergently. [‡]Some experts would add rifampin if dexamethasone is also given.

[§]Addition of an aminoglycoside should be considered.

TABLE 90-5 EMPIRICAL THERAPY FOR PURULENT MENINGITIS

PREDISPOSING FACTOR	ANTIMICROBIAL THERAPY
Age	
<1 mo	Ampicillin plus cefotaxime or ampicillin plus an aminoglycoside
1-23 mo	Vancomycin plus a third-generation cephalosporin* [†]
2-50 yr	Vancomycin plus a third-generation cephalosporin* ^{††}
>50 yr	Vancomycin plus ampicillin plus a third-generation cephalosporin*
Immunocompromised state	Vancomycin plus ampicillin plus cefepime or meropenem
Basilar skull fracture	Vancomycin plus a third-generation cephalosporin*
Head trauma; after neurosurgery	Vancomycin plus ceftazidime, cefepime, or meropenem

Modified from Tunkel AR, Hartman BJ, Kaplan, SL, et al: Practice guidelines for the management of bacterial meningitis, Clin Infect Dis 39:1267–1284, 2004.

*Cefotaxime or ceftriaxone.

[†]Some experts add rifampin if dexamethasone is also given.

^{††}Add ampicillin if meningitis caused by *Listeria monocytogenes* is suspected.

the potential risk of herniation if a lumbar puncture is performed. In this setting, emergency empirical antimicrobial therapy, and adjunctive dexamethasone therapy (if indicated), after obtaining blood cultures should be initiated before sending the patient to the CT scanner.

Specific Antimicrobial Therapy for Meningitis

After the infecting meningeal pathogen is isolated and susceptibility testing results are known, antimicrobial therapy can be modified for optimal treatment of patients with bacterial meningitis (Table 90-6). Recommended dosages of antimicrobial agents for adults with infections of the CNS are shown in Table 90-7.

One pathogen requires special discussion. Specific therapy for pneumococcal meningitis depends on the in vitro susceptibility of the organism to penicillin and the third-generation cephalosporins. Results of surveillance studies in the United States show that the prevalence of penicillin-resistant *S. pneumoniae* ranges from 25% to more than 50%; rates are as high as 60% in some parts of Latin America and as high as 80% in some countries in Asia. Penicillin can never be recommended as empirical therapy in patients with suspected pneumococcal meningitis. As an empirical regimen, the combination of vancomycin plus a third-generation cephalosporin (i.e., cefotaxime or ceftriaxone) is

TABLE 90-6 ANTIMICROBIAL THERAPY FOR PATIENTS WITH MENINGITIS

MICROORGANISM	THERAPY OF CHOICE
BACTERIA	
<i>Haemophilus influenzae</i>	
β-Lactamase negative	Ampicillin
β-Lactamase positive	Ceftriaxone or cefotaxime
<i>Neisseria meningitidis</i>	
Penicillin MIC <0.1 μg/mL	Penicillin G or ampicillin
Penicillin MIC 0.1-1.0 μg/mL	Ceftriaxone or cefotaxime
<i>Streptococcus pneumoniae</i>	
Penicillin MIC ≤0.06 μg/mL	Penicillin G or ampicillin
Penicillin MIC ≥0.12 μg/mL	
Ceftriaxone or cefotaxime MIC <1.0 μg/mL	Ceftriaxone or cefotaxime
Ceftriaxone or cefotaxime MIC ≥1.0 μg/mL	Vancomycin* plus ceftriaxone or cefotaxime
Enterobacteriaceae [†]	Ceftriaxone or cefotaxime
<i>Pseudomonas aeruginosa</i>	Ceftazidime [‡] or ceftepime [‡]
<i>Acinetobacter baumannii</i> [†]	Meropenem
<i>Listeria monocytogenes</i>	Ampicillin or penicillin G [§]
<i>Streptococcus agalactiae</i>	Ampicillin or penicillin G [§]
<i>Staphylococcus aureus</i>	
Methicillin-sensitive	Nafcillin or oxacillin
Methicillin-resistant	Vancomycin*
<i>Staphylococcus epidermidis</i>	Vancomycin*
SPIROCHETES	
<i>Treponema pallidum</i>	Penicillin G
<i>Borrelia burgdorferi</i>	Ceftriaxone or cefotaxime
MYCOBACTERIA	
<i>Mycobacterium tuberculosis</i>	Isoniazid + rifampin + pyrazinamide + ethambutol
FUNGI	
<i>Cryptococcus neoformans</i>	Amphotericin B preparation [§] + flucytosine
<i>Coccidioides immitis</i>	Fluconazole
<i>Histoplasma capsulatum</i>	Liposomal amphotericin B
<i>Candida</i> species	Amphotericin B preparation [§] ± flucytosine

MIC, Minimum inhibitory concentration.

*Addition of rifampin may be considered; see text for indications.

[†]The choice of a specific antimicrobial agent must be guided by in vitro susceptibility testing.

[‡]Addition of an aminoglycoside should be considered.

[§]Amphotericin B deoxycholate, liposomal amphotericin B, or amphotericin B lipid complex.

recommended. After susceptibility studies of the isolated pneumococcus are performed, antimicrobial therapy can be modified for optimal treatment (see Table 90-7).

Viral meningitis is usually a benign self-limited illness. Recovery of patients with HSV-2 meningitis is usually complete without neurologic sequelae, and it is not clear whether antiviral treatment alters the course of mild meningitis.

The preferred antimicrobial regimen for the treatment of CNS syphilis is intravenous aqueous crystalline penicillin G at a dosage of 18 to 24 million units daily in divided doses every 4 hours or by continuous infusion for 10 to 14 days. Alternatively, procaine penicillin (2.4 million units intramuscularly daily) plus probenecid (500 mg orally four times daily), both for 10 to 14 days, can be used.

Parenteral antimicrobial therapy is usually needed to treat the neurologic manifestations of Lyme disease, including meningitis. The current recommendation is to treat most patients with Lyme meningitis with intravenous ceftriaxone at a dosage of 2 g daily

TABLE 90-7 RECOMMENDED DOSAGES OF ANTIMICROBIAL AGENTS FOR MENINGITIS IN ADULTS WITH NORMAL RENAL AND HEPATIC FUNCTION

ANTIMICROBIAL AGENT	TOTAL DAILY DOSE*	DOSING INTERVAL (hr)
Amikacin [†]	15 mg/kg	8
Amphotericin B deoxycholate	0.7-1.0 mg/kg	24
Ampicillin	12 g	4
Cefepime	6 g	8
Cefotaxime	8-12 g	4-6
Ceftazidime	6 g	8
Ceftriaxone	4 g	12-24
Ethambutol [§]	15 mg/kg	24
Fluconazole	400-800 mg [‡]	24
Flucytosine ^{§,}	100 mg/kg	6
Gentamicin [†]	5 mg/kg	8
Isoniazid ^{§,§}	300 mg	24
Liposomal amphotericin B	3-4 mg/kg	24
Meropenem	6 g	8
Nafcillin	9-12 g	4
Oxacillin	9-12 g	4
Penicillin G	24 million units	4
Pyrazinamide [§]	15-30 mg/kg	24
Rifampin [§]	600 mg	24
Tobramycin [†]	5 mg/kg	8
Sulfamethoxazole-trimethoprim	10-20 mg/kg ^{**}	6-12
Vancomycin ^{††}	30-60 mg/kg	8-12

*Unless indicated, therapy is administered intravenously.

[†]Need to monitor peak and trough serum concentrations.

[‡]Dose of 800-1200 mg is recommended for patients with coccidioidal meningitis.

[§]Oral administration.

^{||}Maintain serum concentrations of 50-100 µg/mL.

[§]Initiate therapy at a dose of 10 mg/kg.

^{**}Dosage based on trimethoprim component.

^{††}Maintain serum trough concentrations of 15-20 µg/mL.

for 14 days (range, 10 to 28 days); no evidence supports treatment durations longer than 4 weeks.

In patients with tuberculous meningitis, the most important principle of therapy is early initiation on the basis of strong clinical suspicion; it should not be delayed until proof of infection has been obtained. The American Thoracic Society, in conjunction with the CDC and the Infectious Diseases Society of America, recommends 2 months of isoniazid, rifampin, ethambutol, and pyrazinamide, followed by 7 to 10 months of isoniazid and rifampin for patients with drug-sensitive tuberculous meningitis. Therapy for tuberculous meningitis may need to be individualized, with longer durations of therapy used for patients with more severe illness or HIV.

Therapy for cryptococcal meningitis in patients with AIDS is usually an amphotericin B preparation (i.e., amphotericin B deoxycholate, liposomal amphotericin B, or amphotericin B lipid complex) plus flucytosine for 2 weeks, followed by consolidation therapy with fluconazole for 8 weeks. For non-AIDS patients with cryptococcal meningitis, the optimal use of fluconazole is less clear. In a retrospective review of HIV-1–negative patients with CNS cryptococcosis, the patients were more likely to receive an induction regimen containing amphotericin B and subsequent therapy with fluconazole. Most experts recommend high-dose fluconazole (800 to 1200 mg daily) as first-line therapy for coccidioidal meningitis.

The current recommendation is to treat *Histoplasma* meningitis with liposomal amphotericin B over 4 to 6 weeks, followed by

itraconazole for at least 1 year. Amphotericin B, alone or in combination with flucytosine, also is the treatment of choice for *Candida* meningitis.

Adjunctive Therapy

For adult patients with bacterial meningitis, adjunctive dexamethasone should be administered to those with suspected or proven pneumococcal meningitis. This recommendation is based on a prospective, randomized, double-blind trial enrolling 301 adults with bacterial meningitis. Adjunctive dexamethasone was associated with a reduction in the proportion of patients who had unfavorable outcomes (15% vs. 25%, $P = .03$) and in the proportion of patients who died (7% vs. 15%, $P = .04$). The benefits were most striking for the subgroup of patients with pneumococcal meningitis and those with moderate to severe disease as assessed by the admission Glasgow Coma Scale.

Dexamethasone is administered at a dosage of 10 mg intravenously every 6 hours (with the first dose given concomitant with or just before the first dose of an antimicrobial agent for maximal attenuation of the subarachnoid space inflammatory response) for 4 days. Adjunctive dexamethasone should not be used in patients who have already received antimicrobial therapy or the meningitis is found not to be caused by *S. pneumoniae*. Despite the positive benefits of adjunctive dexamethasone for adults with bacterial meningitis described previously, the routine use of adjunctive dexamethasone for patients with bacterial meningitis in the developing world has been controversial.

Tuberculous meningitis is associated with persistent morbidity and mortality despite the availability of effective antituberculous chemotherapy. Use of adjunctive corticosteroids has abrogated the signs and symptoms of disease, and early treatment with adjunctive dexamethasone should be used in all patients with tuberculous meningitis.

Patients with cryptococcal meningitis may have increased intracranial pressure or hydrocephalus, or both. Therapeutic modalities for these complications include shunting of CSF and frequent, high-volume lumbar punctures.

Encephalitis

Definition

Encephalitis is inflammation of the brain parenchyma that is associated with neurologic dysfunction. In the absence of pathologic evidence of brain inflammation, an inflammatory response in the CSF or parenchymal abnormalities on neuroimaging are often used as surrogate markers of brain inflammation; however, encephalitis can occur without significant CSF pleocytosis or demonstrable neuroimaging abnormalities. Encephalitis and meningitis share many features. Both syndromes can manifest with fever, headache, and altered mental status, although the encephalitis patient suffers from more severe alterations in mental status.

There is also clinical overlap between encephalitis and encephalopathy. Patients with encephalopathy, however, exhibit confusion early in the course of their illness that can quickly progress to obtundation. Causes of encephalopathy include metabolic disturbances, hypoxia, ischemia, intoxications, organ dysfunction, paraneoplastic syndromes, and systemic infections.

Epidemiology and Etiology

Encephalitis causes significant morbidity and mortality, and it is a significant burden on the health care system. The hospital admission rate in one study was 7.3 per 100,000 people. The case-fatality rate among patients with encephalitis varies from 3.8% to 7.4% and is significantly higher among patients also infected with HIV. There is significant morbidity among survivors of encephalitis, with resultant loss of productivity and the need for prolonged rehabilitation or skilled nursing care.

Infectious causes of encephalitis are diverse and include viruses (most common), bacteria, fungi, and parasites. Clues in the patient's history that aid identification include seasonal variation, geographic location, prevalence of disease in the local community, travel history, recreational activities, occupational exposures, insect contact, animal contact, vaccination history, and immune status of the patient.

The most commonly identified viral causes in the United States are herpes simplex virus type 1 (HSV-1), West Nile virus, and the enteroviruses, followed by other herpesviruses (e.g., varicella-zoster virus). Other agents may be highly endemic regionally (e.g., La Crosse virus in the Midwest) or internationally (e.g., rabies virus, Japanese encephalitis virus). Bacterial agents, including *Ehrlichia* species and *Rickettsia rickettsii*, are potentially treatable causes of encephalitis, and prompt administration of appropriate antimicrobial therapy may be lifesaving.

Perhaps the most challenging aspect of encephalitis is that no pathogen is identified in 50% to 70% of cases. Up to 10% of patients have a noninfectious cause.

Clinical Presentation

Because encephalitis is infrequently confirmed by pathologic means, the signs and symptoms of neurologic dysfunction are used as surrogate markers, and they are often nonspecific. The clinical signs and symptoms of encephalitis are determined by the specific area of the brain involved and by the severity of the infection. Some organisms show neurotropism for particular anatomic sites. HSV-1 infection almost universally involves the temporal lobe, and the clinical presentation typically includes temporal lobe seizures. With this comes an associated change in personality, decreasing consciousness, focal neurologic findings (including dysphagia), paresthesias and weakness, and focal seizures. Sudden onset of fever and headache can also accompany these mental status changes.

Diffuse brain involvement is frequently seen with arboviral infections, and it is associated with global impairment in neurologic function and coma. Fever and headache frequently precede the onset of altered mental status, which can range from mild confusion to obtundation. Other neurologic manifestations may include behavioral changes (e.g., psychosis), focal paresis or paralysis, cranial nerve palsies, and movement disorders (e.g., chorea). About 80% of patients infected with West Nile virus are asymptomatic, and about 20% have only fever. Symptomatic patients may have fever, headache, myalgia, and flaccid paralysis. A maculopapular rash is seen in 50% of patients.

Evidence of inflammation or infection at sites distant from the CNS may be useful in making a microbiologic diagnosis for patients with encephalitis and myelitis. For instance, rickettsial

diseases, varicella-zoster virus, and West Nile virus often have associated skin manifestations. Stomatitis and ulcerative lesions in the mouth or an exanthem in a peripheral distribution can suggest enterovirus infection. Patients with tuberculous and fungal meningoencephalitis may have suggestive pulmonary findings.

A syndrome frequently misclassified as encephalomyelitis based on the similar clinical presentation is postinflammatory encephalomyelitis. The most widely cited example is acute disseminated encephalomyelitis (ADEM), which is seen primarily in children and adolescents. ADEM is characterized by poorly defined white matter lesions on magnetic resonance imaging (MRI) that enhance after gadolinium administration. Postinflammatory encephalomyelitis is likely mediated by an immunologic response to an antecedent antigenic stimulus such as infection or immunization. Viral infections associated with ADEM include measles, mumps, rubella, varicella-zoster, Epstein-Barr, cytomegalovirus, herpes simplex, hepatitis A, and coxsackievirus. Immunizations temporally associated with ADEM include vaccines for Japanese encephalitis, yellow fever, measles, influenza, smallpox, anthrax, and rabies, but a direct causal association with these vaccines is difficult to establish. ADEM usually begins between 2 days and 4 weeks after the antigenic stimulus, and patients develop rapid onset of encephalopathy, with or without meningeal signs. The neurologic features depend on the location of the lesions.

Another important disorder to consider is anti-N-methyl-D-aspartate receptor (NMDAR) encephalitis, which is the most common cause of autoimmune encephalitis after ADEM. The disorder is seen in patients of all ages but occurs mostly in young adults and children with or without teratomas. Patients usually have an acute behavioral change, psychosis, and catatonia that evolves to include seizures, memory deficit, dyskinesias, speech problems, and autonomic and breathing dysregulation. Symptoms are more often neurologic in children and psychiatric in adults, but in most cases, symptoms progress to a similar syndrome.

Diagnosis

The initial laboratory testing of an individual should include a complete blood count, tests of renal and hepatic function, and coagulation studies. A low white blood cell count, low platelet count, and elevated liver transaminase levels may suggest *Ehrlichia* or *Anaplasma* infection. A baseline chest radiograph should be obtained because a focal infiltrate can suggest particular pathogens (e.g., fungal or mycobacterial infections).

Neuroimaging studies are important to perform for all patients with encephalitis; MRI is more sensitive at detecting abnormalities than CT, and it is the preferred study. Diffusion-weighted MRI is superior to conventional MRI for the detection of early signal abnormalities in viral encephalitis caused by HSV, enterovirus 71, and West Nile virus. In patients with HSV encephalitis, there may be significant edema and hemorrhage in the temporal lobes. Patients with flavivirus (e.g., West Nile virus, Japanese encephalitis virus) encephalitis may display characteristic patterns of mixed-intensity or hypodense lesions on T1-weighted images of the thalamus, basal ganglia, and midbrain. In patients with ADEM, MRI usually reveals multiple

focal or confluent areas of signal abnormality in the subcortical white matter and, sometimes, in subcortical gray matter on T2-weighted and fluid attenuation inversion recovery (FLAIR) sequences; the lesions are usually enhancing and display similar stages of evolution.

Electroencephalography is rarely specific for a given pathogen in patients with encephalitis, but results can be helpful in identifying the degree of cerebral dysfunction by detecting subclinical seizure activity, and it may provide information about the specific area of the brain involved. Many patients with HSV encephalitis demonstrate a temporal lobe focus with periodic lateralizing epileptiform discharges (PLEDs).

Lumbar puncture with CSF analysis (i.e., cell count and differential, glucose and protein levels) and a measurement of the opening pressure should be performed unless there is a specific contraindication. Most patients with viral encephalitis have a mononuclear cell pleocytosis with cell counts ranging from 10 to 1000/mm³. Early in the disease process, CSF pleocytosis may be absent, or there may be an elevation in neutrophils. The CSF protein concentration is typically elevated, but usually less than 100 to 200 mg/dL, whereas the CSF glucose concentration is typically normal. CSF viral cultures are usually not recommended.

Brain biopsy has largely been replaced by CSF molecular tests. For certain types of infections, however, brain biopsy may be diagnostic. In rabies infections, for example, Negri bodies are a distinctive histopathologic feature. Intranuclear eosinophilic amorphous bodies surrounded by a halo may be seen in diseases such as HSV encephalitis.

Testing for specific agents includes laboratory methods such as antigen detection, culture, serology, and molecular diagnostics. HSV encephalitis is a treatable and relatively common cause of encephalitis, and an HSV PCR should be performed on the CSF of all patients with a clinical diagnosis of encephalitis. False-negative PCR test results can occur within the first 72 hours after onset, and if HSV encephalitis is strongly suspected (e.g., in a patient with temporal lobe involvement), a repeat HSV PCR on a second sample of CSF within 3 to 7 days is recommended. Enterovirus and varicella PCR should be done on CSF because they are also common causes of encephalitis; however, detection of antibodies to varicella-zoster virus in the CSF appears to have greater sensitivity than detection of viral DNA.

Testing for other agents should be individualized with consideration of the patient's exposures, travel, season of the year, and clinical and laboratory characteristics. Many infections require acute and convalescent (i.e., paired) serum samples to determine a diagnosis. A serum specimen collected during the acute phase of the illness should be stored and tested in parallel when the convalescent serum sample is drawn. Immunoglobulin M (IgM) and immunoglobulin G (IgG) capture enzyme-linked immunosorbent assays (ELISAs) have become useful and widely available for the diagnosis of arboviral encephalitis. Detection of intrathecal IgM antibody is a specific and sensitive method for the diagnosis of West Nile virus infection. There is substantial cross-reactivity among the flaviviruses (e.g., West Nile virus, St. Louis encephalitis virus, Japanese encephalitis virus); plaque-reduction neutralization assays may be helpful in distinguishing which flavivirus is involved in the event of elevated titers.

Serologic testing for *Rickettsia*, *Ehrlichia*, and *Anaplasma* species should be performed for all encephalitis patients during the appropriate season and with travel to or residence in endemic areas, especially because these are treatable causes. Empirical therapy should not be withheld from patients with a compatible clinical presentation because antibodies are not always detectable early in the course of illness.

Identification of NMDAR antibodies confirms the diagnosis of anti-NMDAR encephalitis and should lead to the search for a tumor. The tumor is almost always an ovarian teratoma.

Treatment

One of the most important first steps in managing encephalitis is to consider treatable causes. Specific antiviral therapy is usually limited to infections caused by herpesviruses (especially HSV-1 and varicella-zoster virus) and HIV. Acyclovir (10 mg/kg intravenously every 8 hours in adults with normal renal function) should be administered to patients with encephalitis. Empirical therapy for acute bacterial meningitis should be initiated when clinical and laboratory testing is compatible with bacterial infection. If rickettsial or ehrlichial infections are suspected, empirical doxycycline should be administered. The management of West Nile virus infection is supportive care.

In patients with suspected postinfectious encephalomyelitis (i.e., ADEM), high-dose intravenous corticosteroids (1 g of methylprednisolone intravenously daily for at least 3 to 5 days) are usually recommended, followed by an oral taper for 3 to 6 weeks. For patients diagnosed with anti-NMDAR encephalitis, treatments have included corticosteroids, intravenous immunoglobulins, and plasmapheresis. If a tumor is detected, removal is important because it accelerates improvement and decreases relapses.

BRAIN ABSCESS

CNS infections can manifest as abscesses in the parenchyma or as parameningeal infections. Prion infections produce clinical signs confined to the brain and spinal cord.

Definition

A *brain abscess* is a focal collection of infected material in the brain parenchyma that results in a necrotic center surrounded by inflammatory cells.

Pathology and Pathophysiology

Brain abscesses produce symptoms and findings similar to those of other space-occupying lesions (e.g., brain tumors), but they often progress more rapidly and affect meningeal structures more frequently than tumors. They originate or extend from extracerebral locations. Examples include blood-borne metastases from unknown sources, lungs, or heart (i.e., endocarditis); direct extensions from parameningeal sites of infection (i.e., otitis, cranial osteomyelitis, facial infections, and sinusitis); and infections from sites of recent or remote head trauma or neurosurgical procedures.

The infection is often polymicrobial. Commonly isolated pathogens are aerobic and microaerobic streptococci and gram-negative anaerobes such as *Bacteroides* and *Prevotella*. Less common are gram-negative aerobes and *Staphylococcus*.

Actinomyces, *Nocardia*, and *Candida* are found even less often. In immunosuppressed individuals, *Cryptococcus* (i.e., microabscesses) and *Toxoplasma* are common causes of abscesses. Surgical specimens are culture positive for 70% of antibiotic-treated patients and 95% of patients undergoing surgery before antibiotic administration.

Clinical Presentation

The classic clinical picture is composed of elements reflecting the infectious nature of the lesion (e.g., fever), those related to focal brain involvement, and those due to an increasing intracranial mass effect. Elements of one or two categories are often absent in a given case, particularly early in the disease course. For example, almost one half of patients may not have a fever or leukocytosis. Recent onset of a headache is the most common symptom, which may increase in severity associated with focal signs related to the location of the abscess (e.g., hemiparesis, aphasia), followed by obtundation and coma. Seizures precede the diagnosis in 30% of cases. *Toxoplasma* abscesses are often associated with movement disorders due to their propensity for the basal ganglia. The period of evolution may be as brief as hours or as long as days to weeks with more indolent organisms.

Diagnosis

CSF examination should be avoided; it is seldom diagnostic, and results can be normal. Lumbar puncture in the setting of a mass lesion carries the risk of transtentorial herniation. Because the brain abscess is seeded from a peripheral site of infection, a search for other sites of infection can help to identify the causative organisms and determine adequate treatment.

MRI with intravenous gadolinium provides better soft tissue contrast than CT and is particularly useful for detecting multiple

abscesses and posterior fossa abscesses or for demonstrating cerebritis, the extent of a mass effect, associated venous thrombosis, and the response to therapy. In the early cerebritis stage, CT results may be normal, but the MRI FLAIR sequence is very sensitive for visualization of brain edema. On T1-weighted images, the area of cerebritis is seen initially as a low-signal-intensity, ill-defined area. T1-weighted images in the later stages of infection show the formation of a rim of slightly higher signal intensity and central necrosis. Contrast administration typically shows ring enhancement with central necrosis. This area of central necrosis appears bright on diffusion-weighted images and dark on apparent diffusion coefficient (ADC) images (Fig. 90-2). MRI of tumors shows the opposite features. Differentiating a brain abscess from tumor is important for the stereotactic approach to ring-enhancing lesions before biopsy or surgical excision. An abscess should be drained centrally, whereas a tumor should be biopsied along its rim.

Nocardia brain abscesses are often multilobulated. *Listeria* brain abscesses are often located in the brain stem.

Treatment

A suspected brain abscess requires urgent intervention. Unless the surgical procedure poses a substantial risk, aspiration of the lesion is needed for microbial diagnosis. If treatment of cerebral edema is necessary, high-dose intravenous dexamethasone (16 to 24 mg/day in four divided doses) may be used for short periods until surgical intervention is possible. Corticosteroids may retard formation of a capsule around the brain abscess and the immune response to infection.

Seizures should be controlled because the tonic phase of a generalized seizure may increase intracranial pressure. In a patient with a large abscess, seizures may trigger a brain herniation. Seizure prophylaxis should be initiated in all patients with

FIGURE 90-2 Magnetic resonance imaging features of a brain abscess. **A**, Contrast-enhanced scan shows a ring-enhancing lesion in the left frontal lobe. **B**, The diffusion-weighted image shows restricted diffusion in the cavity due to viscous pus and cellular material. **C**, Corresponding apparent diffusion coefficient map shows dark, viscous material in the cavity and surrounding edema.

cortical or temporal lobe abscesses. Anticonvulsants that can be administered intravenously are the drugs of choice.

Successful antibiotic management of brain abscess is based on knowledge of proven or suspected pathogens and antibiotic properties, such as CNS drug penetration capabilities and the spectrum of activity. Empirical antibiotic therapy without surgical intervention may be used if the primary source of infection outside of the CNS is identified, in patients with cerebritis without capsule formation, or in those with multiple, small abscesses or abscesses in basal ganglia or brain stem. If the organism is unknown, empirical therapy may include vancomycin, metronidazole, and a third-generation cephalosporin. In brain stem abscesses, the possibility of *Listeria* infection should be considered, and treatment should include intravenous ampicillin. In HIV-infected patients with multiple ring-enhancing lesions, empirical therapy for toxoplasmosis should be initiated even if the patient is seronegative for *Toxoplasma*.

Patients undergoing empirical therapy should be followed with repeated CT or MRI. Those who fail to respond should undergo surgical intervention. An important aspect of the management strategy is eradication of the predisposing condition or cause of the brain abscess, such as an oral, ear, cardiac, or pulmonary infection.

PARAMENINGEAL INFECTIONS

Definition

Parameningeal infections include those infections that produce suppuration in potential spaces covering the brain and spinal cord (i.e., epidural abscess and subdural empyema) and those that produce occlusion of the contiguous venous sinuses and cerebral veins (i.e., cerebral venous sinus thrombosis).

Subdural Empyema

Definition

Subdural empyema refers to infection in the space separating the dura and arachnoid.

Pathology and Pathophysiology

Two thirds of subdural empyemas result from frontal or ethmoid sinus infections, 20% from inner ear infections, and the remainder from trauma or neurosurgical procedures. The empyema is caused by direct or indirect extension from infected paranasal sinuses through a retrograde thrombophlebitis. Unilateral empyema is most common because the falx prevents passage across the midline, but bilateral or multiple empyemas can occur. Cortical venous thrombosis or brain abscess develops in about one fourth of patients. In some patients, the subdural empyema may be associated with an epidural abscess or meningitis. These infections occur more often in children than in adults.

Clinical Presentation

Initial symptoms are caused by chronic otitis or sinusitis with superimposed lateralized headache, fever, and obtundation. Vomiting, meningeal signs, and focal neurologic abnormalities (i.e., hemiparesis or seizures) follow. If untreated, obtundation

progresses, and the septic mass and swollen underlying brain produce venous thrombosis or death from herniation.

The major differential diagnosis is meningitis. Nuchal rigidity and obtundation occur in meningitis and subdural empyema, but papilledema and lateralizing deficits are more common in empyema.

Diagnosis

Lumbar puncture should be avoided in patients with subdural empyema to prevent cerebral herniation. Contrast-enhanced CT or MRI can be diagnostic of empyema, showing an extra-axial, crescent-shaped mass with an enhancing rim lying just below the inner table of the skull over the cerebral convexities or in the interhemispheric fissures. On MRI, subdural empyemas have decreased signal intensity on T1-weighted imaging and increased signal intensity on T2-weighted scans. Similar to brain abscess, subdural empyema has high signal intensity on diffusion-weighted images and low signal intensity on ADC maps.

Treatment

Treatment requires prompt surgical drainage of the empyema cavity and high-dose intravenous antibiotics directed at organisms found at the time of craniotomy.

MALIGNANT EXTERNAL OTITIS

Chapter 91 discusses infections of the head and neck.

SPINAL EPIDURAL ABSCESS

Definition and Epidemiology

A *spinal epidural abscess* is an infection in the epidural space between the dura and the bones of the spine around the spinal cord. It can cause paralysis and death. The incidence is 0.5 to 1.0 cases per 10,000 hospital admissions in the United States, and the frequency is increased among injection drug users.

Pathology and Pathophysiology

Infections of the epidural space originate from contiguous spread or through hematogenous routes from a distant source. Cutaneous infection, particularly in the back, is the most common remote source, especially among injection drug users. Abdominal, respiratory tract, and urinary sources are also common. As the use of epidural catheters has increased for pain management, epidural abscess and hematoma have been increasingly reported.

The anatomy of the epidural space dictates the location of the abscess. Because the size of the intravertebral canal remains relatively constant but the circumference of the spinal cord changes, abscess formation is maximal in the thoracic and lumbar regions and minimal at the cervical spine enlargement. Due to the loose connections between the dura and the bones of the spine, the abscess can extend to multiple levels, causing severe and extensive neurologic manifestations.

Causative organisms can be identified by culture or Gram stain from pus obtained at exploration (90% of patients), blood cultures (60% to 90%), or CSF (20%). *S. aureus* is most common, followed by streptococci and gram-negative organisms. Tuberculous abscesses may occur in as many as 25% of patients in high-risk populations. In a recent epidemic, iatrogenic infection

occurred with rare fungi after epidural injections of corticosteroids that were contaminated with a plant pathogen, *Exserohilum rostratum*, that rarely infects humans.

Clinical Presentation

The classic triad of fever, spinal pain, and neurologic deficits may not be identified in all patients, leading to a delay in diagnosis. Patients are usually febrile and have acute or subacute neck or back pain. An important physical finding is focal tenderness over the affected spinous processes. Stiff neck and headache are common. The pain can be mistaken for sciatica, a visceral abdominal process, chest wall pain, or cervical disk disease. If it goes unrecognized at this stage, the symptoms can evolve over a few hours to a few days to weakness, loss of lower extremity reflexes, and paralysis distal to the spinal level of the infection. In this clinical setting, spinal epidural abscess should be assumed, systemic antibiotics begun, and urgent neuroradiologic imaging pursued.

Diagnosis

The diagnosis is made by CT or MRI (Fig. 90-3). The differential diagnosis includes transverse myelitis, intervertebral disk herniation, epidural hemorrhage, and metastatic tumor. These conditions can usually be detected by MRI. Epidural abscess is often accompanied by diskitis or osteomyelitis of the vertebral bodies.

Treatment

Unless culture and sensitivities dictate otherwise, a penicillinase-resistant penicillin should be started empirically as antistaphylococcal treatment for presumed bacterial infection. If methicillin resistance is suspected, vancomycin should be used. Considering

the severity of the disease, additional gram-negative coverage with a third-generation cephalosporin or a quinolone may be needed.

Surgical decompression was previously considered mandatory, but early diagnosis by MRI may allow for effective medical therapy if started before the occurrence of neurologic complications. These patients should be monitored closely, and if signs of neurologic deterioration emerge, surgical intervention may be necessary.

SINUS THROMBOSIS

Septic Cavernous Sinus Thrombosis

Septic cavernous sinus thrombosis usually results from spread of infection from facial structures through facial veins or from the sphenoid or ethmoid sinuses. Symptoms include headache or lateralized facial pain, followed in a few days to weeks by fever and involvement of the orbit (i.e., proptosis and chemosis due to obstruction of the ophthalmic vein). Paralysis of oculomotor nerves follows rapidly. In some instances, sensory dysfunction occurs in the first and second divisions of the trigeminal nerve along with a decrease in the corneal reflex. Further involvement of the contiguous orbital contents follows, with mild papilledema and decreased visual acuity that sometimes progresses to blindness.

Extension to the opposite cavernous sinus or to other intracranial sinuses with cerebral infarction or increased intracranial pressure due to impaired venous drainage can result in stupor, coma, and death. The CSF is abnormal if there is accompanying meningitis or parameningeal infection. The most common causative organism is *S. aureus*, followed by streptococci and pneumococci; anaerobic infection may occur.

FIGURE 90-3 Magnetic resonance imaging shows an epidural abscess due to *Staphylococcus* in the cervical spine of a patient with human immunodeficiency virus infection. **A**, Noncontrast T1-weighted image shows an extensive lesion in the epidural space that extends from C2 to C7. Notice straightening of the cervical spine. **B**, After a laminectomy from C2 to T1 and fusion, the short tau inversion recovery (STIR) image shows fluid collection in the epidural space as a high-signal-intensity lesion. Normal curvature of the spine is seen.

Diagnosis of cavernous sinus thrombosis is usually made by MRI with a venogram. Radiologic evaluation includes imaging of the sphenoidal and ethmoidal sinuses, which may require drainage if infected. Empirical antimicrobial therapy should include an antistaphylococcal agent. An empirical combination therapy with parenteral metronidazole, vancomycin, and ceftriaxone can achieve reasonable CSF and brain penetration and is likely to be active against *S. aureus* and the usual sinus pathogens. Parenteral nafcillin can be added for identified or suspected methicillin-sensitive *S. aureus*.

Lateral Sinus Thrombosis

Septic thrombosis of the lateral sinus results from acute or chronic infections of the middle ear. The infection spreads through emissary veins that connect the mastoid with the lateral venous sinus. It may spread to involve the sigmoid sinus. The symptoms include ear pain followed over several weeks by fever, headache, nausea, vomiting, and vertigo. Mastoid swelling may be seen. Sixth cranial nerve palsies and papilledema can occur, but other focal neurologic signs are rare.

The diagnosis can be established by magnetic resonance angiography. Treatment includes an empirical regimen of broad-spectrum intravenous antibiotics to cover staphylococci and anaerobes (i.e., nafcillin or oxacillin with penicillin or metronidazole), but surgical drainage (i.e., mastoidectomy) may be required.

Septic Sagittal Sinus Thrombosis

Septic sagittal sinus thrombosis is uncommon and occurs as a consequence of purulent meningitis, infections of the ethmoidal or maxillary sinuses spreading through venous channels, infected compound skull fractures, or neurosurgical wound infections (rare). Symptoms include manifestations of elevated intracranial pressure (i.e., headache, nausea, and vomiting) that evolve rapidly to stupor and coma. Diagnosis and treatment is similar to the lateral venous sinus thrombosis described earlier.

NEUROLOGIC COMPLICATIONS OF INFECTIVE ENDOCARDITIS

Epidemiology

Neurologic complications occur in one third of patients with bacterial endocarditis, and they triple the mortality rate of the disease. Most complications are related to valvular vegetations. Cerebral (but not systemic) emboli from mitral valve endocarditis are increasingly common. Most emboli, regardless of the bacterial cause of the infection, occur before or early in the course of treatment. By 2 weeks of therapy, the risk of embolization decreases dramatically. Mycotic aneurysms in the brain complicate endocarditis in 2% to 10% of patients and are more common in acute than subacute disease.

Pathophysiology and Clinical Manifestations

Cerebral emboli are distributed in the brain in proportion to cerebral blood flow. Most emboli lodge in the branches of the middle cerebral artery peripherally, with resultant hemiparesis. Focal seizures may result. Multiple microabscesses, however, can result in a diffuse encephalopathy similar to that seen in sepsis.

Mycotic aneurysms occur most commonly in the middle cerebral artery, with the aneurysms located distally in the vessel. This differentiates them from congenital berry aneurysms.

Clinical Manifestations

Patients often develop strokes, impaired consciousness, meningitis, focal seizures, and new-onset severe headaches. Strokes may manifest as ischemic lesions or hemorrhagic lesions in the brain parenchyma or subarachnoid space. Patients may have other signs of systemic microembolisms or retinal lesions, splinter hemorrhages in the nail bed, or microscopic hematuria.

Diagnosis

The diagnosis of neurologic involvement from endocarditis is best made with CT or MRI. MRI findings in endocarditis include ischemic lesions, hemorrhagic lesions, subarachnoid hemorrhage, brain abscess, mycotic aneurysm, and cerebral microbleeds. The CSF is abnormal in 70% of patients and simulates purulent meningitis (i.e., polymorphonuclear predominance, elevated protein level, and low glucose level) or a parameningeal infection (i.e., lymphocytic predominance, modest protein elevation, and normal glucose level). Multiple blood cultures may be needed to identify the organisms.

Multidetector CT angiography may be necessary to diagnose aneurysms. Small brain abscesses may complicate the course of endocarditis, but macroscopic abscesses are rare, with most occurring in the setting of acute rather than subacute endocarditis. Multiple microabscesses may escape detection on CT and are not amenable to surgical drainage.

Treatment

Antibiotic treatment of the primary disease is indicated. Stroke is usually treated conservatively. There are no controlled trials for the management of unruptured mycotic aneurysms. The aneurysms may decrease in size with antibiotic therapy, but the risk of rupture is high, and most clinicians advocate surgical management with clipping of the aneurysm or endovascular coiling. However, endovascular coiling may not prevent hemorrhage associated with rupture of a new aneurysm. Patients with infective endocarditis who do not respond to conservative medical therapy can have prompt valve replacement despite intracerebral hemorrhage.

PRION DISEASES

Etiology

Several human diseases have been attributed to a unique infectious protein, the prion. The infectious form of the prion protein is rich in β -sheets, detergent insoluble, multimeric, and resistant to proteinase K treatment.

Prion illnesses (i.e., transmissible spongiform encephalopathies) can be classified as sporadic, hereditary, or acquired. The most common form is sporadic Creutzfeldt-Jakob disease (sCJD). Familial forms include Gerstmann-Sträussler-Scheinker syndrome and familial fatal insomnia.

Acquired forms are caused by the transmission of an abnormal prion protein (PrP) from human to human or from cattle to humans. Accidental transmission of CJD between humans

appears to have occurred with cadaveric dura mater grafting, corneal transplantation, receipt of human growth hormone or pituitary gonadotropin, contaminated electroencephalogram electrodes, and contaminated surgical instruments. This form of CJD has been called iatrogenic CJD (iCJD).

The appearance of variant CJD (vCJD) in Great Britain, which was associated with the outbreak of bovine spongiform encephalopathy and the contamination of beef, greatly increased interest in this group of illnesses. Kuru is another transmissible spongiform encephalopathy that was spread in New Guinea by cannibalism, a practice that ceased in the 1950s. The disease is now almost extinct.

Sporadic Creutzfeldt-Jakob Disease

Epidemiology

Illness from sCJD is seen worldwide, with an incidence of 0.5 to 1.0 cases per 1 million people in the general population per year.

Clinical Manifestations

CJD is frequently diagnosed incorrectly initially. Prodromal symptoms include altered sleep patterns and appetite, weight loss, changes in sexual drive, and impaired memory and concentration. Disorientation, hallucinations, depression, and emotional lability are early signs, followed by a rapidly progressive dementia associated with myoclonus (about 90% of patients). Myoclonus is usually provoked by tactile, auditory, or visual startle stimuli. CJD has an abrupt onset in 10% to 15% of patients.

Other distinctive features include seizures, autonomic dysfunction, and lower motor neuron disease, suggesting amyotrophic lateral sclerosis. Cerebellar ataxia occurs in one third of patients.

Pathology

The pathologic hallmarks of CJD are spongiform or vacuolar changes in the brain without cellular inflammatory infiltrates. The pathogenic isoform of the prion protein can be demonstrated in brain tissue by immunocytochemical staining and by Western blot analysis. The fundamental process involved in human prion propagation is intercellular induction of protein misfolding and seeded aggregation of misfolded prion protein.

Diagnosis

The clinical tetrad supporting the diagnosis of CJD consists of a subacute progressive dementia, myoclonus, typical periodic complexes on electroencephalography, and normal CSF. FLAIR MRI sequences shows extensive curvilinear hyperintensity along the neocortex, called *cortical ribboning*, which affects frontal, parietal, and temporal lobes (in decreasing order of frequency). Routine CSF study is usually normal. A CSF test for the protein

14-3-3, which is released into spinal fluid when brain cells die, in the appropriate clinical context is highly specific and sensitive for CJD.

Treatment

No effective therapy exists. The disease is inexorably progressive. The median time to death from onset is 5 months, and 90% of patients with sporadic CJD die within 1 year.

Although the illness is not communicable in the conventional sense, a risk exists in handling material contaminated with the prion protein. Gloves should be worn when handling blood, CSF, and other body fluids. Instruments must be disinfected and sterilized appropriately.

Infections of the Head and Neck

Edward J. Wing

COMMON COLD

Definition and Epidemiology

The common cold is a syndrome of sore throat, rhinorrhea, and nasal congestion caused by viruses. Adults average two or three colds per year, and children have five to seven colds each year. The common cold accounts for 110 million visits to health care providers, an estimated 20 million lost work days, and at least \$3 billion in expenses for medications. Viruses are transmitted most efficiently by direct contact, but aerosol transmission also occurs.

Pathogenesis and Microbiology

The pathogenesis varies with the pathogen. For example, rhinovirus has no histological effect on the mucosal epithelium, whereas influenza virus destroys it. The syndrome is caused by many viruses including rhinovirus (30% to 40%), influenza virus, parainfluenza virus, adenovirus, coronavirus, respiratory syncytial virus, enteroviruses and metapneumovirus. No organism can be identified in 25% to 30% of cases.

Clinical Presentation

Symptoms include an initial sore throat that develops into rhinorrhea, nasal congestion, sneezing, and cough after several days. Patients may also complain of fever, malaise, and hoarseness. The presence of myalgias may indicate influenza virus, whereas conjunctivitis may indicate adenovirus or enteroviruses. Symptoms peak from 3 to 6 days and last from 7 to 10 days, but viral shedding can occur 2 to 3 weeks after infection.

Laryngitis frequently accompanies the common cold. Patients complain of hoarseness, voice breaks or aphonia. Laryngitis typically lasts 3 days and is self limited. Unusual causes of laryngitis include group A streptococci, *Hemophilus influenzae*, *Corynebacterium diphtheriae*, *Mycobacterium tuberculosis*, and fungi.

Croup is a subglottic viral infection manifesting in children typically under 3 years of age. Patients present with a characteristic rough and stridulous cough and stridor on breathing. Diagnosis is clinical and treatment symptomatic.

Treatment

Treatment of the common cold is symptomatic; treatments include decongestants for nasal congestion, nonsteroidal anti-inflammatory drugs (NSAIDs) for fever and myalgia, lozenges for sore throat, and dextromethorphan for cough. Zinc and Echinacea have not been shown to be effective. There is also no convincing evidence supporting preventative measures. Viral laryngitis and croup are treated symptomatically; there is no evidence that antibiotics help.

For a deeper discussion of these topics, please see Chapter 361, "The Common Cold," in Goldman-Cecil Medicine, 25th Edition.

ACUTE BACTERIAL SINUSITIS

This section focuses on acute community-acquired bacterial sinusitis.

Definition and Epidemiology

Bacterial sinusitis is inflammation and bacterial infection of the paranasal sinuses. Bacterial sinusitis follows the common cold in 0.5% to 2.0% of cases in adults and in 6% to 13% of cases in children. Sinusitis accounts for 23 million health care visits each year and 20 million antibiotic prescriptions per year.

Pathogenesis

Sinusitis occurs when the sinus ostias narrow from inflammation, mucosal cilia become dysfunctional and disrupted, and mucus becomes viscous. The sinuses, which are normally sterile, become colonized with nasal bacteria and infection results. The major organisms identified by sinus puncture are *Streptococcus pneumoniae* and *H. influenzae* (Table 91-1); 30% to 40% of cultures are negative. Fungi cause a rare syndrome of rhinocerebral mucormycosis in diabetics.

Clinical Presentation

The symptoms and signs of acute bacterial sinusitis have a large overlap with the common cold. Table 91-2 shows the sensitivity and specificity of symptoms and signs in sinusitis. Nasal discharge/obstruction, facial pain, and maxillary toothache are suggestive. Physical findings of nasal discharge, facial pain, and pain on palpation of the sinuses are nonspecific and variable. Most important is that symptoms of the common cold peak between days 3 and 6 and resolve by day 10. Sinus infection occurs characteristically after 10 days of infection. There are three patterns of acute bacterial sinusitis: symptoms persisting for more than 10 days; severe symptoms, including fever and purulent nasal discharge over 3 to 4 days; and common cold symptoms that improve and then suddenly worsen.

Diagnosis

The diagnosis of acute bacterial sinusitis is most often made on clinical grounds as noted previously. Imaging can be helpful in situations in which the diagnosis is unclear or there are complications. Unfortunately, the common cold can also result in positive findings. Computed tomography (CT) is the procedure of choice if indicated.

**TABLE 91-1** BACTERIAL CAUSE OF ACUTE SINUSITIS

ORGANISM	ADULTS (n = 339)		CHILDREN (n = 30)	
	Number of Isolates	% of Isolates	Number of Isolates	% of Isolates
<i>Streptococcus pneumoniae</i>	92	41	17	41
<i>Haemophilus influenzae</i>	79	35	11	27

TABLE 91-2 DIAGNOSTIC SIGNS AND SYMPTOMS OF SINUSITIS

SYMPTOM OR SIGN	SENSITIVITY (%)	SPECIFICITY (%)	LIKELIHOOD RATIO
Maxillary toothache	18	93	2.5
No improvement with decongestants	41	80	2.1
Cough	70	44	1.3
Sore throat	52	56	1.2
Headache	68	30	1.0
Purulent secretion	51	76	2.1
Abnormal transillumination	73	54	1.6
Sinus tenderness	48	65	1.4
Fever	16	83	0.9

From Williams JW Jr, Simel DL, Roberts L, Samsa GP: Clinical evaluation for sinusitis: making the diagnosis by history and physical examination, *Ann Intern Med* 117:705–710, 1992.

Treatment

Acute bacterial sinusitis resolves spontaneously within 2 weeks without antibiotic therapy. Antibiotic therapy hastens the resolution of symptoms and is recommended by guidelines from the major national organizations of internists, pediatricians, allergists, and otolaryngologists. Careful review of randomized controlled trials as reported in the Cochrane Database Systematic Reviews, however, concludes that the risks of antibiotics outweigh the benefits in routine cases in adults. The antibiotics of choice are amoxicillin or amoxicillin and clavulanic acid given for 10 days. Macrolides, sulfamethoxazole-trimethoprim, and doxycycline may be less effective because common bacteria are developing resistance. Patients should respond within 48 to 72 hours. Intranasal saline irrigation has been shown to give symptomatic relief. Intranasal steroids may help individuals with underlying allergic rhinitis. There are no convincing data supporting use of antihistamines or α -adrenergic agonists. Surgery may be indicated for people with unresponsive sinusitis or those with intracranial or orbital complications.

Complications that are unusual include intracranial pathology such as subdural empyema, epidural abscess, brain abscess, meningitis and venous sinus thrombosis. Extracranial complications include orbital cellulitis, orbital abscess and subperiosteal abscess (Fig. 91-1). Immediate surgical intervention is indicated for orbital or intracranial abscesses. Refer to the Infectious Diseases Society of America guidelines for upper/respiratory tract infections for treat details.

PHARYNGITIS, STOMATITIS, LARYNGITIS, AND EPIGLOTTITIS

Pharyngitis

Definition and Epidemiology

Pharyngitis or sore throat is mucous membrane inflammation localized to the posterior pharynx and contiguous membranes.

Stomatitis, laryngitis, and epiglottitis are similar processes in the indicated locations. These infections are extremely common. In the acute care setting in the United States, for example, pharyngitis accounts for 7 million pediatric and 6 million adult visits each year. Peak incidence is typically in the winter months.

Etiology

Viruses cause 70% to 90% of cases of pharyngitis with rhinovirus being the most common. Adenovirus, which typically occurs in the late winter, is common in children less than 5 years of age and in young adults. Enteroviruses cause syndromes of herpangina (e.g., coxsackie group A); hand, foot, and mouth disease (e.g., coxsackie A16 and enterovirus 71); and nonspecific illnesses (e.g., group B coxsackie and echovirus). Herpes simplex virus causes pharyngitis and stomatitis in children and college students. Many other viruses cause pharyngitis, including Epstein-Barr virus, influenza virus, parainfluenza virus, and cytomegalovirus.

Group A streptococci (GAS) accounts for 10% to 30% of cases in children and 5% to 0% of cases in adults. In winter months up to 50% of cases may be due to GAS. Other bacterial causes, including group C and G streptococci and *Fusobacterium necrophorum*, are much less common. Noninfectious causes of pharyngitis include Beçhet's syndrome, Kawasaki disease, and aphthous stomatitis.

Clinical Presentation

The main job of clinicians is to distinguish GAS from viral pharyngitis. Typically, GAS presents with sudden onset of pain on swallowing, tender cervical lymph nodes and fever without cough and coryza. Viral etiologies may be accompanied by cough, coryza, and conjunctivitis (typically adenovirus). Scarlet fever consisting of a fine maculopapular rash like "sand paper" that desquamates and a strawberry tongue (prominent lingual papillae) indicates GAS. However, even experienced clinicians can distinguish viral from bacterial causes of pharyngitis only 50% of the time.

FIGURE 91-1 **A**, A child has an orbital abscess as a complication of ethmoid sinusitis. Notice the marked edema and proptosis. **B**, Computed tomography scan of the orbit shows a subperiosteal abscess (*arrow*). (**A**, Courtesy Gary Williams, MD; **B**, From DeMuri GP, Wald ER: Sinusitis. In Bennett JE, Dolin R, Blaser M, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 8, Philadelphia, 2015, Saunders.)

Complications include peritonsillar abscess or Quinsy that occur in adolescents and young adults. Patients appear ill and may have a muffled or “hot potato” voice and foul-smelling breath. The uvula may be displaced and there may be trismus and drooling. Less common complications include contiguous neck space infections. *F. necrophorum* can cause a rare syndrome called postangina septicemia or Lemierre’s syndrome, which manifests with severe sore throat and fever. The lateral pharyngeal space becomes infected with resulting septic thrombophlebitis of the internal jugular vein. The mortality rate can be as high as 50%. Treatment is intravenous penicillin and drainage of any abscess. [Table 91-3](#) lists the danger signs in patients with sore throat.

Diagnosis

Identifying GAS infection is important because treatment can prevent poststreptococcal complications including acute rheumatic fever, scarlet fever and peritonsillar abscess (i.e., quinsy). Rapid antigen detection tests for GAS are specific but only 66% to 90% sensitive. The diagnostic standard is a culture of a careful swab of the tonsils and pharynx. If clinical and epidemiological data suggest GAS, a rapid antigen detection test should be performed. If positive, the patient should be treated. If negative in children and adolescents, a culture should be done and if the culture is positive treatment is indicated. In adults, culture is not always necessary because the rate of complications is low and the incidence of a rheumatic fever is exceptionally low. Otherwise, symptomatic therapy is indicated.

Treatment

Treatment of viral pharyngitis is symptomatic; treatment of GAS pharyngitis is oral penicillin or amoxicillin for 10 days. For patients with a penicillin allergy, first generation cephalosporins

TABLE 91-3 SEVEN DANGER SIGNS IN PATIENTS WITH SORE THROAT

1. Persistence of symptoms longer than 1 week without improvement
2. Respiratory difficulty, particularly stridor
3. Difficulty in handling secretions
4. Difficulty in swallowing
5. Severe pain in the absence of erythema
6. A palpable mass
7. Blood, even small amounts, in the pharynx or ear

(non-life-threatening allergy), clindamycin or clarithromycin for 10 days, or azithromycin for 5 days are reasonable alternatives.

Oral Cavity Infections

Stomatitis

Many viruses can cause stomatitis (see [Pharyngitis](#)). In particular, herpes simplex virus causes stomatitis and is characterized by vesicles and moderate pain. Treatment of primary infection is with oral acyclovir or valacyclovir. Other viruses such as enteroviruses can also cause stomatitis.

Periodontal Infections

Periodontal infections include gingivitis, periodontitis (i.e., the major cause of tooth loss in adults), and periodontal abscess. Acute necrotizing ulcerative gingivitis or Vincent’s angina is characterized by acute pain of the gingiva, a pseudomembrane, and halitosis. Débridement and antibiotics are indicated.

Neck Space Infections

Neck space infections usually result from dental caries. Dental infections can lead to neck space infections involving the lateral

pharyngeal space, the retropharyngeal space, and the submandibular and sublingual space (e.g., Ludwig's angina). These infections are medical emergencies and need to be dealt with surgically as well as with antibiotic treatment. Ludwig's angina is characterized by swelling in the submandibular space, an elevated tongue, and difficulty eating (Fig. 91-2). Treatment consists of surgical decompression and drainage and intravenous antibiotics. Table 91-4 lists neck space infections requiring drainage and decompression.

Aphthous Ulcers

Aphthous ulcers are shallow ulcerations typically lasting for several days to weeks located on the anterior structures of the mouth. The cause is unknown. Treatment is symptomatic except for individuals with extensive persistent disease in whom steroids or thalidomide may be indicated.

Thrush

Thrush refers to superficial *Candida albicans* infection of the tongue, hard and soft palate, and pharynx, which results in a sore

FIGURE 91-2 Early appearance of a patient with Ludwig's angina, who has a brawny, boardlike swelling in the submandibular spaces. (From Megran DW, Scheifele DW, Chow AW: Odontogenic infections, *Pediatr Infect Dis* 3:262, 1984.)

TABLE 91-4 PARAPHARYNGEAL SOFT TISSUE SPACE INFECTIONS AND INDICATIONS FOR SURGICAL DRAINAGE

INFECTION	INDICATIONS FOR SURGERY
Peritonsillar abscess (quinsy)	Abscess or respiratory compromise
Lateral pharyngeal space abscess	Abscess
Jugular vein septic thrombophlebitis	Febrile after 5-6 days of medical therapy
Retropharyngeal abscess	Abscess or respiratory compromise
Ludwig's angina	Abscess or respiratory compromise

mouth and oropharyngeal pain on swallowing. On inspection there are creamy white plaques on the tongue, hard and soft palates, and the pharynx. Patients who are immunocompromised secondary to corticosteroid treatment or underlying conditions such as HIV are susceptible. Treatment is typically topical antifungal agents or oral fluconazole for 5 to 7 days.

Bacterial Epiglottitis

Acute bacterial epiglottitis caused by *H. influenzae* was previously an uncommon but life-threatening illness of children under the age of 5. With widespread use of the *H. influenzae* vaccine in children, the incidence has decreased by 99% in children. More often, the disease occurs in adults in whom a variety of bacteria are responsible, including *S. pneumoniae*, *Staphylococcus aureus*, β -hemolytic streptococci, and *Klebsiella pneumoniae*. Patients typically present with fever and toxicity, drooling, dysphagia, and holding the head extended. Speaking is painful and the laryngeal tracheal area is very tender. Examination may reveal a cherry red visible epiglottitis. Coordinated care, if necessary in the OR, is critical to maintain the airway. Broad-spectrum antibiotics are indicated. Steroids are commonly used but data are lacking to support their use.

ACUTE BACTERIAL OTITIS EXTERNA AND MEDIA

Acute Bacterial Otitis Externa

Acute localized otitis externa is a superficial infection of the outer portion of the ear canal usually related to furunculosis caused by *S. aureus*. It can be treated with oral anti-staphylococcal antibiotics. Acute diffuse otitis externa (i.e., swimmer's ear) begins with itching and progresses to moderate/severe pain on manipulation of the pinna or tragus. The canal is erythematous and swollen. The usual organism is *Pseudomonas aeruginosa*. Treatment consists of acetic acid and alcohol lavage with or without topical antibiotics such as ciprofloxacin or neomycin plus polymyxin.

Malignant otitis externa is a rare infection usually found in elderly diabetic patients that progresses over weeks to months. It is characterized by deep seated pain, otorrhea and granulation tissue on the posterior inferior wall of the external canal. CT scan is the initial imaging modality of choice. The infection can progress to skull-based osteomyelitis and meningitis and has a significant mortality. Treatment is surgical débridement and antipseudomonal systemic therapy.

Acute Bacterial Otitis Media

Definition and Epidemiology

Acute bacterial otitis media is an acute bacterial infection of the middle ear. Almost all children have at least one episode of otitis media in the first 10 years of life, making it the most common bacterial infection seen in children. It accounts for one fourth of all office visits and is the second most common reason for surgical procedures in children (the most common is circumcision). It appears that about one third of children are prone to infection and have multiple episodes, another third have intermediate susceptibility, whereas another third will be relatively resistant.

FIGURE 91-3 Eustachian tube. (From Drake RL: Gray's basic anatomy, Philadelphia, 2012, Elsevier, pp 413–592.)

Pathogenesis

While the disease in adults mimics that in children, children are more susceptible because their Eustachian tubes are shorter and more horizontal (Fig. 91-3). Disease typically results from Eustachian tube blockage and dysfunction that occurs during viral infection. Bacteria colonize the middle ear and cannot be eliminated. The most common causative bacteria are *S. pneumoniae*, nontypable *H. influenzae*, and *Moraxella catarrhalis*.

Clinical Presentation

Acute bacterial otitis media presents with ear pain in over two thirds of patients. The diagnosis can be difficult in young children because the history may be absent or inaccurate. Physical diagnosis typically shows middle ear effusion and an abnormal tympanic membrane that is red and bulging or retracted. Movement of the membrane is limited on application of positive or negative pressure. Perforation, drainage, fever and decreased hearing may occur. Patients may also have vertigo, tinnitus, and nystagmus. The course of otitis media is usually self-limited with most cases resolves within one week.

Treatment

Treatment has been controversial because for most patients otitis media is a self-limited disease. Studies suffer from the difficulty in making an accurate diagnosis and lack of placebo controls. Overuse of antibiotics has resulted in the development of resistant organisms in the United States, complicating treatment of respiratory infections. Antibiotics shorten the course of the disease and may prevent complications such as mastoiditis, facial palsy, brain abscess, epidural abscess and cholesteatoma, although convincing data are lacking because the incidence of these complications has decreased in all patient populations.

Guidelines recommend the use of antibiotics in otitis media, particularly for patients at high risk, for patients in whom there is complicated disease, or when pain relief is important. The failure rate with antibiotics is less. The concerns about antibiotic resistance, however, have made withholding antibiotics and closely observing the patient a reasonable option. A Cochrane review of antibiotics for sore throat, acute otitis media, bronchitis, and the common cold concluded that antibiotics could be delayed if clinicians felt it safe. If symptoms worsen or persist over 48 to 72 hours, then antibiotics should be initiated.

S. pneumoniae, *H. influenzae*, and *M. catarrhalis* have each shown significant resistance to penicillin in resistant years. Despite these increased rates, amoxicillin or amoxicillin/clavulanic acid continue to be the drugs of choice. Alternative choices include cephalosporins or macrolide antibiotics. If there is no improvement after three days, switching antibiotics should be considered.

Serous otitis media refers to fluid in the ear in the absence of signs or symptoms of infection. This is usually self-limited and resolves in 2 to 4 weeks. Persistent fluid for greater than 3 months associated with hearing loss, however, is an indication for tube placement.

Infections of the Lower Respiratory Tract

John R. Lonks

DEFINITION AND EPIDEMIOLOGY

Pneumonia, which is inflammation of the lung parenchyma, is usually caused by an acute infection. When the disease onset occurs outside of the hospital, it is referred to as *community-acquired* pneumonia. It ranges in severity from a mild, self-limited disease to one that is fatal. Community-acquired pneumonia is common, and most patients with pneumonia are treated in the outpatient setting.

Pneumonia is one of the most common reasons for hospitalization among all age groups and accounts for approximately 1 million hospitalizations per year. Each year, approximately 50,000 people in the United States die of influenza and pneumonia. Influenza or pneumonia is the leading cause of death due to infection and the ninth most common cause of death overall.

Numerous microorganisms cause pneumonia, including bacteria, viruses, mycobacteria, and fungi. These agents range from microorganisms that are part of the normal flora to exogenous microorganisms that are inhaled. Noninfectious diseases can mimic pneumonia. The incidence of pneumonia is lowest during early adulthood and increases with each decade of life (Fig. 92-1).

FIGURE 92-1 Rate of hospitalization for pneumonia by age group. PCV7, 7-valent pneumococcal conjugate vaccine. (From Griffin MR, Zhu Y, Moore MR, et al: U.S. hospitalizations for pneumonia after a decade of pneumococcal vaccination, *N Engl J Med* 369:155-163, 2013.)

PATHOLOGY

Bacterial pneumonia usually causes lobar pneumonia, which is consolidation of an entire lobe or a large portion of a lobe, or bronchopneumonia, which is patchy consolidation of the lung. Pneumococcal lobar pneumonia has four stages of the inflammatory response: consolidation, red hepatization, gray hepatization, and resolution. The initial congestion is characterized by fluid, with some neutrophils and bacteria, filling the alveoli. Red hepatization is characterized by red blood cells along with numerous neutrophils and fibrin filling the alveoli. With gray hepatization, there is breakdown of red blood cells and persistence of fibrin and neutrophils. The consolidated exudate within the alveolar spaces then undergoes resolution.

Pathophysiology

The lower respiratory tract is virtually sterile. Normal host defenses that protect against pneumonia include mucus production and cilia; in combination, they form the mucociliary escalator.

Impairment of host defenses leads to increased risk of pneumonia. Loss or suppression of the cough reflex due to stroke and other neurologic diseases, drugs, and alcohol increases the risk of developing pneumonia, as do aging and associated medical illnesses.

Environmental factors such as smoking and respiratory irritants impair ciliary function and increase the risk of developing pneumonia. Mechanical obstruction of an airway by a tumor or foreign body leads to decreased clearance of microorganisms and may produce postobstructive pneumonia. In addition to mechanical clearance, innate host defenses such as phagocytes and antibodies are essential after microorganisms reach the alveoli. Alveolar macrophages and other components of innate immunity are the first line of defense. Subsequently, opsonizing antibodies and neutrophils play an essential role. Impairment of these host defenses (e.g., alveolar macrophages by silica exposure, neutrophils by chemotherapy, antibodies by hypogammaglobulinemia) increases susceptibility to pneumonia. Those infected with human immunodeficiency virus (HIV) are at increased risk for pneumococcal pneumonia.

The two main mechanisms of entry of microorganism into the lung are microaspiration of organisms that colonize the upper respiratory tract and inhalation of airborne particles that contain a pathogenic microorganism. When a sufficient inoculum enters

the lung and normal host defenses are not able to clear the inoculum; bacterial replication leads to a lower respiratory tract infection.

Transmission of Respiratory Pathogens

Some pathogens are transmitted from person to person by droplet transmission. Droplets are created when a person coughs, sneezes, or talks. Transmission can occur during medical procedures such as suctioning, endotracheal intubation, cardiopulmonary resuscitation, or cough-producing procedures. The greatest distance of transmission is unresolved. Historically, a distance of 3 feet or less was assumed for person-to-person droplet transmission. Some data suggest that transmission may occur from as far away as 6 feet. Respiratory droplets have also been defined by their size, usually greater than 5 μm in diameter.

Crowding, as occurs in prisons, barracks, and shelters, is associated with increased spread. Pathogens that are transmitted by the droplet route include *Streptococcus pneumoniae*, *Mycoplasma pneumoniae*, and influenza virus.

Infectious agents such as *Mycobacterium tuberculosis*, fungi, and anthrax spores are airborne. Microorganisms transmitted in this fashion can be spread over long distances (>6 feet) by air currents and normal airflow. The size of the droplet nuclei particles that are transmitted by the airborne route are usually 5 μm or less in diameter.

Etiologic Agents

Many bacteria and viruses cause pneumonia. *S. pneumoniae* (i.e., pneumococcus) is the most common, and the classic description of pneumonia is based on disease caused by pneumococci. Most cases of pneumococcal pneumonia occur between December and April. Pneumococci transiently colonize the upper respiratory tract. Microaspiration leads to entry into the lower respiratory tract. If aspirated in sufficient quantity so that normal host defenses do not clear the bacteria, the patient develops pneumonia. Pneumococci have a polysaccharide capsule that prevents phagocytosis. Antibodies against the polysaccharide capsule, which are acquired from prior exposure or vaccination, opsonize pneumococci, enabling phagocytosis.

Other bacteria that can colonize the oropharynx and cause pneumonia when aspirated include *Haemophilus influenzae*, less commonly *Staphylococcus aureus*, and rarely *Streptococcus pyogenes* (i.e., group A β -hemolytic streptococcal infection). Similarly, *Moraxella catarrhalis* in patients with chronic obstructive pulmonary disease and in the elderly and *Klebsiella pneumoniae* in alcoholics colonize the oropharynx and cause pneumonia. Most cases of community-acquired pneumonia are monomicrobial.

Patients with pneumococcal pneumonia can develop infections at other sites, including empyema, pericarditis, meningitis, endocarditis, and septic arthritis. Approximately one of five patients with pneumococcal pneumonia has bacteremia.

M. pneumoniae usually causes milder disease. Its peak incidence is during the first 2 decades of life. Patients usually do not require hospitalization, but some develop severe disease.

Chlamydia pneumoniae (formerly called *Chlamydia pneumoniae*) is a common cause of community-acquired pneumonia. It usually causes a milder disease and is seen more commonly among patients treated in the outpatient setting.

Legionella, an environmental organism, can cause pneumonia. *Legionella pneumophila* is the most common species of pneumonia, but *Legionella micdadei* and *Legionella bozemanii* can also cause pneumonia. Most cases are sporadic. Outbreaks have occurred from contaminated point sources such as cooling towers and air conditioning units. Transmission usually occurs through inhalation of aerosol particles; microaspiration of water containing *Legionella* has also occurred.

Infrequently, *S. aureus* causes bacterial pneumonia, sometimes as a complication of influenza infection. Community-acquired methicillin-resistant strains (MRSA) have caused secondary bacterial pneumonias.

Viruses, particularly influenza viruses, cause a minority of pneumonias in adults. Patients with influenza are at risk for secondary bacterial pneumonia, most commonly due to *S. pneumoniae*, *H. influenzae*, or *S. aureus*. Respiratory syncytial virus (RSV), a pathogen that usually infects children, has been found more frequently as a cause of pneumonia among the elderly. Adenovirus rarely causes pneumonia in young adults. During 2003, the severe acute respiratory syndrome (SARS) virus emerged in Guangdong Province in southern China, and after initial international spread, it was contained. In 2012, the Middle East respiratory syndrome coronavirus (MERS-CoV) emerged as a cause of severe pneumonia. Most cases occurred in the Middle East.

Viruses such as the influenza viruses predispose patients to secondary bacterial pneumonia. Influenza infection may damage the respiratory epithelium, and resulting dysfunctional innate immune responses enhance susceptibility to secondary bacterial infection.

Fungi that cause pneumonia are not part of the normal flora. Certain dimorphic fungi (e.g., *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*) that reside in the soil cause pneumonia when they are inhaled. Dimorphic fungi form hyphae at ambient temperatures and yeasts at body temperature. The hyphal form is the transmissible form of the fungus. The yeast form is not transmissible from person to person.

These fungi are limited to certain geographic areas: *H. capsulatum* in the Mississippi, Missouri, and Ohio River valleys; *B. dermatitidis* in Southern states bordering the Mississippi and Ohio River basins and Midwestern states bordering the great lakes; and *C. immitis* in the Southwestern United States. *H. capsulatum*, *B. dermatitidis*, and *C. immitis* cause disease in the normal host. *Aspergillus*, a mold, is ubiquitous in the environment; it rarely causes disease in the immunocompetent host. Patients who are immunocompromised or have abnormal airways are at risk for infection with *Aspergillus* but rarely with other molds such as *Zygomycetes* species (Mucorales order), which do have a predisposition for infecting patients with diabetes mellitus.

M. tuberculosis is not part of the normal flora. It is transmitted by small aerosol particles (<5 μm) that are inhaled directly into the alveolus. *M. tuberculosis* is a slow-growing organism that usually causes chronic symptoms; however, it rarely can manifest acutely. Patients with HIV infection, those treated with biologic agents such as tumor necrosis factor (TNF) inhibitors, and the very young and old are particularly susceptible.

The normal flora of an acutely ill hospitalized patient is different from that of a healthy outpatient. Hospitalized patients are

more frequently colonized with *S. aureus*, including methicillin-resistant strains, and gram-negative bacilli, including *Pseudomonas aeruginosa*. When a hospitalized patient aspirates his or her oropharyngeal flora, it may contain one of these organisms. Microorganisms that almost never cause pneumonia include *Candida* species and enterococci.

For a deeper discussion of these topics, please see Chapter 9, "Overview of Pneumonia," in Goldman-Cecil Medicine, 25th Edition.

CLINICAL PRESENTATION

Patients with pneumonia usually have an acute onset of fever, chills, cough, sputum production, dyspnea, and sometimes pleuritic chest pain. Patients may produce blood-tinged sputum that appears rust colored, a classic sign of pneumonia due to *S. pneumoniae*. Extrapulmonary signs and symptoms may include nausea, vomiting, diarrhea, abdominal pain, headache, confusion, arthralgia, myalgias, and change in mental status. Signs and symptoms can be blunted or absent in the elderly. Rales or rhonchi may be heard on auscultation of the chest. A leukocytosis with a left shift (i.e., increased band forms), pulmonary signs and symptoms, and a new infiltrate seen on the chest radiograph are used to diagnose pneumonia.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

When pneumonia is suspected, the next step is to determine the etiologic diagnosis. Unfortunately, there is no single diagnostic

test with a high sensitivity and high specificity. The sputum Gram stain provides useful diagnostic information. Although epithelial cells from the upper respiratory tract and oropharyngeal flora may contaminate an expectorated sputum sample, careful examination of the sputum Gram stain can reveal an area of the specimen that originated from the lower respiratory tract and contains neutrophils, and examination for bacteria in that area can be helpful. However, some patients do not produce sputum, and prior antibiotic use can alter sputum results.

S. pneumoniae is a gram-positive coccus that forms pairs and chains; the cocci are sometimes pointed at one end (i.e., lancet shaped). *H. influenzae* is a pleomorphic gram-negative rod. *S. aureus* is a gram-positive coccus that forms "grape-like" clusters. *M. catarrhalis* is gram-negative diplococcus. These distinct morphologic features allow a presumptive diagnosis of a specific etiologic agent when seen on a Gram stain of sputum (Fig. 92-2).

Mycoplasma, *Legionella*, *Mycobacterium*, and *Chlamydia* species are not seen on the sputum Gram stain. *Mycobacteria* are seen with special acid-fast staining.

Culture of sputum can reveal the etiologic diagnosis, and results should be correlated with findings from the sputum Gram stain. However, pneumococci are fastidious. A study of patients with bacteremic pneumococcal pneumonia found that only 55% of sputum cultures grew pneumococci. *Mycoplasma* species, *Legionella* species, *Mycobacterium* species, and *C. pneumoniae* do not grow on routine agar. Special culture media are required for certain bacteria, such as Löwenstein-Jensen medium for

FIGURE 92-2 Sputum Gram stain. **A**, *Streptococcus pneumoniae*. **B**, *Haemophilus influenzae*. **C**, *Moraxella catarrhalis*. **D**, *Staphylococcus aureus*. PCV7, 7-Valent pneumococcal conjugate vaccine. (A, From Murray PR: Medical microbiology, ed 7, Philadelphia, 2013, Elsevier; B, From de la Maza LM, Pezzlo MT, Shigei JT, Peterson EM: Color atlas of medical bacteriology, Washington, D.C. 2004, ASM Press; C, From Ferri F: Ferri's color atlas and text of clinical medicine, Philadelphia, 2009, Elsevier; D, From Donowitz GR: Acute pneumonia. In Mandell GL, Bennett JE, Dolin R, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 8, Philadelphia, 2015, Churchill Livingstone.)

Mycobacteria and buffered charcoal yeast extract (BCYE) for *Legionella*.

Blood cultures can be helpful. However, the ratio of bacteremic to nonbacteremic pneumococcal pneumonia is approximately 1 : 4. A positive blood culture is very helpful because the etiologic agent is definitely identified and susceptibility data are available to determine appropriate therapy.

Other diagnostic studies used to identify the causative organism include *Legionella* urinary antigen, *Histoplasma* urinary antigen, polymerase chain reaction (PCR) for respiratory viruses, and serologic testing for *Mycoplasma* and *C. immitis*.

Chest radiography of patients with pneumococcal pneumonia can show a consolidative lobar infiltrate or a bronchopneumonic (patchy) pattern; less commonly, it causes an interstitial pattern. A definitive etiologic diagnosis cannot be made based on the chest radiographic appearance.

Not all patients with a new pulmonary infiltrate have pneumonia. Congestive heart failure is commonly confused with pneumonia. Noninfectious causes of pulmonary infiltrates and fever include pulmonary infarction, granulomatosis with polyangiitis (i.e., Wegener's granulomatosis), drug reactions, tumor, cryptogenic organizing pneumonia, hypersensitivity pneumonitis, collagen vascular disease, and acute respiratory distress syndrome (ARDS).

TREATMENT

The definitive treatment for pneumonia is to eradicate the infecting microorganism. Antibiotics are used to kill bacteria and decrease or stop the spread of infection in the lungs. Normal host responses are needed to repair the inflammatory damage in the lungs.

Penicillin therapy has reduced the mortality rate of bacteremic pneumococcal pneumonia from 84% to 17%. However, antibiotics have little to no effect on the mortality rate during the first 5 days of illness.

After the etiologic agent has been identified, the appropriate antibiotic can be given (Table 92-1). If a specific etiologic diagnosis is not made, empirical treatment with one of many antimicrobial agents is recommended. Guidelines are available at

http://www.idsociety.org/IDSA_Practice_Guidelines (accessed November 1, 2014).

The decision to admit a patient with pneumonia is based on clinical prediction rules. The pneumonia severity index (PSI) stratifies patients into one of five risk groups. Those in a low-risk group are treated as outpatients, whereas those in a higher-risk group are admitted to the hospital for treatment. The CURB-65 score (confusion, urea, respiratory rate, blood pressure, and age ≥ 65 years) developed by Lim and colleagues is easier to calculate but has not been as rigorously validated as the PSI. Psychosocial and other factors that affect the decision to admit a patient are not included in the PSI or CURB-65.

For a deeper discussion of these topics, please see Chapter 9, "Overview of Pneumonia," in Goldman-Cecil Medicine, 25th Edition.

PROGNOSIS AND PREVENTION

Patients with bacteremic pneumococcal pneumonia have a higher mortality rate (21%) compared with those who have nonbacteremic pneumococcal pneumonia (13%). Among patients with bacteremic pneumococcal pneumonia, the mortality rate increases with advancing age (Fig. 92-3), number of lobes involved (i.e., one lobe, 12%; two lobes, 24%; and three lobes, 63%), and white blood cell (WBC) count (i.e., leukopenia, 35%; normal peripheral WBC count, 24%; and leukocytosis, 14%). Mortality rates are different for each capsular type of pneumococcus. For example the mortality rate for patients infected with capsular type I is 3%, compared with 22% for patients infected with capsular type III. Patients who survive usually recover without sequelae.

The influenza vaccine protects against not only influenza but also bacterial pneumonia, because patients who do not have influenza are not at risk for secondary bacterial pneumonia. The 13-valent pneumococcal conjugate vaccine followed 6 to 12 months later by the 23-valent pneumococcal polysaccharide vaccine is recommended for those 65 years of age and older who have not been previously vaccinated. Adults less than 65 years with certain immunocompromising conditions or

FIGURE 92-4 Incidence of penicillin-resistant pneumococcal infection from before and after the introduction of the pneumococcal conjugate vaccine for different age groups. (From Kyaw MH, Lynfield R, Schaffner W, Schaffner W, et al: Effect of introduction of the pneumococcal conjugate vaccine on drug-resistant *Streptococcus pneumoniae*, *N Engl J Med* 354:1455–1463, 2006.)

specific underlying medical conditions that put them at a higher risk of pneumococcal infections should also be vaccinated. The conjugate pneumococcal vaccine has reduced invasive pneumococcal disease in children, and decreased carriage in children has reduced transmission and subsequent disease in adults

(Fig. 92-4). Use of the pediatric conjugate vaccine has reduced the number of adult hospital admissions for pneumonia (see Fig. 92-1). It also has decreased antibiotic resistance because the capsular types of pneumococci that are more likely to be antibiotic resistant are included in the vaccine.

Infections of the Heart and Blood Vessels

Cheston B. Cunha and Eleftherios Mylonakis

INFECTIVE ENDOCARDITIS

Definition

Infective endocarditis (IE) is an infection of the endocardium of one or more cardiac valves or, less commonly, the mural endocardium. The pathologic lesion of IE is the vegetation (infected platelet and fibrin thrombus). The pathologic findings of IE were first described in 1646 by Lazare Rivière, a French physician at the University of Montpellier. At autopsy, Rivière described “small round outgrowths resembling the lungs in texture, the largest of which was about the size of a hazelnut, which blocked the aortic valve.” The term *endocarditis* was first used in 1835 by the French physician Jean-Baptiste Bouillaud, but it was not until the 1880s that Sir William Osler was able to synthesize many of the prior clinical, pathologic, and microbiologic findings into a unified description of the disease.

Over the past 6 decades, the epidemiology, risk factors, and treatment of endocarditis have changed significantly. In the pre-antibiotic era, IE was uniformly fatal. Since the advent of antibiotics and valve replacement surgery, IE can be effectively treated and mortality can be significantly reduced, provided the diagnosis is made early. Despite progress, new challenges continue to arise in diagnosis and treatment. As more patients undergo intravascular manipulation, have intracardiac or intravascular devices placed, and harbor more resistant organisms, effective therapy for IE remains a challenge.

Traditionally, IE has been classified, based on the acuteness of onset, as subacute bacterial endocarditis (SBE) or acute bacterial endocarditis (ABE). This classification reflects the virulence of the causative agent: *Staphylococcus aureus* is a common cause of ABE, whereas low-virulence organisms such as viridans streptococci are more likely to be the cause of SBE. IE may also be subdivided according to the nature of the involved valve, as native valve endocarditis (NVE) or prosthetic valve endocarditis (PVE), or by the number of valves involved (multivalvular IE). Some hosts, particularly intravenous drug abusers, are predisposed to IE. IE from invasive procedures is classified as health care–associated IE or nosocomial IE. Endocarditis may be further divided according to the causative organism. These categories are often combined (e.g., *S. aureus* tricuspid valve nosocomial ABE).

Epidemiology

SBE is most common in older adults, and over the last 50 years, the average age of patients diagnosed with IE has gradually

increased. More than one half of all cases of IE occur in patients older than 50 years of age. Rheumatic heart disease has decreased in the modern era and is now a less common predisposing factor.

Recent estimates are that the overall annual incidence of IE in the United States is 12.7 cases per 100,000 persons, a significant increase from prior years. The age-adjusted hospital admission rate has increased by 2.4% annually, mirroring this increase in incidence. SBE usually involves the mitral valve or, less commonly, the aortic valve. IE of the pulmonic valve is relatively rare, and right-sided ABE occurs primarily in intravenous drug abusers. Individuals with congenital heart disease may be predisposed to IE, depending on the lesion.

Pathogenesis

Normal cardiac endothelium is relatively resistant to bacterial invasion. If the cardiac endothelium is damaged, an uninfected platelet and fibrin thrombus may form. This nonbacterial thrombotic endocarditis may become infected due to bacteremia, forming a vegetation. Endothelial damage may result from degenerative valvular disease, rheumatic heart disease, congenital heart disease, or intracardiac instrumentation or devices.

Predisposing Cardiac Factors

Approximately 15% of patients diagnosed with NVE have underlying congenital heart disease. Of these diseases, tetralogy of Fallot has the highest IE potential. Other lesions that predispose to IE include ventricular septal defect, bicuspid valves, and coarctation of the aorta. Significant mitral valve regurgitation is the most important predisposing factor for IE, with mitral valve prolapse accounting for 20% of NVE cases. Degenerative valvular disease predisposes to SBE in the elderly, and the mitral valve is most frequently involved. Aortic valve IE is rare in hypertrophic cardiomyopathy or asymmetric septal hypertrophy.

Noncardiac Predisposing Factors

Central venous catheters and intracardiac devices can cause endocardial injury, predisposing to IE. The most frequent nosocomial IE pathogens are *S. aureus*, coagulase-negative staphylococci, group D enterococci, and aerobic gram-negative bacilli. Infections with these organisms usually occur less than 1 month after the procedure. Nosocomial IE may affect normal or abnormal valves. Because ABE pathogens are more virulent, nosocomial IE is associated with a high mortality rate.

Low-virulence and noninvasive organisms (e.g., viridans streptococci) are the most common SBE pathogens. The SBE

potential of viridans streptococci is directly related to the thickness of the capsule, which permits adherence to damaged cardiac valves. Viridans streptococci are normal inhabitants of the mouth and gastrointestinal tract. Invasive dental procedures frequently cause transient bacteremias that may result in SBE on damaged but not normal cardiac valves. Transient bacteremias of viridans streptococci may form a vegetation in the sterile platelet and fibrin thrombus covering an area of damaged endothelium. The gastrointestinal or genitourinary tract is the usual source of bacteremia in cases of native valve SBE due to group D enterococci.

Diagnosis

Clinical Features

The cardinal clinical features of IE are fever (90% of cases) and heart murmur (85%). In the antibiotic era, fever may not be present if the patient has been taking antibiotics for another reason. SBE often manifests with sweats, malaise, and anorexia. The course of SBE tends to be more indolent and may be accompanied by back pain, joint pains (>50% of patients), or embolic stroke. As SBE progresses, circulating immune complexes may deposit in the kidney, causing interstitial nephritis, glomerulonephritis, and even renal failure. Osler's nodes (painful, subcutaneous nodules on the distal pads of the fingers or toes), Janeway's lesions (hemorrhagic, nonpainful macules on the palms and soles) and Roth's spots (retinal hemorrhages with small central clearing) are classic findings related to microemboli and SBE immune-mediated vasculitis.

Patients with ABE tend to have a more fulminant course because of the greater virulence of the pathogen. The fever of ABE is usually high (>102° F) and is often accompanied by rigors. If there is mechanical dysfunction of the valve, symptoms of congestive heart failure will predominate. Often, a presenting feature of right-sided ABE is septic pulmonary emboli with pleuritic chest pain. The clinical findings of SBE and ABE are presented in Table 93-1.

Clinically, PVE may be considered as early (<2 months after implantation of the valve) or late (>2 months). Early PVE is caused by virulent pathogens (e.g., *S. aureus*) that infect the prosthetic valve before endothelialization is complete. Endothelialization of a mechanical valve is partially protective against transient bacteremias in late PVE. Over time, bioprosthetic valves have the same IE potential as mechanical ones.

An otherwise unexplained high-grade or continuous bacteremia and murmur should suggest IE. An acute versus subacute presentation correlates with the virulence of the IE pathogen. If blood cultures are negative, a diagnosis of infectious culture-negative endocarditis (CNE) should be considered if a murmur, vegetation, and peripheral manifestations of IE are present. The clinical diagnosis of IE relies on a combination of clinical, laboratory, and echocardiographic findings. Epidemiologic clues to the potential IE pathogens are outlined in Table 93-2. The most important finding in IE is the demonstration of continuous bacteremia, usually by multiple positive blood cultures. Table 93-3 contains the modified Duke criteria that are frequently used to predict the likelihood that a patient has IE.

LVF, Left ventricular fibrillation; +, present; –, absent; ±, present or absent.

*Otherwise unexplained.

[†]With septic pulmonary emboli from tricuspid valve ABE.

[‡]Fever may be <102° F in intravenous drug abusers with ABE.

Early PVE pathogens such as *S. aureus* and *Pseudomonas aeruginosa* are typically highly virulent and invasive. Late PVE more closely resembles SBE, is caused by less virulent pathogens, and has a more indolent course. The most common etiologic agents are coagulase-negative staphylococci, but viridans streptococci also cause late PVE. Nosocomial IE results from invasive intravascular or intracardiac procedures that damage the endothelium or the valves; it can also be caused by direct extension of infection, such as from ABE associated with a pacemaker wire. The organisms causing nosocomial IE originate from the skin (e.g., *S. aureus*, coagulase-negative staphylococci), from gastrointestinal or genitourinary procedures (e.g., group D enterococci), or from central venous catheters, ports, or hemodialysis catheters (e.g., *Candida* spp, aerobic gram-negative bacilli). IE related to total parenteral nutrition (TPN) is most often caused by *Candida* spp; other TPN-associated fungemias cause IE less frequently. In intravenous drug abusers, tricuspid valve ABE is usually caused by *S. aureus* or *P. aeruginosa* (depending on the geography and drug-related materials).

Infectious CNE is caused by organisms that are difficult to culture, such as *Legionella* spp, *Brucella* spp, *Tropheryma whippelii*, and *Coxiella burnetii* (which produces Q fever). Legionnaires' disease may cause NVE or PVE. CNE due to *Brucella* spp can be a difficult diagnosis, but an antecedent history of contact with livestock or consumption of unpasteurized dairy products should suggest the diagnosis, and echocardiography often reveals large

TABLE 93-3 MODIFIED DUKE CRITERIA FOR DIAGNOSIS OF INFECTIVE ENDOCARDITIS

DIAGNOSTIC CRITERIA
Definite IE (any of the following): Positive findings for IE in the pathology or microbiology of the vegetation Two major criteria One major and three minor criteria Five minor criteria
Possible IE (any of the following): One major and one minor criteria Three minor criteria
Not IE (any of the following): Definite alternative diagnosis or resolution with <4 days of antibiotic therapy Does not meet the criteria of possible IE
MAJOR CRITERIA
Positive blood cultures for IE (any of the following): Typical microorganism for IE from two separate blood cultures: <ul style="list-style-type: none"> Viridans streptococci, <i>Streptococcus gallolyticus</i> (formerly <i>Streptococcus bovis</i> biotype I), or the nutritional variant strains (<i>Granulicatella</i> spp and <i>Abiotrophia defectiva</i>) HACEK group: <i>Haemophilus</i> spp, <i>Aggregatibacter actinomycetemcomitans</i>, <i>Cardiobacterium hominis</i>, <i>Eikenella corrodens</i>, and <i>Kingella kingae</i> <i>Staphylococcus aureus</i> Community-acquired enterococci, in the absence of a primary focus Persistently positive blood culture, defined as recovery of a microorganism consistent with IE from any of the following: Blood cultures drawn more than 12 hr apart All of three or a majority of four or more separate blood cultures, with first and last drawn at least 1 hr apart *Single positive blood culture for <i>Coxiella burnetii</i> or antiphase I IgG antibody titer >1:800
Evidence of endocardial involvement Positive echocardiogram for IE: *TEE is recommended in patients with prosthetic valves rated at least “possible IE” by clinical criteria, or with complicated IE (paravalvular abscess); TTE as first test in other patients Definition of positive echocardiogram (any of the following): <ul style="list-style-type: none"> Oscillating intracardiac mass, on valve or supporting structures, or in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation Abscess New partial dehiscence of prosthetic valve New valvular regurgitation (increase in or change in preexisting murmur is not sufficient)
MINOR CRITERIA (*Echocardiographic minor criteria have been eliminated)
Predisposition: predisposing heart condition or intravenous drug use Fever: 38.0° C (100.4° F) Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway’s lesions Immunologic phenomena: glomerulonephritis, Osler’s nodes, Roth’s spots, rheumatoid factor Microbiologic evidence: positive blood culture but not meeting major criterion (excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with IE

Modified from Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis, *Clin Infect Dis* 30:633–638, 2000.

IE, Infective endocarditis; IgG, immunoglobulin G; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

*Represents a change from the previously published Duke criteria.

TABLE 93-4 NONSPECIFIC LABORATORY TESTS FOR INFECTIVE ENDOCARDITIS

LABORATORY FINDINGS	PERCENTAGE
Anemia	70-90
Leukocytosis	20-30
Elevated ESR	90-100
C-reactive protein (CRP)	100
Histiocytes in blood smear	25
Positive rheumatoid factor (RF)	50
Circulating immune complexes	65-100
Microscopic hematuria	30-50

ESR, Erythrocyte sedimentation rate.

vegetations. A difficult infectious CNE diagnosis is Q fever. Q fever SBE may be suggested by a history of animal contact. Clinical findings of Q fever are often present, but the diagnosis can be missed because Q fever vegetations are not easily visualized.

Laboratory Findings

With IE, many nonspecific laboratory abnormalities may occur (Table 93-4); when placed in the appropriate context, these can be a significant aid to diagnosis.

Echocardiography is an important element in diagnosis and management; it should be performed for all patients with suspected IE. In those with a low likelihood of having IE or small body habitus, a transthoracic echocardiogram (TTE) may be sufficient. Although TTE is often sufficient to screen for NVE, the “gold standard” remains transesophageal echocardiogram (TEE), which is more sensitive at detecting smaller vegetations, paravalvular abscess, and PVE. If the TTE or TEE demonstrates a vegetation but blood cultures remain negative, the diagnosis of infectious CNE should be considered. A tiered diagnostic approach to such cases is presented in Table 93-5.

Diagnosis of *Legionella*-related IE is based on an antecedent pneumonia and elevated titers of urinary antigen. *Brucella*-related IE is confirmed by titers or by polymerase chain reaction or both. A clue to Q fever CNE is enhanced valve uptake on positron-emission tomography (PET) or computed tomography (CT), and such a result should prompt testing for Q fever. With the advent of sophisticated microbiologic testing, HACEK organisms (*Haemophilus* spp, *Aggregatibacter actinomycetemcomitans* [formerly called *Actinobacillus actinomycetemcomitans*], *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) grow relatively rapidly and no longer manifest as CNE.

Radiologic testing in IE is primarily focused on identifying complications of IE. Although echocardiography is still the preferred method for detecting vegetations, improvements in multislice CT scans have allowed chest CT to detect vegetations and valvular abnormalities in addition to the septic emboli seen in right-sided IE. Magnetic resonance imaging (MRI) of the spine is useful in patients with IE who report back pain; it is the preferred method to detect the presence of vertebral osteomyelitis caused by IE. Mental status changes should prompt CT or MRI imaging of the head to assess for septic emboli to the brain. Although it is less invasive than TEE, cardiac MRI often lacks the special resolution to detect smaller vegetations; however, it may

TABLE 93-5 DIAGNOSTIC APPROACH TO CULTURE-NEGATIVE ENDOCARDITIS

VALVULAR BIOPSY UNAVAILABLE

1. Q fever and *Bartonella* serology: If negative, then use lysis-centrifugation system for blood cultures and inform microbiology laboratory of concern for fastidious organisms to allow use of special media and culture techniques: thioglycolate-, pyridoxal hydrochloride-, or L-cystine-enriched media for *Abitrophia*; buffered charcoal yeast extract (BCYE) agar for *Legionella*; prolonged incubation for HACEK organisms*
2. Rheumatoid factor (RF), antinuclear antibodies (ANA)
3. PCR for *Bartonella* spp and *Tropheryma whipplei*
4. Nested PCR for fungi, tissue for *Cryptococcus neoformans* capsular antigen and urine for *Histoplasma capsulatum* antigen: If negative, then obtain serum serology studies for *Mycoplasma pneumoniae*, *Legionella pneumophila*, *Brucella melitensis*, and *Bartonella* spp by Western blot

VALVULAR BIOPSY AVAILABLE

1. Broad-range PCR for bacteria (16S rRNA) and fungi (18S rRNA)
2. Histologic examination with direct staining for *Chlamydia* spp, *Coxiella burnetii*, *Legionella* spp, fungi, and *T. whipplei*
3. Primer extension enrichment reaction (PEER) or autoimmunohistochemistry (AIHC)

Modified from Fournier PE, Thuny F, Richet H, et al: Comprehensive diagnostic strategy for blood culture-negative endocarditis: a prospective study of 819 new cases, Clin Infect Dis 51:131-140, 2010; and Mylonakis E, Calderwood SB: Infective endocarditis in adults, N Engl J Med 345:1320, 2001.

be helpful in identifying aortic root pseudoaneurysms, sinus of Valsalva aneurysms, and embolic vascular lesions.

Differential Diagnosis and Mimics

The diagnosis of SBE is based on an otherwise unexplained high-grade or continuous bacteremia caused by a known endocarditis pathogen plus a cardiac vegetation. Depending on the duration before presentation (usually 1 to 3 months), IE may be accompanied by peripheral manifestations such as Osler's nodes, Janeway's lesions, splinter hemorrhages, or conjunctival hemorrhages. Splenomegaly or embolic phenomena may also accompany SBE. However, peripheral manifestations that are seen in SBE may also be present in other disorders. Before ascribing peripheral manifestations to SBE, physicians need to rule out other systemic disorders and confirm the diagnosis of SBE.

Clinically, the disorders most likely to mimic SBE are Libman-Sacks endocarditis (associated with systemic lupus erythematosus [SLE]), marantic endocarditis (caused by a malignancy, usually lymphoma, lung cancer, or pancreatic cancer), and atrial myxoma. Myocarditis of any etiology may mimic SBE with fever, murmur, and peripheral embolic phenomena. Cardiomegaly, which is usually present with myocarditis, is typically absent with SBE. Leukopenia and thrombocytopenia may be clues to viral myocarditis, and either finding argues against a diagnosis of SBE. Cardiac echocardiography shows myocarditis but no vegetations, and bacteremia is not present.

SLE, particularly between flares, may mimic SBE with low-grade fevers, murmur, peripheral manifestations, and splenomegaly. Laboratory findings in SLE include the anemia of chronic disease and a mildly to moderately elevated erythrocyte sedimentation rate (ESR). Even if Libman-Sacks vegetations are present, SBE is rare in SLE. A lupus flare may resemble ABE with high fevers (>102° F), tender fingertips (mimicking Osler's

nodes), and funduscopic findings of cotton-wool spots or Roth's spots. Conjunctival and splinter hemorrhages are rare in SLE but common in SBE. Microscopic hematuria is the usual renal manifestation of SBE (i.e., focal glomerulonephritis), but full-blown nephritis with proteinuria and hematuria are typical of SLE renal involvement. Although clinical findings of SLE and SBE may overlap, SBE is ruled out by the absence of high-grade or continuous bacteremia.

Atrial myxomas may mimic SBE with fever, murmurs, and embolic phenomena (e.g., splinter hemorrhages). Highly elevated ESR levels are common with atrial myxomas, but biologically false-positive results on Venereal Disease Research Laboratory (VDRL) testing, elevated rheumatoid factors, and renal involvement are not seen. On TTE or TEE, atrial myxomas appear as masses or vegetations on the atrial surface rather than on a valve as in IE. SBE is ruled out by the absence of bacteremia.

Besides clinical mimics of SBE, there are also echocardiographic mimics, including papillary fibromas, thrombi, calcified valves, myxomatous degeneration, and marantic endocarditis. These disorders are usually unaccompanied by fever or bacteremia. The term *marantic endocarditis* refers to uninfected vegetations with a murmur and negative blood cultures that occur secondary to malignancy. Patients with marantic endocarditis are afebrile unless fever is caused by the underlying malignancy (e.g., lymphoma). The patient with marantic endocarditis due to lymphoma may have fever, splenomegaly, and other manifestations of SBE. Negative blood cultures effectively rule out IE. Infectious CNE (e.g., Q fever) may show little or no visible vegetations. Infectious CNE should be considered if fever, murmur, and vegetation are present along with peripheral manifestations of IE.

Treatment

Effective treatment of IE depends on the antibiotic susceptibility of the pathogen, the penetration of the antibiotic into the vegetation, and the appropriate duration of antibiotic therapy. Antibiotics selected for IE preferably should be bactericidal. In IE, the organisms are deeply embedded in the vegetation, and prolonged therapy is necessary for penetration and sterilization of the vegetation. Early in IE therapy, blood cultures rapidly become negative, but treatment is continued because infection in the vegetation has not been eradicated. Multiplication of bacteria, which is required for bactericidal activity of antibiotics, is reduced within vegetations and is one reason for the requirement for prolonged antibiotics. It is important to note that in cases of *Staphylococcus aureus* endocarditis, blood cultures may not clear rapidly and may remain positive for days despite appropriate antibiotic therapy. Penetration into the vegetation is critical; for example, viridans streptococci are highly susceptible to β -lactam antibiotics but require a prolonged course of antimicrobial therapy to eradicate the pathogens in the vegetation.

Whereas some cases of uncomplicated IE may be treated with 2 weeks of antimicrobial therapy, the usual duration of monotherapy or combination therapy is 4 to 6 weeks, depending on the pathogen. Effective antimicrobial therapy does not eliminate supportive or embolic complications of endocarditis. Therapeutic failure is usually related to valvular destruction, a complication that may require valve replacement. Suppurative intracardiac or extracardiac complications usually require drainage for cure of

TABLE 93-6 PRINCIPLES OF THERAPY FOR INFECTIVE ENDOCARDITIS

1. Antibiotic selection initially is made empirically on the basis of physical examination and clinical history.
2. Bactericidal antibiotics are prescribed.
3. The MIC and MBC are measured to insure adequate dosing of the agent.
4. Intermittent dosing provides superior penetration into the thrombus compared with continuous infusion; penetration is directly related to peak serum level.
5. The patient should be treated in a health care facility for the first 1-2 wk.
6. The usual duration of therapy is 4-6 wk.
7. A 4-wk course is appropriate for an uncomplicated case of NVE (a shorter course of 2 wk may be appropriate in some cases); a 6-wk course is required for the treatment of PVE and those infections with large vegetations (i.e., infection by HACEK organisms*).

IE. The overarching principles of IE therapy are presented in Table 93-6, and Table 93-7 provides an outline of specific antibiotic regimens that may be used to treat IE.

Complications of endocarditis may be intracardiac or extracardiac, and they may also be classified by damage mechanism (i.e., immunologic versus infectious). The infectious intracardiac complications of IE include purulent pericarditis and paravalvular abscess; they manifest clinically with persistent fever or persistent bacteremia despite appropriate antibiotic therapy. Complications may be septic or immunologic; for example, splenic involvement may be immunologic (splenic infarct) or septic (splenic abscess). Embolic events are related to vegetation size. Bland central nervous system emboli (e.g., aseptic meningitis) may complicate SBE, whereas septic emboli (e.g., acute bacterial meningitis) may complicate ABE. Particularly with ABE, there may be valvular perforation or destruction resulting in acute congestive heart failure. It is often these complications that dictate whether and when surgery will occur. The indications for surgical intervention are shown in Table 93-8. As a general principle, paravalvular abscess or intractable congestive heart failure requires urgent surgical intervention. Persistent vegetations or embolic disease that occurs after 1 week of appropriate antibiotic therapy should also prompt surgical consideration.

Prognosis

The prognosis of all forms of IE depends directly on any complications related to the infection. Consequently, early diagnosis and initiation of appropriate antibiotic therapy is the key to limiting mortality. Recent studies have supported the role of early surgical intervention, when appropriate, as a significant aid to decreasing morbidity and mortality, specifically in relation to having fewer embolic events. If treated in a timely fashion and with appropriate antibiotics, the cure rate for viridans streptococci and *S. bovis* is estimated to be 98% in NVE and up to 88% in PVE. Right-sided endocarditis in intravenous drug abusers is usually caused by *S. aureus* and typically has a cure rate of 90% in NVE and 75% to 80% in PVE. However, among non-intravenous drug abusers, cure rates in IE involving *S. aureus* are far lower: 60% to 70% in NVE and 50% in PVE. When gram-negative bacilli or fungal organisms are the causative agent,

TABLE 93-7 ANTIMICROBIAL TREATMENT OF INFECTIVE ENDOCARDITIS

CAUSATIVE ORGANISM	NATIVE VALVE		PROSTHETIC VALVE	
	ANTIBIOTIC THERAPY	COMMENTS	ANTIBIOTIC THERAPY	COMMENTS
Penicillin-susceptible viridans streptococci, <i>Streptococcus bovis</i> , and other streptococci with MIC of penicillin ≤ 0.1 $\mu\text{g}/\text{mL}$	Penicillin G or ceftriaxone for 4 wk*	A 2-wk regimen of penicillin G or ceftriaxone combined with gentamicin may be considered in patients with right-sided NVE without evidence of embolic disease (excluding pulmonary emboli) or other complications.	Penicillin G for 6 wk and gentamicin for 2 wk*	Shorter duration of treatment with an aminoglycoside (2 wk) is usually appropriate for PVE due to penicillin-susceptible viridans streptococci, <i>S. bovis</i> , or other streptococci with MIC of penicillin ≤ 0.1 $\mu\text{g}/\text{mL}$.
Relatively penicillin-resistant streptococci (MIC of penicillin > 0.1 to 0.5 $\mu\text{g}/\text{mL}$)	Penicillin G for 4 wk and gentamicin for 2 wk*		Penicillin G for 6 wk and gentamicin for 4 wk*	
<i>Streptococcus</i> species with MIC of penicillin > 0.5 $\mu\text{g}/\text{mL}$, <i>Enterococcus</i> species, or <i>Abiotrophia</i> species	Penicillin G or ampicillin and gentamicin for 4-6 wk*	6 wk of therapy is recommended for patients with symptoms lasting > 3 mo, myocardial abscess, or selected other complications.	Penicillin G or ampicillin and gentamicin for 6 wk*	A recent study by Fernando-Hidalgo et al. showed that the combination of ampicillin and ceftriaxone is as effective as the combination of ampicillin and gentamicin for treating <i>Enterococcus faecalis</i> IE.
Methicillin-susceptible staphylococci	Nafcillin or oxacillin for 4-6 wk, with or without addition of gentamicin for the first 3-5 days of therapy†	In the few patients infected with a penicillin-susceptible staphylococcus, penicillin G may be substituted for nafcillin or oxacillin.	Nafcillin or oxacillin with rifampin for 6 wk and gentamicin for 2 wk†	It may be prudent to delay initiation of rifampin for 1 or 2 days, until therapy with two other effective antistaphylococcal drugs has been initiated.
Methicillin-resistant staphylococci	Vancomycin, with or without addition of gentamicin, for the first 3-5 days of therapy		Vancomycin with rifampin for 6 wk and gentamicin for 2 wk	If the staphylococcus is resistant to gentamicin, an alternative third agent should be chosen on the basis of in vitro susceptibility testing.
Right-sided staphylococcal NVE in selected patients	Nafcillin or oxacillin with gentamicin for 2 wk	This 2-wk regimen has been studied for infections caused by an oxacillin- and aminoglycoside-susceptible isolate. Exclusions to short-course therapy include any cardiac or extracardiac complications associated with IE, persistence of fever for ≥ 7 days, and infection with HIV. Patients with vegetations > 1 - 2 cm should probably be excluded from short-course therapy.		
HACEK organisms‡	Ceftriaxone for 4 wk	Ampicillin and gentamicin for 4 wk is an alternative regimen, but some isolates may produce β -lactamase, thereby reducing the efficacy of this regimen.	Ceftriaxone for 6 wk	Ampicillin and gentamicin for 6 wk is an alternative regimen, but some isolates may produce β -lactamase, thereby reducing the efficacy of this regimen.

Modified from Mylonakis E, Calderwood SB: Infective endocarditis in adults, *N Engl J Med* 345:1318–1330, 2001.

HIV, Human immunodeficiency virus; IE, infective endocarditis; NVE, native valve endocarditis; PVE, prosthetic valve endocarditis.

*Vancomycin therapy is indicated for patients with confirmed immediate hypersensitivity reactions to β -lactam antibiotics.

†For patients who have IE due to methicillin-susceptible staphylococci and are allergic to penicillin, a first-generation cephalosporin or vancomycin may be substituted for nafcillin or oxacillin. Cephalosporins should be avoided in patients with confirmed immediate-type hypersensitivity reactions to β -lactam antibiotics.

‡HACEK organisms: *Haemophilus* spp, *Actinobacillus actinomycetcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

cure rates are significantly lower (40% to 60%). Increased age, diabetes, aortic valve involvement, and developing complications of IE including congestive heart failure and emboli to the central nervous system are all highly predictive of increased mortality and morbidity.

Infective Endocarditis Prophylaxis

The most recent American Heart Association guidelines state that not all patients require antibiotic prophylaxis and that prophylaxis should be considered only for a specific subset of patients. Antibiotic prophylaxis is indicated for patients with prosthetic heart valves, cardiac transplant recipients with valvular disease, patients with a history of IE, and patients with certain forms of congenital heart disease. Among patients with

congenital heart disease, only those with unrepaired or partially repaired lesions and those with prosthetic material should receive prophylactic antibiotics (grade IIa recommendation).

Typically, antibiotic regimens used for prophylaxis against IE prior to invasive procedures above the waist are directed against viridans streptococci. For invasive dental procedures, the recommended prophylactic agent is amoxicillin, 2 g PO as a single dose 30 to 60 minutes before the procedure. In patients with penicillin allergy, clindamycin or a macrolide may be substituted.

ENDARTERITIS AND SUPPURATIVE PHLEBITIS

The term *infectious endarteritis* refers to an intravascular infection of the arteries that affects coarctation of the aorta, aortic

TABLE 93-8 ECHOCARDIOGRAPHIC INDICATIONS FOR SURGICAL INTERVENTION IN INFECTIVE ENDOCARDITIS**VEGETATION**

Persistent vegetation after systemic embolization
 Anterior mitral valve leaflet vegetation (particularly if ≥ 1 embolic events occur during the first 2 wk of antimicrobial therapy)*
 Increase in vegetation size despite appropriate antimicrobial therapy*†

VALVULAR DYSFUNCTION

Acute aortic or mitral insufficiency with signs of ventricular failure†
 Heart failure unresponsive to medical therapy†
 Valve perforation or rupture†
 Large abscess or extension of abscess despite appropriate antimicrobial therapy†

PARAVALVULAR EXTENSION

Valvular dehiscence, rupture, or fistula†
 New heart block†
 Large abscess or extension of abscess despite appropriate antimicrobial therapy†

Modified from Baddour LM, Wilson WR, Bayer AS, et al: Infective Endocarditis: diagnosis, antimicrobial therapy, and management of complications: a statement for healthcare professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, and the Councils on Clinical Cardiology, Stroke, and Cardiovascular Surgery and Anesthesia, American Heart Association; endorsed by the Infectious Diseases Society of America, *Circulation* 111:e394–e433, 2005.

*Surgery may be required because of risk of embolization.

†Surgery may be required because of failure of medical therapy or heart failure.

valve shunts, or a patent ductus arteriosus, analogous to IE at other sites. As with IE, continuous or high-grade bacteremia in the absence of an intracardiac vegetation should suggest the diagnosis. Imaging studies (e.g., PET scans) delineate the extent of arterial involvement. Treatment is the same as for IE.

The term *suppurative thrombophlebitis* refers to an intravenous infection that is characterized by an intravascular abscess; it is a complication of the use of central venous catheters. Patients have phlebitis with high fevers ($>102^{\circ}$ F, compared with $<102^{\circ}$ F in uncomplicated phlebitis with fevers) and bacteremia due to a skin organism (e.g., *S. aureus*). Treatment consists of a combination of antibiotic therapy and resection of the involved venous segment.

CENTRAL VENOUS CATHETER–RELATED BLOODSTREAM INFECTIONS

Central venous catheter–related bloodstream infections are relatively common, with an annual incidence of approximately 200,000 in the United States. Central venous catheter infection should be suspected if the patient develops fevers, chills, or hypotension without another obvious source of infection. The likelihood of infection increases with the length of time the catheter is in place. In addition to the clinical signs, blood cultures, drawn from the periphery as well as the line, should demonstrate growth of the causative organism. If the culture drawn from the catheter shows growth of bacteria at least 2 hours earlier than the peripheral blood cultures do, infection associated with the central line, rather than bacteremia in the setting of a catheter, should be strongly suspected.

Treatment of catheter-related infections varies depending on what action will be taken with the catheter (i.e., removal,

exchange, or salvage). In any case, empirical antibiotic therapy should be initiated against the most likely pathogens. Empirical therapy should cover *S. aureus* and nosocomial gram-negative bacilli. Therapy may then be modified based on the results of blood cultures or catheter tip culture. If a catheter-related bloodstream infection is suspected, immediate removal of the catheter should occur if the infection has led to septic shock or IE. The line also should be removed if blood cultures remain positive for the causative organism for 72 hours longer, or if evidence of septic thrombophlebitis develops.

Salvage therapy may be considered in hemodynamically stable patients except when the infection is caused by *S. aureus*, *P. aeruginosa*, *Bacillus* spp, *Micrococcus* spp, *Propionibacterium acnes* or other propionibacteria, fungi, or mycobacteria. Salvage therapy relies on concurrent use of systemic antimicrobial agents and antibiotic or ethanol locks.

Guidewire exchange should be reserved for cases in which there is a high risk for complications if the original catheter were to be removed. Guidewire exchange has a lower chance of eliminating the infection than does removal of the catheter.

For a deeper discussion of these topics, please see Chapter 76, “Infective Endocarditis,” in Goldman-Cecil Medicine, 25th Edition.

Skin and Soft Tissue Infections

Sajeev Handa

DEFINITION

Skin and soft tissue infections (SSTIs) comprise infections of skin, subcutaneous tissue, fascia, and the muscle by a multitude of organisms.

EPIDEMIOLOGY

SSTIs are among the most common infections found in all age groups, although the exact incidence is unknown. Several factors predispose to development of SSTIs:

- Epidermal breaks caused by trauma, surgical wounds, human or animal bites, or dry and irritated skin with concomitant tinea infection
- Immunosuppressed states caused by malnutrition, diabetes mellitus, or acquired immunodeficiency syndrome (AIDS)
- Chronic venous or lymphatic insufficiency

PATHOLOGY

Infectious Mechanisms

Microbes penetrate the integument after entering through a cut, bite, or hair follicle. Components of the host's defense system, including oxygen radicals, complement, immunoglobulins, macrophages, lymphocytes, and granulocytes, are recruited to the site of invasion through a vast plexus of dermal capillaries.

Bacteria contain proteins whose *N*-terminal amino acid sequence begins with an *N*-formyl-methionine group that is chemoattractive to phagocytes, including macrophages and granulocytes. Other microbial cell wall components, such as the zymosan of yeast, endotoxins of gram-negative bacteria, and the peptidoglycans of gram-positive bacteria, activate the alternative complement pathways, producing serum-derived chemotactic factors. Efflux of phagocytes occurs from the capillary through endothelial cell interstices and follows the gradient of chemotactic factors derived from bacteria and serum to the site of active infection.

Activated endothelial cells also produce chemotactic cytokines such as interleukin-8 (IL-8). Activated granulocytes synthesize leukotriene B_4 from arachidonic acid, a potent chemoattractant for leukocytes. Production of proinflammatory cytokines such as IL-1, IL-6, and tumor necrosis factor augments immune function, inducing fever, priming neutrophils, and increasing antibody production and synthesis of acute phase reactants such as C-reactive protein.

Cytokine-driven stimulation of endothelial cells generates nitric oxide and prostaglandins, both of which cause

vasodilatation. The net physiologic effect is greater blood flow to the tissue, causing acute inflammation. As described by Celsus (30 BC-38 AD), acute inflammation is characterized by rubor (i.e., redness), calor (i.e., increased heat), tumor (i.e., swelling), dolor (i.e., pain), and, as added by Virchow in the 19th century, function laesa (i.e., loss of function). Chapter 86 discusses host defenses against infection in more depth.

Pathologic Manifestations

Impetigo is characterized by thick, crusted lesions with rounded or irregular margins that typically occur on the face. Most cases are caused by *Staphylococcus aureus*, including methicillin-resistant *S. aureus* (MRSA), or by group A streptococci (e.g., *Streptococcus pyogenes*). Certain strains of streptococci causing impetigo have been implicated in the development of poststreptococcal glomerulonephritis.

Folliculitis is a superficial bacterial infection of the hair follicles. Purulent material is found in the epidermis. It manifests as clusters of multiple, small, raised, pruritic, erythematous lesions that are typically less than 5 mm in diameter.

Furuncles (i.e., boils) are infections of the hair follicle. Purulent material extends through the dermis into the subcutaneous tissue, where small abscesses may form. A carbuncle is coalescence of several inflamed follicles into a single inflammatory mass. Purulent drainage exudes from multiple follicles.

Cellulitis is superficial inflammation of the skin and underlying tissues. It is characterized by erythema, warmth, and tenderness of the involved area (Fig. 94-1). Erysipelas is a variant of cellulitis that is predominantly caused by toxin-producing *S. pyogenes*. It manifests as a superficial, spreading, warm, erythematous (fiery red) lesion distinguished by its indurated and elevated margin. Lymphatic involvement and vesicle formation are common. Groups B, C, and D streptococci may also be implicated (Fig. 94-2).

Necrotizing fasciitis is a progressive and rapidly spreading inflammatory reaction deep in the fascia that is associated with secondary necrosis of the subcutaneous tissues. Thrombosis of the dermal vessels is responsible for tissue necrosis. Necrotizing fasciitis may be polymicrobial (type I), involving aerobic microbes (e.g., streptococci, staphylococci, gram-negative bacilli) and anaerobes (e.g., *Peptostreptococcus*, *Bacteroides*, *Clostridium* species), or it may be monomicrobial (type II) and caused by *S. pyogenes* (Fig. 94-3). When involving the scrotum and perineal area, it is known as *Fournier's gangrene*.

Pyomyositis is a less serious infection involving the musculature that results from direct inoculation of bacteria. For example,

FIGURE 94-1 Ill-defined erythema and edema with bullae formation is characteristic of lower extremity cellulitis. (From Pride HB: Cellulitis and erysipelas. In Zaoutis LB, Chiang VW, editors: Comprehensive pediatric hospital medicine, Philadelphia, 2007, Mosby, Fig. 156-1.)

FIGURE 94-2 Sharply defined erythema and edema is characteristic of erysipelas. (From Pride HB: Cellulitis and erysipelas. In Zaoutis LB, Chiang VW, editors: Comprehensive pediatric hospital medicine, Philadelphia, 2007, Mosby, Fig. 156-2.)

FIGURE 94-3 Spontaneous necrotizing fasciitis due to *Clostridium septicum*. The patient developed sudden onset of severe pain in the forearm. Swelling rapidly ensued, and he sought medical treatment. Crepitus was found on physical examination, and gas in the soft tissue was verified with routine radiographs. Immediate surgical débridement revealed necrotizing fasciitis but sparing of the muscle. Notice the purple-violaceous appearance of the skin. (From Stevens DL, Aldape MJ, Bryant AE. Necrotizing fasciitis, gas gangrene, myositis and myonecrosis. In Cohen J, Powderly WG, Opal SM, editors: Infectious diseases, ed 3, London, 2010, Mosby, Fig. 10-11.)

infection can result from injection drug use or from secondary seeding by *S. aureus* or group A β -hemolytic streptococci from an incidental bacteremia or a hematoma caused by nonpenetrating trauma.

Ecthyma is an ulcerative pyoderma of the skin that extends into the dermis (unlike impetigo). It is caused by group A streptococci and *Pseudomonas* species.

ETIOLOGY AND CLINICAL PRESENTATION

Causative Organisms

A multitude of organisms can cause SSTIs. However, three are most common: *S. pyogenes*, *S. aureus*, and *Streptococcus agalactiae*.

S. pyogenes (i.e., group A β -hemolytic streptococci) is a gram-positive coccus that may cause erysipelas, streptococcal cellulitis, necrotizing fasciitis, myositis, myonecrosis, and streptococcal toxic shock syndrome. Streptococcal cellulitis arises from infection of wounds, burns, or surgical incisions and may progress to involve large areas. Injection drug users and individuals with impaired lymphatic drainage are at high risk. Systemic manifestations include fever, chills, malaise with or without associated lymphangitis, and bacteremia. In contrast to erysipelas, the affected area is not raised, and the demarcation between involved skin and uninvolved skin is indistinct. The lesions tend to be more pink than fiery red.

Streptococcal toxic shock syndrome manifests with hypotension and is associated with acute kidney injury, elevated aminotransferases, rash or soft tissue necrosis, and coagulopathy. It may be complicated by the acute respiratory distress syndrome. Isolation of the organism from a sterile site provides a definite diagnosis.

S. aureus is a gram-positive coccus that is found in the anterior nares of up to 30% of healthy people. It is responsible for a variety of invasive and suppurative infections. Localized SSTIs include furuncles, carbuncles, bullous and nonbullous impetigo, mastitis, ecthyma, cellulitis, and wound and foreign body infections. Bacteremia may be complicated by septicemia, endocarditis, pericarditis, pneumonia, empyema, osteomyelitis, and abscesses of the soft tissue, muscle, and viscera.

Staphylococcal toxic shock syndrome is typically associated with tampon use but may occur after childbirth or surgery and can be associated with cutaneous lesions. It manifests with the acute onset of fever, erythroderma, hypotension, and multisystem involvement (e.g., acute kidney injury, elevated levels of aminotransferases, coagulopathy, nausea, vomiting, diarrhea).

Community-associated MRSA is the most common identifiable cause of SSTIs in the emergency department. Isolates contain genes encoding for multiple toxins, including cytotoxins that result in leukocyte destruction and tissue necrosis.

S. agalactiae (a group B streptococcus) is a gram-positive diplococcus. It may account for up to one third of SSTIs among adults. Cellulitis, foot ulcers, and infection of decubitus ulcers are common manifestations. Cellulitis has been associated with foreign bodies such as breast or penile implants. Less commonly, polymyositis, blistering dactylitis, and necrotizing fasciitis may occur.

Other Organisms

Aeromonas hydrophila, *Aeromonas veronii*, and *Aeromonas schubertii* are gram-negative rods found in salt and fresh water. They may cause mild to severe wound infections after injury, producing cellulitis, myonecrosis, and rhabdomyolysis. Necrotizing fasciitis has been reported with *A. veronii* and *A. schubertii* infections. *Aeromonas* wound infections have also been reported as a result of the medicinal use of leeches.

Arcanobacterium haemolyticum is a gram-positive, weakly acid-fast bacillus. It has been isolated from soft tissue infections, including chronic ulcers, cellulitis, and paronychia.

Bacillus anthracis is a gram-positive bacillus that forms spores. Transdermal inoculation of the spores from even incidental trauma can result in cutaneous anthrax. It manifests initially as a small, pruritic papule that becomes surrounded by painless, non-purulent vesicles that easily rupture, leaving a black eschar at the base of the ulceration. Uncomplicated disease heals without scar formation in 1 to 3 weeks. Serious cutaneous disease is marked by extensive edema, worsening inflammation, and toxemia (Fig. 94-4).

Bartonella henselae is a gram-negative bacillus that causes cat-scratch disease. Between 3 and 10 days after a bite or scratch from a cat or other vector, a tender, erythematous papule appears. Lymphadenopathy ipsilateral to the site of inoculation occurs 1 to 3 weeks later, and the patient typically experiences constitutional symptoms. The lymphadenopathy may take months to resolve.

Capnocytophaga canimorsus is a thin, gram-negative bacillus with tapered ends. It is strongly associated with dog (primarily) and cat bites and scratches. Asplenic patients are at particular risk for sepsis due to this organism.

Clostridium perfringens is an anaerobic, large, gram-positive rod. It can cause cellulitis or life-threatening necrotizing infections of skin, muscle, and other soft tissues. The latter is characterized by rapidly progressive tissue destruction, gas in tissues, shock, and death. Conditions such as trauma or illicit drug injection produce anaerobic tissue conditions that favor

the organism. The condition can also develop in patients with bowel carcinoma or neutropenia. Gram stain of tissue or exudate reveals large, gram-positive rods and no inflammatory cells.

Edwardsiella tarda is a gram-negative rod found in fresh water environments. It is associated with wound infections, abscesses, and bacteremia. The mortality rate is high among patients with liver disease and iron overload.

Eikenella corrodens is a gram-negative bacillus that is part of the normal human oral flora. It is an important pathogen in human bite wounds, closed-fist injuries, and infections seen in chronic finger or nail biters. Severe soft tissue infection may occur, leading to septic arthritis and osteomyelitis.

Erysipelothrix rhusiopathiae is a gram-positive rod, but it may appear as gram-negative because of rapid decolorization. Its major reservoir is in domestic swine, and infection occurs by direct cutaneous contact through a cut or abrasion. Disease is characterized as erysipeloid (i.e., subacute cellulitis with vesiculation), as a diffuse cutaneous eruption with systemic symptoms, or as bacteremia that is often associated with endocarditis.

Francisella tularensis is a gram-negative coccobacillus found in rabbits, hares, hamsters, and rodents. Ulceroglandular tularemia occurs 3 to 5 days after humans are inoculated cutaneously during contact with any of these species. A papule is formed initially, followed by ulceration with enlargement of the regional lymph nodes. Vesicles may be seen. If left untreated, the ulcer remains for weeks before healing, leaving a residual scar. Suppuration of the affected lymph nodes is the most common complication, occurring despite appropriate treatment (Fig. 94-5). *B. anthracis* and *F. tularensis* have been used as agents in bioterrorism.

Cryptococcus neoformans, *Candida albicans*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*, and opportunistic fungi can have skin manifestations. Opportunistic fungi, including *Aspergillus* species, fungi in the order Mucorales, and *Fusarium* species, can infect the skin of immunocompromised patients. Skin manifestations of fungal infections include papules, nodules, circumscribed erythematous lesions, ulcers, verrucous lesions, and eschars.

FIGURE 94-4 Cutaneous anthrax lesion on the skin of the forearm caused by the bacterium *Bacillus anthracis*. (From Centers for Disease Control and Prevention: Public health image library. Available at <http://phil.cdc.gov/Phil/home.asp>. Accessed October 31, 2014.)

FIGURE 94-5 Tularemic ulcer with eschar formation after percutaneous inoculation of *Francisella tularensis*. (From Beard CB, Dennis DT: Tularemia. In Cohen J, Powderly WG, Opal SM, editors: Infectious diseases, ed 3, London, 2010, Mosby.)

Exposure to herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) at abraded skin sites allows entry into the epidermis and dermis. Infection typically occurs from sexual contact, but it occasionally occurs at extraoral or extragenital sites, such as the hands of health care workers, producing a painful erythema primarily at the junction of the nail bed and skin (i.e., whitlow). This progresses to a vesicopustular lesion that can mimic a bacterial infection (i.e., paronychia). Sexually transmitted diseases are discussed in [Chapter 100](#).

Mycobacterium marinum is an atypical, acid-fast bacillus; it is the most common atypical mycobacterium that causes infection in humans. After inoculation of a skin abrasion or puncture wound in salt or fresh water (nonchlorinated), lesions appear as papules on an extremity. Lesions progress to shallow ulcers and form scars. Typically, lesions are solitary, but they may take on the appearance of ascending, sporotrichoid-like, nodular lymphangitis that may involve the local joint or tendons.

Mycobacterium leprae is a slow-growing, acid-fast bacillus that cannot be grown in vitro. It is the cause of leprosy (Hansen's disease). It is primarily transmitted by the airborne route and causes chronic disfiguring skin lesions and nerve damage.

 For a deeper discussion of this topic, please see [Chapter 326, "Leprosy \(Hansen's Disease\)"](#) in *Goldman-Cecil Medicine, 25th Edition*.

Pasteurella multocida is a gram-negative coccobacillus that may occur at the site of a scratch or bite from a dog or cat. Cellulitis results within 24 hours of the injury, producing swelling, erythema, tenderness, serous or purulent discharge with or without regional lymphadenopathy, chills, and fever.

Pseudomonas aeruginosa is a gram-negative rod and primarily a nosocomial pathogen. In the community, serogroup 0:11 may cause folliculitis related to the use of hot tubs, whirlpools, and swimming pools. Typically, the eruption occurs 48 hours after exposure and consists of tender, pruritic papules, papulopustules, or nodules. It is an important pathogen in burn wound infections, which may progress to sepsis.

Sporothrix schenckii is a dimorphic fungus ubiquitous primarily in the tropical parts of North and South America. Cutaneous inoculation from thorny plants (e.g., rose bushes) is followed by development of a painless papule that enlarges slowly to become a nodular lesion with a violaceous hue or ulceration. Secondary lesions may form along the lymphatic drainage distribution.

Primary varicella-zoster virus (VZV) infection occurs by the respiratory route but may occur through contact with infected lesions. Viremia results in crops of papules that primarily occur on the trunk and progress to vesicles and then to pustules, followed by crusting. Zoster or shingles represents reactivation of the latent virus in the sensory neurons of the dorsal root ganglion, resulting in pain that proceeds to a rash in the distribution of the affected dermatome in a few days. The appearance of papules and vesicles in a unilateral dermatomal distribution confirms the diagnosis. Ramsay Hunt syndrome occurs when the VZV infection involves the geniculate ganglia and causes a painful eruption in the ear canal and tympanic membrane that is associated with ipsilateral seventh cranial nerve palsy. Vesicles that appear on the tip of the nose (i.e., Hutchinson's sign) may be preceded by development of ophthalmic zoster and involvement of the cornea.

Immunosuppressed individuals are at higher risk for disseminated disease.

Vibrio vulnificus is a gram-negative bacillus that is spread by contamination of a superficial wound with warm seawater. It can cause rapidly developing and intense cellulitis, necrotizing vasculitis, and ulcer formation. Aggressive soft tissue infection may occur with necrosis, fever, sepsis, and bullae formation. Ingestion of raw oysters, particularly by immunocompromised (e.g., liver cirrhosis, iron overload) patients may be followed 1 to 3 days later by septicemia associated with necrotizing cutaneous lesions.

[Table 94-1](#) provides a classification for the spectrum of skin involvement by bacteria and fungi.

DIAGNOSIS

A thorough medical history is critical; it should assess the specific risk factors, such as travel history, animal contacts, marine exposures, occupational and avocational hazards (e.g., farming, gardening), and immune status. If an animal bite has occurred, the timing of the bite, circumstances of injury, and health status of the animal should be determined. Human bites are classified as self-inflicted, occlusal (i.e., intentional), or closed-fist injuries.

In addition to wound assessment, evaluation for other transmissible pathogens, including human immunodeficiency virus (HIV), HSV, *Treponema pallidum* (the etiologic agent of syphilis), and hepatitis B and C viruses, should be pursued. A thorough clinical examination should follow. Initial antimicrobial management, if indicated, is directed by the history and physical examination findings.

Evaluation of hospitalized patients should include a complete blood count and a basic metabolic panel. The C-reactive protein level may be useful as a marker for inflammation and guidance for treatment. The creatine phosphokinase concentration may be helpful, but it is not specific for cases of compartment syndrome and necrotizing fasciitis involving the musculature. Cultures are not indicated for uncomplicated common forms of SSTIs managed in the outpatient setting. The benefit of blood cultures for cellulitis in hospitalized patients is uncertain because the yield is low. Cultures are indicated for patients who require incision and drainage because of the risk of deep structure and underlying tissue involvement.

The most sensitive and specific test for the diagnosis of HSV and VZV cutaneous lesions is nucleic acid amplification. A sample is scraped from the base of an active dermal lesion with a swab. Direct fluorescent antibody testing is less sensitive. Incision and drainage of these lesions is contraindicated.

Special Diagnostic Considerations

Animal Bites

Blood cultures, tissue biopsy, and aspirates for culture of aerobic or anaerobic organisms are preferred methods in cases of animal bites.

Human Bites

Wounds swabs may produce misleading information in cases of human bites. A Gram stain should be performed to assess

**TABLE 94-1 CLASSIFICATION OF BACTERIAL AND MYCOTIC INFECTIONS OF THE SKIN**

DISEASE OR DISORDER	MICROORGANISMS
PRIMARY PYODERMAS	
Impetigo	<i>Staphylococcus aureus</i> , group A streptococci
Folliculitis	<i>S. aureus</i> , <i>Candida</i> spp, <i>Pseudomonas aeruginosa</i> (diffuse folliculitis)
Furuncles and carbuncles	<i>S. aureus</i>
Paronychia	<i>S. aureus</i> , group A streptococci, <i>Candida</i> , <i>P. aeruginosa</i>
Ecthyma	Group A streptococci, <i>Pseudomonas</i> spp.
Erysipelas	Group A streptococci
Chancriform lesions	<i>Treponema pallidum</i> , <i>Haemophilus ducreyi</i> , <i>Sporothrix</i> , <i>Bacillus anthracis</i> , <i>Francisella tularensis</i> , <i>Mycobacterium ulcerans</i> , <i>Mycobacterium marinum</i>
Membranous ulcers	<i>Corynebacterium diphtheriae</i>
Cellulitis	Group A or other streptococci, <i>S. aureus</i> ; rarely, various other organisms
INFECTIOUS GANGRENE AND GANGRENOUS CELLULITIS	
Streptococcal gangrene and necrotizing fasciitis	Group A streptococci, mixed infections with Enterobacteriaceae and anaerobes
Progressive bacterial synergistic gangrene	Anaerobic streptococci plus a second organism (<i>S. aureus</i> , <i>Proteus</i> spp.)
Gangrenous balanitis and perineal phlegmon	Group A streptococci, mixed infections with enteric bacteria (<i>Escherichia coli</i> , <i>Klebsiella</i> spp.), anaerobes
Gas gangrene, crepitant cellulitis	<i>Clostridium perfringens</i> and other clostridial species; <i>Bacteroides</i> spp., peptostreptococci, <i>Klebsiella</i> spp., <i>E. coli</i>
Gangrenous cellulitis in immunosuppressed patients	<i>Pseudomonas</i> , <i>Aspergillus</i> spp., agents of mucormycosis
PREEXISTING SKIN LESIONS WITH SECONDARY BACTERIAL INFECTIONS	
Burns	<i>P. aeruginosa</i> , <i>Enterobacter</i> spp., various other gram-negative bacilli, various streptococci, <i>S. aureus</i> , <i>Candida</i> spp., <i>Aspergillus</i> spp.
Eczematous dermatitis and exfoliative erythrodermas	<i>S. aureus</i> , group A streptococci
Chronic ulcers (varicose, decubitus)	<i>S. aureus</i> , streptococci, coliform bacteria, <i>P. aeruginosa</i> , peptostreptococci, enterococci, <i>Bacteroides</i> spp., <i>C. perfringens</i>
Dermatophytosis	<i>S. aureus</i> , group A streptococci
Traumatic lesions (abrasions, animal bites, insect bites)	<i>Pasturella multocida</i> , <i>C. diphtheriae</i> , <i>S. aureus</i> , group A streptococci
Vesicular or bullous eruptions (varicella, pemphigus)	<i>S. aureus</i> , group A streptococci
Acne conglobata	<i>Propionibacterium acnes</i>
Hidradenitis suppurativa	<i>S. aureus</i> , <i>Proteus</i> spp. and other coliforms, streptococci, peptostreptococci, <i>P. aeruginosa</i> , <i>Bacteroides</i> spp.
Intertrigo	<i>S. aureus</i> , coliforms, <i>Candida</i> spp.
Pilonidal and sebaceous cysts	Peptostreptococci, <i>Bacteroides</i> sp., coliforms, <i>S. aureus</i>
Pyoderma gangrenosa	<i>S. aureus</i> , peptostreptococci, <i>Proteus</i> spp. and other coliforms, <i>P. aeruginosa</i>
CUTANEOUS INVOLVEMENT IN SYSTEMIC INFECTIONS	
Bacteremias	<i>S. aureus</i> , group A streptococci (and other groups such as D), <i>Neisseria meningitidis</i> , <i>Neisseria gonorrhoeae</i> , <i>P. aeruginosa</i> , <i>Salmonella typhi</i> , <i>Haemophilus influenzae</i>
Infective endocarditis	Viridans streptococci, <i>S. aureus</i> , group D streptococci, and others
Fungemias	<i>Candida</i> spp., <i>Cryptococcus</i> spp., <i>Blastomyces dermatitidis</i> , <i>Fusarium</i>
Listeriosis	<i>Listeria monocytogenes</i>
Leptospirosis (Weil's disease and pretibial fever)	<i>Leptospira interrogans</i> serotypes
Rat-bite fever	<i>Streptobacillus moniliformis</i> , <i>Spirillum minus</i>
Melioidosis	<i>Burkholderia pseudomallei</i>
Glanders	<i>Burkholderia mallei</i>
Carrion's disease (verruca peruana)	<i>Bartonella bacilliformis</i>
SCARLET FEVER SYNDROMES	
Scarlet fever	Group A streptococci, rarely <i>S. aureus</i>
Scalded skin syndrome	<i>S. aureus</i> (phage group II)
Toxic shock syndrome	Group A streptococci, <i>S. aureus</i> (pyrogenic toxin-producing strains)
PARAINFECTIOUS AND POSTINFECTIOUS NONSUPPURATIVE COMPLICATIONS	
Purpura fulminans (manifestation of disseminated intravascular coagulation)	Group A streptococci, <i>N. meningitidis</i> , <i>S. aureus</i> , pneumococcus
Erythema nodosum	Group A streptococci, <i>Mycobacterium tuberculosis</i> , <i>Mycobacterium leprae</i> , <i>Coccidioides immitis</i> , <i>Leptospira autumnalis</i> , <i>Yersinia enterocolitica</i> , <i>Legionella pneumophila</i>
Erythema multiforme–like lesions (rarely), guttate psoriasis	Group A streptococci
OTHER LESIONS	
Erythrasma	<i>Corynebacterium minutissimum</i>
Nodular lesions	<i>Candida</i> , <i>Sporothrix</i> , <i>S. aureus</i> (botryomycosis), <i>M. marinum</i> , <i>Leishmania brasiliensis</i> ; leprosy due to <i>M. leprae</i> can cause popular lesions, nodular, and ulcerative lesions
Hyperplastic (pseudoeplitheliomatous) and proliferative lesions (e.g., mycetomas)	<i>Nocardia</i> spp., <i>Pseudallescheria boydii</i> , <i>Blastomyces dermatitidis</i> , <i>Paracoccidioides brasiliensis</i> , <i>Phialophora</i> , <i>Cladosporium</i>
Vascular papules/nodules (bacillary angiomatosis, epithelioid angiomatosis)	<i>Bartonella henselae</i> , <i>Bartonella quintana</i>
Annular erythema (erythema chronicum migrans)	<i>Borrelia burgdorferi</i>

Modified from Mandell GL, Bennett JE, Dolin R, editors: Mandell, Douglas, and Bennett's principles and practice of infectious diseases, ed 7, Philadelphia, 2009, Churchill Livingstone.

organisms, neutrophils (i.e., inflammation), and squamous epithelial cells (i.e., superficial contamination). If feasible, tissue biopsy or aspiration of the infected site can provide specimens for aerobic and anaerobic culture.

Traumatic Wounds

The optimal time to acquire specimens for cultures is immediately after débridement of the wound site. Analysis of initial cultures should focus on common pathogens, and additional testing should be reserved for uncommon or rare infections associated with unusual circumstances, such as *Vibrio* species after salt water exposure. Tissue biopsy and special stains may be required in certain situations, such as suspected infection with *M. marinum*.

Burn Wounds

Before sampling, the burn area must be clean and devoid of topical antimicrobial agents. Surface swabs or tissue biopsies are recommended for obtaining culture samples, and histopathologic examination can monitor for the presence and extent of infection. Quantitative evaluation of swab or culture specimens is recommended twice weekly to monitor colonization. Evidence of systemic infection related to the wound should prompt blood cultures.

Diabetic Foot Infections

Superficial swab cultures of ulcerations can be misleading and should be avoided. If surgical débridement is performed, deep tissue specimens should be sent to the microbiology laboratory for evaluation.

Radiographs should be obtained if bone involvement is suspected, and they may also be useful in demonstrating soft tissue gas before crepitus is detected (Fig. 94-6). Magnetic resonance imaging is the most sensitive modality. Chapter 87 discusses the laboratory diagnosis of infectious diseases in more detail.

Differential Diagnosis

Many noninfectious conditions can mimic SSTIs:

- Brown recluse spider bite
- Contact dermatitis
- Gout
- Psoriatic arthritis with distal dactylitis
- Reiter's syndrome

FIGURE 94-6 Radiograph of patient with clostridial myonecrosis shows gas in the tissues. (Courtesy J.W. Tomford, MD.)

- Relapsing polychondritis
- Ruptured Baker's cyst
- Mixed cryoglobulinemia due to immune complex disease from chronic hepatitis C or B infection (may have an erythematous rash)
- Pyoderma gangrenosum
- Sweet's syndrome (acute febrile neutrophilic dermatosis)
- Venous stasis

TREATMENT

Pharmacologic and Supportive Care

Mild cases of cellulitis may be managed on an outpatient basis with dicloxacillin, amoxicillin, or cephalexin. Clindamycin or levofloxacin may be used in patients allergic to penicillin. Severe cellulitis should be managed with parenteral cefazolin, nafcillin, or oxacillin. Clindamycin or vancomycin may be used in patients with allergies to penicillin. Concomitant tinea infection should be treated with a topical antifungal agent such as clotrimazole or terbinafine.

Mild cases of community-acquired MRSA may be managed with clindamycin, trimethoprim-sulfamethoxazole, or tetracycline if antibiotics are indicated. The latter two agents do not, however, provide adequate streptococcal coverage. Severe cases requiring parenteral antibiotics require vancomycin, daptomycin, telavancin, ceftaroline, clindamycin, or linezolid. A β -lactam antibiotic may be considered for hospitalized patients with nonpurulent cellulitis, with modification to MRSA-active treatment if there is no clinical response. Cellulitis associated with an abscess requires surgical drainage.

In addition to supportive care, urgent surgical consultation should be obtained in the event that crepitus, bullae, rapidly evolving cellulitis, or pain disproportional to physical examination findings suggests necrotizing fasciitis. Initial parenteral therapy with vancomycin, daptomycin, linezolid with piperacillin-tazobactam, cefepime plus metronidazole, or a carbapenem is appropriate. Type II necrotizing fasciitis due to *S. pyogenes* or clostridial myonecrosis should prompt combined therapy with parenteral penicillin and clindamycin. The use of intravenous immune globulin in cases of necrotizing fasciitis remains controversial.

Compartment syndrome requires emergent surgical decompression to prevent muscle necrosis and irreversible neuronal damage. Cellulitis or wound infections attributed to *A. hemolyticum* may be treated with clindamycin, erythromycin, vancomycin, or tetracycline. HSV and VZV infections are susceptible to acyclovir, famciclovir, or valacyclovir if treatment is indicated.

Special Treatment Considerations

Animal Bites

Mild cases of animal bites may be treated with amoxicillin-clavulanate. For patients with a penicillin allergy, a fluoroquinolone plus clindamycin or sulfamethoxazole-trimethoprim plus metronidazole are alternatives that may be used in oral or parenteral forms. Inpatient parenteral agents including ampicillin-sulbactam or piperacillin-tazobactam may be used for patients who are not allergic to penicillin.

Tularemia is treated with gentamicin, tobramycin, streptomycin, doxycycline, or ciprofloxacin. Azithromycin is the drug of choice for cat-scratch disease. For individuals at risk for *E. rhusiopathiae* infection, the treatment of choice is penicillin or ampicillin or use of a third-generation cephalosporin or fluoroquinolone in penicillin-allergic patients.

Animal handlers with cutaneous anthrax infection require treatment with ciprofloxacin or levofloxacin. Cases of suspected bioterrorism must be reported immediately.

Marine Lacerations and Punctures

The treatment regimen for marine lacerations and punctures should include doxycycline and ceftazidime or a fluoroquinolone. Treatment of fresh water injuries should include a third- or fourth-generation cephalosporin (i.e., ceftazidime or cefepime) or a fluoroquinolone. If *M. marinum* is suspected, treatment with clarithromycin, minocycline, doxycycline, sulfamethoxazole-trimethoprim, or rifampin plus ethambutol is appropriate.

Human Bites

Patients who have human bite wounds without evidence of infection should receive prophylactic treatment with amoxicillin-clavulanate for 3 to 5 days. Closed-fist injuries require radiographic evaluation and consultation with a hand surgeon for possible wound exploration. Parenteral treatment with ampicillin-sulbactam or moxifloxacin is recommended.

Burn Wounds

Systemic therapy with antibiotics and antifungals are reserved for burn patients demonstrating signs of sepsis or septic shock. Infection due to mucormycoses requires liposomal amphotericin B.

Diabetic Foot Infections

Simple infections such as cellulitis are most often caused by group A streptococci or *S. aureus* and should be managed accordingly. If ulcers do not have purulence or inflammation, antimicrobials are not indicated. Severe limb-threatening infections require surgical evaluation and broad-spectrum antibiotic coverage because infection tends to include aerobic and anaerobic

organisms. Empirical therapy directed at *P. aeruginosa* is not usually necessary unless the patient has other risk factors. MRSA-active treatment is recommended for patients with a history of MRSA, when the local prevalence of MRSA is high in the community, or if the infection is severe. All wounds require adequate wound irrigation and débridement.

PROGNOSIS

Full recovery is expected for patients with simple SSTIs provided they receive appropriate treatment. For those who develop complications such as necrotizing fasciitis, the estimated mortality rate is between 30% and 70%. The prognosis is guarded for patients with multiple comorbidities and those who are immunosuppressed.

Intraabdominal Infections

Edward J. Wing

INTRODUCTION

Intraabdominal infections are serious conditions that usually result from perforation or obstruction of abdominal organs. These infections often require surgical intervention to drain abscesses, repair perforations, and relieve obstructions. The cause is typically polymicrobial infection, including aerobic and anaerobic bacteria that require broad antibiotic coverage. Guidelines for diagnosis and therapy have been developed by the Surgical Infection Society and the Infectious Diseases Society of America (Tables 95-1, 95-2, and 95-3). This chapter focuses on the most common intraabdominal infections found in adults.

APPENDICITIS

Definition and Epidemiology

Appendicitis is an acute inflammation of the appendix that is usually caused by an obstruction of the lumen by an appendicolith. Appendicitis is the most common cause of emergency surgery worldwide. In the United States in 2007, appendicitis accounted for 295,000 hospital discharges and \$7.4 billion in hospital costs. The lifetime risk is 7% to 12%, with a slight preponderance among men.

Pathology

The normal appendix is 5 to 10 cm long and typically lies anterior to the cecum. Locations that affect the clinical manifestations include retrocecal, pelvic, and retroileal variants. Obstruction of the proximal appendix is typically caused by an appendicolith;

less common causes are tumors, mesenteric lymphadenitis, parasites, and seeds. Obstruction leads to swelling, compromise of the blood supply, and inflammation with a resulting neutrophilic infiltrate of the appendicular wall. Gangrene of the wall and rupture eventually occurs.

TABLE 95-2 REGIMENS USED FOR INITIAL EMPIRICAL TREATMENT OF BILIARY INFECTION IN ADULTS

INFECTION	REGIMEN
Community-acquired acute cholecystitis of mild to moderate severity	Cefazolin, cefuroxime, or ceftriaxone
Community-acquired acute cholecystitis of severe physiologic disturbance, advanced age, or immunocompromised status	Imipenem-cilastatin, meropenem, doripenem, piperacillin-tazobactam, ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole*
Acute cholangitis after bilioenteric anastomosis of any severity	Imipenem-cilastatin, meropenem, doripenem, piperacillin-tazobactam, ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole*
Health care-associated biliary infection of any severity	Imipenem-cilastatin, meropenem, doripenem, piperacillin-tazobactam, ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole, vancomycin added to each regimen*

From Solomkin JS, Mazuski JE, Gradley JS, et al: Diagnosis and management of complicated intraabdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America, *Surg Infect* 11:79–109, 2010.

*Because of increasing resistance of *Escherichia coli* to fluoroquinolones, local population susceptibility profiles and, if available, isolate susceptibility should be reviewed.

TABLE 95-1 AGENTS AND REGIMENS FOR THE INITIAL EMPIRICAL TREATMENT OF EXTRABILIARY COMPLICATED INTRAABDOMINAL INFECTION

REGIMEN	COMMUNITY-ACQUIRED INFECTION IN CHILDREN	COMMUNITY-ACQUIRED INFECTION IN ADULTS	
		Mild to Moderate Severity*	High Risk or Severity [†]
Single agent	Ertapenem, meropenem, imipenem-cilastatin, ticarcillin-clavulanate, and piperacillin-tazobactam	Cefoxitin, ertapenem, moxifloxacin, tigecycline, and ticarcillin-clavulanic acid	Imipenem-cilastatin, meropenem, doripenem, and piperacillin-tazobactam
Combination	Ceftriaxone, cefotaxime, cefepime, or ceftazidime, each in combination with metronidazole; gentamicin or tobramycin, each in combination with metronidazole or clindamycin and with or without ampicillin	Cefazolin, cefuroxime, ceftriaxone, cefotaxime, ciprofloxacin, or levofloxacin, each in combination with metronidazole [‡]	Cefepime, ceftazidime, ciprofloxacin, or levofloxacin, each in combination with metronidazole*

From Solomkin JS, Mazuski JE, Gradley JS, et al: Diagnosis and management of complicated intraabdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America, *Surg Infect* 11:79–109, 2010, Table 2.

*Includes perforated or abscessed appendicitis and other infections of mild to moderate severity.

[†]Includes severe physiologic disturbance, advanced age, and immunocompromised states.

[‡]Because of increasing resistance of *Escherichia coli* to fluoroquinolones, local population susceptibility profiles and, if available, isolate susceptibility should be reviewed.

TABLE 95-3 INTRAVENOUS ANTIBIOTICS FOR EMPIRICAL TREATMENT OF COMPLICATED INTRAABDOMINAL INFECTION

ANTIBIOTIC	ADULT DOSAGE*
β-LACTAM/β-LACTAMASE INHIBITOR COMBINATION	
Piperacillin-tazobactam	3.375 g q6h [†]
Ticarcillin-clavulanic acid	3.1 g q6h; FDA labeling indicates 200 mg/kg/day in divided doses q6h for moderate infection and 300 mg/kg/day in divided doses q4h for severe infection
CARBAPENEMS	
Doripenem	500 mg q8h
Ertapenem	1 g q24h
Imipenem-cilastatin	500 mg q6h or 1 g q8h
Meropenem	1 g q8h
CEPHALOSPORINS	
Cefazolin	1-2 g q8h
Cefepime	2 g q8-12h
Cefotaxime	1-2 g q6-8h
Cefoxitin	2 g q6h
Ceftazidime	2 g q8h
Ceftriaxone	1-2 g q12-24h
Cefuroxime	1.5 g q8h
Tigecycline	100-mg initial dose, then 50 mg q12h
FLUOROQUINOLONES	
Ciprofloxacin	400 mg q12h
Levofloxacin	750 mg q24h
Moxifloxacin	400 mg q24h
Metronidazole	500 mg q8-12h or 1500 mg q24h
AMINOGLYCOSIDES	
Gentamicin or tobramycin	5-7 mg/kg [‡] q24h [§]
Amikacin	15-20 mg/kg [‡] q24h [§]
Aztreonam	1-2 g q6-8h
Vancomycin	15-20 mg/kg [¶] q8-12h [§]

From Solomkin JS, Mazuski JE, Gradley JS, et al: Diagnosis and management of complicated intraabdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America, *Surg Infect* 11:79-109, 2010.

FDA, U.S. Food and Drug Administration.

*Dosages are based on normal renal and hepatic function.

[†]For *Pseudomonas aeruginosa* infection, dosage may be increased to 3.375 g q4h or 4.5 g q6h.

[‡]Initial dosage regimens for aminoglycosides should be based on adjusted body weight.

[§]Monitoring of serum drug concentration should be considered for dosage individualization.

[¶]Initial dosage regimens for vancomycin should be based on total body weight.

The bacteriology of acute appendicitis, including rupture, is polymicrobial, with gut aerobes (*Escherichia coli* is most common) and anaerobes (*Bacteroides fragilis* is most common). Typically, 10 to 14 different organisms can be isolated. This picture is similar to other intraabdominal infections such as diverticulitis.

Clinical Presentation

Classically, acute appendicitis begins with anorexia followed by periumbilical pain. The pain is steady, moderately severe, and sometimes cramping. After 4 to 6 hours, the pain migrates to the right lower quadrant, where the site of maximal tenderness is located at McBurney's point. This point is 0.5 to 2 inches inside the right anterior spinous process of the ilium on a line to the

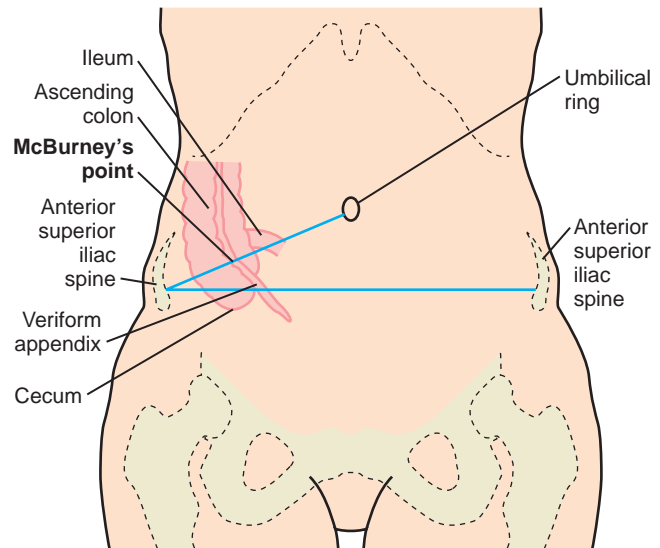

FIGURE 95-1 Various anatomic positions of the vermiform appendix.

umbilicus (Fig. 95-1). Seventy-five percent of patients vomit once or twice.

Evidence of peritoneal irritation includes rebound and guarding. Patients are typically supine and do not want to move. Pain may also be elicited by flexion and internal rotation of the right hip (i.e., obturator sign) or passive extension of the right hip (i.e., psoas sign). Palpation of the left lower quadrant pain may produce right lower quadrant pain (i.e., Rovsing's sign).

Patients usually have little fever or tachycardia. Determining whether a patient has a ruptured appendix, which occurs in 25% of cases, can be difficult. If the clinical presentation is delayed 4 to 5 days and rupture has occurred, there may be fever, tachycardia, and a palpable mass.

Variations in the presentation include initial right lower quadrant pain, back and flank pain (i.e., retrocecal appendix), suprapubic pain (i.e., pelvic appendix), and left lower quadrant pain (i.e., long appendix). The elderly may have no periumbilical or right lower quadrant pain. Children may not be able to give an accurate history, and in pregnant women, the appendix may be pushed upward by the expanding uterus. At 8 months' gestation, the pregnant woman's pain may be in the right upper quadrant.

Diagnosis

The diagnosis of acute appendicitis is important but can be difficult. A careful meta-analysis reported that the history, physical examination, and inflammatory markers are singly unreliable predictors of the diagnosis, but when combined, they are accurate. A careful history and physical examination should be obtained. Pain migrating from the umbilical area to the right lower quadrant should be sought in the history. Signs of peritoneal irritation, including rebound, percussion tenderness, guarding, and rigidity, should be determined. The total white blood cell count, number of neutrophils, percentage of bands, and level of C-reactive protein should be measured.

The Alvarado system was developed to aid in the diagnosis of appendicitis (Table 95-4). Using the mnemonic MANTRELS, it

scores the impact of eight factors: *migration, anorexia, nausea and vomiting, tenderness in the right lower quadrant, rebound of pain, elevation of temperature, leukocytosis, and shift to the left.* A patient with a score of 5 or 6 is usually observed, but an individual with a score of 7 or greater should undergo surgery.

Two prospective trials demonstrated the accuracy of helical computed tomography (CT) with contrast for the diagnosis of acute appendicitis. The initial CT findings of appendicitis are enlargement of the appendix, usually to an appendiceal diameter of more than 6 mm (Fig. 95-2). The wall is thickened and enhances with contrast. Later findings include inflammation,

thickening of the cecal wall, and pericecal fat stranding. An appendicolith is a helpful sign. If perforation has occurred, extensive inflammatory changes are seen, which may include an abscess cavity. Although there has been controversy about whether CT scans are necessary or more accurate than clinical assessment in every case, the current standard of care in emergency departments includes a CT scan. Use of CT has reduced the rate of finding normal appendices at surgery from between 11% and 15% to between 3% and 5%.

Diagnostic ultrasound is accurate if carefully performed and can be particularly useful in small children and pregnant women. Because of its accuracy and lack of ionizing radiation, magnetic resonance imaging (MRI) has become the scanning modality of choice in many centers for children, pregnant women, and other patients. Nonetheless, CT scanning is rapid and more likely available, and it is therefore the procedure of choice for most patients.

The differential diagnosis for acute appendicitis is long. It includes urinary tract infection and stones; gynecologic problems such as a ruptured ovarian cyst, ectopic pregnancy, and pelvic inflammatory disease; and bowel pathology, including diverticulitis and Crohn's disease.

Treatment

Laparoscopic (75% of procedures) or open appendectomy is the treatment of choice for emergent cases. If rupture is identified, antibiotics and drainage are indicated. Pretreatment antibiotics in all cases prevent wound infection and intraabdominal infections as indicated by a Cochran review. Antibiotics to cover *E. coli*

and *B. fragilis* are recommended by the guidelines from the Surgical Infection Society and Infectious Diseases Society of America (see Tables 95-1 and 95-3). The recommendations also apply to other intraabdominal infections, such as diverticulitis. Antibiotics should be stopped after surgery in simple cases. If rupture has occurred, it is usually safe to stop antibiotics after 5 to 7 days.

Some studies over the past decade have advocated antibiotics alone for the treatment of acute appendicitis. Although provocative and potentially a future direction for care, the lack of a sufficient number of controlled trials, the difficulty of confirming the diagnosis in trials, and the high recurrence and complication rates make this approach unsuitable for general application.

Prognosis

The mortality rate in the United States is extremely low for uncomplicated cases. Rupture, however, results in an overall 1% mortality rate and a 5% rate in elderly patients. Wound infection occurs in 1% to 20%. The rate of fetal loss in pregnant women with appendicitis is 1.5%, but the rate is 20% to 35% in cases of rupture.

● DIVERTICULITIS

Definition and Epidemiology

Diverticulitis is inflammation and infection resulting from perforation of diverticula of the bowel wall, usually in the sigmoid colon. Diverticulitis is diagnosed in more than 2 million patients each year and accounted for 219,000 hospital discharges in 2009 in the United States. It is also the most common cause of sigmoid colon resection.

Diverticula occur in less than 10% of people younger than 40 years and in 50% to 80% of those older than 80 years. Between 10% and 25% of individuals with diverticulosis develop diverticulitis. Rates of diverticulosis in rural Africa and Asia are less than 1%. Diet is thought to be a critical risk factor. Supporting this hypothesis was a study measuring diverticulosis in Japanese populations in Japan (1% prevalence) and individuals of Japanese heritage living in the United States (52% prevalence).

Pathology

Diverticula are herniations of the mucosa and muscularis through the colonic wall between the taeniae coli where the main blood vessels penetrate the wall. Diverticulitis results from macroscopic or microscopic perforations, resulting in inflammation, local infection, and in severe cases, free air and diffuse peritonitis (Fig. 95-3).

Clinical Presentation and Diagnosis

Noninflamed diverticula cause no symptoms. Patients with uncomplicated diverticulitis have left lower quadrant pain often accompanied by nausea and fever. CT, which is the diagnostic test of choice, may show pericolic soft tissue stranding, colonic wall thickening, and a phlegmon. Between 10% and 20% of patients have severe pain, tenderness, fever, and leukocytosis, and they require hospital admission for intravenous antibiotics. The differential diagnosis for diverticulitis includes urinary tract infection, gastroenteritis, inflammatory bowel disease, perforated colonic cancer, appendicitis, and bowel obstruction.

Complicated diverticulitis occurs when the perforation is not contained. Patients may have severe abdominal pain, free air, guarding, rigidity, and multisystem failure. Complications include abscess seen in pericolic, retroperitoneal, or pelvic areas on CT; purulent or feculent peritonitis; and colovesical, colovaginal, or coloenteric fistulas (5% occurrence). Percutaneous drainage of abscesses or surgery, including sigmoid resection, is usually indicated in these situations.

Treatment and Prognosis

Uncomplicated diverticulitis can be treated on an outpatient basis with oral antibiotics, and more severe cases are treated with intravenous antibiotics for 7 to 10 days on an inpatient basis (see Tables 95-1 and 95-3). Although data from a Cochrane review and a controlled trial conducted in Sweden suggest that not all patients need to be treated with antibiotics, the standard of care in the United States is to treat with antibiotics. The most important organisms to cover in this polymicrobial infection are *E. coli* and *B. fragilis*. Complicated diverticulitis requires point source control (i.e., drainage or bowel resection), intravenous antibiotics to cover bowel flora, and systemic resuscitation. Fistulas require surgical resection and repair.

Colonoscopy should be done 6 to 8 weeks after an episode of diverticulitis to rule out colonic cancer. The recurrence rate of diverticulitis is approximately 20%. A high-fiber diet, weight loss, and exercise are recommended to prevent recurrence. Sigmoid resection may be considered after the second recurrence, depending on age, medical condition, and the frequency and severity of episodes. If the sigmoid colon is removed, more than 95% of patients have no further episodes.

● CHOLECYSTITIS AND CHOLANGITIS

Definition and Epidemiology

Gallstones occur in 11% to 36% of the population. Approximately 20% of patients with gallstones develop temporary obstruction of the cystic duct at some time. This results in biliary colic (i.e., episodes of right upper quadrant pain) lasting 1 to 5 hours. Cholecystitis occurs when the cystic duct is obstructed for longer periods. Intraluminal pressure increases, compromising blood and lymphatic flow, and it may result in acute inflammation and infection.

Among patients with gallstones, 6% to 12% have stones in the common duct or choledocholithiasis. Cholangitis results from obstruction of the common duct, usually by common duct stones, leading to inflammation and often to severe infection.

Clinical Presentation

Patients with biliary pain have various sites of maximal pain and radiation of pain (Fig. 95-4). Classic signs of acute cholecystitis include unremitting right upper quadrant pain that is more severe than biliary colic, fever, anorexia, nausea, and vomiting. Murphy's sign (i.e., inspiratory arrest with deep palpation of the right upper quadrant) is positive. Accuracy is increased by assessing the gallbladder with ultrasound and eliciting pain with the probe (i.e., sonographic Murphy's sign).

Elderly patients and patients with diabetes may have more subtle clinical presentations. A mild leukocytosis may be

FIGURE 95-3 Diverticulosis. (From the Netter Collection of Medical Illustrations. Available at www.netterimages.com. Accessed October 31, 2014.)

identified. Bacterial contamination of the gallbladder occurs in 15% to 30%. If obstruction continues, gangrenous cholecystitis, necrosis of the gallbladder wall and abscess or empyema may occur. Perforation, which rarely occurs, is usually limited to the subhepatic space. Infection by gas-forming organisms may result in emphysematous cholecystitis.

Acute cholangitis with common duct obstruction can cause mild and self-limited disease to fulminant, life threatening

infection. Two thirds of patients have Charcot's triad (i.e., right upper quadrant pain, fever, and jaundice). Fever is often accompanied by rigors. The addition of hypotension and mental status changes results in Reynolds pentad (i.e., jaundice, fever, abdominal pain, shock, and altered mental status), a sign of severe disease. Leukocytosis and elevated alkaline phosphatase and bilirubin levels are typical. Bile cultures usually show bowel organisms, and blood cultures are positive in 30% to 40% of cases.

FIGURE 95-4 **A**, Sites of the most severe pain during an episode of biliary pain in 107 patients with gallstones (% values add up to >100% because of multiple responses). The subxiphoid and right subcostal areas were the most common sites; note that the left subcostal region was not an unusual site of pain. **B**, Sites of pain radiation (%) during an episode of biliary pain in the same group of patients. (Modified from Burnicardi FC, Andersen DK, Billiar TR, et al: *Schwartz's principles of surgery*, ed 9, New York, 2009, McGraw-Hill.)

For a deeper discussion of these topics, please see Chapter 155, "Diseases of the Gallbladder and Bile Ducts," in *Goldman-Cecil Medicine, 25th Edition*.

Diagnosis

Ultrasonography is 95% sensitive and specific for the diagnosis. In cholecystitis, ultrasound shows a thickened gallbladder wall and pericholecystic fluid. In cholangitis, ultrasound shows a dilated common duct, but obstructing gallstones are difficult to identify. Endoscopic retrograde cholangiopancreatography (ERCP) is required for a definitive diagnosis of cholangitis. The differential diagnosis includes peptic ulcer disease with or without perforation, pancreatitis, appendicitis, hepatitis, myocardial infarction, and pneumonia.

Treatment

Biliary colic is usually self-limited. Acute cholecystitis usually requires intervention to relieve obstruction of the cystic duct, but it may remit spontaneously. Laparoscopic cholecystectomy is indicated emergently if there is gangrene or perforation; otherwise, surgery should be done within 1 to 3 days. Antibiotics are routinely given to cover bowel flora. Ceftriaxone can be given for mild to moderate disease, whereas broader coverage such as imipenem-cilastatin or piperacillin-tazobactam should be given for more severe disease (see [Tables 95-1, 95-2, and 95-3](#)).

Acute cholangitis should be treated initially with fluid resuscitation and antibiotics. ERCP is indicated for diagnosis and relief of obstruction. Emergency decompression of the biliary tract by ERCP or surgery may be indicated for severely ill patients.

INFECTIONS OF SOLID ORGANS

Hepatic Abscess

Liver abscess is usually caused by bacteria or *Entamoeba histolytica*. Both are rare. The incidence of bacterial abscess is 10 to 20 cases per million people per year, and the incidence of amebic abscess is 1 case per million per year in the United States. Worldwide, however, 10% of people are infected with gastrointestinal *E. histolytica*, and liver abscess is the most common extraintestinal manifestation.

The biliary tract is the most common source of infection for bacterial hepatic abscess. Other sources include direct extension (e.g., perforated appendicitis), portal vein (e.g., abdominal infection), hepatic artery (e.g., bacterial line infection), and trauma. In 20% to 40% of cases, no cause is found. The bacteriology of hepatic abscess reflects the source, with polymicrobial bowel flora being the most common. Hematogenous sources are usually staphylococcal or streptococcal species. Less common organisms include *Klebsiella pneumoniae*, which is identified particularly in case series from Asia, and *Candida* species found in immunocompromised patients.

Liver abscess usually manifests with fever for days to weeks. Right upper quadrant abdominal pain and tenderness are found in one half of patients and jaundice in one fourth. Peripheral blood leukocyte counts are elevated in three fourths, and two thirds have an obstructive liver profile with an elevated alkaline phosphatase level. [Table 95-5](#) illustrates the differences between amebic and bacterial liver abscesses.

Patients with amebic liver abscess tend to be younger men with more right upper quadrant pain and a more acute course than those with bacterial hepatic abscess. There often is a history of travel or residence in a highly endemic geographic area.

Ultrasound is the preferred initial diagnostic test because it is rapid and can help to identify biliary sources. CT is more specific and can identify other causes of liver abscess, such as extension from an intraabdominal abscess. The right lobe is most commonly infected, and 50% of cases are multifocal.

Drainage of liver abscesses is essential. Percutaneous aspiration of the abscess is therapeutic and diagnostic. Repeated aspirations or catheter placement may be necessary. Antibiotics are directed by the likely source and by results of Gram stain and culture. Blood cultures are positive in 50% of cases and may be

TABLE 95-5 AMEBIC AND PYOGENIC LIVER ABSCESES

FEATURE	AMEBIC LIVER ABSCESS	PYOGENIC LIVER ABSCESS
EPIDEMIOLOGY

*Approximate percentage of cases.

the only positive culture. Therapy is usually given for 4 to 6 weeks. Rupture or sepsis syndrome occurs rarely. Surgery may be necessary if there is a lack of response, rupture, or complex multilocular abscesses.

The serologic analysis for *E. histolytica* is 95% sensitive but cannot distinguish gastrointestinal disease from hepatic abscess. Treatment for amebic infection is oral metronidazole for 7 to 10 days.

Pancreatic Infection

Although most episodes of pancreatitis are self-limited, infected necrotizing pancreatitis has a mortality rate approaching 30%. Acute pancreatitis is characterized by upper abdominal pain that often radiates to the back and is accompanied by nausea and vomiting. The serum amylase concentration is greater than three times the normal value, and CT shows typical inflammation in the pancreas. Eighty percent of acute pancreatitis cases are mild, whereas 20% of cases are moderate to severe.

Patients with infected necrotizing pancreatitis typically develop fever, leukocytosis, and increased abdominal pain several weeks after the onset of pancreatitis. The standard of care includes antibiotics to cover cultured microorganisms (typically enteric bacteria or *Staphylococcus aureus*), and surgical débridement is delayed for 4 to 6 weeks if possible. Because early surgical intervention may increase the mortality rate, delayed débridement is recommended.

Pancreatic abscess usually occurs 2 to 6 weeks after an episode of acute pancreatitis. Treatment is percutaneous drainage plus antibiotics. Distinguishing pancreatic necrosis from necrosis plus infection and pseudocyst from abscess can be difficult.

 For a deeper discussion of these topics, please see Chapter 144, "Pancreatitis," in Goldman-Cecil Medicine, 25th Edition.

Splenic Abscess

Splenic abscess usually results from a hematogenous source, particularly endocarditis; consequently, the infecting bacteria are usually streptococcal and staphylococcal species. Patients have left upper quadrant pain, fever, an enlarged spleen, and an elevated white blood cell count. Ultrasound is diagnostic, and splenectomy is curative. Percutaneous aspiration plus antibiotics can also be effective.

Extravisceral Abscesses

Extravisceral abscesses typically occur from perforation of the bowel, resulting from inflammation or iatrogenic sources such as endoscopy and surgery. Other causes include peritonitis, ruptured solid organ abscess, and penetrating trauma. The clinical presentation varies widely with the location and cause. CT is the most useful imaging modality. Point source control, usually with percutaneous aspiration or surgical drainage, is essential for treatment. Antibiotic coverage is secondary and should be directed at the cause as identified by location, Gram stain, and culture.

PERITONITIS

Primary Peritonitis

Primary or spontaneous bacterial peritonitis usually occurs in patients with cirrhosis and ascites or in children with nephrotic syndrome. The source is not apparent. The bacteriologic analysis reflects aerobic bowel flora, including *E. coli*, *K. pneumoniae*, and gram-positive organisms. Anaerobes are uncommon.

Clinical presentation includes fever, abdominal pain, ascites, and deteriorating liver function test results. Diagnosis is likely if aspirated ascitic fluid has greater than 250 neutrophils/ μL . A diagnosis of primary peritonitis is made if a secondary source is ruled out. Culture and Gram stain may be negative. Patients usually respond after 48 to 72 hours of antibiotics. Patients with cirrhosis and ascites who have had one episode of spontaneous peritonitis are at risk for further episodes and are candidates for antibiotic prophylaxis. A meta-analysis of 13 trials concluded that prophylaxis resulted in decreased morbidity and mortality.

Secondary Peritonitis

Secondary peritonitis usually results from perforation of bowel and contamination by mixed enteric organisms. Other sources include rupture of the urinary tract or gynecologic organs. Bacteriology usually identifies polymicrobial infection with aerobes and anaerobes, reflecting the mucosal surface of the source. The peripheral blood leukocyte count is usually elevated.

Patients are usually febrile and have signs of peritoneal irritation: abdominal wall tenderness, rebound, and rigidity. Tenderness may be maximal over the origin of the peritonitis (e.g., ruptured viscus). Because movement causes pain, patients keep their knees bent and have quiet respirations.

Ultrasound and CT may reveal the origin of peritonitis. Aspiration of ascitic fluid usually reveals the causative organisms. Antibiotic therapy to cover the suspected or identified organisms should be begun immediately. It usually includes coverage of bacteria causing intraabdominal infection as discussed previously.

Surgical approach is aimed at controlling the source (e.g., perforated appendix), débridement, and drainage of abscesses.

Peritonitis during Peritoneal Dialysis

Rates of peritonitis during long-term peritoneal dialysis average less than 1 case in 24 months, but a few patients have higher rates. Bacteria usually represent skin flora, with *Staphylococcus epidermidis*, *S. aureus*, and streptococcal species predominating. Most patients have abdominal pain and tenderness but no fever. Neutrophil counts greater than 100 cells/ μ L and bacteria in a cloudy dialysate confirm the diagnosis.

Treatment can usually be accomplished intraperitoneally on an outpatient basis. Several antibiotic regimens have proved effective. Removal of the peritoneal catheter may be necessary (10% to 20% of cases) if there is a catheter tunnel infection, an unusual organism such as a fungus, or persistent infection.

Tuberculous Peritonitis

Primary tuberculous peritonitis often has a gradual onset. Symptoms include fever, abdominal pain, and weight loss. Pulmonary tuberculosis often exists. Signs may include tender, “doughy” masses or ascites. Symptoms and signs may be subtle.

Peritoneal fluid is exudative and contains 500 to 2000 cells/ μ L, mostly lymphocytes. Culture of peritoneal fluid is positive in

only 25% of cases. The diagnosis is made by biopsy of nodules seen on the peritoneum during laparoscopy. Treatment consists of standard antituberculous therapy.

Infectious Diarrhea

Awewura Kwara

DEFINITION AND EPIDEMIOLOGY

Acute diarrhea is defined as an increase in frequency of bowel movements, to three or more times daily with at least 200 g of stool per day, lasting less than 14 days. In clinical practice, three or more loose stools per day is considered to represent diarrhea. *Infectious diarrhea* is diarrhea that has an infectious etiology and is often associated with symptoms and signs of enteric involvement, such as nausea, vomiting, abdominal cramps, passage of bloody stool (dysentery), or systemic symptoms. When diarrhea lasts longer than 14 days, it is considered to be *persistent diarrhea*. The term *chronic diarrhea* refers to illness that last longer than 1 month. Organisms responsible for infectious diarrhea include bacteria, viruses, and parasites.

Globally, there are an estimated 1.7 billion cases of diarrhea annually, with acute infectious diarrhea causing more than 2 million deaths per year. Infectious diarrhea is the second leading cause of death in children younger than 5 years of age, killing an estimated 760,000 such children every year. In the United States, an estimated 211 to 375 million episodes of acute diarrhea occur annually, with more than 900,000 hospitalizations and about 6000 deaths. Foodborne illnesses alone account for about 76 million cases and 5000 deaths in the US each year.

PATHOLOGY

Diarrhea is an alteration of movement of ions and water that leads to an increase in water content, volume, or frequency of stools. Under normal conditions, up to 9 L of fluid is passed through the adult gastrointestinal tract daily. Almost 98% of this fluid is absorbed, and only 100 to 200 mL is excreted in stools. Enteric pathogens or microbial toxins that are ingested can overcome host defenses and alter this balance toward a net secretion, leading to diarrhea. A large number of microorganisms are normally ingested with every meal. Host defense mechanisms against enteric pathogens include low gastric pH, rapid transit of bacteria through the proximal small intestine, cellular immune responses, and antibody production. In addition, large numbers of normal bacterial flora inhabit the intestines and prevent colonization by enteric pathogens.

Alteration of the normal defense mechanisms can put individuals at risk for infectious diarrhea. Individuals with gastric resection or achlorhydric states have increased frequency of infection due to *Salmonella*, *Giardia lamblia*, and helminths, whereas some organisms, such as *Shigella* or rotavirus, survive the extreme acidity of the gastric environment. Some viral, bacterial, and parasitic infections are more common in patients with impaired cellular or humoral immunity. More than 99% of the

normal colonic flora is made up of anaerobic bacteria; they produce fatty acids and cause acidic pH, which is important for resistance to colonization. Alteration of the bacterial flora due to broad-spectrum antibiotic therapy predisposes some individuals to the development of *Clostridium difficile* infection.

The virulence factors employed by enteric pathogens include inoculum size, adherence factors, toxin production, and invasion. Organisms such as *Shigella*, enterohemorrhagic *Escherichia coli* (EHEC), *G. lamblia*, and *Entamoeba histolytica* need as few as 10 to 100 organisms to produce infection, whereas *Vibrio cholerae* needs 10^5 to 10^8 organisms to cause disease. Many pathogens, including *V. cholerae* and enterotoxigenic *E. coli* (ETEC), must adhere to the gastrointestinal tract to establish infection. They produce virulence factors that allow the organisms to attach to the brush border of the intestinal epithelium. Several enteric pathogens produce disease through the production of toxins. These include enterotoxins that cause secretory diarrhea, cytotoxins that cause cell destruction and inflammatory diarrhea, and neurotoxins that act on the nervous system. Other bacteria cause disease by invasion and destruction of mucosal epithelial cells.

Enterotoxin-Induced Secretory Diarrhea

Ingested enterotoxin-producing bacteria colonize the small bowel and multiply to large numbers. The bacteria then produce enterotoxin, which binds to the mucosa and causes watery diarrhea through hypersecretion of isotonic fluid that overwhelms the absorptive capacity of the colon. *V. cholerae* produces the cholera toxin, a heterodimeric protein composed of one A and five B subunits. The enterotoxin binds to the intestinal mucosa and activates adenylate cyclase to produce cyclic adenosine monophosphate (cAMP), which causes increased chloride secretion and decreased sodium absorption, leading to hypersecretion of fluid. ETEC, which causes traveler's diarrhea, produces both a heat-labile enterotoxin that acts by the same mechanism as the cholera toxin and a heat-stable enterotoxin that causes secretory diarrhea through activation of guanylate cyclase to produce cyclic guanosine monophosphate (cGMP).

Cytotoxin-Induced Diarrhea

In contrast to enterotoxins, cytotoxins elaborated by enteric pathogens destroy mucosal epithelial cells, causing bloody diarrhea with inflammatory cells (dysentery). *Shigella dysenteriae* produces the shiga toxin, which causes dysenteric diarrhea in patients with shigellosis. Other toxin-producing bacteria include *Vibrio parahaemolyticus*, *C. difficile*, and shiga toxin-producing strains of *E. coli* (STEC) that cause hemorrhagic colitis and hemolytic-uremic syndrome (HUS).

Invasive Diarrhea

Some bacteria cause dysentery through direct invasion and destruction of intestinal mucosa rather than through production of a cytotoxin. *Shigella* and enteroinvasive *E. coli* invade and multiply in epithelial cells and spread to adjacent cells. Diarrhea is often accompanied by fever, abdominal cramps, and small amounts of bloody mucoid stools. Other bacteria, such as *Salmonella typhi* and *Yersinia enterocolitica*, penetrate the mucosa before disseminating into the bloodstream to cause a systemic illness.

Bacterial Food Poisoning

Bacterial food poisoning is caused by ingestion of preformed toxins in food; this results in a toxic illness rather than an enteric infection. The toxins may include cytotoxins, enterotoxins, and neurotoxins. Pathogens that produce bacterial food poisoning include *Staphylococcus aureus*, *Clostridium perfringens*, and *Bacillus cereus*. These organisms grow in food and produce toxins that are ingested directly in the food. Symptoms occur soon after food ingestion, with incubation periods of 1 to 16 hours and high attack rates. The illness is rarely associated with fever, and symptoms usually resolve within 12 to 24 hours after onset.

The staphylococcal and *B. cereus* toxins act on the nervous system to cause vomiting. *S. aureus* causes vomiting and diarrhea within 2 to 7 hours after ingestion of improperly cooked or stored food containing its heat-stable enterotoxin. *C. perfringens* produces secretory and cytotoxin-induced watery diarrhea within 8 to 14 hours after ingestion of contaminated vegetables, meat, or poultry. *B. cereus* often contaminates fried rice, vegetables, or sprouts; it produces one of two toxins which cause disease resembling that of *S. aureus* or *C. perfringens* infection within 1 to 6 hours after ingestion. Ingestion of the bacteria with subsequent

in vivo toxin production often results in disease with a longer incubation period (8 to 16 hours).

SPECIFIC PATHOGENS

The epidemiologic and clinical features of common enteric pathogens and the recommended methods for diagnosis and treatment are summarized in [Tables 96-1](#) and [96-2](#).

Shigella

Diarrhea due to *Shigella* occurs after ingestion of fecally contaminated food or water. The main species include *S. dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*. Ingestion of as few as 10 to 100 microorganisms can lead to infection because the bacteria are relatively resistant to gastric acid. Person-to-person transmission is common, and the attack rate is highest among infants and young children in child care centers. The incubation period is 6 to 72 hours. Illness may initially manifest as noninflammatory, watery diarrhea caused by enterotoxin production or multiplication of bacteria in the small intestines. Invasion of the colonic epithelium and mucosa often manifests as dysentery. Complications of shigellosis include HUS, which is associated with *S. dysenteriae* type 1, and Reiter's chronic arthritis syndrome, which is associated with *S. flexneri* infection.

Salmonella

Salmonella typhi causes typhoid fever, but not diarrhea. Nontyphoidal salmonellosis results from ingestion of contaminated meat, dairy, or poultry products or from direct contact with animals such as birds, pet turtles, snakes, and other reptiles. An oral inoculum of 10^5 to 10^8 organisms is needed but smaller inocula can cause disease in patients with impaired gastric acidity or compromised immunity. The organisms invade the distal

TABLE 96-1 EPIDEMIOLOGIC AND CLINICAL CHARACTERISTICS OF COMMON ENTERIC PATHOGENS

ORGANISM	EPIDEMIOLOGIC FEATURES	COMMON CLINICAL FEATURES
<i>Campylobacter jejuni</i>	Consumption of undercooked poultry, travel to tropical and semitropical regions	Acute watery diarrhea, fever, abdominal pain, fecal evidence of inflammation (positive fecal leukocytes, lactoferrin, or occult blood)
<i>Vibrio cholerae</i>	Inadequately cooked seafood, travel to endemic regions	Acute dehydrating watery diarrhea; fever is usually absent
<i>Clostridium difficile</i>	Antibiotic use, recent hospitalization, elderly patients with coexisting conditions	Diarrhea with fever, fecal evidence of inflammation, marked leukocytosis
Enterotoxigenic <i>Escherichia coli</i>	Travel to tropical and semitropical regions	Watery diarrhea, abdominal cramps, nausea and vomiting; leukocytes absent in stools
Nontyphoidal <i>Salmonella</i>	Foodborne outbreaks, exposure to animals	Acute watery diarrhea, fever, abdominal pain, evidence of inflammation
<i>Shigella</i>	Person-to-person transmission, daycare center contact	Severe diarrhea with fever, abdominal pain, bloody diarrhea, fecal evidence of inflammation
Shiga toxin-producing <i>E. coli</i>	Foodborne outbreaks, undercooked hamburgers, raw seed sprouts, water and wading pool exposure	Abdominal pain, bloody stools, absence of fever, fecal evidence of inflammation
Noncholeraic <i>Vibrio</i>	Ingestion of shellfish and undercooked seafood	Watery diarrhea, abdominal cramps, nausea; fever and vomiting are less frequent
<i>Yersinia enterocolitica</i>	Contaminated food or water, inadequately cooked meats, unpasteurized milk	Acute watery diarrhea, fever, abdominal pain, bloody diarrhea
Norovirus <i>Cyclospora</i>	Winter outbreaks in congregate settings, outbreaks on cruise ships Foodborne outbreaks, travel to tropical and subtropical regions (especially Nepal)	Watery diarrhea, nausea, vomiting, abdominal pain Persistent noninflammatory diarrhea
<i>Cryptosporidium</i> <i>Entamoeba histolytica</i>	Waterborne outbreaks, travel to tropical and subtropical regions Travel to tropical regions, recent immigration from endemic regions	Persistent noninflammatory diarrhea Bloody diarrhea, extraintestinal involvement (liver abscess)
<i>Giardia lamblia</i>	Waterborne outbreaks, travel to mountainous areas of North America, Russia	Abdominal pain, persistent watery diarrhea, flatulence, steatorrhea, nausea and vomiting

TABLE 96-2 DIAGNOSIS AND RECOMMENDED ANTIMICROBIAL TREATMENT FOR DIARRHEA WITH SPECIFIC PATHOGENS IN ADULTS

ORGANISM	DIAGNOSIS	RECOMMENDATIONS
<i>Campylobacter jejuni</i>	Routine stool culture	Erythromycin 250 mg qid or azithromycin 500 mg daily for 7 days
<i>Vibrio cholerae</i> O1	Stool culture in special salt-containing media (TCBS), test isolate for O1 serotype	Doxycycline 300 mg single dose, or single dose of fluoroquinolone, or tetracycline 500 mg qid for 3 days, or TMP-SMZ 160/800 mg bid for 3 days
<i>Clostridium difficile</i>	Stool test for <i>C. difficile</i> toxin A or B by EIA, or PCR for the B toxin gene	Stop implicated antibiotic. For mild to moderate illness, metronidazole 500 mg tid for 10 days; for severe illness, vancomycin 125 mg qid for 10-14 days
Enterotoxigenic <i>Escherichia coli</i>	Stool culture for <i>E. coli</i> , with assay for enterotoxin	Fluoroquinolone orally for 3 days (e.g., ciprofloxacin 500 mg bid, levofloxacin 500 mg daily, norfloxacin 400 mg bid). If susceptible, TMP-SMZ 160/800 mg bid for 3 days
Nontyphoidal <i>Salmonella</i>	Routine stool culture	Antimicrobials not recommended. If extraintestinal involvement or immunocompromise is present, TMP-SMZ (if susceptible) or quinolone as above, or ceftriaxone 100 mg/kg/day in one or two divided doses for 7 to 14 days, or longer if endovascular infection or relapsing
<i>Shigella</i>	Routine stool culture	Fluoroquinolone for 3 days (e.g., ciprofloxacin 500 mg bid, levofloxacin 500 mg daily, norfloxacin 400 mg bid). If susceptible, TMP-SMZ 160/800 mg bid for 3 days
Shiga toxin–producing <i>E. coli</i>	Stool culture with sorbitol-MacConkey agar, followed by serotyping for O157, then H7, with EIA for shiga toxins	Antibiotics and antimotility drugs should be avoided
Noncholeraic <i>Vibrio</i>	Stool culture in special salt-containing media (TCBS)	Fluoroquinolone orally for 3-5 days (ciprofloxacin 500 mg bid, levofloxacin 500 mg daily, norfloxacin 400 mg bid)
<i>Yersinia enterocolitica</i>	Stool culture on MacConkey media incubated at 25° to 28° C	Antibiotics usually not required. For severe infection or bacteremia, treat with TMP-SMZ or fluoroquinolone or doxycycline plus aminoglycoside
<i>Cyclospora</i>	Stool trichrome or acid-fast stain for parasites	TMP-SMZ 160/800 mg bid for 7-10 days
<i>Cryptosporidium</i>	Stool trichrome or acid-fast stain for parasites, EIA for <i>Cryptosporidium</i> species	Self-limited in immunocompetent persons. If severe or if patient is immunocompromised, consider paromomycin 500 mg tid for 7 days
<i>Isospora</i>	Stool trichrome or acid-fast stain for parasites	TMP-SMZ 160/800 mg bid for 7-10 days
<i>Entamoeba histolytica</i>	Stool examination for ova and parasites, EIA for <i>E. histolytica</i>	Metronidazole 750 mg tid for 5-10 days, plus iodoquinol 650 mg tid for 20 days or paromomycin 500 mg tid for 7 days
<i>Giardia</i>	Stool examination for ova and parasites, EIA for <i>Giardia</i> species	Metronidazole 500 to 750 mg tid for 7-10 days

bid, Twice a day; EIA, enzyme immunoassay; PCR, polymerase chain reaction; qid, four times a day; tid, three times a day; TCBS, thiosulfate-citrate-bile salts-sucrose agar; TMP-SMZ, trimethoprim-sulfamethoxazole.

ileum and cause diarrhea with fever, nausea, or vomiting. Diarrhea usually resolves in 2 to 3 days. Complications include bacteremia and metastatic seeding of atherosclerotic plaques and prostheses. Antimicrobial treatment does not shorten the duration of diarrhea and may prolong intestinal carriage in stools; therefore, antibiotics are indicated only for cases of severe disease or extraintestinal involvement.

Campylobacter jejuni

Disease caused by *Campylobacter jejuni* usually results from ingestion of undercooked poultry or direct contact with animals. The infective dose is 10^4 to 10^6 organisms, with an incubation period of 1 to 5 days. Acute watery diarrhea is the most common presentation; less frequently, systemic symptoms including fever may occur. Prodromal symptoms such as fever, myalgia, headache, and malaise may precede diarrhea. Complications include reactive arthritis, especially associated with the human leukocyte antigen B27 (HLA-B27), and Guillain-Barré syndrome, which can occur 2 to 3 weeks after diarrhea has resolved. Antibiotic therapy shortens the carriage state.

Vibrio

V. cholerae can be divided by the O-antigen of lipopolysaccharide into more than 150 strains. The toxigenic strains *V. cholerae* O1 and O139 produce cholera toxin and are associated with clinical illness. The infectious oral inoculum is about 10^5 to 10^8 organisms, with an incubation period of 6 hours to 5 days. Classic

cholera starts with vomiting, abdominal pain, and diarrhea. Diarrhea progresses to voluminous watery stools which have been described as “rice water” because they are clear with flecks of mucus. Massive diarrhea can lead to dehydration and shock within a few hours. The illness may be fulminant, with death occurring 3 to 4 hours after onset. Fever and bacteremia are rare. In endemic areas, the diagnosis is usually made on clinical grounds.

The characteristics of noncholeraic *Vibrio* species are covered in Tables 96-1 and 96-2.

Diarrhea-Causing Escherichia coli

There are several types of diarrheagenic *E. coli*, each with a different pathogenesis leading to diarrhea. In addition to ETEC and STEC, these include enteropathogenic, enteroinvasive, enteroaggregative, and diffusely adherent *E. coli*. ETEC is the most common cause of traveler’s diarrhea. It results in an enterotoxin-mediated watery diarrhea with abdominal cramps and vomiting. Enteropathogenic *E. coli* has been associated with epidemic diarrhea in neonates.

EHEC or STEC is acquired by eating contaminated food or water. The oral inoculum is 10 to 100 organisms, with an incubation period of 3 to 4 days. Most disease in the United States is caused by *E. coli* O157:H7, an enterohemorrhagic strain. It is classically associated with bloody diarrhea, abdominal pain, and fecal leukocytes. Systemic complications include HUS in children and thrombotic thrombocytopenia purpura in adults.

Antibiotic therapy has not been shown to reduce morbidity and may increase the risk of HUS in children.

Clostridium difficile

C. difficile is the main cause of nosocomial diarrhea among adults in the United States. Virtually all antibiotics have been implicated in the development of *C. difficile* infection, but the most common agents are clindamycin, cephalosporins, fluoroquinolones, and penicillins. Spores occur in the environment and are resistant to alcohol-based handwashing solutions. The spores of toxigenic *C. difficile* are ingested, survive gastric acidity, germinate, and colonize the lower intestinal tract, where they elaborate two exotoxins, toxin A (an enterotoxin) and toxin B (a cytotoxin). The toxins disrupt cell and tight junctions, leading to fluid leakage. The cellular toxicity results in formation of a pseudomembrane.

The epidemic strain referred to as the North American pulsed-field gel electrophoresis type 1 (NAP1) strain is associated with a severe course, higher mortality, and increased risk of relapse. Three bacterial factors have been implicated in outbreaks of *C. difficile* infection caused by the NAP1 strain, including increased production of toxins A and B, fluoroquinolone resistance, and production of a binary toxin. Patients often have abdominal pain and watery diarrhea but may also have bloody stools. Markers of severe infection include pseudomembranous colitis, acute renal failure, marked leukocytosis, hypotension, and toxic megacolon. The indigenous intestinal microbiota is important for colonization resistance and for recovery from antibiotic-associated *C. difficile* colitis.

Yersinia enterocolitica

Y. enterocolitica is a zoonosis caused by ingestion of contaminated food or water or undercooked meats. Oral inoculation requires 10^9 organisms for infection, with an incubation period of 3 to 7 days. The illness may mimic acute appendicitis and may be complicated by ileal perforation, mesenteric adenitis, or terminal ileitis. Postinfectious reactive polyarthritides and Reiter's syndrome may occur.

Viral Causes of Diarrhea

Viruses tend to cause diarrhea by adhering to the intestinal mucosa and disrupting the absorptive and secretory processes without causing inflammation. They may invade intestinal villous epithelial cells and cause sloughing of villi. Rotavirus was the most common cause of severe diarrhea in children in the past, but the incidence has fallen dramatically with widespread use of the rotavirus vaccine. Norovirus is highly contagious and is a very common cause of foodborne gastroenteritis in adults and children in the United States. It has been the cause of epidemic diarrhea on cruise ships. There is neither a vaccine nor specific treatment. Other viruses that cause diarrhea are adenoviruses, sapoviruses, and astroviruses. The incubation period is usually longer than 14 hours, and vomiting may be a prominent feature of diarrheal disease caused by viral agents.

Protozoan Causes of Diarrhea

Important parasitic causes of diarrhea include *G. lamblia*, *Cryptosporidium parvum*, and *E. histolytica*. Contaminated water sources tend to be the cause of outbreaks. *G. lamblia* multiplies

in the small intestine and attaches to or invades, but does not destroy, mucosa cells. Ingestion of a few organisms can lead to disease. *C. parvum*, *Isospora belli*, and *Cyclospora cayentanesis* occasionally cause self-limited diarrhea in immunocompetent individuals but may cause severe disease in patients with advanced acquired immunodeficiency syndrome (AIDS). *E. histolytica* causes a syndrome ranging from mild diarrhea to fulminant amebic colitis and extraintestinal amebic abscesses.

Traveler's Diarrhea

Traveler's diarrhea affects 10% to 40% of travelers from industrialized countries who visit tropical and semitropical developing countries. The causative agent is identified in about one half of cases, and 80% of those identified are bacterial pathogens, most often ETEC or enteroaggregative *E. coli*. Other bacterial causes include *Shigella*, *Salmonella*, *Campylobacter*, *Aeromonas*, noncholeraic *Vibrio*, and *Plesiomonas*. The viral etiologies include rotavirus and norovirus; parasitic causes are rare. Patients with traveler's diarrhea should be treated empirically with antibiotics without stool examination.

CLINICAL PRESENTATION

The epidemiologic and clinical characteristics are important to identify the potential etiologic agent and to guide management (see [Table 96-1](#)). The initial evaluation should consider the severity of illness, signs of dehydration, and intestinal inflammation indicated by the fever, abdominal pain, blood in stools (dysentery), or tenesmus. Important epidemiologic clues in the history include age, travel history, ingestion of undercooked or raw food and meat, antibiotic use, sexual activity, daycare attendance, and outbreaks involving others with similar exposure (see [Table 96-1](#)). Fever (temperature 38.5°C or 101.3°F or higher) is associated with invasive pathogens that cause intestinal inflammation. The examination should determine the severity of dehydration and need for rehydration as well as the likely cause. Signs of dehydration or hypovolemia include lax skin turgor and tenting, dry mucus membranes, decreased urination, tachycardia, and hypotension.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The approach to diagnosis and management of infectious diarrhea is shown in [Figure 96-1](#). Examination of stools for erythrocytes and white blood cells (leukocytes) using methylene blue staining or the lactoferrin test can help differentiate diarrhea caused by invasive pathogens from that caused by noninvasive pathogens. Most cases of diarrheal illnesses are self-limited, and almost half resolve within 1 day. Therefore, microbiologic investigation is usually not necessary for patients who are seen within 24 hours of the onset of illness unless certain conditions are present.

The indications for stool culture include severe diarrhea (six or more stools per day), diarrhea lasting longer than 1 week, fever, dysentery, hospitalization, inflammatory diarrhea, and multiple cases in a suspected outbreak. Routine stool culture will identify *Shigella*, *Salmonella*, *Campylobacter*, and *Aeromonas*. If the patient has bloody diarrhea or HUS, stool culture for *E. coli* O157 and tests for shiga-like toxin should be performed. Enzyme immunoassay for *C. difficile* toxins A and B or polymerase chain reaction

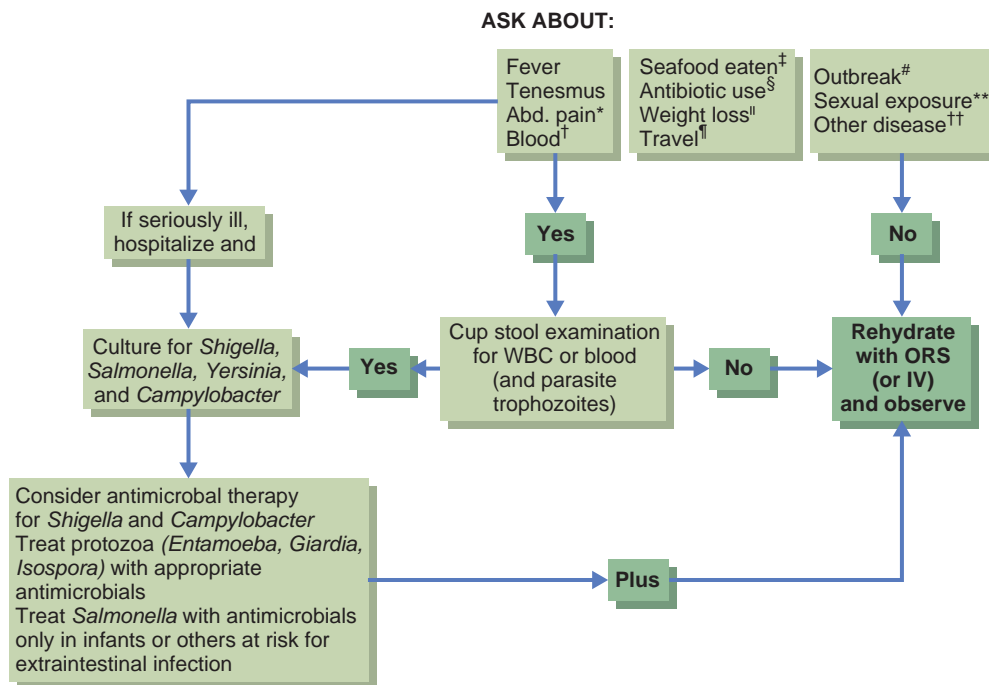

FIGURE 96-1 Approach to the diagnosis and management of acute infectious diarrhea. Abd., Abdominal; IV, intravenous; ORS, oral rehydration solution; WBC, white blood cell. *If unexplained abdominal pain and fever suggest an appendicitis-like syndrome, culture for *Yersinia enterocolitica*. †Bloody diarrhea, in the absence of fecal leukocytes, suggests enterohemorrhagic *Escherichia coli* or amebiasis (where leukocytes are destroyed by the parasite). ‡Ingestion of inadequately cooked seafood prompts consideration of *Vibrio* infections or noroviruses. §Associated antibiotics should be stopped and *Clostridium difficile* considered. ¶Persistence of diarrhea (>10 days) with weight loss prompts consideration of giardiasis, cryptosporidiosis, or inflammatory bowel disease. ||Travel to tropical areas increases the chance of enterotoxigenic *E. coli* (ETEC) as well as viral, protozoal (*Giardia*, *Entamoeba*, *Cryptosporidium*), and, if fecal leukocytes are present, invasive bacterial pathogens. #Outbreaks should prompt consideration of *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, ETEC, *Vibrio*, *Salmonella*, *Campylobacter*, or *Shigella* infection. **Sigmoidoscopy in symptomatic homosexual men should distinguish proctitis in the distal 15 cm (caused by herpesvirus, gonococcal, chlamydial, or syphilitic infection) from colitis (*Campylobacter*, *Shigella*, or *C. difficile* infection). ††In immunocompromised hosts, a wide range of viral (e.g., cytomegalovirus, herpes simplex virus, rotavirus), bacterial (e.g., *Salmonella*, *Mycobacterium avium* complex, *C. difficile*), protozoal (e.g., *Cryptosporidium*, *Isospora*, *Microsporidium*, *Entamoeba*, *Giardia*) and parasitic (*Strongyloides* hyperinfection syndrome) agents should be considered. (Modified from Guerrant RL, Shields DS, Thorson SM, et al: Evaluation and diagnosis of acute infectious diarrhea, *Am J Med* 78:91–98, 1985.)

for toxin B should be obtained if there is a history of recent antibiotic use, hospitalization, or age greater than 65 years with coexisting conditions, immunosuppression, or neutropenia. Consider protozoa, and check stools for ova and parasites (e.g., trophozoites) and/or for *Giardia* antigen test if diarrhea duration is greater than 7 days. If a patient has AIDS, stools should be checked for *Cryptosporidium*, *Microsporidium*, and *Mycobacterium avium* complex.

TREATMENT

Initial therapy should include fluid and electrolyte repletion with or without antimicrobial therapy. Oral rehydration is often adequate unless the patient is comatose or severely dehydrated. Nutritional support with continued feeding improves outcomes in children. In children, the BRAT diet (bananas, rice, apple-sauce, and toast) with avoidance of milk products is often recommended, but supporting evidence is limited.

Oral Fluid Therapy

In most patients with diarrhea, fluid repletion can be achieved with oral rehydration therapy using isotonic fluids containing glucose and electrolytes. An effective solution can be prepared by the addition of 2 tablespoons of sugar, one fourth of a teaspoon

of salt (NaCl), and one fourth of a teaspoon of baking soda (NaHCO₃) to 1 L of boiled drinking water. In the United States, fluids containing sodium in the range of 45 to 75 mEq/L (such as Pedialyte or Rehydrolite solutions) are recommended. Fluid should be administered in large quantities until there is clinical evidence that fluid balance is restored, and then as maintenance therapy. Oral rehydration therapy can be life-saving for patients in developing countries with severe diarrhea.

Intravenous Fluid Therapy

Massive fluid loss due to diarrhea should be rapidly replaced by the administration of intravenous fluids. Lactated Ringer's solution is the fluid of choice because the composition is similar to electrolyte loss during diarrhea. The rate of fluid administration and maintenance should be guided by clinical signs including vital signs, appearance of the mucosa, neck veins, and skin turgor.

Antimicrobial Therapy

Most cases of infectious diarrhea do not require antimicrobial therapy. However, antibiotics may decrease the volume of diarrhea (e.g., in cholera) or the duration and severity of the illness. Antibiotics are effective in the treatment of shigellosis, traveler's

diarrhea, *Campylobacter* infection, and *C. difficile* infection. In uncomplicated salmonellosis, antibiotics may prolong the shedding of salmonella. The choice and dose of antimicrobials for specific pathogens are described in Table 96-2. For traveler's diarrhea in adults, empiric therapy with ciprofloxacin 500 mg twice a day, or trimethoprim-sulfamethoxazole (TMP-SMZ) 160/800 mg twice a day, for 3 to 5 days is adequate. For antibiotic-associated *C. difficile* colitis, broad-spectrum antibiotics should be discontinued, if possible. The first-line therapy is metronidazole 500 mg three times a day orally for 10 to 14 days. For severely ill patients, oral vancomycin 125 mg four times a day for 10 to 14 days should be initiated. Persistently recurrent *C. difficile* disease has been treated successfully with replacement of bowel flora.

Symptomatic Therapy

Antidiarrheal agents such as loperamide and bismuth subsalicylate can be used in some instances for symptomatic relief. Loperamide inhibits intestinal peristalsis and has some antisecretory properties. When used with or without antibiotics in cases of traveler's diarrhea, it may reduce the duration of diarrhea by about 1 day. Antimotility agents should be avoided in patients with bloody or suspected inflammatory diarrhea. The use of these agents has been implicated in prolonging the duration of fever in shigellosis, development of toxic megacolon in *C. difficile* colitis, and development of HUS in children with STEC infection. Bismuth subsalicylate can alleviate stool output in children as

well as the symptoms of abdominal pain, diarrhea, and nausea in patients with traveler's diarrhea.

PROGNOSIS

The prognosis is generally good but is variable depending on the etiology and the severity of illness. Most patients recover completely within 3 to 5 days. However, serious complications including death, can occur. Serious disease and death is usually seen in individuals who become severely dehydrated, infants, elderly patients, and those with underlying medical conditions or immunosuppression (e.g., AIDS). Untreated severe dehydration may lead to shock, renal failure, and death. Postinfectious reactive polyarthritis and Reiter's syndrome can complicate cases due to *Yersinia*, *Campylobacter*, *Shigella*, and Guillain-Barré syndrome may occur after diarrhea caused by *Campylobacter*.

Infections Involving Bones and Joints

Jerome Larkin

DEFINITION

The term *osteomyelitis* refers to infection of any component of the bony skeleton, whereas *septic arthritis* refers to infection of native or prosthetic joints. Associated structures such as tendons, ligaments, and bursae can also become infected, especially if they involve prosthetic or biografted material. Osteomyelitis and septic arthritis can each occur as a result of seeding during an episode of bacteremia, as a consequence of vascular insufficiency, as a complication of trauma, or by extension from a contiguous focus of infection in an adjacent tissue or structure.

In the case of hematogenous infection, the bacteremia itself may be relatively transient and of little clinical consequence. Hematogenous osteomyelitis is common in children but accounts for only about 20% of osteomyelitis in adults. The vertebrae and pelvis are the most commonly involved sites.

Peripheral vascular disease leading to tissue hypoxia, often related to diabetes, hypertension, hyperlipidemia, or smoking, is the biggest risk factor for the development of osteomyelitis in adults older than 50 years of age. There is often antecedent soft tissue infection or destruction as a result of vascular insufficiency and neuropathy. It is most common in the lower extremities, particularly in the feet, and often occurs in diabetics.

Trauma, especially when it involves open fracture, with its attendant disruption of the bony architecture and vascular supply, is a major risk factor for development of osteomyelitis and septic arthritis. This is particularly true when an open fracture (such as from a fall or a motor vehicle accident), is heavily contaminated with soil or other environmental materials. Such fractures often require internal fixation (i.e., placement of rods, screws, or other metal devices) to stabilize the bone. The presence of such internal fixation devices provides a nidus for bacteria and other microorganisms, including fungi, to elude the immune system and incubate. Chronic osteomyelitis is a possible complication of such injuries and is often a result of multiple or unusual organisms. It may occur despite aggressive débridement and prophylactic antibiotic treatment at the time of injury and can arise months or even years afterward. Individuals who experience prolonged periods of immobility (e.g., paraplegia) are also at risk for osteomyelitis. Infection typically involves the pelvis, sacrum, and lower spine, corresponding to areas of unrelieved pressure and resulting pressure sores.

Osteomyelitis may be thought of as being acute or chronic. The former is typically hematogenous and associated with signs of inflammation in the overlying soft tissue, with onset occurring over the course of days to 1 week. Radiographs are usually normal

at presentation. Chronic osteomyelitis is typically more indolent, with onset over the course of months. It is more likely to show bony destruction on plain radiographs at the time of presentation and is often associated with a draining sinus tract. Sequestra (areas of dead bone) and involucra (new bone formed around sequestra) may also be seen on radiographs. Whereas with acute osteomyelitis, a 6-week course of antibiotics may effect a cure, chronic osteomyelitis more typically requires surgical intervention and a prolonged (≥ 3 months) course of antibiotic therapy.

PATHOPHYSIOLOGY

Characteristics of the vascular supply of the bone and properties of the most common pathogen, *Staphylococcus aureus*, may combine to lead to infection. Although bone is generally resistant to infection, the vasculature of the metaphysis contains capillary loops composed of a single layer of discontinuous endothelial cells, which may allow bacteria to enter the extracellular matrix. Additionally, these capillary beds appear to lack functionally active phagocytes. *S. aureus* is able to elaborate proteins expressed on its surface that promote adherence to tissues of the extracellular matrix. When engulfed by osteoblasts, *S. aureus* can survive for prolonged periods in an almost sporelike state, leading to potential recurrences of infection. Finally, many bacteria can elaborate biofilms that allow them to elude clearance by the immune system. Prosthetic material, such as that used in joint replacements and other grafts, can serve as a platform for the formation of such biofilms.

In the case of septic arthritis, there is usually some underlying joint abnormality (e.g., rheumatoid arthritis), although this abnormality may be as mundane as osteoarthritis. It is hypothesized that relatively trivial injuries, which may even go unnoticed or unremembered by the patient, can cause minor bleeding into the joint, providing a hospitable environment for bacteria to incubate.

CLINICAL PRESENTATION AND DIAGNOSIS

Patients with osteomyelitis often have pain at the site of infection. The overlying soft tissue may have signs of inflammation or tissue destruction; the latter is often seen in diabetics with soft tissue ulceration. Historically, the diagnosis of osteomyelitis relied on the presence of lucency on plain radiographs of the affected area. The diagnosis could be confirmed histologically by bone biopsy with culture to identify the pathogenic organism. Currently, the diagnosis is typically based on magnetic resonance imaging (MRI) with gadolinium, which demonstrates marrow edema with or without bony destruction. Alternatively, the diagnosis

may be made by three-phase bone scanning or computed tomography. These modalities may be especially helpful for patients with renal insufficiency who cannot undergo gadolinium-enhanced studies due to the risk of nephrogenic systemic fibrosis. An elevated C-reactive protein (CRP) level or erythrocyte sedimentation rate (ESR) supports the diagnosis.

Microbiologic diagnosis of osteomyelitis is made by positive blood cultures or by bone biopsy and culture. Culture of cutaneous ulcers is typically not helpful because the results usually demonstrate multiple colonizing organisms and do not correlate with organisms isolated on bone culture. An exception is the isolation of *S. aureus* or *Salmonella* from a draining fistula or, on occasion, *Pseudomonas* from an ulcer. In the former case, the bacterium can be presumed to be the pathogen; in the latter, a decision would have to be made to include coverage of *Pseudomonas* spp in an empirical antibiotic regimen. If cultures of bone obtained by bone aspirate under radiographic guidance are negative, either the procedure should be repeated or an open biopsy with culture should be performed.

Septic arthritis almost always manifests with the cardinal features of inflammation (i.e., erythema, swelling, warmth, and pain) when it involves the extremities. Fever is frequently present, and there is often an associated bacteremia. Septic arthritis of the spine, pelvis, or hip may require imaging, usually MRI, because these sites are difficult to assess by examination alone. Persistent back, pelvic, or hip pain that is otherwise unexplained should prompt radiographic evaluation even in the absence of fever.

The diagnosis of septic arthritis ultimately relies on joint aspiration. Such procedures should occur before the administration of antibiotics. Fluid should be sent for cell count with differential, crystal analysis, Gram stain, aerobic and anaerobic culture, and fungal and acid-fast stains and cultures. Positive stains or cultures are taken as evidence of infection in most cases in which an appropriate clinical syndrome is also present. White blood cell (WBC) counts higher than 50,000 cells/ μ L are suggestive of infection. In cases that are difficult to diagnosis and in instances in which antibiotics were given before aspiration, it may be appropriate to have cultures held for up to 14 days. Specialized culture techniques for fastidious organisms such as anaerobes and nutritionally deficient streptococci may be required. Ultimately, tagged WBC scans may help to clarify the presence or absence of septic arthritis in difficult cases. Evolving molecular technologies such as polymerase chain reaction (PCR) and 16S ribosomal sequencing may offer alternative and more rapid and precise diagnosis in the future.

Most cases of osteomyelitis and septic arthritis are caused by *Staphylococcus* spp, *Streptococcus* spp, and aerobic gram-negative bacilli, although almost any pathogenic microorganism can cause such an infection in the appropriate circumstance. Infecting *Staphylococcus* spp include both *S. aureus* and coagulase-negative staphylococci. The latter are often implicated in prosthetic joint infections and infections associated with orthopedic hardware. *Streptococcus* spp that cause bone and joint infections include groups A, B, C, G, and F, as well as *Abiotrophia* and *Gemella* (formerly termed “nutritionally deficient streptococci”).

Gram-negative organisms account for as many as 30% of hematogenous infections. They are seen more commonly in the

elderly as a result of urinary tract infection with associated bacteremia. Isolated species include *Escherichia coli*, *Haemophilus influenzae*, and *Haemophilus parainfluenzae*. Infections with *Serratia marcescens* and *Pseudomonas* spp are associated with exposure to water and are usually nosocomial or related to intravenous drug use.

Fungi such as *Candida*, *Aspergillus*, and *Zygomycetes* may cause bone and joint infections particularly in immune-compromised patients, diabetics, and those who have suffered trauma. *Nocardia* and other acid-fast organisms may be seen after trauma or in association with prosthetic joints, and several attempts at débridement may be needed before the organism can be isolated. *Propionibacterium acnes* is often isolated from shoulder infections, especially those involving prosthetic joints. The variety of potential pathogens underscores the need to obtain appropriate specimens for culture before administration of antibiotics.

Infection with *Borrelia burgdorferi*, the causative agent of Lyme disease, can lead to a multifocal or monoarticular septic arthritis. Fluid analysis is consistent with bacterial septic arthritis but is negative for typical organisms on culture. Associated findings of erythema migrans, diffuse myalgias and arthralgias, cranial nerve palsies, fever, and aseptic meningitis may also be present. PCR analysis of joint fluid has a reported sensitivity between 30% and 75%. Diagnosis relies on serology and associated findings in patients who reside in endemic areas. Later-stage disease may manifest with a less inflammatory-appearing effusion, often without any other symptoms. Treatment is with doxycycline or ceftriaxone, depending on the stage of disease.

Neisseria gonorrhoeae can cause a solitary or multifocal septic arthritis often associated with tenosynovitis and skin lesions. It is usually seen in sexually active younger adults. Culture of the joint fluid may be negative, but testing of specimens from the pharynx, urethra, or rectum is usually positive by nucleic acid amplification. The treatment of choice is ceftriaxone.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of both osteomyelitis and septic arthritis includes noninfectious inflammatory disorders such as gout, pseudogout, rheumatoid arthritis, inflammatory bowel disease, and other inflammatory and autoimmune disorders. Occasionally, neoplasms such as sarcomas or metastatic lesions may manifest similarly to osteomyelitis. Infection with several viruses such as rubella, parvovirus B19, and hepatitis B virus can manifest with arthritis.

Chronic recurrent multifocal osteomyelitis is a noninfectious inflammatory lesion of bone that is thought to be autoimmune in nature and is characterized by findings on MRI similar to those of osteomyelitis. It is culture-negative and unresponsive to antibiotics. The diagnosis is one of exclusion and often is made only after several attempts at diagnosing and treating presumed bacterial osteomyelitis. Although it is typically seen in children, it can also occur in adults.

TREATMENT

Treatment of osteomyelitis involves débridement of appropriate infected or necrotic tissue and the administration of antibiotics. It is critically important to remove all necrotic or devitalized tissue. If not removed, such tissue may serve as a nidus of chronic

or recurrent infection. In this regard, it is often necessary to remove any fixating hardware, plastic device, bone graft, or other donor tissue if the infection has been present for longer than 1 month or is recurrent. Cadaveric donor tissue infections often are caused by atypical organisms such as *Clostridium* spp. Historically, sequestra developed in sites of chronically infected bone. These are produced by the action of the immune system and histologically are characterized by granulomatous tissue that serves to isolate the infection. Although this reaction is effective in containing the infection, it represents a risk for recurrence as well as an area of bone weakening. Any sequestra that are discovered should be surgically excised.

Infection that occurs in the immediate postoperative period (i.e., within 1 month after placement of hardware and grafts) and appears to involve only the soft tissue may be treated with débridement and antibiotics alone with a reasonable chance of success. Occasionally, infected hardware must be left in place to stabilize the bone while a fracture is healing. In such cases, it may be necessary to continue antibiotic treatment until the hardware can be removed. Infected spine hardware, which must remain in place, may necessitate prolonged antibiotic treatment, at times even indefinitely. The addition of rifampin for susceptible staphylococcal infections with retained hardware improves the overall cure rates.

Septic arthritis requires either repeated aspiration or serial débridement of the joint until active purulence has resolved. This is indicated by decreasing cell counts and sterilization of joint fluid cultures. Prosthetic joint infection typically requires removal of the infected prosthesis and placement of an antibiotic spacer for 4 to 6 weeks while antibiotics are administered. This is followed by placement of a new prosthesis after all signs and symptoms of infection have resolved. Selected infections with coagulase-negative *Staphylococcus* and *Streptococcus* spp may be treated with débridement, joint retention, and a course of antibiotics lasting 6 weeks or longer. Consideration should then be given to chronic suppressive antibiotic therapy, assuming that an appropriate agent is available.

Antibiotic treatment should be with agents that are active against the infecting organism, depending on culture and susceptibility data. β -lactams are the preferred agents in most cases. Therapy with quinolones for Enterobacteriaceae and, in combination with rifampin, for *Staphylococcus* spp may be considered. These drugs have the advantage of high oral bioavailability that results in tissue levels that approach or are equal to those achieved when they are given intravenously. Care should be taken regarding drug interactions with rifampin as well as the risks of *Clostridium difficile* colitis and Achilles tendon rupture with quinolones. In the face of negative cultures, empirical therapy with an agent that is active against typical pathogens, including methicillin-resistant *S. aureus* (MRSA), is reasonable. Caution should be exercised in the use of daptomycin because there have been failures in the treatment of bone infections with this drug. Vancomycin remains the standard agent for empirical therapy to cover resistant staphylococci (e.g., MRSA). Prior administration of antibiotics may lead to negative cultures even in cases of unequivocal infection. In this situation, empirical therapy should be based on the activity of the agents previously administered as well as the potential pathogens based on exposure history.

In all cases, the clinical response to treatment of the infection should inform subsequent decision making regarding the need for additional débridement or changes in antibiotic therapy. Monitoring of inflammatory markers such as CRP or ESR is helpful in determining the adequacy of response to treatment. In particular, if these markers are elevated at the start of treatment, they should fall to normal or near-normal levels by the time the treatment is finished. Signs and symptoms of inflammation at the site of infection should have also resolved by the cessation of treatment. There have been few randomized controlled trials comparing different durations of antimicrobial therapy. In general, acute osteomyelitis should be treated for 4 to 6 weeks. It is reasonable to continue treatment if the patient has improved but has failed to resolve elevated inflammatory markers or local signs of inflammation. Such patients should be closely monitored and evaluated for the need for additional débridement or other measures aimed at diagnosis and source control. Chronic osteomyelitis may require 12 or more weeks of therapy, and treatment is usually individualized based on the clinical situation.

Patients undergoing therapy should also be monitored weekly for toxicity to antibiotics. Assessment of renal and hepatic function, complete blood counts, and drug levels are typically monitored, depending on the specific agent used. In the case of aminoglycosides, renal function and peak and trough levels of antibiotics should be measured twice weekly. Adjunctive therapies such as bone grafting, revascularization procedures, and the placement of muscle flaps to cover and protect exposed bone may be used in the appropriate clinical situation.

Native joint septic arthritis may be treated with a 4-week course of antibiotics; prosthetic joint infections are typically treated for 6 weeks or longer. Monitoring for toxicity and response to treatment is similar to that for osteomyelitis.

PROGNOSIS

The prognosis for most cases of osteomyelitis or septic arthritis is excellent, assuming adequate diagnosis, débridement, and antimicrobial therapy. The most common complication is residual pain and/or decreased function of the affected bone or joint. However, these effects are relatively rare and relatively minor. An exception is prosthetic joint infections: 25% to 50% of patients experience some loss of function as a result of the infection. Recurrence rates for chronic osteomyelitis, especially in diabetics, may be as high as 30%. In more complex cases, such as open contaminated fractures or infected hardware that require retention, complications including non-union, prosthesis failure, and chronic osteomyelitis may occur. Ultimately, infections that cannot be controlled may lead to the need for amputation and its attendant loss of function and mobility. Occasionally, bone or joint infections can disseminate to other joints or to the bloodstream, resulting in life-threatening sepsis. Such cases usually involve infection with *S. aureus* and fortunately remain the exception.

 For a deeper discussion on this topic, please see Chapter 272, "Infections of Bursae, Joints, and Bones," in Goldman-Cecil Medicine, 25th Edition.

Urinary Tract Infections

Joao Tavares and Steven M. Opal

DEFINITION AND DIAGNOSIS

The term *urinary tract infection* (UTI) refers to significant bacteriuria in a patient with symptoms or signs attributable to the urinary tract and no alternative diagnosis. UTI includes asymptomatic bacteriuria, urethritis, cystitis, pyelonephritis, catheter-associated UTI, prostatitis, and urosepsis. This chapter focuses primarily on the two major forms of UTI, cystitis and pyelonephritis.

A practical classification divides these infections into uncomplicated and complicated UTI. Uncomplicated UTIs are episodes of cystitis and mild pyelonephritis occurring in healthy, premenopausal, sexually active, nonpregnant women with no history suggestive of abnormalities in the urinary tract. All other episodes of UTI are deemed to be potentially complicated and deserving of further evaluation.

The presence of dysuria, increased frequency of urination, suprapubic tenderness, and hematuria associated with bacteriuria or pyuria on urinalysis is unequivocally consistent with the diagnosis of cystitis. Back or flank pain, nausea, vomiting, and the presence of fever or rigors suggest infection of the upper urinary tract, although it is not easy to distinguish cystitis from pyelonephritis on clinical grounds alone. The diagnosis of UTI gets more difficult when patients cannot ascribe symptoms to the urinary tract (e.g., patients with paraplegia or neurogenic bladder, confused elderly or sedated patients) or when they have atypical symptoms, such as changes in mental status, agitation, or hypotension. Sometimes patients have urinary symptoms without bacteriuria (the pyuria-dysuria or “urethral syndrome” commonly caused by *Chlamydia trachomatis* or other difficult-to-culture genitourinary pathogens).

Bacteriuria is the hallmark of UTI. In women, *asymptomatic bacteriuria* is defined as two consecutive voided midstream urine specimens with isolation of the same bacterial strain at levels of at least 10^5 colony-forming units (CFU) per milliliter from patients without genitourinary symptoms. In men, a single clean-catch, midstream voided urine specimen with one bacterial species at a concentration greater than 10^5 CFU/mL defines asymptomatic bacteriuria. The diagnosis of asymptomatic bacteriuria is also established in both women and men from a single catheterized urine specimen (not an indwelling catheter) with one bacterial species isolated at concentrations greater than 10^2 CFU/mL.

To increase the sensitivity of the tests, *significant bacteriuria* is defined as greater than 10^2 CFU/mL of urine in a woman with symptoms of uncomplicated cystitis and pyuria (≥ 5 white blood

cells per milliliter of urine per high-power field). Among women with symptoms of uncomplicated pyelonephritis and men with UTI, significant bacteriuria is defined as greater than 10^4 CFU/mL plus pyuria. In patients with complicated UTI, a concentration of 10^5 CFU/mL or higher is required for the definition of significant bacteriuria independently of pyuria.

In order for these definitions to be valid, the urine must remain in the bladder for at least 2 hours, and after urine collection the sample should be incubated immediately. If urine is not incubated immediately, it can be refrigerated for up to 8 hours before proper incubation.

The presence of asymptomatic bacteriuria is not equivalent to UTI except for pregnant women, neutropenic patients, and individuals with anatomic or functional defects in the urinary tract. The presence of white blood cell casts indicates pyelonephritis, and this finding suggests a complicated UTI with obstructive lesions of the kidney or collecting system (e.g., papillary necrosis). It is difficult to define asymptomatic bacteriuria in the patient who has undergone renal transplantation, and bacteriuria in such patients often indicates the need to treat for UTI.

LABORATORY FINDINGS

Young, sexually active women with typical symptoms of UTI have a high pretest probability for UTI. Therefore, no laboratory test is indicated. In this population, pretreatment urine analysis and culture are indicated only if the diagnosis is not straightforward or if an antibiotic-resistant organism is suspected. Urine analysis and culture are indicated in all cases of suspected complicated UTI. Blood cultures are mandatory for patients with suspected pyelonephritis. Imaging studies are indicated if kidney stones, malignancy, obstructive uropathy, and urologic malformations are suspected.

EPIDEMIOLOGY

At the extremes of age, men are more prone to UTI than women. In young boys, urethral malformation is commonly the cause, and in older men, UTI is usually caused by bladder neck obstruction secondary to prostatic hypertrophy. Homosexual men are at increased risk for acquiring UTIs. Teenage girls and sexually active women have more UTIs than their male counterparts. A higher than expected incidence of UTI among young girls might suggest sexual abuse. Sexually active women have the highest rate of UTI. Postmenopausal women have increased prevalence of UTI due to estrogen deficiency and age-related pelvic relaxation with poor bladder emptying.

The most common etiologic agent in patients with uncomplicated UTI is *Escherichia coli* (90% of cases), followed by *Staphylococcus saprophyticus*. Other agents include *Klebsiella* spp, *Enterococcus faecalis*, *Enterococcus faecium*, *Proteus* spp, *Providencia stuartii*, and *Morganella morganii*. In patients with complicated UTI, *E. coli* is still the most frequent uropathogen, but at a lower rate than in uncomplicated UTI. Other causative organisms are *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, *Enterobacter* spp, *Serratia marcescens*, *Stenotrophomonas maltophilia*, *Enterococcus* spp, and *Candida* spp.

Anaerobic agents are infrequent causes of UTI; when present, they represent fistulae between the digestive tract and the urinary tract. *Staphylococcus aureus* UTI most often represents bacteremia with bacteriuria resulting from clearance of bloodstream bacteria by the kidney. Whereas 1% of individuals with a UTI get pyelonephritis, 20% to 40% of pregnant women with a UTI develop pyelonephritis, and 30% of patients with pyelonephritis have bacteremia. In diabetic and transplanted patients with UTI, the incidence of bacteremia is higher.

PATHOGENESIS

There are at least three routes by which bacteria can enter the bladder or kidney: ascending, hematogenous, and lymphatic. Lymphatic spread is the least common route. The hematogenous route is important for gram-positive organisms such as *S. aureus* or *Candida* spp but unimportant for gram-negative bacilli. The ascending route is the most important for enteric bacteria, and this mechanism is supported by higher frequency of UTI in women, given the shorter length of the female urethra, and in individuals with an indwelling Foley catheter.

Before reaching the urinary bladder or kidney, the microorganism must colonize the external part of the urinary tract.

Probably the most important aspect in the establishment of UTI is the interaction between host factors (e.g., secretor phenotype, P1 blood group, uroplakin I and II) and bacterial virulence factors (the adhesins, P fimbriae, and type I fimbriae [pili]). The urinary bladder is normally covered by a glycosaminoglycan surface that prevents binding of bacteria that transiently enter the bladder. P-fimbriated uropathogenic *E. coli* bind to alpha 1-4 linked, galactose-galactose disaccharide moieties found on uroepithelial cells, and these gal-gal glycolipids are also expressed on the P1 blood group. People with P1 blood group are overrepresented among individuals with either recurrent UTI and pyelonephritis. Also, people who lack P1 blood group are less prone to complicated UTI.

Studies have shown that P-fimbriated *E. coli* is present in 60% to 100% of isolates from patients with UTI. Ascending UTI infection can be inhibited experimentally by epithelial cell surface receptor analogues. Type I fimbriae bind to glycoprotein uroplakin I and II. *E. coli* expressing type I fimbriae are responsible for most cases of cystitis.

Once *E. coli* is attached to uroepithelial cells, both mechanical and biochemical factors facilitate the development of full-blown UTI. The local trauma and mechanical massage of the urethra during sexual intercourse help deliver bacteria into the bladder and, if vesicoureteral reflux or another ureteral anatomic defect is present, into the kidney. Foley catheter placement also helps to propel bacteria into the bladder, and all patients with a long-term indwelling catheter in place will eventually develop UTI. All uropathogenic organisms have the ability to multiply in the urine.

From the standpoint of the host, other factors associated with the development of UTI are a new sex partner (within 1 year), use of diaphragms and spermicides, family history of UTI in a first-degree relative, and lower expression of CXCR1, an

interleukin 8 receptor. Pathogenic factors associated with the development of UTI are flagellae, diverse adhesins, siderophores, toxins, polysaccharide coating, and the ability to cause a deleterious inflammatory response.

Patient behaviors that are not associated with UTI include precoital or postcoital voiding patterns, daily beverage consumption, frequency of urination, delayed voiding habits, wiping patterns, tampon use, douching, use of hot tubs, and type of underwear.

TREATMENT

The goal of treatment in uncomplicated UTI is to decrease symptoms and prevent complications. Treatment should be guided by two important principles: the prevalence of resistant genitourinary pathogens in the community and collateral damage to ecologic microbiota (i.e., the risk of propagation of resistant organisms). First-line agents for uncomplicated UTI are nitrofurantoin, trimethoprim-sulfamethoxazole (TMP-SMX), and fosfomycin trometamol; alternative agents are the fluoroquinolones (except moxifloxacin) and the β -lactams (Table 98-1).

Treatment of complicated UTI should be based on culture results and the other comorbidities that are present. Recurrent UTI in sexually active women can be prevented with postcoital TMP-SMX 40/200 mg single dose (if the patient has more than two UTIs per year related to coitus) or with daily, every other day, or weekly antibiotic. If the patient has a UTI

unrelated to coitus or there are fewer than two UTIs per year related to coitus, the prevention of the UTI recurrence can be achieved with patient-initiated therapy. Daily topical application of intravaginal estriol can be helpful in postmenopausal women. After completion of the treatment, urine culture is indicated for pregnant women and on an individualized basis for other patients with complicated UTI.

 For a deeper discussion on this topic, please see Chapter 284, "Approach to the Patient with Urinary Tract Infection," in Goldman-Cecil Medicine, 25th Edition.

Health Care–Associated Infections

Steven “Shaefer” Spires and Thomas R. Talbot

INTRODUCTION

A health care–associated infection (HAI) is an infection that did not exist or was not incubating at the time of admission to the health care facility. Infections with an onset of more than 48 hours after admission and within 7 to 30 days after facility discharge are defined as HAIs. These infections can occur in all types of health care settings, including acute care units, long-term care facilities, rehabilitation facilities, outpatient dialysis clinics, and outpatient surgical centers.

HAIs cause a substantial degree of morbidity and mortality. A 2011 survey conducted by the Centers for Disease Control and Prevention (CDC) Emerging Infection Program reported an acute care hospital HAI prevalence of 6.8%. Extrapolating from acute care admission data (about 35 million admissions per year), approximately 2 million acute care HAIs occur annually in the United States. Beyond the extensive morbidity and mortality they cause, HAIs are costly, calculated as \$13,973 per infection in one review. These costs are likely to be underestimated because of incomplete estimation of the outpatient costs of parenteral antibiotics, skilled nursing care, physical rehabilitation, and lost work days.

As of January 2011, the Centers for Medicare and Medicaid Services (CMS) required public reporting of certain facility-specific HAI outcomes as part of value-based purchasing. As of January 2013, the following acute care–related HAIs are required for reporting by CDC’s National Healthcare Safety Network (NHSN): catheter-associated urinary tract infections (CAUTIs) and central line–associated bloodstream infections (CLABSIs) in intensive care units (ICUs), colon and abdominal hysterectomy surgical site infections (SSIs), hospital-onset *Clostridium difficile* infections (CDIs), and hospital-onset methicillin-resistant *Staphylococcus aureus* (MRSA) bacteremias. The importance of preventing HAIs has never been more apparent.

The major types of HAIs include the infections reported to CMS, hospital-acquired pneumonia (HAP) or ventilator-associated pneumonia (VAP), and multidrug-resistant organisms (MDROs). MDROs are pathogens with resistance to various important antibiotics (e.g., MRSA, vancomycin-resistant *Enterococcus* (VRE), antibiotic-resistant gram-negative bacilli). This chapter reviews the major classes of HAIs, with a focus on prevention, diagnosis, and treatment.

HEALTH CARE EPIDEMIOLOGY AND INFECTION PREVENTION

In the age of increasing MDROs, shortage of new antibiotics, and public reporting of HAIs, the importance of efforts to prevent HAIs is growing. The fields of health care epidemiology and infection prevention focus on the practices of tracking HAIs in a systematic fashion (i.e., surveillance) to implement evidence-based HAI prevention practices.

Although HAIs were once thought to be the cost of being critically ill and receiving care in a hospital, several key events occurred during the past decade that shifted that perception. In 2006, Pronovost and colleagues implemented a “simple and inexpensive intervention” in 103 ICUs in the state of Michigan while participating in the Michigan Health and Hospital Association Keystone ICU project. This landmark study showed a reduction in the median rate of CLABSIs from 2.7 per 1000 catheter days to zero. These results shifted the discussion from merely controlling HAIs to preventing them. Other major events have included recognition and effectiveness of using bundles of evidence-based practices to reduce HAIs; recognition of the HAI burden in nonacute, non-ICU settings; and importance of quality improvement science in reducing HAIs.

The prevention of HAIs has become increasingly possible, and various types of prevention interventions can reduce the HAI burden dramatically. In 2010, Wenzel and Edmund described these interventions as horizontal and vertical strategies (Table 99-1). Horizontal infection prevention strategies are broad practices (e.g., hand hygiene, isolation precautions) aimed at preventing many or all types of HAIs, regardless of the specific pathogen, procedure, or device. Vertical HAI prevention strategies are directed at specific types of HAIs or target a specific organism. Vertical strategies include using procedural checklists or standardized bundles and MRSA decolonization.

CATHETER-ASSOCIATED URINARY TRACT INFECTIONS

In a survey performed by the CDC in 2011, CAUTIs were the second most common device-associated infection. The incidence of CAUTIs in 2011 ranged from 0 to 4.2 per 1000 catheter days, compared with the 2006-2007 period, when rates were between 3.4 and 7.7 per 1000 catheter days. The estimated additional cost of a CAUTI was \$589 to \$758 per infection in 1998 dollars, and

- Steps to prevent needlestick injuries
- MDRO decolonization
- Education of health care workers on IC/IP protocols

VERTICAL STRATEGIES (SPECIFIC TO HAI TYPE)**CAUTI**

Urinary catheter placed only for appropriate indications:
 Urinary retention or obstruction
 Need for accurate UOP measurement in critical illness
 Incontinence and perineal or sacral wounds
 Comfort care use for terminal illness

Consider alternatives:
 Condom catheters
 Intermittent catheterization

Proper insertion and maintenance:
 Maintain aseptic technique
 Properly secure catheter to patient
 Maintain closed drainage system
 Maintain unobstructed flow

Urinary catheter premeditated stop order or RN-initiated discontinuation policy

Anti-infective catheters if infection rates remain high

VAP

Use noninvasive ventilation when able

On intubation:
 Semirecumbent position (30–45 degrees) unless contraindicated
 Hypopharyngeal suctioning
 Avoid gastric overdistention
 Use cuffed ET tube
 Oral care (with chlorhexidine oral rinse), tooth brushing
 Keep ventilatory circuit closed unless changing for soiling or malfunctioning
 Daily targeted sedation management
 Spontaneous breathing trial if screening finds applicable
 Use weaning protocols to minimize duration of ventilation

CLABSI

Use checklist for device insertion:
 Bundle supplies
 All present use at least face mask, then proceduralist uses sterile gown and gloves, mask, and head cap
 Avoid femoral line placement if possible
 Skin antisepsis with alcohol and >0.5% chlorhexidine
 Use of chlorhexidine-impregnated dressing or sponge at insertion site
 Empower personnel to stop nonemergent insertion if improper technique is followed

Maintenance:
 Access as infrequently as feasible
 Scrub the access hub or port with antiseptic
 Daily audits for assessment of device need and potential discontinuation

SSI

Preoperative strategies:
 Nonirritative hair removal with clippers (not razors)
 Eradicate remote infection
 Decolonization of *Staphylococcus aureus* if carrier
 Smoking cessation
 Glucose control, hemoglobin A_{1c} <7% if possible
 Avoid immunosuppressive medication in perioperative period
 Identify and address malnutrition

Intraoperative strategies:
 In OR: proper ventilation, minimize traffic, proper attire, and surgical scrub
 Proper skin preparation (chlorhexidine plus alcohol or povidone plus alcohol) and draping
 Antimicrobial prophylaxis; proper timing, dosing, and intraoperative redosing
 Maintain normothermia
 Glucose control
 Tissue oxygenation, preoperative and postoperative supplementation

CDI

Prevention of acquisition:
 Antimicrobial stewardship

Prevention of transmission:
 Contact precautions (e.g., empirical placement for those suspected of CDI before confirmation of diagnosis)
 Hand hygiene with soap and water before leaving the patient's room
 Continue contact precautions until discharge
 Appropriate environmental cleaning with bleach-containing agents

CAUTI, Catheter-associated urinary tract infection; CDI, *Clostridium difficile* infection; CLABSI, central line–associated bloodstream infection; ET, endotracheal; HAI, health care–associated infection; IC/IP, infection control or prevention; ICU, intensive care unit; MDRO, multidrug-resistant organism; OR, operating room; PPE, personal protective equipment; RN, registered nurse; SSI, surgical site infection; UOP, urine output; VAP, ventilator-associated pneumonia.

*Current data are not strong for prevention of CAUTI, VAP, and CDI by this method.

the total annual cost associated with CAUTIs in U.S. hospitals in 2007 was estimated between \$390 and \$450 million.

CAUTI complications include cystitis, pyelonephritis, and in up to 4%, bacteremia. Although urinary catheter–associated bacteremias are rare, they are an underappreciated cause of health care–associated bacteremias and have been estimated to cost an additional \$3744 per episode. Most of the epidemiologic data on CAUTIs are from ICU patients. However, some studies describe rates of CAUTI among the non-ICU population that are similar to rates among ICU patients when calculated in catheter days, and in some instances, the absolute number of infections is higher outside of the ICU.

Most health care–associated urinary tract infections are catheter associated. A catheterized patient's daily risk of developing bacteruria is about 3% to 10%. Indwelling urinary catheters disrupt several mechanisms of the natural defense against infection, including urine flow, length of the urethra, and micturition to prevent attachment of potential pathogens to the

uroepithelium. Tamm-Horsfall proteins, the most abundant soluble proteins in the urine, play a significant role by binding uropathogenic bacteria, facilitating wash out, and lowering the threshold for activating local innate immunity. These soluble proteins are prevented from entering the lower urinary tract by the catheters.

An indwelling catheter allows colonization, attachment, and biofilm formation by certain microorganisms. Most of the organisms causing CAUTIs arrive by ascending the urethra from the meatus and perineum. The most common uropathogens identified in CAUTIs are *Escherichia coli*, *Candida* species, *Klebsiella* species, *Pseudomonas aeruginosa*, and *Enterococcus* species (Fig. 99-1).

Common symptoms of a urinary tract infection (e.g., dysuria, urinary frequency) may not be useful in diagnosing a patient with an indwelling catheter. However, the most common clinical manifestations of a CAUTI are fever ($\geq 38^\circ\text{C}$) and bacteruria. Other signs and symptoms of a CAUTI can include rigors,

FIGURE 99-1 Causative pathogens by specific type of health care-associated infection as reported to the Centers for Disease Control and Prevention National Healthcare Safety Network. CAUTI, Catheter-associated urinary tract infections; CLABSI, central line-associated bloodstream infections; SSI, surgical site infections; VAP, ventilator-associated pneumonia. (Modified from Sievert DM, Ricks P, Edwards JR, et al: Antimicrobial-resistant pathogens associated with healthcare-associated infection: summary of data reported to the National Healthcare Safety Network at the Centers for Disease Control and Prevention, 2009-2010, *Infect Control Hosp Epidemiol* 34:1-14, 2013.)

altered mental status, pelvic or suprapubic pain, costovertebral angle tenderness, and acute onset of hematuria without another underlying cause. One of these signs or symptoms plus a positive urine culture with a known uropathogen ($>10^5$ colony-forming units) strongly suggests a CAUTI. Pyuria (>5 leukocytes/mL of urine) is not always a reliable indicator for infection in patients with indwelling catheters; pyuria and asymptomatic bacteruria are not necessarily indications for treatment. Risk factors for CAUTI acquisition include duration of catheterization, underlying fatal illness, age older than 50 years, having a nonsurgical underlying illness, and nonadherence to proper catheter care (E-Table 99-1).

The most effective method of preventing CAUTIs is to avoid placing urinary catheters unless absolutely necessary and to restrict catheter use to institutionally accepted indications. Proper insertion and care of urinary catheters are paramount (see Table 99-1). Maintenance of unobstructed flow with the collection bag below the bladder, use of a closed catheter system (even when sampling urine), and discontinuation of the catheter as soon as appropriate are key elements for preventing a CAUTI. Nurse-directed discontinuation protocols in which frontline personnel have defined parameters for removing catheters without requiring a provider's order are increasingly used to eliminate unnecessary catheters. The routine use of antimicrobial-coated catheters is not recommended except when infection rates remain elevated despite proper adherence to all other prevention strategies.

Treatment of asymptomatic bacteriuria usually is not recommended. Treatment of CAUTI is based on current Infectious Disease Society of America (IDSA) guidelines, and the choice of antimicrobial regimen should be based on the local antibiogram and identified syndrome (e.g., pyelonephritis). Before treatment, urine culture and sensitivity results are used to evaluate a resistant organism and tailor an empirical antimicrobial regimen.

Most clinicians prefer to replace or discontinue the catheter after a urinary tract infection is diagnosed. Guidelines recommend replacement if it has been in place for more than 2 weeks.

TABLE 99-2 DEFINITIONS OF TYPES OF NOSOCOMIAL PNEUMONIA

PNEUMONIA TYPE	DEFINITION
Health care–associated pneumonia (HCAP)	Pneumonia in any patient who was hospitalized in an acute care hospital for 2+ days within 90 days of infection; resided in an NH or LTCF; received recent IV antibiotic therapy, chemotherapy, or wound care within the past 30 days of the current infection; or attended a hospital or hemodialysis clinic
Hospital-acquired pneumonia (HAP)	Pneumonia that occurs at least 48 hours after admission and that was not incubating at the time of admission
Ventilator-associated pneumonia (VAP)	Pneumonia that arises 48-72 hours after endotracheal intubation

Data from American Thoracic Society, Infectious Diseases Society of America: Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia, *Am J Respir Crit Care Med* 171:388-416, 2005.
IV, Intravenous; LTCE, long-term care facility; NH, nursing home.

There is good evidence based on review by expert committees (grade A-III evidence) that duration of treatment can be 7 days if symptoms quickly resolve or 10 to 14 days if resolution is delayed. There is moderate evidence based on expert committees' opinions (grade B-III) that a 5-day course of levofloxacin can be considered if patients are not severely ill and the organism is sensitive to the drug. In nonpregnant women younger than 65 years of age, a 3-day course of antibiotic therapy can be considered after the urinary catheter has been removed (grade B-II).

HOSPITAL-ACQUIRED PNEUMONIA

HAP has become the most common HAI. Most HAPs occur in the ICU, and more than 90% are VAPs. Health care–associated pneumonia (HCAP) is considered along with HAP because of the etiologic similarities. Other definitions are given in Table 99-2.

The incidence of HAP or VAP is difficult to determine due to the various definitions that have been used for surveillance and the subjective nature of these diagnoses. Some studies have estimated that the incidence of VAP ranges from 2 to 16 cases per 1000 ventilator days. VAP is associated with increased length of hospital stay (10 days in one study), costs (approximately \$40,000), and mortality (attributable mortality rate of 13%, highest among surgical patients).

Risk factors for VAP include conditions that lead to increased aspiration or impairment of host defenses and bacterial colonization of the respiratory and upper gastrointestinal tracts (see E-Table 99-1). In a ventilated patient, the body's natural mechanical defense mechanisms (e.g., ciliated epithelium, mucus, cough) are interrupted, leading to colonization of the lower airways by potentially pathogenic organisms. The most significant source of these organisms tends to be the patient's own oropharynx and upper gastric contents.

The most commonly implicated respiratory pathogens are *S. aureus* and *P. aeruginosa*, followed by several Enterobacteriaceae species and *Acinetobacter baumannii* (see Fig. 99-1). Colonization with MDROs correlates with increasing duration of hospitalization. Guidelines argue that late (>4 days after admission) compared with early HAP may be the most useful factor when determining empirical antimicrobial therapy. Although bacteria play the largest role in HAP, fungi and viruses also must be considered in immunosuppressed patients.

**E-TABLE 99-1 RISK FACTORS FOR DEVELOPING A HOSPITAL-ACQUIRED INFECTION****CATHETER-ASSOCIATED URINARY TRACT INFECTION**

Duration

Female gender

Age >50 yr

Not maintaining an unobstructed, closed drainage system

VENTILATOR-ASSOCIATED PNEUMONIA

Endotracheal tube

Underlying chronic lung disease

Age >70 yr

Depressed levels of consciousness

Gastric alkalization

Nasogastric or enteral feeding tube

Previous antibiotic exposure

CENTRAL LINE–ASSOCIATED BLOODSTREAM INFECTION

Prolonged hospitalization before insertion

Duration of catheterization

Site of catheterization (femoral > subclavian)

Heavy colonization at the site of insertion and on the hub

Neutropenia

Total parenteral nutrition

Substandard maintenance of the catheter

SURGICAL SITE INFECTION

Increased age

Perioperative hyperglycemia

Obesity

Smoking

Immunosuppressive medications

Infections present at time of surgery

Malnutrition

Operative characteristics: inadequate surgical scrub and skin preparation have been implicated, along with poor timing and dosing of antimicrobial prophylaxis, lower-skilled surgeon, longer operative time, inappropriate tissue oxygenation, and not maintaining normothermia

CLOSTRIDIUM DIFFICILE INFECTION

Age >65 yr

Antimicrobial exposure

Health care exposure

Gastric acid suppression (controversial whether this is an independent risk factor)

TABLE 99-3 MODIFIED CLINICAL PULMONARY INFECTION SCORE (CPIS)

CLINICAL CRITERIA	INFORMATION	POINTS*
Temperature (°C)	≥36.5 and ≤38.4	0
	≥38.5 and ≤38.9	1
	≤36 or ≥39	2
Leukocyte count (per μL)	≥4,000 and ≤11,000	0
	<4,000 or >11,000	1
	<4,000 or >11,000 + ≥500 bands	2
Tracheal secretions	Absent/rare	0
	Abundant/nonpurulent	1
PaO ₂ /FIO ₂ (mm Hg)	Abundant + purulent	2
	>240 or ARDS	0
Chest radiographic findings	≤240 and no evidence of ARDS	2
	No infiltrate	0
Microbiology [†]	Diffuse or patchy infiltrate	1
	Localized infiltrate	2
	Negative	0
	Positive	2

Data from Fartoukh M, Maitre B, Honore S, et al: Diagnosing pneumonia during mechanical ventilation: the clinical pulmonary infection score revisited, *Am J Respir Crit Care Med* 168:173–179, 2003.

ARDS, Acute respiratory distress syndrome.

*With the use of these clinical criteria, a clinical pulmonary infection score of 6 or greater has an 85% sensitivity for detecting pulmonary infection.

[†]Gram stain results of directed or blind, protected endotracheal aspirate.

One definition of HAP or VAP includes clinical, radiographic, and microbiologic criteria. The Clinical Pulmonary Infection Score (CPIS) system is useful in determining when antimicrobial therapy is necessary (Table 99-3). A score of 6 or greater has 85% sensitivity in diagnosing a pulmonary infection. Signs and symptoms indicating an infection include fever ($\geq 38^\circ\text{C}$), peripheral leukocytosis, purulent sputum, and worsening respiratory status. A tracheal aspirate for Gram stain and culture provides the last piece of diagnostic information. When several of these signs and symptoms exist in the absence of a pulmonary infiltrate, alternative diagnoses should be considered, including ventilator-associated tracheobronchitis.

Duration of hospitalization is a significant factor to consider when initiating empirical therapy because of the increasing likelihood of MDRO colonization with prolonged length of stay. In early HAP (≤ 4 days), more community-acquired organisms may be targeted, except when the patient has certain qualifiers for HCAP (see Table 99-2) or is known to be colonized with resistant organisms. However, in late HAP (including VAP and HCAP), the IDSA guidelines recommend adding empirical coverage for resistant gram-positive organisms (including MRSA) and for multidrug-resistant Enterobacteriaceae (level II evidence according to the American Thoracic Society [ATS]/IDSA guidelines for HAP). Dual coverage for multidrug-resistant *P. aeruginosa* should also be considered. An example of an empirical regimen for late-onset HAP is vancomycin or linezolid plus an antipseudomonal β -lactam/ β -lactamase inhibitor, carbapenem, or cephalosporin.

INFECTIONS ASSOCIATED WITH VASCULAR CATHETERS

The NHSN collects data on CLABSIs, and public reporting is required for CLABSIs in ICUs. In 2011, the incidence of CLABSIs ranged from 0 to 3.7 cases per 1000 catheter days, compared with 1 to 5.6 cases per 1000 catheter days in 2006

through 2007. Although CLABSIs have the lowest prevalence among HAIs, the cost per episode and morbidity rate remain high. The estimated additional cost of an infection related to an intravenous catheter is \$4000 to \$56,000 per episode. The attributable increase in length of stay has been between 6.5 and 22 days, and the attributable mortality rate is about 10% among hospitalized patients.

The most common pathogens that cause primary CLABSIs are flora arising at the percutaneous insertion site or from contamination of the catheter hub. Hematogenous seeding from a gastrointestinal or other endovascular source occurs but is less likely. The most common pathogens that cause CLABSIs are coagulase-negative staphylococci, *Candida* species, *S. aureus*, and *Enterococcus* species (see Fig. 99-1). The risk factors for CLABSI are provided in E-Table 99-1. The rising proportion of infections caused by *Enterococcus* species and *Candida* species since the 2006-2007 period suggests that skin colonization is being adequately addressed by the adoption of evidence-based prevention strategies and that an increasing fraction of CLABSIs are caused by secondary hematogenous seeding. Patients who are more severely ill, are neutropenic, have burns, or are on total parenteral nutrition are also at increased risk for candidemia. Other types of catheter-related infections include phlebitis, exit site infection, and pocket and tunnel infection.

Many CLABSIs are preventable through the use of evidence-based prevention practices for line insertion and maintenance. Strategies include appropriate decolonization of the skin before insertion with chlorhexidine plus alcohol, use of maximal sterile barriers (i.e., proceduralist wears sterile gloves and gown, cap, and mask, and a large barrier drape is placed over the patient), hand hygiene, and sterile technique (see Table 99-1). Appropriate maintenance of the central line mandates scrubbing the hub with antiseptic and discontinuing the catheter as soon as it is not needed.

For a patient with a fever or systemic symptoms who has a central venous catheter, a bloodstream infection should be suspected. The diagnostic evaluation should begin with paired peripheral and catheter blood samples for culture before initiation of antimicrobial therapy. In a suspected case of bloodstream infection, the exudate at the exit site should be cultured.

The type of device (e.g., peripheral vs. central, short term vs. long term), associated infectious complications, and the implicated organism all play a role in treatment. For CLABSIs associated with short-term, nontunneled catheters and no complicating factors (e.g., suppurative thrombophlebitis, endocarditis, intravascular hardware), it may be appropriate to treat for 7 to 14 days after removal of the catheter. However, for long-term catheters, salvage may be attempted with systemic plus antibiotic lock therapy (level B-II evidence, indicating a moderate amount of evidence from well-designed clinical trials or cohort or case series). Salvage of catheters associated with *S. aureus* bacteremia and fungemia have largely been unsuccessful, and it is not recommended. In the setting of an endovascular complication, removal of the catheter is strongly recommended, and systemic antibiotic therapy should be prolonged (i.e., 4 to 6 weeks) (level B-II). In many cases, septic thrombophlebitis may require surgical attention. Tunnel and pocket infections may also require débridement, but after the catheter is removed, 7 to 14 days of antimicrobial therapy should be sufficient.

SURGICAL SITE INFECTIONS

Standard definitions of SSIs classify them as superficial incisional, deep incisional (involving fascia or muscle), and organ space depending on the depth of tissue involvement. Most SSIs occur within 30 days of the operation, but some may develop later, especially in the setting of implanted foreign bodies (e.g., arthroplasty). During 2006 to 2008, the overall risk of SSI was 1.9 cases per 100 procedures. Approximately 500,000 SSIs occur annually, costing an estimated \$45 billion per year. Patients who develop an SSI have an increased risk of death.

Endogenous seeding from the patient's skin flora is the most common avenue of infection. *S. aureus* and coagulase-negative *Staphylococcus* cause more than 40% of SSIs. In clean-contaminated operations, including open abdominal surgeries, gram-negative bacilli are predominant. An SSI should be suspected when postoperative patients have wound-associated purulent drainage, pain, tenderness, swelling, or redness. Positive culture growth from an aseptically obtained specimen is most convincing.

Many practices are used to prevent SSIs (see Table 99-1). One of the earliest and most effective strategies has been active surveillance and subsequent reporting of infection rates to the surgeons and staff. Much of the reduction in rates was attributed to the Hawthorne effect (i.e., active monitoring changes the behaviors of those being monitored). Other important interventions designed to reduce SSIs include antimicrobial prophylaxis (i.e., the right drug at the right dose and right time), appropriate skin antisepsis, and maintenance of glucose control (see Table 99-1).

Management of SSIs often involves opening of the incision, evacuation of infected tissue, and allowing the wound to heal by second intention. The decision for initiating antibiotics is made on an individual basis and depends on the appearance of the wound, systemic signs of infection, depth of the infection, host's immune system, and type of surgery. Culture and Gram stain results help to dictate antibiotic coverage. For SSIs from a clean operation, empirical therapy covering *S. aureus* and *Streptococcus* species is recommended. For procedures involving the perineum, intestinal tract, or urogenital tract, broader coverage is needed to address gram-negative and anaerobic pathogens. When the SSI occurs within 48 hours of the index operation, *Streptococcus pyogenes* and *Clostridium* species are often implicated.

IMPORTANCE OF ANTIMICROBIAL STEWARDSHIP: CLOSTRIDIUM DIFFICILE INFECTION

CDI is defined as diarrhea or toxic megacolon with detection of the *C. difficile* organism or toxin A or B, or both, in the stool or evidence of pseudomembranous colitis detected endoscopically, surgically, or histopathologically. This colonic infection is often accompanied by fever and leukocytosis.

The incidence and severity of CDIs have been increasing, and most reports implicate the emerging BI/NAP1/027 strain and the aging population of hospitalized patients, who are disproportionately affected by CDI. The BI/NAP1/027 strain hypersporulates (i.e., produces more of toxins A and B than previous strains) and produces a third binary toxin. Although resistance to the primary antimicrobials used to treat CDI—metronidazole and oral vancomycin—is rare, the BI/NAP1/027 epidemic strains

show an increased resistance to fluoroquinolones. There is a concern that the increasing widespread use of fluoroquinolones may be providing a selective advantage for this epidemic strain. However, virtually every antibiotic has been associated with increasing the risk of CDI.

The continued rise of CDI, increasing resistance to antimicrobials by many different pathogens, and lack of antimicrobials with novel mechanisms of action underscore the importance of antimicrobial stewardship. Antimicrobial stewardship is a strategy that emphasizes optimal selection, dose, and duration of antimicrobial therapy, producing the best clinical outcome while decreasing the risk of subsequent complications.

The consequences of poor stewardship include the emergence of resistance, CDI, and excessive drug expenditures. Antimicrobials have different probabilities of invoking resistance or CDI. Strategies implemented by antimicrobial stewardship programs include provider education and guidelines, de-escalation or tailoring of empirical therapy when possible, use of more appropriate empirical treatments, and front-end restriction of certain antibiotics.

For a deeper discussion of these topics, please see Chapter 283, "Approach to the Patient with Suspected Enteric Infection," and Chapter 296, "Clostridial Infections," in Goldman-Cecil Medicine, 25th Edition.

MULTIDRUG-RESISTANT PATHOGENS

MDROs are organisms that are resistant to more than one class of antimicrobial agents, although the names of some (e.g., MRSA, VRE) imply resistance to only one drug. According to NHSN data reported from the 2009-2010 period, more than one half of reported HAIs were caused by MDROs (Table 99-4).

Infections caused by MDROs lead to increased length of hospitalization, health care costs, and mortality rates for patients compared with those who are infected by antimicrobial-susceptible organisms. Kollef and colleagues found that patients who received inadequate antimicrobial therapy for their HAIs had an infection-related mortality rate 2.37 times that of those in the ICU who received adequate coverage. The principal reason for inadequate coverage was multidrug resistance.

The predominant gram-positive MDRO pathogens are MRSA and VRE. Methicillin resistance in *S. aureus* is caused by the production of an alternate penicillin-binding protein (PBP2A) that has a low affinity for β -lactam antibiotics and forms stable peptidoglycan products in the presence of adequate levels of the β -lactam. MRSA infections tend to have worse outcomes compared with methicillin-susceptible *S. aureus* (MSSA), but the typical health care-acquired strains are not necessarily more virulent. However, community-acquired MRSA, the most prevalent of which is the USA-300 strain, tends to be more virulent, and 87% of these isolates produce the Panton-Valentine leukocidin toxin, which is associated with greater leucocyte destruction and tissue necrosis. The largest reservoirs of MRSA are patients with the greatest contact with the health care system, and most carriers are asymptomatic.

Vancomycin resistance in *S. aureus* is another concern. Vancomycin intermediate-resistant strains, vancomycin heteroresistant strains, and vancomycin-resistant strains are being detected.

TABLE 99-4 PATHOGENIC ISOLATES RESISTANT TO SELECTED ANTIMICROBIAL AGENTS ACCORDING TO THE NHSN, 2009–2010

ORGANISM	ANTIMICROBIAL	CLABSI	CAUTI	VAP	SSI
<i>Staphylococcus aureus</i>	Oxacillin	54.6%	58.7%	48.4%	43.7%
<i>Enterococcus faecium</i>	Vancomycin	82.6%	82.5%	82.6%	62.3%
<i>Klebsiella pneumoniae</i>	Ceftriaxone or ceftazidime	28.8%	26.9%	23.8%	13.2%
	Carbapenems	12.8%	12.5%	11.2%	11.2%
<i>Escherichia coli</i>	Ceftriaxone or ceftazidime	19.0%	12.3%	16.3%	10.9%
	Fluoroquinolones	41.8%	31.2%	35.2%	25.3%
<i>Enterobacter</i> spp.	Ceftriaxone or ceftazidime	37.5%	38.5%	30.1%	27.7%
	Carbapenems	4.0%	4.6%	3.6%	2.4%
<i>Pseudomonas aeruginosa</i>	Fluoroquinolones	30.5%	33.5%	32.7%	16.9%
	Piperacillin-tazobactam	17.4%	16.6%	19.1%	6.8%
	Cefepime	26.1%	25.2%	28.4%	10.2%
	Carbapenems	26.1%	21.3%	30.2%	11.0%
<i>Acinetobacter baumannii</i>	Carbapenems	62.6%	74.1%	61.2%	37.3%

Modified from Sievert DM, Ricks P, Edwards JR, et al: Antimicrobial-resistant pathogens associated with healthcare-associated infection: summary of data reported to the National Healthcare Safety Network at the Centers for Disease Control and Prevention, 2009–2010, *Infect Control Hosp Epidemiol* 34:1–14, 2013.

CAUTI, Catheter-associated urinary tract infection; CLABSI, central line–associated bloodstream infection; NHSN, National Healthcare Safety Network; SSI, surgical site infection; VAP, ventilator-associated pneumonia.

The intermediate resistance or decreased susceptibility to vancomycin is thought to result from cell wall and biomatrix thickening, making the drug target more difficult to reach. Complete vancomycin resistance occurs by acquisition of the *vanA* gene from VRE. VRE, unlike many MRSA strains, is almost entirely a health care–associated phenomenon. Clusters of *vanA* or *vanB* genes are carried on mobile genetic elements that are readily transmitted between strains. These genes encode peptidoglycan precursors that have a low affinity for vancomycin.

Gram-negative MDROs have a greater tendency to form resistance to multiple antimicrobials, and new antimicrobials to target these pathogens are not available. The Enterobacteriaceae are gram-negative bacteria that usually reside in the gastrointestinal tract, are glucose fermenters, and account for about 29% of HAIs. These organisms tend to be the most common pathogens in SSIs associated with abdominal operations. The non-glucose fermenting organisms, including *P. aeruginosa*, *Acinetobacter baumannii*, and *Stenotrophomonas maltophilia*, account for about 9% of HAIs.

Multidrug-resistant gram-negative bacteria are making their way into the limelight largely due to the emergence of isolates that are resistant to most or all available antimicrobials (e.g., MDROs that exhibit β -lactamases, extended-spectrum β -lactamases, carbapenem and fluoroquinolone resistance). The predominant carbapenem-resistance mechanisms are the loss of OprD, an outer membrane protein, *Klebsiella pneumoniae* carbapenemases (KPCs), and the metallo- β -lactamases (MBLs), which hydrolyze the carbapenem. The New Delhi metallo- β -lactamase 1 (NDM1) is one of the first MBLs to cause outbreaks in the United States. The carbapenemases and MBLs are easily transmissible and tend to be associated with other genes encoding mechanisms of resistance to other antimicrobial classes. Fluoroquinolone resistance can occur by efflux pumps or mutations in genes encoding the drug targets DNA gyrase and topoisomerase IV.

Limiting the spread of MDROs in the health care setting should be a comprehensive and system-wide program at any institution. Infection prevention programs should include optimized surveillance practices to identify emerging MDROs and appropriate intervention strategies. The mainstay of these programs includes use of evidence-based prevention practices and antimicrobial stewardship programs.

Sexually Transmitted Infections

Philip A. Chan and Susan Cu-uviv

INTRODUCTION

Sexually transmitted infections (STIs) encompass a wide variety of organisms that have been causing human disease for thousands of years. Recognition of STIs can be challenging due to the heterogeneous nature and multiple symptoms of a single disease. Diagnosis and management of STIs is further complicated by underlying social bias and hesitancy by medical providers and patients to discuss issues related to sexuality and disease transmission.

The diagnosis of STIs should be based on a detailed history with special attention to sexual orientation and behaviors, a physical examination, and laboratory confirmation when appropriate. Professional and respectful attitudes by medical providers are essential to obtaining an accurate clinical history pertinent to STIs. Patients often deny risky behavior because of embarrassment or social stigma. Patients may also underestimate risky behaviors, and the diagnosis of STIs should therefore be based on a combination of history, clinical examination, and diagnostic testing.

A detailed sexual history should be obtained from all individuals with a suspected STI. They should be informed that the information is necessary to appropriately diagnose and manage STIs. The history should include the sexual preferences of male and female partners; the number of main, casual, and one-time partners; and the use of condoms, drugs, and alcohol. The history of partners should be elicited, including current symptoms and diagnosed STIs. If possible, counseling and education should be incorporated during the encounter. Prevention topics include abstinence, routine testing, disclosure of STIs to partners, behavior modification (i.e., avoiding risky sexual activities), condom use, and prophylactic treatment for exposures.

Because of the diverse nature of STIs, it is useful to categorize the infections in a few major groups. There is overlap between different categories, and clinical judgment must be used to accurately diagnose STIs. For example, STIs that typically manifest with an ulcer may occasionally manifest with urethritis. Many STIs are asymptomatic. When an individual has one STI, others should be considered. The main categories of STIs are urethritis and cervicitis, genital ulcer disease, and genital warts. Symptomatic individuals with an STI usually fit into one of these categories.

URETHRITIS AND CERVICITIS

Urethritis and cervicitis are characterized by dysuria, burning, and urethral discharge. The discharge may range from barely

noticeable to watery to frank pus. Urethritis has been categorized as gonococcal (i.e., caused by *Neisseria gonorrhoeae* and visible on Gram stain) or nongonococcal (i.e., commonly caused by *Chlamydia trachomatis*). Nongonococcal urethritis can be caused by other organisms, many of which are rarely tested for. Urethritis has historically been classified as gonococcal or nongonococcal because *N. gonorrhoeae* can easily be visualized on Gram stain. Most patients with symptomatic urethritis should be treated empirically with antibiotics directed against gonorrheal and chlamydial organisms without waiting for test results.

Chlamydia

Definition and Epidemiology

Chlamydia is the most prevalent bacterial STI in the United States and the world. The infection is caused by the bacterium *C. trachomatis*, which causes 30% to 40% of nongonococcal urethritis and cervicitis cases. In the United States, approximately 1.4 million cases were reported to the Centers for Disease Control and Prevention (CDC) in 2011, with an estimated number of infections that is more than twice the number of reported cases.

Age is a factor. Chlamydia has a 5% to 10% prevalence among adolescents and young adults. Other risk factors include having multiple sex partners, having unprotected sex, or living in a lower socioeconomic area. In men, chlamydia is rarely associated with complications. In women, untreated chlamydia is associated with potentially severe complications, including pelvic inflammatory disease (PID), ectopic pregnancy, and infertility.

The CDC recommends all sexually active women age 25 years or younger and other at-risk women be screened for chlamydia. Screening should also be considered for individuals who have a history of chlamydia or other STIs, have new or multiple sex partners, or exchange sex for drugs or money. All pregnant women should be screened. Men who have sex with men (MSM) should be screened at least annually and more frequently if there are ongoing risk factors such as multiple partners. The rationale for screening men is to prevent symptomatic epididymitis, proctitis, and urethritis.

Pathology

C. trachomatis is an obligate intracellular, gram-negative bacterium that is evolutionary distinct from other bacteria. Several serovars of *C. trachomatis* are associated with human disease. They include serovars A-C (i.e., trachoma or ocular disease), D-K (i.e., anogenital disease), and L1-L3 (i.e., lymphogranuloma venereum [LGV]). *C. trachomatis* exists as an extracellular

elementary body before attachment to susceptible epithelial cells and subsequent endocytosis. On entering the cell, the elementary form of *C. trachomatis* reorganizes into a reticulate body within vacuoles that is functionally active, leading to growth and replication of the organism.

Clinical Presentation

Chlamydia may manifest with signs and symptoms ranging from none to life-threatening PID in women. When individuals have symptoms, the most common is urethritis in men and cervicitis in women. The incubation period varies but is usually 7 to 14 days after exposure.

Among men, 40% to more than 90% of chlamydia cases may be asymptomatic. Urethritis usually manifests as dysuria or discharge. *C. trachomatis* and *N. gonorrhoeae* infections are common causes of epididymitis in younger men. The infection typically manifests with unilateral testicular pain, swelling, and tenderness. *C. trachomatis* infection may also cause prostatitis and proctitis; the latter is typically found in MSM. The rates of transmission from infected men to women are as high as 65%.

In women and men, more than 85% of infections are asymptomatic. When symptomatic, *C. trachomatis* infection in women can be difficult to diagnose due to the nonspecific nature of symptoms. The classic manifestation is cervicitis, which can cause discharge, bleeding, pelvic pain, cervical friability, and ulcers. Complications of chlamydia include chronic pelvic pain, infertility, ectopic pregnancy, and PID. The incidence of PID due to *C. trachomatis* infection depends on the population studied, but it ranges from 0% (in lower-risk populations) to 30%. PID usually manifests as abdominal or pelvic pain, cervical motion tenderness, and uterine or adnexal tenderness. Infection may also cause perihepatitis (i.e. Fitz-Hugh–Curtis syndrome), which is inflammation of the liver capsule. It occurs in 5% to 15% of PID cases. Chlamydia is the leading cause of preventable infertility worldwide.

Chlamydia may cause conjunctivitis and ocular trachomatis, the most common cause of preventable blindness worldwide. The disease also may manifest with pharyngitis and LGV. Classically a disease endemic in Africa, Southeast Asia, and the Caribbean, LGV has been identified in the United States and Europe, particularly among MSM with symptoms of proctitis. Typically, LGV manifests with genital ulceration and inguinal lymphadenopathy.

Diagnosis and Differential Diagnosis

C. trachomatis cannot be routinely cultured on growth media, which has made diagnosis difficult. The introduction of nucleic acid amplification testing (NAAT) was a major advance and is now the standard diagnostic test. NAAT encompasses several laboratory methods including polymerase chain reaction (PCR), transcription-mediated amplification, and strand displacement amplification. The reported sensitivity of NAAT is 80% to 90%, with a specificity of 99%. The test may be performed on urine and vaginal or urethral (men) endocervical swab specimens. NAAT may also be performed on rectal and pharyngeal swab specimens, but it must be validated before use.

Individuals who test positive and are treated for chlamydia should not be retested for at least 3 weeks after treatment. NAAT

may remain positive during this time due to remnant material that does not signify persistent infection. Repeat testing to demonstrate cure should be performed for pregnant women or those with a concern about persistent infection. Individuals are usually retested every 3 months and at least once each year. Having had an STI places individuals at risk for becoming infected again. For individuals with multiple partners, including MSM, general STI testing that includes chlamydia is recommended every 3 to 6 months.

Treatment

Standard treatment regimens for urethritis or cervicitis due to chlamydia are azithromycin (1 g taken once orally) or doxycycline (100 mg twice daily for 7 days). These two medications are equally effective and cure more than 95% of infections. Azithromycin is the preferred agent due to simplicity of dosing, which facilitates adherence. Azithromycin can also be used in pregnancy. Other drugs that are effective in treating chlamydia include quinolones and penicillin. Sulfonamides (e.g., Bactrim) and cephalosporins should not be used. Doxycycline, ofloxacin, and levofloxacin are contraindicated in pregnant women.

Epididymitis due to chlamydia should be treated with doxycycline (100 mg taken orally twice per day for 10 days). Treatment for LGV proctitis depends on the severity of symptoms and should include doxycycline (100 mg orally twice each day for up to 3 weeks). In women, PID should be treated with ceftriaxone (250 mg given once intramuscularly) to cover gonorrhea and doxycycline (100 mg taken orally twice each day for 14 days) for chlamydia. Women who are pregnant or who have concerning symptoms should be hospitalized and started on intravenous antibiotics, including cefoxitin (2 g given intravenously every 6 hours) or cefotetan (2 g given intravenously every 12 hours) and doxycycline (100 mg taken orally every 12 hours). The duration depends on clinical improvement but is usually 2 weeks. Alternative treatment regimens include clindamycin (900 mg given intravenously every 8 hours) and gentamicin (2-mg/kg loading dose followed by 1.5 mg/kg every 8 hours).

Prognosis

The natural history of untreated *C. trachomatis* infection varies. Individuals may remain asymptomatic for long periods, and the infection may resolve spontaneously or progress to symptoms and complications. Approximately 20% of individuals diagnosed with chlamydia but without symptoms may clear the infection before returning for treatment. Infection does not translate to protective immunity, and reinfection is common (10% to 20%). In some regions, expedited partner therapy is allowed, and medical providers may prescribe treatment for sex partners without seeing them.

Gonorrhea

Definition and Epidemiology

Gonorrhea is caused by the bacterium *N. gonorrhoeae* and is the second most common reportable STI in the United States behind chlamydia. Similar to chlamydia, gonorrhea is a significant cause of urethritis in men and cervicitis in women and has the same

complications. In the United States, the rate of gonorrhea declined in 2009 to a nadir of 98.1 cases per 100,000 people. Much of this was attributed to screening and treatment programs. Since 2009, however, cases of gonorrhea have increased each year to 104.2 cases per 100,000, with more than 300,000 cases reported in 2011.

Most individuals diagnosed with gonorrhea are adolescents or young adults. MSM have also emerged as an important at-risk group. Risk factors for infection include younger age, multiple sexual partners, race or ethnicity, low socioeconomic status, and previous STIs. African Americans and Latinos have significantly higher rates of gonorrhea than whites in the United States.

Pathology

N. gonorrhoeae is a gram-negative bacterium with an outer membrane, peptidoglycan cell wall, and cytoplasmic membrane. Several components contribute to the virulence of the organism. Attachment to columnar epithelial cells is facilitated by pili, which extend from the cell surface and allow entry into the host cell by endocytosis. Organisms without pili are thought to be noninfectious. Gonococci are able to replicate within host epithelial cells and phagocytes. After mucosal infection, immune activation of neutrophils produces significant inflammation and exudate as pus.

Clinical Presentation

Gonorrhea is transmitted during sex with an infected partner. The risk of infection ranges from 20% to 50% per single act of sexual intercourse and increases with multiple acts. The incubation period is 2 to 7 days. When symptomatic, individuals with gonorrhea tend to have more purulent discharge than individuals with nongonococcal urethritis. In men, urethritis is the most common symptom at clinical presentation. Ten percent of men may be asymptomatic. Other manifestations of gonorrhea include epididymitis, proctitis, and pharyngitis. Rare but severe complications include abscesses and urethral strictures.

Between 50% and 80% of women with gonorrhea are asymptomatic. Typical symptoms include those of cervicitis, such as pelvic or adnexal pain, discharge, dysuria, and abnormal bleeding. As in men, gonorrhea can cause proctitis and pharyngitis in women. Most of these infections are asymptomatic. The most common complication of gonorrhea is PID, which occurs in 10% to 40% of women. It may result in severe infection, chronic pelvic pain, and infertility. Infection during pregnancy may lead to complications such as premature labor, rupture of membranes, and spontaneous abortions.

Gonorrhea infection may also be associated with perihepatitis (Fitz-Hugh–Curtis syndrome). In less than 3% of individuals, disseminated gonococcal infection can lead to a classic triad of tenosynovitis (i.e., affecting multiple tendons), dermatitis (i.e., painless, few transient pustular lesions), and polyarthralgias (i.e., nonpurulent forms). Alternatively, individuals with disseminated infection may have purulent arthritis alone. Clinical presentation usually includes fever and other nonspecific systemic symptoms.

Diagnosis and Differential Diagnosis

N. gonorrhoeae is a gram-negative diplococcus that can be visualized easily on Gram stain of purulent material. However, the most

common method of diagnosis is NAAT, which has more than 98% sensitivity. The major disadvantage of NAAT is the inability to evaluate antibiotic susceptibilities. *N. gonorrhoeae* can also be cultured from swab specimens from the rectum, urethra, pharynx, or cervix. Samples often contain many different microorganisms. Selective media such as modified Thayer-Martin media (with vancomycin, colistin, nystatin, and trimethoprim) is used to inhibit growth of indigenous flora. The sensitivity of cultures varies from 65% to 95%. When drug resistance is a concern, cultures should be sent for sensitivity testing.

Treatment

Antibiotic resistance of *N. gonorrhoeae* continues to be a worldwide problem. In the last decade, treatment of gonorrhea has been complicated by a slow and progressive increase in higher minimum inhibitory concentrations (MICs) for commonly used antibiotics, including first-line cephalosporins. The resistance patterns of gonorrhea vary by region.

To address the concern of antibiotic resistance, uncomplicated urogenital gonorrhea should be treated with dual therapy; one agent should be ceftriaxone (250 mg given once intramuscularly) and the other azithromycin (1 g taken once orally). Azithromycin can also treat concurrent chlamydia. Alternatively, doxycycline (100 mg taken orally twice each day for 7 days) may be given instead of azithromycin. High resistance rates (10% to 20%) limit the use of tetracyclines. This regimen is 99% effective in curing gonorrhea. Cefixime (400 mg taken once orally) should be reserved only if there is ceftriaxone resistance. In patients allergic to ceftriaxone, azithromycin monotherapy (2 g taken orally once) may be used cautiously. Gastrointestinal side effects are common with the higher dose of azithromycin.

Other antibiotics with activity against gonorrhea include spectinomycin. Antibiotics that should not be used to treat gonorrhea due to resistance include penicillins and fluoroquinolones. Disseminated or complicated gonococcal infections should be treated with intravenous ceftriaxone and doxycycline or azithromycin. The duration of these regimens depend on the clinical course and response to therapy.

Prognosis

Gonorrhea is curable with proper antibiotic therapy. Untreated disease often resolves over several weeks, but prompt treatment halts transmission and prevents complications.

Vaginitis

Definition and Epidemiology

The term *vaginitis* refers to disorders of the vagina characterized by inflammation or irritation of the vulva and an abnormal vaginal discharge. Although a separate entity from urethritis, there is significant overlap of symptoms and the organisms that cause vaginitis and urethritis. The three main types of infectious vaginitis are *Candida* vulvovaginitis, bacterial vaginosis, and trichomoniasis. The latter two are strongly associated with sexual transmission.

Trichomoniasis is the most common nonviral STI worldwide. In the United States, 3.1% of women between the ages of 14 and 49 years are infected with *Trichomonas vaginalis*. Screening is recommended for trichomoniasis in women who are at high risk for

other STIs as determined by commonly accepted measures (i.e., having new or multiple partners). Screening for bacterial vaginosis in pregnant women is a controversial topic.

Pathology

Candida albicans and *Candida glabrata* are the most common organisms responsible for *Candida* vulvovaginitis. These species may colonize asymptomatic women but their presence does not necessarily mean infection. Symptomatic cases are caused by an overgrowth of the species and penetration of the superficial vaginal epithelial cells. Overgrowth can result from increased estrogen levels or suppression of other vaginal flora by antibiotics.

Trichomoniasis is caused by the protozoan *T. vaginalis*, which infects the squamous epithelium in the urogenital tract. *T. vaginalis* is not normally present in the vagina and has an incubation period of a few days.

Bacterial vaginosis is caused by a variety of organisms flourishing in the vaginal ecosystem in conjunction with a reduction of normally occurring lactobacilli. The bacterium *Gardnerella vaginalis* is especially prominent in cases of bacterial vaginosis and is thought to infect the vaginal epithelium, creating a biofilm to which other bacteria may adhere. *G. vaginalis* is also the organism thought to play the most likely role in sexual transmission of bacterial vaginosis.

Clinical Presentation

Symptoms of vaginitis may include pruritus (i.e., primary feature of *Candida* vulvovaginitis); a change in the volume, color, or odor of discharge; burning; irritation; erythema; dyspareunia; spotting; and dysuria. In the case of trichomoniasis and bacterial vaginosis, infection is often asymptomatic but can be transmitted sexually. Symptomatic trichomoniasis in women most commonly includes a purulent vaginal discharge and erythema and irritation of the vulva. An abnormal odor is also often associated with infection.

Bacterial vaginosis manifests with milder symptoms of irritation and erythema and is rarely associated with dysuria or dyspareunia. Patients with bacterial vaginosis most commonly have a notably fishy odor in the vaginal discharge, which may also be abnormally colored or textured.

Diagnosis and Differential Diagnosis

Laboratory testing and microscopy are needed for a diagnosis of vaginitis. Examination of vaginal pH can be a helpful differentiating tool. *Candida* vulvovaginitis typically does not cause a change in vaginal pH, whereas bacterial vaginosis and trichomoniasis do increase the pH up to 6. The identification of *Candida* organisms on a wet mount or culture of discharge from women with characteristic clinical symptoms indicates *Candida* vulvovaginitis.

The diagnosis of trichomoniasis may be based on laboratory testing (NAAT), motile trichomonads on a wet mount, or positive culture results. Amsel's criteria or Nugent's criteria may be used to diagnose bacterial vaginosis when Gram stain or microscopy is available.

Treatment

Vaginitis is curable with proper antibiotic therapy. Trichomoniasis is treated with metronidazole (2 g taken orally once or 500 mg

orally twice each day for 7 days) or tinidazole. Pregnant women can be treated with 2 g of metronidazole in a single dose at any stage of pregnancy. The safety of tinidazole has not been fully established.

Treatment of all recent sexual partners is recommended because trichomoniasis is almost exclusively transmitted by sexual contact. The same twice-daily regimen of 500 mg of oral metronidazole is the primary treatment for bacterial vaginosis; however, the single 2-g oral dose is *not* recommended for treatment of bacterial vaginosis. Treatment of *Candida* vulvovaginitis with a single 150-mg dose of fluconazole is highly effective. Use of a topical agent depends on whether the case is considered complicated or uncomplicated. Only topical azole therapies, applied for 7 days, are recommended for use by pregnant women.

Prognosis

Bacterial vaginosis is treatable with various antibiotics, but the primary concern is failure of normal *Lactobacillus* flora to reestablish colonization in the vagina. This leads to repeated infections and necessitates prolonged treatment. Oral and vaginal administration of *Lactobacillus* bacteria is sometimes recommended. Bacterial vaginosis increases risk of infection with human immunodeficiency virus (HIV), herpes simplex virus type 2 (HSV-2), and *N. gonorrhoeae*, making treatment critical for the management of other STIs.

Other Causes of Nongonococcal Urethritis

There are several other known causes of urethritis and cervicitis and likely more that are unknown. Significant causes may include *Mycoplasma genitalium*, HSV, *Treponema pallidum*, adenovirus, and *Ureaplasma urealyticum*. *U. urealyticum* can be part of the normal flora, and its role in urethritis has not been validated.

The most common of these organisms is *M. genitalium*. It is a bacterium that lacks a cell wall, cannot be Gram stained, and is very difficult to grow in culture. The organism accounts for 15% to 25% of men with nongonococcal urethritis in the United States and is thought to be a cause of cervicitis and PID in women. Empirical treatment of symptomatic individuals includes azithromycin (1 g taken orally once) and doxycycline (100 mg orally twice daily for 7 days).

GENITAL ULCER DISEASE

Genital ulcers are a major manifestation of several STIs. Genital ulcers are best classified as painful (e.g., HSV, chancroid) or non-painful (e.g., syphilis). LGV due to *Chlamydia* also manifests with ulcerations. Ulcers may be classified as single (e.g., syphilis, chancroid) or multiple or grouped (e.g., HSV). All of these STIs manifest with diverse signs and symptoms, and clinical examination alone may be inadequate for accurate diagnosis (Table 100-1).

Syphilis

Definition and Epidemiology

Syphilis is caused by the spirochete *T. pallidum*, which can result in a wide spectrum of clinical disease. At the beginning of the 20th century, it was thought that an astounding 10% of the general population in the United States had syphilis. The CDC began reporting rates of syphilis in 1941. The rates peaked in the early 1940s at almost 600,000 cases and subsequently reached a

**TABLE 100-1** DIFFERENTIAL DIAGNOSIS OF GENITAL ULCER DISEASE

DISEASE	PRIMARY LESION	ADENOPATHY	SYSTEMIC FEATURES	DIAGNOSIS AND TREATMENT
Genital herpes (HSV-1/2)				
Primary	Incubation 2-7 days; multiple, painful vesicles on erythematous base; lasts 7-14 days	Tender, soft, and usually bilateral	Fever, malaise	Viral cultures, DFA, antibody testing, Tzanck smear
Recurrent	Grouped, painful vesicles on erythematous base; lasts 3-10 days	None	None	Tx: acyclovir, famciclovir, or valacyclovir for 7-10 days (shorter for recurrent cases)
Primary syphilis (<i>Treponema pallidum</i>)	Incubation 10-90 days (average, 21) Chancre: painless papule that ulcerates with firm, raised border and smooth base; usually single; may be genital or almost anywhere; heals in 3-6 wk without treatment	1 wk after chancre appears; bilateral or unilateral; firm, discrete, no overlying skin changes, painless, nonsuppurative	During later stages	Nontreponemal tests (RPR, VDRL), treponemal tests (FTA-ABS), darkfield microscopy; cannot be cultured Tx: see Table 100-3
Chancroid (<i>Haemophilus ducreyi</i>)	Incubation 3-5 days; vesicle or papule to pustule to ulcer; soft, not indurated; very painful	1 wk after primary in 50%; painful, unilateral in two thirds; suppurative	None	Gram stain and culture. Tx: azithromycin, ceftriaxone, ciprofloxacin
Lymphogranuloma venereum (<i>Chlamydia trachomatis</i> serovars L1, L2, L3)	Incubation 5-21 days; self-limited, painless papule, vesicle, or ulcer; lasts 2-3 days; found in only 10-40%	5-21 days after primary; one third bilateral, tender, matted iliac or femoral groove sign; multiple abscesses; coalescent, caseating, suppurative; thick yellow pus; sinus tracts; fistulas; strictures; genital ulcerations	Fever, arthritis, pericarditis, proctitis, meningoencephalitis, keratoconjunctivitis, preauricular adenopathy, erythema nodosum	NAAT for <i>Chlamydia</i> Tx: incision and drainage, doxycycline
Granuloma inguinale (donovanosis)	Incubation 9-50 days; at least one painless papule that gradually ulcerates; ulcers are large (1-4 cm), irregular, nontender, with thickened; rolled margins and beefy red tissue at base; older portions of ulcer show depigmented scarring, white areas; advancing edge contains new papules	No true adenopathy; in one fifth of patients, subcutaneous spread through lymphatics leads to indurated swelling or abscesses of groin (pseudobuboes)	Metastatic infection of bones, joints, liver	Wright or Giemsa staining with short, plump, bipolar staining pattern, Donovan bodies in macrophage vacuoles Tx: doxycycline
Condyloma acuminatum (genital warts)	Characteristic large, soft, fleshy, cauliflower-like excrescences around vulva, glans, urethral orifice, anus, perineum	None	None	Clinical diagnosis, biopsy if necessary Tx: topical podophyllin, surgery, others

DFA, Direct fluorescent antibody test; FTA-ABS, fluorescent treponemal antibody absorption test; HSV, herpes simplex virus; NAAT, nucleic acid amplification test; RPR, rapid plasma reagin; Tx, treatment; VDRL, venereal disease research laboratory.

nadir in 2000 with a rate of 2.1 cases per 100,000 people in the general population. However, since that time, the number of reported syphilis cases has been increasing. The major at-risk group is MSM, but the disease is observed in people across all ages, genders, sexual orientations, socioeconomic status, and racial and ethnic classes.

The resurgence of a generalized syphilis epidemic among MSM with HIV infection or acquired immunodeficiency syndrome (HIV/AIDS) has had important consequences. Clinicians at STI clinics and those treating individuals with HIV/AIDS need to be aware of guidelines for the diagnosis and treatment of syphilis in this population. Given the increasing number of MSM living with HIV/AIDS, it is not uncommon to see co-infection in this population. All MSM, regardless of HIV status, should be considered for syphilis screening on an annual basis and more frequently if they have other risk factors.

Pathology

T. pallidum organisms are thinly coiled bacteria that move in a corkscrew motion. *T. pallidum* cannot be cultured, hindering diagnosis and study of the organism. *T. pallidum* infects and penetrates mucosal membranes, resulting in the classic chancre lesion. The organism then infects local lymph nodes and disseminates systemically. The median incubation period is

approximately 3 weeks. In more than 60% of infected individuals, syphilis does not progress to tertiary stages. Immune host factors are thought to contribute to the development of tertiary syphilis.

Clinical Presentation

Ninety-five percent of primary syphilis cases involve the genitals. The estimated risk of transmission from an individual with primary syphilis to an uninfected individual is 30% per sexual act. Syphilis may also be transmitted through oral-genital exposure and with any contact of a primary lesion. Inoculation of the organism by surgeons through needlesticks has been well documented and typically does not result in a chancre at the site of infection (i.e., syphilis d'emblee).

The four classic stages of syphilis are primary, secondary, latent, and tertiary. Staging is best thought of as a continuum rather than discrete stages of infection. The states can manifest individually, but individuals often have symptoms consistent with primary and secondary symptoms. The primary and secondary stages of syphilis are extremely infectious, and cases of transmission during the tertiary stage have been reported.

It can be very difficult to diagnose primary syphilis based solely on the physical examination. The primary chancre is a painless, clean-based, indurated ulcer. The borders are firm and raised.

It is teeming with spirochetes and should be considered extremely infectious. It is rare for a primary chancre to be absent, but it may go unnoticed. The chancre spontaneously heals without treatment over several weeks.

Secondary syphilis usually manifests as a diffuse, maculopapular rash that classically involves the palms and soles. However, a wide range of early skin manifestations exists, including macular, papular, pustular, vesicular, or any combination of these. Vesicular lesions may easily be confused with other STIs, including herpes simplex. Syphilis may also have late skin manifestations, including nodular, squamous, or gummosis appearances.

The rash typically develops a few weeks after the chancre and results from dissemination of the organism. Up to 80% of patients have some cutaneous manifestations of disease. The rash is usually symmetrical and pink, with no pain or burning, and it usually spares the face. It resolves on its own over weeks to months and may be confused with pityriasis rosea, erythema multiforme, drug rashes, tinea, measles, and seborrheic dermatitis. The maculopapular rash of secondary syphilis is considered noninfectious, although lesions in axillary or inguinal folds or other regions exposed to chaffing may erode and become infectious.

Syphilis then enters a latent stage, during which an infected individual has no symptoms but does have positive serologic test results (Table 100-2). Tertiary syphilis may then develop at any point from years to decades after the initial infection.

Approximately 30% to 40% of individuals with untreated syphilis infection develop tertiary disease, which can include neurosyphilis, cardiovascular syphilis, and gummatous disease. Neurosyphilis has classically been thought of as a complication of tertiary syphilis. However, *T. pallidum* may invade and cause

symptoms of the central nervous system at the time of initial infection. Early neurosyphilis may be characterized by signs and symptoms of meningitis and milder symptoms, including headache. Other manifestations of neurosyphilis include otosyphilis (i.e., hearing loss) and ocular syphilis, which is classically characterized as posterior uveitis. Late neurosyphilis may manifest with general paresis (i.e., progressive dementia, forgetfulness, psychiatric disease, and personality change), Argyll-Robertson pupils (i.e., no response to light but normal accommodation), and tabes dorsalis (i.e., ataxia and lancinating pains). The most common finding in late neurosyphilis is irregular pupils.

Gummas, a result of immune system activation, may develop in any tissue or organ in the body. Classic cardiovascular symptoms of syphilis include aortitis, which often affects the ascending thoracic aorta causing a tree-bark appearance with dilation and aortic valve regurgitation.

Diagnosis and Differential Diagnosis

The diagnosis of syphilis is limited by the inability of *T. pallidum* to grow on standard laboratory media. Diagnostic testing for syphilis relies on the direct and indirect measurement of antibodies against treponema. Nontreponemal tests such as the rapid plasma regain (RPR) and venereal disease research laboratory (VDRL) test rely on anticardiolipin antibodies, which usually resemble antibodies against treponema. These tests are usually sensitive but nonspecific, and false-positive results are relatively common, especially in individuals with other autoimmune diseases or who are pregnant. Nontreponemal tests report antibodies in terms of dilutions; a titer of 1:2 is extremely low compared with a titer of 1:1024. This measurement can be used as a general representation of spirochete load in the patient. With treatment, nontreponemal test results often revert to nonreactive.

Treponemal tests such as the fluorescent treponemal antibody absorption (FTA-ABS) test rely on antibodies that directly target the organism and are therefore more specific. Tests results may be positive or negative, and a positive result usually remains so for life. The normal testing algorithm employs the sensitive, nontreponemal tests, followed by a more specific, treponemal test to confirm the diagnosis. The inherent limitation of antibody testing results in many cases of unclear diagnoses.

Several mistakes may be made by clinicians in the diagnosis of syphilis. In primary syphilis, the initial nontreponemal test result may be negative. A patient with a lesion suspicious for syphilis should undergo repeat testing or empirical treatment regardless of the serologic results. In the event of a recent exposure, a patient should be counseled that a syphilis test and HIV antibody test may be negative. A patient who is treated early in the course of disease may never develop an antibody response and may therefore never have a positive test result.

After successful treatment, patients with an initial episode of syphilis should see a fourfold decrease in nontreponemal titers at 6 months. Titers may never return to normal and should be followed periodically. For MSM, CDC guidelines suggest yearly STI testing and more frequent testing (3 to 6 months) for patients with multiple partners, anonymous partners, or other risk factors for infection.

TABLE 100-2 SEROLOGIC TESTING FOR SYPHILIS

FEATURES	NONTREPONEMAL	TREPONEMAL
Technique	Antibody to cardiolipin- lecithin (RPR, VDRL)	Antibody to <i>Treponema pallidum</i> (FTA-ABS, EIA)
Indications	Screening and assessing response to therapy; should be quantified by diluting serum and reporting in titers	Confirmatory test; usually remains positive for life; may be used as a screening test in some settings
Positive for syphilis		
Primary	77%	86%
Secondary	98%	100%
Early latent	95%	99%
Late latent	73%	96%
False positives	1-2% of the population may have a false-positive RPR/VDRL; common in pregnancy, recent immunization, autoimmune diseases, acute infectious illness, HIV, chronic liver disease, prozone reaction (negative result due to high antibody titers)	Borderline positive is common in pregnancy, and test should be repeated

EIA, Enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption test; HIV, human immunodeficiency virus infection; RPR, rapid plasma reagin; VDRL, venereal disease research laboratory test.

Treatment

Despite the classic staging of syphilis as primary, secondary, latent, or tertiary, the disease is best thought of in terms of early infection (<1 year) or late infection (≥ 1 year) when considering treatment. *T. pallidum* remains sensitive to penicillin. Individuals with early syphilis can be treated with a single intramuscular injection of benzathine penicillin G (Bicillin), which achieves high and prolonged serum concentrations. Individuals with late syphilis or disease of unknown duration should be treated with three weekly injections of intramuscular benzathine penicillin G (Table 100-3). This cures most patients.

Although penicillin remains the drug of choice, doxycycline may also be used in individuals who have severe allergies to penicillin. However, every effort should be made to use penicillin because of the sensitivity of the organism. For pregnant women who are allergic to penicillin, penicillin desensitization should occur in collaboration with a pharmacist and an allergist specialist. As a result of treatment, individuals may experience a febrile reaction (i.e., Jarisch-Herxheimer reaction). Symptoms are caused by killing of the spirochetes and should not be confused with an allergic reaction.

The co-epidemic of syphilis and HIV has led to an increase in individuals with manifestations of neurosyphilis. In cases of syphilis with neurologic symptoms, a lumbar puncture is warranted to rule out neurologic involvement. Any pleocytosis or increase in protein concentration warrants treatment for neurosyphilis. A cerebrospinal fluid (CSF) sample should be sent for VDRL testing, but the test lacks sensitivity (50%), and a negative test result does not rule out neurosyphilis. Usually, HIV-negative individuals with syphilis without neurologic symptoms should not undergo a lumbar puncture. Many HIV-infected individuals with syphilis, however, have asymptomatic neurosyphilis. The clinical implications of this are unclear, but these individuals may fail intramuscular therapy at a high rate. Some experts recommend CSF examination in all HIV-infected individuals with a CD4⁺ count lower than 350 cells/ μ L or a nontreponemal titer greater than 1:32. These criteria capture almost everyone with asymptomatic neurosyphilis.

TABLE 100-3 SYPHILIS TREATMENT

CLINICAL CATEGORY	REGIMEN OF CHOICE	ALTERNATIVE*
Early syphilis (<1 year)	Benzathine penicillin, 2.4 million units IM, given once	Penicillin desensitization Doxycycline, 100 mg PO bid for 14 days Tetracycline, 500 mg PO qid for 14 days Azithromycin 2 g PO qd
Late syphilis (≥ 1 year) or unknown duration	Benzathine penicillin, 2.4 million units IM, given once each week for 3 wk	Penicillin desensitization Doxycycline, 100 mg PO bid for 28 days Tetracycline, 500 mg PO qid for 28 days
Neurosyphilis	Penicillin G, 4 million units IV q4h or 24 million units by continuous infusion qd for 10-14 days	Penicillin desensitization Ceftriaxone 2 g qd IM or IV for 10-14 days

*If patient has a penicillin allergy.

Individuals with neurosyphilis should be treated with intravenous penicillin G for 10 to 14 days. In tertiary disease with manifestations of neurologic disease, treatment with intravenous penicillin halts disease progression but does not reverse existing structural damage. Ocular disease or other similar neurologic manifestations should be treated as neurosyphilis. Nontreponemal titers should be followed to ensure an appropriate response. Repeat treatment may be necessary in a small number of cases.

Prognosis

Although penicillin is the treatment of choice for syphilis, it has not been validated in clinical trials but is based on a long history of clinical use. However, a significant number of individuals with syphilis do not respond with the recommended decline in nontreponemal titer. Individuals who do not respond should be retreated.

 For a deeper discussion of these topics, please see Chapter 319, "Syphilis," in Goldman-Cecil Medicine, 25th Edition.

Herpes Simplex Virus

Definition and Epidemiology

Herpes simplex virus types 1 and 2 (HSV-1/2) cause a wide variety of clinical disease. HSV-1 is usually the cause of herpes labialis (i.e., cold sores), and HSV-2 is the cause of genital herpes, although there may be overlap. After infection occurs, HSV-1/2 enters a latent state and may later reactivate to cause disease in a subset of individuals.

The overall prevalence of HSV-1 and HSV-2 in the population is approximately 60% and 20%, respectively. However, the incidence of HSV-1 infection approaches 90% to 100% among middle-aged adults. Seroprevalence of HSV-2 is associated with a patient's sexual activity, including number of partners and history of other STIs, and with age, gender (women are at higher risk than men), and race or ethnicity. More than 50 million people in the United States are infected with genital HSV-1/2, and most are asymptomatic. CDC guidelines do not recommend routine screening for HSV-1/2 in people without symptoms. There is no evidence that screening for HSV-1/2 reduces its spread or has an impact on the disease. HSV-1/2 is not a reportable disease in the United States.

Pathology

HSV-1 and HSV-2 are two of eight double-stranded DNA human herpesviruses. Others are varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and human herpesviruses 6, 7, and 8. Infection with one type of HSV does not prevent or increase the chances of infection with other types. After initial infection, HSV-1/2 enters a latent state within neuronal cells of sensory or autonomic peripheral ganglia. Reactivation can occur at any time and is mediated in part by immune factors. HSV-1 most commonly infects the trigeminal ganglia and HSV-2 the sacral nerve root ganglia (S2-S5).

Clinical Presentation

Transmission of HSV-1/2 is through skin-to-skin contact, including sexual contact at mucosal surfaces, including the oropharynx,

vagina, rectum, cervix, and conjunctivae. Importantly, transmission may occur in the absence of symptoms.

The stages of HSV-1/2 infection include primary, latent, and recurrent. Primary infection of genital HSV-1/2 may include fever, headache, other systemic symptoms, and the classic local symptoms of painful genital vesicles or ulcers (multiple) and lymphadenopathy. Oral infections of HSV-1 may include gingivostomatitis and pharyngitis. Symptoms may vary from none to serious and require hospitalization. HSV-1/2 then enters a latent state. Reactivation occurs in a subset of individuals with symptoms less severe than those of primary infection. Some individuals have no reactivation, and others have more than three reactivations per year.

Complications of HSV-1/2 infection include meningitis and proctitis. Recurrent episodes of meningitis (i.e., Mollaret's meningitis) may be caused by HSV-1/2. Other manifestations of HSV-1/2 include herpetic whitlow (e.g., infection of a finger of a health care worker), herpes gladiatorum (e.g., HSV-1/2 skin infections in athletes such as wrestlers), and ocular disease (e.g., keratitis, acute retinal necrosis). HSV-1/2 infection may rarely be associated with erythema multiforme, hepatitis, and encephalitis.

Diagnosis and Differential Diagnosis

The diagnosis of HSV-1/2 is typically made clinically. If possible, lesions should be tested for HSV-1/2 using viral culture (50% sensitivity), PCR, or direct fluorescent antibody (DFA) testing. Alternatively, serology testing for immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies is available. This test should be reserved for individuals with suspected primary infection or to document chronic infection, and it should usually not be used for screening purposes.

Treatment

Recommended regimens for primary HSV-1/2 infection include acyclovir (400 mg orally three times per day for 7 to 10 days or 200 mg orally five times per day for 7 to 10 days), famciclovir (250 mg orally three times each day for 7 to 10 days), or valacyclovir (1 g orally twice each day for 7 to 10 days). Treatment can also be used for reactivation disease: acyclovir (400 mg orally three times each day for 5 days, 800 mg orally twice each day for 5 days, or 800 mg orally three times each day for 2 days), famciclovir (125 mg orally twice each day for 5 days or 1000 mg orally twice each day for 1 day or 500 mg once followed by 250 mg twice each day for 2 days), or valacyclovir (500 mg twice each day for 3 days or 1 g orally once each day for 5 days).

Individuals with frequent recurrences may be candidates for suppressive therapy. Severe disease should be treated with intravenous acyclovir (5 to 10 mg/kg intravenously every 8 hours). Duration and transition to oral medication should be based on clinical improvement but is usually 7 to 10 days. The safety of systemic acyclovir, valacyclovir, and famciclovir therapy in pregnant women is not established.

Prognosis

Although HSV-1/2 infection cannot be cured, most people are asymptomatic, and suppressive therapy is available. Individuals with HSV-1/2 infection should be educated regarding the

disease, including transmission and available treatments. They should be encouraged to discuss their status with sexual partners, including the possibility that transmission may occur in the absence of symptoms. Individuals should abstain from sex during an outbreak.

Chancroid

Chancroid is a rare cause of genital ulceration in the United States. The infection is caused by the gram-negative rod *Haemophilus ducreyi* and is endemic in parts of Africa and the Caribbean. Classic symptoms include a single or multiple, painful, nonindurated genital ulcers and inguinal lymphadenopathy. Growth of the organism in cultures requires hemin-containing media, and it may appear as a school of fish on Gram stain. PCR may be available in certain areas.

Testing for HSV-1/2 and syphilis should always be performed. Recommended treatment regimens include azithromycin (1 g orally once), ceftriaxone (250 mg intramuscularly once), or ciprofloxacin (500 mg orally twice each day for 3 days). Ciprofloxacin is contraindicated in pregnant and lactating women.

Granuloma Inguinale

Granuloma inguinale is also known as donovanosis. It is caused by the gram-negative bacterium *Klebsiella granulomatis*. The disease is rare in the United States (24 cases in 2010) but endemic in regions of Africa, India, Oceania, and the Caribbean. Clinical manifestations include painless, ulcerative genital lesions with erythema. Classic Donovan bodies may be observed on histopathology.

The recommended treatment regimen is doxycycline (100 mg orally twice each day for at least 3 weeks). Alternative regimens include azithromycin, ciprofloxacin, and sulfamethoxazole-trimethoprim. Azithromycin may be useful for treating granuloma inguinale during pregnancy. Doxycycline and ciprofloxacin are contraindicated in pregnant women.

Other Causes of Genital Ulcers

Other causes of genital ulcers should be considered when the results of routine testing are negative. Noninfectious causes include trauma, Behçet's disease, malignancy, and drug-mediated disease

OTHER SEXUALLY TRANSMITTED INFECTIONS

Genital Warts

Human papillomavirus (HPV) is responsible for a spectrum of cutaneous and mucosal disease, ranging from genital warts to invasive cancer. HPV has been linked to cervical, anal, and oropharyngeal cancer. There are more than 100 types of HPV. Sexually transmitted HPV infection is responsible for genital warts and anogenital carcinoma. More than 80% of sexually active adults acquire HPV infection in their lifetime. Genital warts tend to be benign and asymptomatic, and 90% are caused by HPV types 6 and 11. The HPV types most often linked to anogenital carcinoma are 16 and 18; HPV-16 is the most common.

Warts are usually described as flat and papular in the genital regions. Diagnosis of genital warts is usually made by clinical examination. If unclear, a biopsy may be performed. Treatment

of genital warts may include podofilox (0.5% solution or gel), imiquimod (5% cream), sinecatechins (15% ointment), cryotherapy, podophyllin resin (10% to 25% concentration), trichloroacetic acid (TCA), and surgical excision.

HPV vaccination is available with Gardasil (quadrivalent vaccine) and Cervarix (bivalent vaccine). The main objective of vaccination is to prevent cervical and other cancers. The vaccines are also effective in preventing genital warts. The vaccines are most effective before sexual debut. Guidelines suggest vaccination of males and females between the ages of 11 to 26 years. Vaccines may be administered to individuals as young as 9 years old. The guidelines state there is insufficient evidence to vaccinate individuals older than 26 years.

Pubic Lice

Pubic lice (i.e., *Pediculosis pubis*) may spread from the genitalia to other areas of the body. The most common symptom is pruritus. Small macules and localized lymphadenopathy may occur. Diagnosis of this STI is made by light microscopy of the organism.

Treatment includes permethrin (1% cream applied to affected areas, rinsed off in 10 minutes) or pyrethrins (similar application). Alternative medications include malathion (0.5% lotion) or ivermectin. Clothing, bed sheets, and other linens should be thoroughly washed.

Scabies

Scabies is caused by the skin mite *Sarcoptes scabiei*. Transmission occurs by skin contact, and among adults, it is usually sexual. Clinical presentation usually includes pruritus and small ery-

thematous papules that are classically present on the wrists, forearms, fingers, and genital areas.

Diagnosis is usually based on clinical presentation and examination of skin scrapings. Recommended treatment regimens include permethrin (5% cream applied from the neck down and washed off after 8 to 14 hours) or ivermectin.

Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Brian T. Montague, Aadia I. Rana, Edward J. Wing, and Timothy P. Flanigan

DEFINITION AND EPIDEMIOLOGY

The human immunodeficiency virus (HIV) is a retrovirus from the lentivirus family. The first descriptions of the disease came in 1982, when HIV-associated wasting occurring in large numbers of young adults in a Ugandan fishing community was described as “slim disease.” In the United States in the same year, the designation acquired immunodeficiency syndrome, or AIDS, was applied to a syndrome identified in previously healthy men who had sex with men (MSM). It was characterized by serious infections with unusual opportunistic pathogens, such as pneumonia from *Pneumocystis carinii* (now called *Pneumocystis jirovecii*) or development of the formerly rare tumor, Kaposi’s sarcoma. Such infections had previously been found only among patients with severe cellular immunodeficiency, and studies confirmed profound immunodeficiency in these individuals. When similar opportunistic infections (OIs) were subsequently observed in injection drug users and in men with hemophilia along with their female sexual partners, it became clear that this syndrome was caused by an agent transmitted either through sexual contact or through infusion of blood or blood products.

The HIV virus was identified in 1983, and its role as the causative agent of AIDS was confirmed in 1984. By 1993, AIDS had become the leading cause of death among American adults aged 25 to 44 years, a trend that was dramatically reversed by the introduction of effective combination antiretroviral therapy (ART) at the end of 1995. By the end of 2006, approximately 1.1 million persons in the United States were living with HIV and AIDS, and an estimated 56,300 persons are estimated to have become infected that year. More than 20% of people living with HIV remain unaware of their status; they are at risk for serious health complications and for transmitting the virus to others.

TRANSMISSION

Although it was initially observed most frequently among homosexual men and intravenous drug users in the United States, heterosexual intercourse has been the dominant mode of HIV transmission throughout most of the world. The virus is present in semen and cervicovaginal secretions of infected individuals and can be transmitted by either partner during vaginal or anal

intercourse. The concurrent presence of other sexually transmitted diseases, especially those associated with genital ulcerations, strongly facilitates sexual transmission of HIV.

Vertical transmission of HIV from an infected mother to her child may occur in utero, during labor, or through breastfeeding. In the absence of antiretroviral treatment (ART), HIV infects 25% to 30% of infants born to HIV-infected mothers. The rate of vertical transmission can be reduced to less than 2% by prenatal and perinatal treatment of the mother and postnatal treatment of the infant with effective antiretroviral drugs.

Before the nationwide implementation of a blood screening test in late 1985, infection by means of transfused blood or blood products accounted for almost 3% of AIDS cases in the United States. Since 1985, all blood products in North America have been screened for HIV antigens and antibodies to HIV. The risk of transfusion-acquired HIV infection in North America and western Europe is now exceedingly small, but not absent.

HIV infection may occur after accidental parenteral exposures among health care workers. After injury by an HIV-contaminated hollow needle, the risk of infection is approximately 0.3%. Observational data suggest that this risk can be reduced at least 10-fold by prompt postexposure prophylaxis.

For a deeper discussion of these topics, please see Chapter 387, “Prevention of Human Immunodeficiency Virus Infection,” in Goldman-Cecil Medicine, 25th Edition.

EPIDEMIOLOGY

HIV is a reportable condition in the United States. Individual states and the Centers for Disease Control and Prevention (CDC) together monitor incident cases of HIV, the number of persons known to be living with HIV, and the incidence of AIDS diagnosis. The CDC has established clear surveillance criteria for the diagnosis of AIDS, which include having a CD4⁺ T-helper lymphocyte count (CD4 count) lower than 200 cells/mm³, having been diagnosed with any of a large number of OIs indicative of defects in cellular or humoral immunity, and having certain neoplasms or other conditions associated with severe immunodeficiency. With ART, the clinical significance of an AIDS diagnosis is more limited, although tracking the number of AIDS

cases remains important epidemiologically as a marker of late diagnosis and limitations in access to care.

Since the early 1980s, HIV infection has become a worldwide pandemic. HIV continues to spread throughout all continents. Since the late 1990s, exceptionally rapid transmission has occurred throughout India, Southeast Asia, Southern Africa, the former Soviet Union, and some parts of Eastern Europe. Because of latency between HIV infection and the development of AIDS-associated illnesses, the clinically recognized epidemic of AIDS has lagged 6 to 8 years behind the spread of the virus into new populations. Worldwide, 1.7 million deaths were attributed to HIV in 2011, and an estimated 34 million people were living with HIV, including 3.3 million children. In 2011, an estimated 2.5 million people were newly infected with HIV—a 24% decrease from the 3.1 million estimated in 2001. In 2009, there were an estimated 370,000 new infections in children and between 42,000 and 60,000 maternal deaths. Persons from sub-Saharan Africa accounted for 70% of all new HIV infections globally. Morbidity and mortality from HIV and associated infections in many resource-poor communities has been high. As access to ART in low- and middle-income countries improves, morbidity and mortality from HIV should fall, leading to an increase in the prevalence of those living with HIV.

In the United States, HIV infection has increased rapidly among women in the last decade; in several rural areas of the Southeast, women accounted for more than one half of new cases in 2005. Over the last several years, there has also been a resurgence of HIV infection among young MSM. A disproportionate number of North American men and women infected by HIV are African American or Hispanic. Transmission by injection drug

use has been a major factor in this imbalance, given that it has occurred most commonly in impoverished inner-city areas, where intravenous drug abuse is most prevalent. Since 2003, transmission by injection drug use has significantly declined in the United States, whereas heterosexual transmission has continued to increase. Recent studies in the United States have shown clearly that even when treatment is readily available, the fraction of persons who are retained in care and achieve virologic suppression remains as low as 25% (Fig. 101-1). There are increasing calls for coordinated interventions directed toward identifying persons with HIV, linking them to care, promoting retention, and supporting sustained adherence to antiviral therapy. This is termed the Seek, Test, Treat, and Retain (STTR) strategy for HIV control.

For a deeper discussion of these topics, please see Chapter 384, “Epidemiology of Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome,” in Goldman-Cecil Medicine, 25th Edition.

PATHOLOGY

The core of HIV contains two single-stranded copies of the viral RNA genome, together with the virus-encoded enzymes reverse transcriptase, protease, and integrase (Fig. 101-2). Surrounding the structural (p24 and p18) proteins is a lipid bilayer derived from the host cell, through which protrude the transmembrane (gp41) and surface (gp120) envelope glycoproteins. The HIV envelope glycoproteins have a high affinity for the CD4 molecule on the surface of T-helper lymphocytes and other cells of monocyte-macrophage lineage. After HIV binds to CD4, the envelope undergoes a conformational change that facilitates

FIGURE 101-1 The HIV treatment cascade. Estimates show the progressive loss to follow-up as one moves from diagnosis to linkage to care, retention, and achievement of virologic suppression with antiretroviral therapy. (Data from HIV in the United States: the Stages of Care. CDC Fact Sheet, 2012. Available at http://www.cdc.gov/hiv/pdf/research_mmp_StagesofCare.pdf. Accessed November 3, 2014; and from Gardner EM, McLees MP, Steiner JF, et al: The spectrum of engagement in HIV care and its relevance to test-and-treat strategies for prevention of HIV infection, *Clin Infect Dis* 52:793-800, 2011.)

FIGURE 101-2 HIV viral replication. Key steps in the pathway targeted by antiretroviral therapy include membrane binding and fusion, reverse transcription, integration of proviral DNA, and protein synthesis. LTR, Long terminal repeat; mRNA, messenger RNA. (Modified from Furtado MR, Callaway DS, Phair JP, et al: Persistence of HIV-1 transcription in patients receiving potent antiretroviral therapy, *N Engl J Med* 340:1614–1622, 1999.)

binding to another cellular coreceptor (the most important of these are the chemokine receptors CCR5 and CXCR4). This second binding event promotes a major conformational change that causes approximation of the viral and cellular membranes; fusion of these membranes is mediated by insertion of the newly exposed fusion domain of the envelope gp41 into the host cell membrane.

As a result of these processes, the HIV nucleoprotein complex enters the cytoplasm, where the RNA viral genome undergoes reverse transcription by the virally encoded reverse transcriptase. The resulting double-stranded viral DNA enters the nucleus, where proper localization of the viral preintegration complex is

mediated by host proteins, and integration of the DNA provirus into the host chromosome is catalyzed by the retroviral integrase. Latently infected resting memory CD4 lymphocytes serve as reservoirs of persistent infection for the life of the infected patient even with effective ART (see later discussion). However, the bulk of viral replication takes place in activated T cells, which are both more susceptible to HIV infection and more capable of supporting productive HIV replication.

When a CD4 lymphocyte is activated, expression of HIV messenger RNA (mRNA) is enhanced. Core proteins, viral enzymes, and envelope proteins are encoded by the *gag*, *pol*, and *env* genes of HIV, respectively. Recent data indicate that more than 100 host

proteins, in addition to the viral proteins, may be important for viral replication. Viral particles are assembled at the cell membrane, each containing two copies of unspliced mRNA within the core as the viral genome, and virions then are released from the cell by budding. Productive viral replication is lytic to infected T cells. A number of other host cells, including macrophages and certain dendritic cells, are also infected by HIV, but viral replication does not appear to be lytic to these cells.

Following acute infection, high-level viral multiplication occurs in mucosal lymphoid tissues of the gut and in other lymphatic sites, and plasma HIV RNA levels (i.e., the plasma viral load [PVL]) often exceed 1 million copies per milliliter during the second to fourth weeks after infection. Almost all instances of acute HIV infection are caused by R5 tropic viruses, viruses that use the chemokine receptor CCR5 for cellular entry. During subsequent weeks, the PVL decreases, often rapidly. This decrease in viremia results largely from a partially effective immune response. After 6 to 12 months, the PVL typically stabilizes at a level denoted the viral *set point*, and it may remain at approximately that level for several years (Fig. 101-3). The set point, assessed as the PVL at 6 to 12 months after infection, is a significant predictor of the subsequent rate of progression of HIV disease but accounts for only half of the population variability in disease progression rates.

After recovery from the acute retroviral syndrome, the patient may feel entirely well for several years, but even in the asymptomatic infected individual, more than 100 billion new virions may be produced daily. Rapid production and turnover of circulating CD4 cells also occurs throughout the course of HIV infection,

and a progressive decline in circulating CD4 cells occurs in most individuals. As disease progresses, a more dramatic CD4 cell decline is observed, following a sharp rise in the PVL (see Fig. 101-3). Cell lysis associated with HIV replication accounts only partially for this progressive loss of CD4 cells. During the years of clinical latency, virions are present in large numbers in the follicular dendritic processes of the germinal centers of the lymph nodes, which undergo both hyperplasia and progressive fibrosis. As HIV disease progresses over several years, the lymphatic tissue atrophies and plasma viremia intensifies. In later-stage HIV disease, there is often persistent high-level viremia.

The decline in the number of CD4 cells is accompanied by profound functional impairment of the remaining lymphocyte populations. Anergy may develop early in HIV infection and eventually occurs in almost all persons with AIDS. T-helper lymphocyte proliferation in response to antigenic stimuli is dramatically impaired, T-cell cytotoxic responses are diminished, and natural killer cell activity against virus-infected cells is greatly impaired. Decrease in function as well as number of CD4 cells is central to the immune dysfunction, and this impairment partly underlies the failure of B-lymphocyte function, as measured by impaired capacity to synthesize antibody in response to new antigens.

For a deeper discussion of these topics, please see Chapter 385, "Immunopathogenesis of Human Immunodeficiency Virus Infection," in Goldman-Cecil Medicine, 25th Edition.

CLINICAL PRESENTATION

Acute HIV Infection and the Acute Retroviral Syndrome

Up to 50% of HIV-infected persons report a mononucleosis-like syndrome (*acute retroviral syndrome*) occurring 2 to 6 weeks after initial infection. The symptoms may include fever, sore throat, lymph node enlargement, rash, arthralgias, and headache, and they usually persist for several days to 3 weeks (Table 101-1). The rash is typically maculopapular and short-lived and usually affects the trunk or face. Ten percent of infected individuals experience an acute, self-limited aseptic meningitis, which on lumbar puncture is characterized by cerebrospinal fluid (CSF) pleocytosis with detectable HIV in the CSF. The acute retroviral syndrome is often sufficiently severe that the patient seeks medical attention. It is critical to maintain a high index of suspicion for acute HIV retroviral syndrome because a very high plasma HIV RNA level during this period indicates a high likelihood of HIV transmission to sexual or needle-sharing partners, or from mother to infant.

FIGURE 101-3 Natural history of HIV without antiretroviral therapy. Following acute infection, an initial burst of viral replication causes an immediate drop in the CD4 count. Partially effective cell-mediated immunity suppresses viral replication to a nadir level and allows for a rise in the CD4 count to a plateau that is less than a normal CD4 count. Left without treatment, the CD4 count declines somewhat proportionally to the nadir viral level until the patient begins to experience significant immune deficiency. At that time, the viral count may rise and the patient typically becomes symptomatic. Though this usually occurs within 8 to 10 years, considerable variability exists, with some patients progressing to AIDS within a few years and others without a significant decline in CD4 count after 20 years.

TABLE 101-1 SIGNS AND SYMPTOMS ASSOCIATED WITH HIV ACUTE RETROVIRAL SYNDROME

SIGN OR SYMPTOM	FREQUENCY (%)
Fever	98
Lymph node enlargement	75
Sore throat	70
Myalgia or arthralgia	60
Rash	50
Headache	35

Spectrum of Disease Associated with HIV

Untreated HIV infection usually results in a slow, nonlinear progression to severe immunodeficiency. However, the progression of disease varies greatly among individuals. Within 10 years after infection, approximately 50% of untreated individuals will develop AIDS, 30% will have milder symptoms, and fewer than 20% will be entirely asymptomatic (see Fig. 101-3). Children and adolescents progress to AIDS at a slower rate than older persons; fewer than 30%, in the absence of ART, will develop AIDS within 10 years after HIV infection. The rate of progression of immunodeficiency is not influenced by the route of HIV transmission and, in the long term, does not appear to differ by gender, although typically women with HIV infection tend to experience more rapid disease progression with lower levels of HIV in plasma.

First Impacts of HIV

Clinically recognized lymph node enlargement occurs in 35% to 40% of asymptomatic HIV-infected persons but is not significantly associated with either rate of progression of immunodeficiency or subsequent development of lymphoma. During early HIV infection, thrombocytopenia, probably caused by autoimmune platelet destruction, is common. Most HIV-infected individuals remain asymptomatic until their CD4 count falls to less than 200 cells/mm³, a fact that contributes to the late diagnosis of disease. In parts of the world where tuberculosis is hyperendemic, persons with HIV with CD4 counts greater than 200 cells/mm³ are at high risk for development of tuberculosis.

Early Immunodeficiency

Patients with moderate immunodeficiency (CD4 counts between 200 and 500 cells/mm³) exhibit diminished antibody response to protein and polysaccharide antigens, as well as decreased cell-mediated immune function. These functional impairments are manifested clinically by a threefold to fourfold increase in the incidence of bacteremic pneumonias caused by common pulmonary pathogens (especially *Streptococcus pneumoniae* and *Haemophilus influenzae*) and by a marked increase in incidence of active pulmonary tuberculosis in endemic areas (Table 101-2).

Mucocutaneous lesions may be the first manifestations of immune dysfunction. These include reactivation of varicella-zoster (shingles), recurrent genital herpes simplex virus (HSV) infections, oral or vaginal candidiasis, and oral hairy leukoplakia (see later discussion). The earliest clinical manifestation of HIV infection in women may be frequent recurrence of *Candida* vaginitis in the absence of predisposing factors. Recurrent large, painful genital, perianal, or perineal ulcers caused by HSV type 2, are more frequent in women than in men. HIV-infected women show an increased prevalence of high-grade squamous intraepithelial lesions on Papanicolaou (Pap) smear. Both men and women may show similarly increased rates of dysplasia or neoplasia on rectal Pap smear.

Opportunistic Infections

With advanced immunodeficiency, indicated by CD4 counts lower than 200 cells/mm³, patients are at high risk for development of OIs (see Table 101-2). Before the availability of effective

TABLE 101-2 PROGRESSIVE COMPLICATIONS OF HIV INFECTION BY CD4 COUNT

CD4 COUNT (CELLS/MM ³)	OPPORTUNISTIC INFECTION OR NEOPLASM
>500	Herpes zoster Tuberculosis
200-500	Oral hairy leukoplakia <i>Candida</i> pharyngitis (thrush) Kaposi's sarcoma, mucocutaneous Bacterial pneumonia, recurrent Cervical or anal neoplasia
100-200	<i>Pneumocystis jirovecii</i> pneumonia <i>Histoplasma capsulatum</i> infection, disseminated Kaposi's sarcoma, visceral Progressive multifocal leukoencephalopathy Lymphoma, non-Hodgkin's
<100	<i>Candida</i> esophagitis Cytomegalovirus retinitis <i>Mycobacterium avium-intercellulare</i> <i>Toxoplasma gondii</i> encephalitis <i>Cryptosporidium parvum</i> enteritis <i>Cryptococcus neoformans</i> meningitis Herpes simplex virus, chronic, ulcerative Cytomegalovirus esophagitis or colitis Primary central nervous system lymphoma

antiretroviral drugs and use of prophylactic antibiotics, 60% of HIV-infected North American men developed *Pneumocystis* pneumonia (PCP). Incidence of *Toxoplasma* encephalitis before the availability of ART in the United States was estimated to be as high as 3.9 per 100 patient-years. CD4 counts lower than 50 cells/mm³ indicate profound immunosuppression and, in the absence of effective ART, are associated with a high mortality rate within the subsequent 12 to 24 months.

Cytomegalovirus (CMV) retinitis, which can lead rapidly to blindness, and disseminated *Mycobacterium avium-intracellulare* (MAI) infection occur frequently in the absence of therapy. They respond adequately to specific therapy only if it is accompanied by effective control of viral replication.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Identification of persons with HIV and support of linkage to effective care are critical public health priorities. Recent studies have demonstrated reduced transmission of HIV associated with ART. Despite the acknowledged priority of early diagnosis, the median CD4 count at diagnosis has remained fairly constant in the range of 175 cells/mm³, indicating persistent delays in testing and treatment.

The CDC and the U.S. Preventive Services Task Force recommend that all persons between the ages of 13 and 64 years be tested for HIV once, with repeat testing and testing outside of this age group based on assessed risk for infection and reinfection. All pregnant women should routinely be offered HIV testing. The CDC, to meet this goal, further recommends that HIV testing be considered a part of routine medical care, without any requirement for written consent or formal pretest and post-test counseling. Pretest discussion is important to ensure that patients appreciate that they are being tested and that treatment is available if they are found to be HIV positive.

Standard testing for HIV infection begins with detection of antibodies to HIV in serum or in oral fluid. Positive antibody tests are confirmed by assessing for the presence of at least two

viral proteins through Western blot assays. These techniques are highly sensitive in detecting HIV antibody, but individuals who have been infected recently may be antibody negative. During a window period, typically 1 to 2 weeks, infected persons have detectable HIV RNA and core p24 antigen in their plasma. If the initial enzyme-linked immunosorbent assay (ELISA) result is negative in a person recently exposed to HIV, repeat ELISA at 6 weeks and 3 months are indicated. In a person who is at high risk for HIV exposure, an indeterminate Western blot reaction pattern often represents early seroconversion; in such cases, a positive plasma HIV RNA concentration (i.e., >10,000 copies/mL) indicates acute HIV infection.

Rapid point-of-care testing methods play an important role in HIV testing in many clinical and community settings. These rapid test kits can provide results within 30 minutes, but they require confirmation by antibody-based tests. Fourth-generation assays for HIV have recently been developed; they combine tests for antibodies and viral proteins in a single assay.

TREATMENT

Initial Counseling and Ambulatory Evaluation

Once HIV infection is recognized, the physician should discuss, in an unhurried manner, the clinical course and treatment of HIV infection and the use of immunologic and virologic studies (e.g., CD4 counts, PVL assays) to guide therapy. The physician should then emphasize that, with effective currently available ART, HIV disease progression can be prevented indefinitely. Stigma related to HIV remains an important concern and a key barrier to engagement in care. Addressing this as part of post-test counseling and intake to care is key to retention in care for persons newly diagnosed.

Prevention of further transmission through unprotected sex or sharing of needles must be discussed at the first visit and periodically thereafter. It is important to emphasize that these high-risk activities place not only the other person but also the patient at risk because they may lead to transmission of new and potentially drug-resistant HIV strains to the patient.

The initial evaluation should include both an HIV-oriented review of systems and a complete physical examination. In particular, the skin must be examined for HIV-associated rashes and Kaposi's sarcoma. Examination of the oral cavity may reveal thrush, gingivitis, hairy leukoplakia, superficial ulcers caused by HSV, aphthous ulcers, or lesions characteristic of Kaposi's sarcoma. In persons with very advanced disease, the optic fundi may have hemorrhagic lesions characteristic of CMV retinitis. Lymph node enlargement, hepatomegaly, splenomegaly, and any genital lesions should all be carefully noted. Neurologic examination for both peripheral neuropathy and decreased global cognition deserves close attention.

Laboratory Monitoring

The CD4 count and the PVL should be measured at the first visit, and the patient should be shown the results. Graphic illustrations of the interaction between PVL and CD4 can be useful to increase patient understanding. HIV genotyping to assess for drug resistance should also be performed (see later discussion).

The PVL is a key measure of treatment adherence and is repeated at intervals, initially every 3 to 4 months. For patients

with suppressed virus who are stable on ART, current guidelines allow for PVL monitoring at 6-month intervals. For those who are not taking or have only recently started ART and have a CD4 count lower than 200 cells/mm³, CD4 monitoring is typically repeated every 3 to 4 months along with the PVL monitoring. Once a patient is stable on treatment, with suppressed virus (<200 copies) and CD4 counts higher than 200 cells/mL, the value of CD4 monitoring is less clear, and guidelines allow for extending the monitoring interval to yearly.

Screening for Associated Infections

Tuberculosis

Purified protein derivative (PPD) testing should be performed early in the course of HIV infection. Induration of 5 mm or more should be considered positive. Any patient with a positive PPD test result should be evaluated for the presence of active tuberculosis; if no active disease is present, the patient should receive 9 months of prophylaxis with isoniazid or combination drug therapy for a shorter period (see [Chapter 92](#)). If active tuberculosis is identified, multidrug therapy should be initiated after careful consideration of possible interactions with antiretroviral medications.

Sexually Transmitted Diseases

Serologic testing for syphilis should be followed by prompt treatment if the patient is confirmed to be positive. Syphilis infections are common within many populations highly impacted by HIV, and co-infection with syphilis increases the risk of transmission of HIV to others. Regular screening is recommended.

Hepatitis

Liver disease is an important cause of morbidity and mortality for persons with HIV. Screening for hepatitis A, B, and C at baseline is recommended, and those not immune to hepatitis A or B should receive immunization. Hepatitis C is highly prevalent among persons who acquired HIV from injection drug use, and increasing numbers of cases of sexual transmission of hepatitis C among MSM with HIV are being described. Given the lack of an effective vaccine for hepatitis C, regular screening is recommended for persons with ongoing risk of exposure.

Other Infections

Screening for antibodies to *Toxoplasma gondii* should be considered for persons with low CD4 counts who are potentially in need of prophylaxis. Persons from endemic areas may be screened for histoplasmosis and coccidiomycosis and considered for prophylaxis if positive.

Immunization

Antibody responses to polysaccharides are better among patients with higher CD4 counts. The optimal timing of immunization is uncertain. For persons with low CD4 counts, most physicians provide initial immunization and reimmunization for certain vaccines after immune reconstitution occurs. Live vaccines should be avoided in persons with CD4 counts lower than 200 cells/mm³.

Pneumococcus

All persons with HIV should receive a dose of PCV14 (Pneumovax), followed by a dose of PPV23 (Pneumovax) at least 8 weeks later. If previously vaccinated with PPV23, the patients should receive PCV13 at least 1 year after PPV23. Patients should have a CD4 cell count greater than or equal to 200/microliter. A second PPV23 dose is recommended 5 years after the first PPV23.

Influenza Virus

Persons with HIV have excess morbidity and mortality associated with influenza and its complications. They should receive seasonal influenza vaccination yearly.

Herpes Zoster

Reactivation of herpes zoster viral infection, resulting in shingles, is a significant cause of morbidity among persons with HIV disease. Because the shingles vaccine is a live attenuated vaccine, additional studies were conducted to assess the safety of this vaccine in persons with HIV. Although there were no reports of excess risk in these trials, final review is still pending, and the vaccine does not carry an indication from the U.S. Food and Drug Administration (FDA) for use in persons with HIV.

Human Papillomavirus

The CDC recommends use of the human papillomavirus (HPV) vaccine in boys or girls at age 11 or 12 regardless of HIV status, in MSM, and in persons with immune compromise, including those with HIV, up to the age of 26 if not previously vaccinated.

Hepatitis A and B Viruses

Persons with HIV should be assessed by serology for prior exposure to hepatitis A and B. Those found to be susceptible to infection should receive immunization.

Other Health Screening

Cervical Cancer

HIV-infected women should have two Pap smears 6 months apart; if the they are both normal, Pap smears should be repeated once a year. Persons with cellular atypia on a Pap smear should be referred for colposcopy.

Rectal Cancer

HPV is associated with risk of cervical cancer in women and rectal cancer in both men and women. Although some advocate for regular screening, clear guidelines have not yet been developed for rectal cancer.

ANTIRETROVIRAL THERAPY

The goal of ART is to ensure that HIV-infected persons can lead symptom-free, productive lives. Currently available therapy makes achieving this goal possible in almost all individuals with early, asymptomatic HIV infection who have not acquired major resistance mutations as a result of earlier, suboptimal ART. The current recommendations in the United States are that therapy should be offered to all persons infected with HIV. In much of the world, thresholds for treatment based on CD4 count are

still in effect, reflecting in part the allocation of limited resources to those who are likely to experience the most immediate benefits.

Antiretroviral Drug Regimens

Evidence-based guidelines for ART have been developed by the U.S. Department of Health and Human Services. The most commonly used antiretroviral agents are presented in [Table 101-3](#). The current preferred and alternative regimens for first-line treatment are summarized in [Table 101-4](#). With rare exceptions, all recommended regimens consist of at least three fully active drugs. Increasingly, coformulation of medications has allowed the combination of multiple drugs to be taken in single tablets. Three single-tablet daily regimens are currently approved for the treatment of HIV, and more are in development. The reduced pill burden can significantly improve adherence to treatment and minimize the risk of treatment failure. The World Health Organization publishes guidelines for HIV treatment programs in resource-limited settings. They delineate first- and second-line therapies selected based on efficacy, cost, and availability.

Clinical trials assessing the benefits of early treatment have demonstrated the many health impacts of HIV that occur even before the onset of demonstrable immune deficiency. Persons who undergo structured treatment interruptions and delay treatment until their CD4 count drops to less than 500 cells/mm³ experience higher rates of cardiovascular disease, kidney disease, liver disease, and neurocognitive disorders. Although the risk increases with declining CD4 count and worsening immune function, early effects can in some cases be demonstrated before the onset of marked immunodeficiency. The demonstrated benefit of initiating ART before the CD4 count drops to less than 500 cells/mm³ was primarily attributable to these noninfectious complications of HIV disease.

TABLE 101-3 MOST FREQUENTLY USED ANTIRETROVIRAL MEDICATIONS BY CLASS

DRUG CLASS	MEDICATION
Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs)	Tenofovir
	Abacavir
	Lamivudine
	Emtricitabine
	Zidovudine
	Didanosine*
	Stavudine*
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Efavirenz
	Nevirapine
	Etravirine
	Rilpivirine
Protease inhibitors [†]	Atazanavir
	Darunavir
	Fosamprenavir
	Lopinavir
	Saquinavir
Integrase inhibitors	Raltegravir
	Elvitegravir
	Dolutegravir
CCRS inhibitor	Maraviroc
	Fusion inhibitor

*Infrequently used due to toxicity.

[†]Most protease inhibitors require a second medication to boost the levels of the drug by inhibiting drug metabolism. Ritonavir at a dose of 100 mg daily is most commonly used. Cobicistat was recently approved for use as part of a fixed-dose combination, and its potential for expansion is currently being studied.

TABLE 101-4 PREFERRED AND ALTERNATIVE REGIMENS FOR FIRST-LINE ANTIRETROVIRAL THERAPY ACCORDING TO DHHS GUIDELINES

PILL BURDEN	COMBINATION*	LIMITATIONS†
PREFERRED REGIMENS		
Single pill	Atripla (tenofovir, emtricitabine, efavirenz)	CrCl >50, teratogenicity
2 pills once daily	Truvada (tenofovir, emtricitabine) + dolutegravir	CrCl >50
3 pills once daily	Truvada (tenofovir, emtricitabine) + atazanavir + ritonavir	CrCl >50, cirrhosis Child Pugh class A
3 pills once daily	Truvada (tenofovir, emtricitabine) + darunavir + ritonavir	CrCl >50, cirrhosis Child Pugh class A
BID regimen: 1 pill daily, 1 pill twice daily	Truvada (tenofovir, emtricitabine) + raltegravir	CrCl >50
ALTERNATIVE REGIMENS		
Single pill	Complera (tenofovir, emtricitabine, rilpivirine)	CrCl >50,‡ PPI contraindicated
Single pill	Stribild (tenofovir, emtricitabine, elvitegravir, cobicistat)	CrCl >70,‡ cirrhosis Child Pugh class A
Single pill	Triumeq (abacavir lamivudine dolutegravir)	HLA-B5701 negative, CrCl >50
3 pills once daily	Epzicom (abacavir, lamivudine) + atazanavir + ritonavir	HLA-B5701 negative,‡ CrCl >50,‡ cirrhosis Child Pugh score <5
3 pills once daily	Epzicom (abacavir, lamivudine) + rilpivirine	HLA-B5701 negative, CrCl >50,‡ PPI contraindicated, cirrhosis Child Pugh score <5
BID regimen: 1 pill daily, 1 pill twice daily	Truvada (tenofovir, emtricitabine) OR Epzicom (abacavir, lamivudine) + etravirine	CrCl >50,‡ HLA-B5701 negative (abacavir), cirrhosis Child Pugh score <5 (abacavir)
4 pills once daily	Truvada (tenofovir, emtricitabine) OR Epzicom (abacavir, lamivudine) + fosamprenavir + ritonavir	CrCl >50,‡ HLA-B5701 negative (abacavir), cirrhosis Child Pugh score <5 (abacavir)
5 pills once daily	Truvada (tenofovir, emtricitabine) OR Epzicom (abacavir, lamivudine) + lopinavir/ritonavir	CrCl >50,‡ HLA-B5701 negative (abacavir), cirrhosis Child Pugh score <5 (abacavir)

CrCl, Creatinine clearance (measured in mL/min/1.73 m²); DHHS, U.S. Department of Health and Human Services; HLA, human leukocyte antigen; PPI, proton pump inhibitors.

*New antiretroviral medications as well as new formulations of medications are approved frequently. For the most up-to-date listing of preferred and alternative regimens, refer to the DHHS Guidelines for the Use of Antiretroviral Medications (see Recommended Readings).

†Tenofovir, lamivudine, and emtricitabine all require dose adjustment when the CrCl drops to <50, preventing the use of fixed-dose combinations.

‡HLA-B5701 is a genetic marker indicating risk for a hypersensitivity reaction to abacavir. Screening is indicated before the medication is started, and abacavir should not be used if the marker is present.

As persons with HIV live longer on ART, more typical diseases associated with aging become the focus of care. It can be challenging to distinguish what additive effects HIV may have to the risks associated with these conditions, particularly if comorbid substance use, smoking, and other risk factors are highly prevalent. As HIV is controlled with treatment, recognizing these risks and focusing on providing the best quality primary care will be critical to helping ensure that patients with HIV live full and healthy lives.

Baseline Resistance Testing and Development of Drug Resistance

Inconsistent intake of ART can lead to the development of HIV strains resistant to antiviral medications. At least 16% of new infections (one in six) contain mutations affecting susceptibility to one or more antiretroviral medications. For this reason, measurement of baseline resistance is recommended before ART is initiated. Close monitoring of persons with inconsistent adherence is critical. Some resistance mutations, particularly M184V, which confers resistance to lamivudine and emtricitabine, have been observed to develop with as little as a few weeks of inconsistent treatment.

When to Change Therapy

When an effective antiretroviral regimen is initiated in an asymptomatic patient with no previous ART, the PVL should decrease sharply, usually by 10-fold in 4 weeks and to an undetectable level (<50 copies/mL) within 16 to 24 weeks. If reduction of this magnitude is not achieved, the physician should assess with the patient whether adherence has been adequate. If adherence has been nearly complete (>95%), the physician and patient should consider retesting for resistance mutations and changing to

another effective regimen. Minority viral subpopulations carrying resistance mutations can rapidly overtake the sensitive virus once the selective pressure exerted by the medications. These subpopulations may become detectable only while on treatment.

If a given regimen achieves a reduction of PVL below detectable limits and continuing adherence is achieved, the patient can anticipate effective viral suppression for many years and perhaps indefinitely. Small elevations in PVL on a single determination are usually not significant. One may consult the International AIDS Society—USA resistance guidelines, which are regularly updated (www.iasusa.org/guidelines/index.html). If an antiretroviral drug must be stopped for any reason, it is important to stop temporarily all antiretroviral drugs. Alternatively, a completely new effective regimen may be initiated to sustain complete virologic suppression.

Prophylaxis against Opportunistic Infections

During the first 15 years of the HIV pandemic, the most effective medical interventions for HIV infection were prophylactic measures against OIs. The greatest success was in preventing PCP in individuals with CD4 counts lower than 200 cells/mm³; routine use of prophylaxis resulted in a greater than fourfold decrease (from 60% to <15%) in the frequency of PCP as the initial OI in North American men with HIV infection.

Specific antimicrobial prophylaxis (Table 101-5) is also effective for prevention of *T. gondii* encephalitis in patients with anti-*Toxoplasma* antibodies and CD4 counts lower than 100 cells/mm³ and for prevention of active tuberculosis in patients with positive tuberculin skin test results at any CD4 level. Prophylaxis against disseminated MAI infection is recommended at lower CD4 counts (<50 cells/mm³). Prophylaxis against CMV retinitis

TABLE 101-5 RECOMMENDATIONS FOR PRIMARY AND SECONDARY PROPHYLAXIS FOR PERSONS WITH HIV INFECTION

PATHOGEN	CD4 THRESHOLD (CELLS/MM ³)	ADDITIONAL INDICATION	PREFERRED	ALTERNATE
PRIMARY PROPHYLAXIS				
<i>Pneumocystis jirovecii</i>	<200		TMP-SMX SS or DS tablet daily	Dapsone, atovaquone
Toxoplasmosis	<100	Anti- <i>Toxoplasma</i> IgG detectable	TMP-SMX SS or DS tablet daily	Pyrimethamine-dapsone and pyrimethamine-sulfadoxine
<i>Mycobacterium avium-intercellulare</i>	<50		Azithromycin 1200 mg weekly	Clarithromycin 500 mg bid
SECONDARY PROPHYLAXIS				
<i>Mycobacterium tuberculosis</i>	Any	History of exposure to TB confirmed by PPD test or IGRA	Isoniazid depending on sensitivities	Rifampin, isoniazid+rifapentene
Cryptococcosis	<200	History of cryptococcal meningitis or cryptococcal antigen positive	Fluconazole	NA
Coccidiomycosis	<150	Antihistoplasma IgG detectable or history of coccidiomycosis	Fluconazole or itraconazole	NA
Histoplasmosis	<150	Anticoccidiomyces IgG detectable	Itraconazole	NA
Cytomegalovirus (CMV)	<50	Ocular or extraocular findings consistent with CMV infection	Ganciclovir 3 g/day	NA

DS, Double-strength; IgG, immunoglobulin G; IGRA, interferon- γ release assay; NA, not applicable; PPD, purified protein derivative; SS, single-strength; TB, tuberculosis; TMP-SMX, trimethoprim-sulfamethoxazole.

is moderately effective in patients with CD4 counts lower than 50 cells/mm³, but prompt initiation of effective ART with early treatment of active disease is the currently preferred strategy. Prophylaxis is very effective against recurrent HSV type 2 infection (with acyclovir, famciclovir, or valacyclovir) and against recurrent *Candida* esophagitis (with fluconazole) but should generally be reserved for those patients with recurrent symptomatic disease. Persons from areas where histoplasmosis or coccidiomycosis is endemic should be considered for primary prophylaxis (with fluconazole) if they have detectable antibodies and their CD4 count is lower than 150 cells/mm³. No guidelines exist for cryptococcal antigen screening.

After the CD4 count rises on ART, withdrawal of prophylaxis against specific OIs is reasonable. After initiation of effective ART and two consecutive CD4 counts at least 3 months apart that exceed 100 cells/mm³, prophylaxis against CMV and MAI may be withdrawn safely; likewise, if the two consecutive counts exceed 200 cells/mm³, prophylaxis against PCP and *T. gondii* may be withdrawn.

 For a deeper discussion of these topics, please see Chapter 389, "Prophylaxis and Management of Complications of HIV/AIDS: Infectious, Neoplastic, and Metabolic," in Goldman-Cecil Medicine, 25th Edition.

MANAGEMENT OF SPECIFIC CLINICAL MANIFESTATIONS OF HIV INFECTION

Clinical manifestations of HIV include not only OIs associated with immunodeficiency but also HIV-associated malignancies and other noninfectious complications of HIV. The manifestations of HIV vary significantly in time of onset (see Table 101-2). Before the onset of infectious complications, some HIV-associated cancers such as non-Hodgkin's lymphoma and HPV-associated carcinomas can develop. Infectious complications such tuberculosis can manifest at any CD4 count and occur with increased frequency in association with HIV. Infectious complications that occur with higher CD4 counts respond to routine

therapy for the specific infection (e.g., appropriate β -lactam antibiotic for pneumococcal pneumonia, standard multidrug therapy for pulmonary tuberculosis), whereas OIs occurring with CD4 counts lower than 200 cells/mm³ require chronic suppressive therapy after treatment of the acute infection (e.g., PCP pneumonia, CMV retinitis, *Cryptococcus neoformans* meningitis).

 For a deeper discussion of these topics, please see Chapter 389, "Prophylaxis and Management of Complications of HIV/AIDS: Infectious, Neoplastic, and Metabolic," in Goldman-Cecil Medicine, 25th Edition.

Initial Assessment of HIV-Associated Illnesses

Assessment of a patient's immunologic status is key in the evaluation of persons with HIV when there is a new presenting illness or complaint. If the patient is on ART and has had a recent CD4 assessment, that count is the best indicator of their status. Persons without recent CD4 testing should be presumed to be immunocompromised unless there is clear information to suggest the contrary. If there has been a treatment interruption, the CD4 count should return to its prior nadir after about 12 months of interruption. During an acute illness, the absolute CD4 count may decline; therefore, a measured CD4 count during an acute illness can underestimate an individual's true immune function.

Constitutional Symptoms

Nonspecific symptoms may be the initial clinical manifestations of severe immunodeficiency. Patients may develop unexplained fever, night sweats, anorexia, weight loss, or diarrhea. These symptoms may last for weeks or months before the development of identifiable OIs in patients who do not receive effective ART. Most persistent fevers occurring late in the course of HIV infection reflect a definable OI. The most common cause of unexplained fever and anemia in patients with CD4 counts lower than 50 cells/mm³ is disseminated MAI infection. This may be diagnosed by bone marrow biopsy, but blood cultures in

Mycobacterium-selective media are usually positive. Treatment usually results in resolution of fever and weight gain. Aggressive non-Hodgkin's lymphoma may cause unexplained fever and weight loss, a rapidly enlarging spleen, or asymmetrical lymph node enlargement.

Wasting and Changes in Body Morphology

Cachexia may be prominent in advanced HIV disease. In some instances, the wasting is caused by an intercurrent infectious process. Heightened production of tumor necrosis factor may contribute to fever, cachexia, and hypertriglyceridemia in advanced HIV disease. If orthostatic hypotension occurs, especially if it is associated with hyperkalemia, the possibility of adrenal insufficiency, which rarely can result from CMV adrenalitis, should be investigated. Most patients with AIDS-associated cachexia gain weight and achieve a sense of well-being after initiation of effective ART. If the cachexia is refractory, weight gain may be enhanced by administration of recombinant growth hormone, nonmethylated androgens, or megestrol, but definitive indications for these therapies have not been established.

Older antiviral agents, particularly nucleoside/nucleotide reverse transcriptase inhibitors (e.g., didanosine, stavudine) and the early protease inhibitors, were associated with alterations in fat distribution known as lipodystrophy and lipoatrophy. Patients with long-term exposure to these medications may develop a loss of fat in the face and on the extremities. At the same time, they develop prominent central obesity including a buffalo hump and marked abdominal obesity. These changes typically persist even after the medication is discontinued and are associated with increased risk of cardiovascular disease.

Cutaneous Disease

Cutaneous infections ultimately occur in most patients with untreated HIV infection. Persons with HIV experience both higher rates of more typical skin infections (e.g., folliculitis, cellulitis) and OIs such as disseminated herpes zoster or HSV, bacillary angiomatosis, and fungal infections. Most of these diseases respond to specific therapy. Noninfectious skin manifestations include exacerbation of underlying psoriasis, seborrhea dermatitis, and eosinophilic folliculitis. Skin lesions can equally be associated with some disseminated infectious complications or malignancies. If a patient has unexplained constitutional symptoms, a thorough skin examination may provide important findings to support a diagnosis.

 For a deeper discussion of these topics, please see Chapter 392, "Skin Manifestations in Patients with Human Immunodeficiency Virus Infection," in Goldman-Cecil Medicine, 25th Edition.

Oral Disease

Oral *Candida* stomatitis (thrush) is often the earliest recognized OI. Early thrush may be entirely asymptomatic; as the infection becomes more extensive, it causes pain on eating. The characteristic cheesy white exudate on the mucous membranes can easily be scraped off, and the underlying mucosa may be normal or inflamed.

Xerostomia is common among patients with HIV and is often underappreciated. It can be a significant contributor to poor dentition and gingivitis, which can contribute to other adverse health consequences for the patient.

Severe gingivitis can be a significant problem in patients with AIDS, leading to local and systemic infection as well as loss of teeth.

Oral ulcers may be caused by HSV, but often they represent aphthous lesions of uncertain cause. Small oral aphthous ulcers may respond to topical corticosteroids, whereas large oral or esophageal ulcers require oral administration of thalidomide or corticosteroids. It is important to obtain cultures for HSV and CMV to exclude a viral origin before initiating corticosteroid or thalidomide therapy. Thalidomide should not be used in women of childbearing age because of its teratogenic effect.

Oral hairy leukoplakia is a white, lichenified, plaque-like lesion most commonly seen on the lateral surfaces of the tongue that is probably caused by Epstein-Barr virus (EBV). It is painless, may remit and relapse spontaneously, and almost always responds to effective ART.

Kaposi's sarcoma has a predilection for the oral cavity and skin. Oral lesions may be purple, red, or blue and may be raised or flat. Usually painless, these lesions cause symptoms when they enlarge, bleed, or ulcerate (see later discussion).

Esophageal Disease

Symptomatic esophageal disease seldom occurs with CD4 counts greater than 100 cells/mm³. Pain on swallowing and substernal burning are common and most often indicate *Candida* esophagitis, particularly when oral thrush is present. Diagnostic esophagoscopy with biopsy, cytology, and culture should be performed if symptoms do not rapidly respond (within 3 to 5 days) to antifungal therapy.

If esophagoscopy shows ulcerative lesions, they are usually caused by CMV (50%), aphthae (45%), or HSV (5%). Because each of these lesions is responsive to appropriate therapy, definitive etiologic diagnosis is essential. CMV esophageal ulcers respond well to intravenous ganciclovir or foscarnet therapy for 2 to 3 weeks or until resolution is confirmed endoscopically. Esophageal ulcerations caused by HSV usually respond well to intravenous acyclovir.

 For a deeper discussion of these topics, please see Chapter 390, "Gastrointestinal Manifestations of HIV and AIDS," in Goldman-Cecil Medicine, 25th Edition.

Pulmonary Diseases

Pulmonary infections are common in persons living with HIV and range from nonspecific interstitial pneumonitis to life-threatening pneumonias (Table 101-6). HIV-infected persons have a threefold to fourfold increased risk of bacterial pneumonia, usually caused by encapsulated bacteria, including *S. pneumoniae* and *H. influenzae*. The increased risk begins with modest degrees of immunodeficiency (CD4 counts of 200 to 500 cells/mm³). The onset is often abrupt, and the response to prompt initiation of therapy is usually good; however, delay in appropriate antimicrobial therapy may result in a fulminant downhill course. For those with CD4 counts greater than 200 cells/mm³,

TABLE 101-6 PULMONARY COMPLICATIONS OF HIV INFECTION: DIFFERENTIAL DIAGNOSIS AND TREATMENT

CONDITION	CHARACTERISTICS	CHEST RADIOGRAPH	DIAGNOSIS	TREATMENT
<i>Pneumocystis jirovecii</i> pneumonia	Subacute onset, dry cough, dyspnea	Interstitial infiltrate most common	BAL or induced sputum for organism by stain	TMP-SMX, pentamidine or atovaquone or primaquine + clindamycin
Bacterial (<i>Pneumococcus</i> , <i>Haemophilus</i> most common)	Acute onset, productive cough, fever, chest pain	Lobar or localized infiltrate	Sputum Gram stain and culture, blood culture	Cefuroxime or alternative antibiotics
Tuberculosis	Chronic cough, weight loss, fever	Localized infiltrate, lymphadenopathy	Sputum acid-fast stain and mycobacterial culture	Isoniazid, rifampin, pyrazinamide, ethambutol
Kaposi's sarcoma	Asymptomatic or mild cough	Pulmonary nodules, pleural effusion	Open lung biopsy	Chemotherapy

BAL, Bronchoalveolar lavage; TMP-SMX, trimethoprim-sulfamethoxazole.

therapy should follow existing guidelines for empirical treatment of pneumonia (see [Chapter 92](#)). Pursuit of diagnostic studies that can support a definitive diagnosis is important, particularly if the patient's CD4 count is near 200 cells/mm³ or the features or clinical course of pneumonia are atypical.

As with acute bacterial pneumonia, active pulmonary tuberculosis may develop at a time when the CD4 count remains well above 200 cells/mm³ (see [Table 101-6](#)). Chest radiographs in HIV-infected patients may show features of primary tuberculosis, including hilar adenopathy, lower or middle lobe infiltrates, miliary pattern, or pleural effusions, as well as classic patterns of reactivation. Extrapulmonary *Mycobacterium tuberculosis* infection also occurs with increased frequency in patients with advanced immunodeficiency. Both pulmonary and extrapulmonary tuberculosis respond promptly to the use of four antituberculosis drugs.

Pneumonia caused by PCP remains a common life-threatening infection in persons with AIDS. Patients frequently report a gradual onset of nonproductive cough, fever, and shortness of breath with exertion; a productive cough suggests another process. A substernal "catch" with inspiration is common and is suggestive of PCP. In contrast to the acute onset of PCP in other immunocompromised patients, AIDS patients with PCP may have pulmonary symptoms for weeks before consulting a physician. Arterial hypoxemia is typical and rapidly worsens with slight exertion. Oxygen desaturation with exercise, as measured by pulse oximetry, can suggest the diagnosis. The chest radiograph often shows a subtle interstitial pattern but may be entirely normal. The presence of pleural effusions suggests a cause other than PCP.

If PCP is suspected clinically, therapy should be started immediately; treatment for several days does not interfere with the ability to make a specific diagnosis. Confirmation of PCP is essential; delay in establishing a correct diagnosis of another treatable condition may be lethal. An induced sputum sample can sometimes confirm the diagnosis, but most patients require bronchoalveolar lavage, which is adequate to diagnose PCP in more than 95% of patients. Treatment with high-dose trimethoprim-sulfamethoxazole (TMP-SMX) for 3 weeks is effective therapy (see [Table 101-6](#)). Patients with PCP and arterial hypoxemia (oxygen tension 75 mm H₂O on breathing of room air) benefit from the administration of corticosteroids (40 mg of prednisone twice daily), with tapering of the drug over a 3-week period.

For a deeper discussion of these topics, please see [Chapter 391, "Pulmonary Manifestations of Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome,"](#) in *Goldman-Cecil Medicine, 25th Edition*.

Disseminated histoplasmosis and coccidioidomycosis occur with much greater frequency in persons with HIV infection. Either fungal infection can cause nodular infiltrates or a miliary pattern on chest radiography. Histoplasmosis usually involves bone marrow as well as skin, and examination of the bone marrow often shows the organism. Standard treatment of disseminated mycoses in AIDS patients is high-dose liposomal amphotericin. Because relapse is common, oral azole therapy (fluconazole for coccidioidomycosis, itraconazole for histoplasmosis) must be continued even after resolution of signs and symptoms. For patients treated for histoplasmosis, secondary prophylaxis may be discontinued after 1 year of therapy, provided that the CD4 count is at least 150 cells/mm³, blood cultures are negative, and the HIV serum *Histoplasma* antigen titers are low. Patients treated for systemic, meningeal, or diffuse pulmonary coccidioidomycosis have a greater risk of relapse and probably should continue suppressive therapy indefinitely.

For a deeper discussion of these topics, please see [Chapter 332, "Histoplasmosis,"](#) and [Chapter 333, "Coccidioidomycosis,"](#) in *Goldman-Cecil Medicine, 25th Edition*.

Cardiovascular Disease

As the population with HIV ages, cardiovascular disease is becoming an increasingly important cause of morbidity and mortality. Persons with HIV experience higher rates of cardiovascular disease. Even with suppressive ART, some increased risk remains, likely attributable in part to risk factors such as persistent residual immunologic activation, high rates of tobacco use, hyperlipidemia, metabolic syndrome, diabetes, or chronic kidney disease.

Pericarditis and Pericardial Effusions

Pericardial effusions are a well recognized complication of HIV disease and may be result from infections or malignancy (see [Chapter 10](#)). In many cases, no specific cause is identified and effusions resolve without specific treatment. In places where tuberculosis is endemic, constrictive pericarditis secondary to tuberculosis is an important consideration. In addition, pericarditis and effusions secondary to acute infections and both non-Hodgkin's lymphoma and Kaposi's sarcoma may occur.

Congestive Heart Failure

In addition to ischemic cardiomyopathy, persons with HIV may develop congestive heart failure due to an HIV-associated dilated cardiomyopathy and infectious myocarditis.

Gastrointestinal Diseases

HIV affects the gastrointestinal tract early in infection, with profound depletion of memory CD4 T cells in gut-associated lymphoid tissue within the first few weeks of infection. However, symptomatic disease of the gut is unusual in the early stage of infection.

With advanced immunodeficiency (CD4 count <50 cells/mm³), gastrointestinal disease manifesting as dysphagia, diarrhea, or colitis is common. Each process may contribute to inadequate nutrition, compounding the weight loss associated with advanced HIV disease. Nausea and vomiting are often related to medications. If symptoms of nausea and vomiting do not respond to empirical therapy with histamine-2 (H₂) antagonists or antiemetics, more extensive gastrointestinal evaluation is indicated.

 For a deeper discussion of these topics, please see Chapter 390, "Gastrointestinal Manifestations of HIV and AIDS," in Goldman-Cecil Medicine, 25th Edition.

Diarrhea

Diarrhea occurs, at least intermittently, in many persons with advanced immunodeficiency and may be caused by a variety of microorganisms (Table 101-7) as well as by certain antiretroviral and other medications. In many instances, no clear cause is found. Stool specimens should be cultured for the common bacterial pathogens. *Salmonella*, *Campylobacter*, and *Yersinia* species are frequent causes; the diarrhea usually responds to standard antimicrobial therapy. Patients may also have recurrent episodes of diarrhea associated with *Clostridium difficile* toxin; this probably reflects the frequent use of broad-spectrum antibiotics.

In cases of persistent diarrhea, a fresh stool specimen should be examined for parasites, using a modified acid-fast stain for *Cryptosporidium parvum*, microsporidia, and *Isospora belli*, the most common enteric protozoal infections in AIDS patients. Microsporidial infection may require biopsy with electron microscopy for diagnosis. Although cryptosporidiosis can be self-limited, massive diarrhea (up to 10 L/day) may occur.

Isosporiasis responds to oral TMP-SMX, and several microsporidial species respond to albendazole. Symptoms of both cryptosporidiosis and isosporiasis resolve with effective ART.

If stool diagnostic studies are negative and diarrhea persists, patients should undergo endoscopy (see Chapter 34). Biopsy of the duodenum or small bowel may show histologic evidence of cryptosporidial, microsporidial, MAI, or CMV infection. Biopsy of the colon may indicate HSV proctitis, CMV colitis, or MAI infection. For patients with refractory diarrhea, symptomatic treatment may improve the quality of life.

Hepatitis

Abnormalities on liver function testing are common in HIV disease and often are nonspecific. Elevations of serum alanine aminotransferase and aspartate aminotransferase often represent chronic active hepatitis B or C but may reflect hepatic inflammation caused by medications, including TMP-SMX and antiretroviral agents. Alcohol use is highly prevalent among persons with HIV and may contribute, as can use of other drugs such as MDMA ("ecstasy").

Marked elevations in serum alkaline phosphatase levels may reflect infiltrative disease of the liver (e.g., MAI, CMV, tuberculosis, tumor) but also may occur in patients with acalculous cholecystitis, cryptosporidiosis, or AIDS-associated sclerosing cholangitis. Syphilitic hepatitis has been well described and may be characterized by a more pronounced elevation in alkaline phosphatase.

Viral hepatitis, particularly hepatitis C, is an important cause of morbidity and mortality among persons with HIV. More than 80% of persons with HIV who have a history of injection drug use are co-infected with hepatitis C, and the risk of progression to end-stage liver disease is greater for those with HIV hepatitis C co-infection. Occult hepatitis infections (antibody negative but with detectable RNA or DNA) have been described for both hepatitis B and hepatitis C, particularly in the context of advanced immunodeficiency. The response to hepatitis C therapy has historically been significantly worse for those co-infected with HIV, but this may be less true with the new generation of direct-acting agents for treatment of hepatitis C.

Genital Diseases

Primary and secondary syphilis remains a concern among persons with HIV, particularly MSM. Early neurologic

TABLE 101-7 AIDS-ASSOCIATED DIARRHEA: DIFFERENTIAL DIAGNOSIS AND TREATMENT

CAUSE	CHARACTERISTICS	DIAGNOSIS	TREATMENT
<i>Cryptosporidium parvum</i>	Variable from high-frequency to large-volume diarrhea	Acid-fast stain of stool	Nitazoxanide ART
<i>Clostridium difficile</i>	Abdominal pain, fever common	<i>C. difficile</i> toxin in stool or endoscopy	Metronidazole or vancomycin
Cytomegalovirus	Small bowel movements with blood or mucus (colitis)	Colonoscopy and biopsy	Ganciclovir
<i>Mycobacterium avium-intracellulare</i>	Abdominal pain, fever, retroperitoneal lymphadenopathy	Blood culture or endoscopy with biopsy	Multidrug regimen including clarithromycin, ethambutol
<i>Salmonella</i> or <i>Campylobacter</i>	Sometimes with blood or mucus in bowel movements (colitis)	Stool culture	Fluoroquinolone (check sensitivities)
Microsporidia	Watery diarrhea	Calcofluor white or trichrome staining of stool; electron microscopy of biopsy material	Albendazole, ART
<i>Isospora belli</i>	Watery diarrhea	Acid-fast stain of stool	TMP-SMX

ART, Antiretroviral therapy; TMP-SMX, trimethoprim-sulfamethoxazole.

involvement has been well described, and a thorough history and examination to exclude neurologic complications is important in the evaluation of incident cases. Treatment regimens for persons with HIV, based on stage of presentation, are the same as for those without HIV. However, persons with HIV take longer to achieve a full reduction in rapid plasma reagin (RPR) titer and may continue to have low-level demonstrable RPR titers even after successful treatment.

Recurrent genital ulcers are most often caused by HSV. Viral culture or specific immunofluorescence of ulcer scrapings confirms the diagnosis.

Candida species, most often *Candida albicans*, can cause an irritating vulvovaginitis in women with HIV infection as well as in healthy HIV-seronegative women. A potassium hydroxide preparation of the cheesy white exudate reveals budding yeast or pseudohyphae.

Bacterial vaginosis and trichomoniasis are common, and although both typically respond to specific treatment (e.g., metronidazole), bacterial vaginosis often recurs.

For more information on sexually transmitted diseases, see Chapter 100.

Nervous System Diseases

Nervous system complications ultimately occur in most persons with untreated HIV infection. They range from mild cognitive disturbances or peripheral neuropathy to severe dementia and life-threatening central nervous system (CNS) infections. As with other lentiviruses, HIV enters microglial cells of the CNS early in the course of infection. Both direct neuronal destruction and effects of viral proteins on neuronal cell function may contribute to nervous system disease in AIDS.

Cognitive Dysfunction

Intellectual impairment rarely occurs early in HIV infection, but subtle changes (e.g., decreased learning accuracy and learning speed) may be present in patients with only moderate immunodeficiency. AIDS dementia complex (ADC) often begins insidiously and usually progresses over months to years. ADC is characterized by poor concentration, diminished memory, slowing of thought processes, motor dysfunction, and occasionally behavioral abnormalities characterized by social withdrawal and apathy. Symptoms of clinical depression overlap with many of the characteristics of early ADC and must be considered carefully in differential diagnosis and therapy.

Computed tomography (CT) of the head in ADC reveals only atrophy, with enlarged sulci and ventricles, but these findings do not reliably predict cognitive deficits. The CSF is most often normal on examination. Motor abnormalities may include a progressive gait ataxia. As the disease progresses, patients may

develop focal neurologic complications characterized by spastic weakness of the lower extremities and incontinence secondary to vacuolar myelopathy.

Focal Lesions of the Central Nervous System

A large variety of neurologic problems can complicate the later stages of HIV infection. A neuroanatomic classification of these manifestations is presented in Table 101-8. Some of the more frequent or treatable problems are discussed here and in the next section.

Several opportunistic complications of HIV infection produce focal CNS lesions. Patients with focal neurologic signs, seizures of new onset, or recent onset of rapidly progressive cognitive impairment should undergo magnetic resonance imaging (MRI) or CT of the brain. Toxoplasmosis, CNS lymphoma, and progressive multifocal leukoencephalopathy (PML) are the most common causes of CNS focal lesions in this setting (Table 101-9).

In the absence of ART, *T. gondii* encephalitis occurs in up to one third of HIV-infected patients who have serologic evidence of *T. gondii* infection, but is rare in individuals who have no such antibodies. Patients often have progressive headache and focal neurologic abnormalities, usually associated with fever. CT with contrast usually shows multiple ring-enhancing lesions. MRI is a more sensitive technique and often shows multiple small lesions

TABLE 101-8 NEUROANATOMIC CLASSIFICATION OF NEUROLOGIC COMPLICATIONS OF HIV INFECTION

CATEGORY	CONDITION
Meningitis and headache	Aseptic meningitis Cryptococcal meningitis Tuberculous meningitis Neurosyphilis
Diffuse brain diseases	
With preservation of consciousness	AIDS dementia complex Neurosyphilis
With decreased arousal	<i>Toxoplasma</i> encephalitis Cytomegalovirus encephalitis
Focal brain diseases	Tuberculous brain abscess Primary central nervous system lymphoma Progressive multifocal leukoencephalopathy Cerebral toxoplasmosis Neurosyphilis
Myelopathies	Subacute or chronic progressive vacuolar myelopathy Cytomegalovirus myelopathy
Peripheral neuropathies	Predominantly sensory polyneuropathy Toxic neuropathies Autonomic neuropathy Cytomegalovirus polyradiculopathy
Myopathies	Noninflammatory myopathy Zidovudine myopathy

TABLE 101-9 NEUROLOGIC COMPLICATIONS OF HIV INFECTION

CONDITION	CLINICAL ONSET			NEURORADIOLOGIC FEATURES		
	Time	Alertness	Fever	Number of Lesions	Characteristics of Lesions	Location of Lesions
Cerebral toxoplasmosis	Days	Reduced	Common	Usually multiple	Spherical, ring enhancing	Basal ganglia, cortex
Primary CNS lymphoma	Days to weeks	Variable	Absent	One or few	Irregular, weakly ring enhancing	Periventricular
PML	Weeks to months	Variable	Absent	Often multiple	Multiple lesions visible on MRI	White matter

MRI, Magnetic resonance imaging; PML, progressive multifocal lymphoma.

not apparent on CT. Management includes initiation of empirical therapy with pyrimethamine, sulfadiazine, and folinic acid. Brain biopsy should be reserved for patients with neurologic deterioration, those with no serum antibodies to *T. gondii* who have neuroimaging findings atypical for toxoplasmosis, those with discordant results between PCR of the CSF for EBV and thallium-enhanced single-photon emission computed tomography (SPECT) scans, and those whose lesions do not respond after 10 to 14 days of antiprotozoal treatment. After the initial response, patients must remain on chronic suppressive therapy until a sustained rise in CD4 count (>200 cells/mm³) is achieved with effective ART.

Primary CNS lymphoma complicates advanced HIV infection in 3% to 6% of cases and is almost invariably associated with detectable EBV DNA in the CSF. Lesions may be single or multiple and are often weakly ring enhancing. Irradiation often provides remission, which may be sustained as immune function is restored by effective ART.

PML is a demyelinating disease caused by a papovavirus (JC virus). Presenting signs and symptoms may include progressive dementia, visual impairment, seizures, and hemiparesis. MRI usually shows multiple lesions predominantly involving the white matter. These lesions are usually less visible on CT than on MRI and are not ring enhancing, helping to distinguish PML from other mass lesions of the CNS. There is no effective specific treatment for PML; the disease often, but not always, regresses in response to effective ART.

 For a deeper discussion of these topics, please see Chapter 394, "Neurologic Complications of Human Immunodeficiency Virus Infection," in Goldman-Cecil Medicine, 25th Edition.

Central Nervous System Diseases without Prominent Focal Signs

Evaluation of the HIV-infected patient with fever and headache is difficult because of the often subtle manifestations of serious CNS lesions in immunocompromised patients. Management of bacterial meningitis is the same as for non-immunocompromised patients. Meningeal diseases in HIV-infected patients often fall into the broad categories of aseptic meningitis, chronic meningitis, and meningoencephalitis.

 For a deeper discussion of these topics, please see Chapter 394, "Neurologic Complications of Human Immunodeficiency Virus Infection," in Goldman-Cecil Medicine, 25th Edition.

Aseptic Meningitis

Patients with aseptic meningitis, which can be a manifestation of the acute retroviral syndrome, complain most often of headache. Their sensorium is generally intact, and findings on neurologic examination are normal. In the individual with established HIV infection, aseptic meningitis may result from several potentially treatable causes.

Chronic Meningitis

Patients with chronic meningitis characteristically have headache, fever, difficulty in concentrating, or changes in sensorium.

CSF examination shows low glucose concentration, elevated protein level, and mild to modest lymphocytic pleocytosis.

Cryptococcal meningitis is the most common type. The presence of cryptococcal antigen in serum or CSF or a positive CSF India ink preparation establishes the diagnosis. Treatment with amphotericin B for at least 2 weeks, followed by high-dose fluconazole, is usually effective. Serial lumbar punctures, with removal of CSF to decrease intracranial pressure, may be necessary in the early management of cryptococcal meningitis.

M. tuberculosis can cause subacute or chronic meningitis in the HIV-infected patient. Antituberculosis therapy should be considered in the setting of chronic meningitis if the cryptococcal antigen test is negative.

Coccidioides immitis or *Histoplasma capsulatum* may cause subacute or chronic meningitis in patients who reside in, or have a history of travel to, endemic regions (i.e., the U.S. southwestern deserts and the Ohio and Mississippi River drainage areas, respectively).

Neurosyphilis in patients with HIV is more common and may manifest earlier after infection. Patients may experience headaches and dizziness in the early phases, which can be followed by personality change, ischemic strokes, ataxia, seizures, and paralysis.

Meningoencephalitis

Patients with meningoencephalitis manifest alterations in sensorium varying from mild lethargy to coma. Patients are usually febrile, and neurologic examination often shows evidence of diffuse CNS involvement. CT or MRI may show only nonspecific abnormalities, whereas electroencephalography often is consistent with diffuse disease of the brain.

CMV encephalitis is rare and difficult to diagnose; it occurs only in the setting of CD4 counts lower than 50 cells/mm³. Patients may demonstrate confusion, cranial nerve abnormalities, or long tract signs. CSF findings may resemble those of bacterial meningitis, with a modest polymorphonuclear leukocyte pleocytosis and depressed CSF glucose levels. CT scanning or MRI may reveal periventricular abnormalities. Many patients have associated CMV retinitis. PCR detection of CMV DNA in CSF appears to be a sensitive and specific method for diagnosis of CMV encephalitis and polyradiculopathy (persistent back pain and weakness of the lower extremities).

Meningoencephalitis caused by HSV is unusual in HIV infection.

HIV-Associated Malignancies

The incidence of AIDS-associated malignancies has declined significantly since the advent of effective ART. Among HIV-infected MSM, the frequency of Kaposi's sarcoma fell from 40% at the outset of the epidemic to less than 15% in 1999. Human herpesvirus 8 is the causative agent. In many instances, lesions resolve after institution of effective ART. Systemic chemotherapy can cause remission in many patients with symptomatic visceral disease. Kaposi's sarcoma remains common in many parts of the developing world.

Non-Hodgkin's lymphomas (largely B cell, with small noncleaved or immunoblastic histology) occur 150 to 250 times more often in HIV-infected persons than in the general

population. Up to 40% of AIDS-related systemic lymphomas, and almost all of those in a primary CNS location, are related to EBV. Extranodal presentation of these tumors is the rule, and there is a high frequency of gastrointestinal or intracranial presentation. Chemotherapy for systemic disease or radiation therapy for CNS disease usually provides a clinical response, which may be maintained if it is accompanied by effective ART.

Other malignancies, including Hodgkin's disease, have an increased incidence in patients with untreated HIV infection. Now that more treated persons are surviving, an increasing incidence of a variety of non-AIDS-defining malignancies is being observed. Among these, increased rates of anal cancer, non-small cell lung cancer, Hodgkin's disease, and liver cancer (related to hepatitis viruses) have been associated with HIV.

 For a deeper discussion of these topics, please see Chapter 394, "Neurologic Complications of Human Immunodeficiency Virus Infection," in Goldman-Cecil Medicine, 25th Edition.

Renal Disorders

Renal insufficiency in patients with HIV may be a consequence of nephrotoxic drug administration, long-term use of certain antiviral agents (particularly tenofovir), substance use (e.g., heroin), or HIV-associated nephropathy (HIVAN). HIVAN typically improves with ART. In some cases, renal biopsy is indicated to establish a diagnosis, particularly if rapid decline in glomerular function is observed. In the United States, HIVAN is seen almost exclusively in African Americans and usually manifests as heavy proteinuria and progressive renal insufficiency. Without treatment, most patients develop end-stage renal disease within several months. Treatment is primarily with combination antiretroviral drugs.

Musculoskeletal and Rheumatologic Disorders

Musculoskeletal complaints are common among patients with HIV, and distinguishing acute complications of HIV from more indolent degenerative joint disease or recurrent muscle strain is important. Septic arthritis is a particular concern in persons who use injection drugs or have hemophilia.

Reiter's syndrome has been associated with HIV, and patients with HIV may experience a more severe or more prolonged course. Flares related to immune reconstitution have been described; they frequently respond quickly to doxycycline.

Declining CD4 counts in persons with psoriasis is associated with flares of both cutaneous disease and psoriatic arthritis. Standard therapy for both can now be supplemented if necessary with disease-modifying antirheumatic drugs.

Both lupus and rheumatoid arthritis, when present, may be relatively quiescent in persons with low CD4 counts. When treatment for HIV is initiated and the CD4 count rises, these persons may experience flares of their underlying connective tissue disease.

Avascular necrosis of the hip has been well described in persons with HIV, including those on ART. MRI may be necessary to confirm the diagnosis, and surgery is the mainstay of treatment.

Muscle weakness, if localized, may be indicative of myelopathy-neuropathy. If weakness is proximal or is associated with myalgia and tenderness, myopathy should be suspected. ART is the primary treatment for HIV-associated myopathy. Myopathy may rarely be caused by zidovudine toxicity.

Immune Reconstitution Inflammatory Syndrome

Persons with low CD4 counts at the start of treatment who experience a rapid rise in CD4 count on treatment may be at risk for development of what is termed the immune reconstitution inflammatory syndrome (IRIS). The syndrome results from the development of a pronounced immune response to a previously tolerated antigen, usually an infection. The specific symptoms depend on the pathogen or antigen and the involved area of the body. Entities commonly associated with IRIS include *M. tuberculosis* and other mycobacteria, *Pneumocystis pneumonia*, cryptococcal infections, herpesviruses, and hepatitis B or C virus. Treatment is supportive, although in severe cases, for example IRIS associated with meningitis or inflammation of the lungs leading to respiratory compromise, corticosteroids may be used to reduce inflammation and alleviate the symptoms.

 For a deeper discussion of these topics, please see Chapter 395, "Immune Reconstitution Inflammatory Syndrome in HIV/AIDS," in Goldman-Cecil Medicine, 25th Edition.

PREVENTION OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Three approaches—behavioral modification, treatment of sexually transmitted diseases, and ART—have had a major impact on HIV transmission. All of these activities are supported by expanded testing and improved linkage to care.

In several communities at increased risk for HIV (e.g., homosexually active men in the United States and western Europe, young adults in Uganda and Thailand), adoption of safer sexual practices, specifically the use of condoms during sexual activity, has been associated with a decrease in incidence of HIV infection. Sustaining these behavioral changes over long periods is challenging and requires behavioral reinforcement. Several recent controlled trials have demonstrated that male circumcision can decrease the risk of acquiring HIV infection by more than half.

Increasingly, ART is becoming a key goal of prevention programs. Antiretroviral treatment of HIV-infected pregnant women and their infants in the peripartum period has decreased maternal-child transmission from 25% to less than 5% in North America. If a pregnant woman maintains viral suppression during pregnancy and during breast-feeding, the risk of transmission to her infant is less than 1%.

Prophylactic use of ART has been shown to be effective for postexposure prophylaxis after occupational exposures to HIV and after unprotected sexual exposures. Recently, studies have shown the benefit of preexposure prophylaxis in preventing transmission of HIV among high-risk MSM, and the fixed-dose combination of tenofovir and emtricitabine has received an FDA indication for this use. The most compelling reinforcement of the importance of ART for prevention was a large multisite clinical

trial of discordant couples that demonstrated a reduction of almost 100% in transmission to partners.

The development of an effective vaccine is the target of active research. Early clinical trials of vaccine candidates are ongoing but to date have demonstrated, at most, limited protection. Induction of brisk T-cell responses to HIV antigens has neither protected against HIV acquisition nor decreased the magnitude of HIV replication among vaccinated subjects. A legitimate goal for vaccines, the induction of antibody responses that can broadly inhibit or neutralize the infectivity of diverse HIV strains, has so far eluded vaccine developers.

For a deeper discussion of these topics, please see Chapter 387, "Prevention of Human Immunodeficiency Virus Infection," in Goldman-Cecil Medicine, 25th Edition.

PROGNOSIS

With ART, survival in many cohorts approaching that of age-matched controls. Because of the high rates of co-infection with viral hepatitis in many populations, liver disease remains a significant cause of morbidity and mortality, accounting for a significant portion of the early mortality still associated with HIV. In endemic areas, tuberculosis is a similar cause of early mortality among persons with HIV infection. Even with effective ART, persons with HIV still experience some excess risk of cardiovascular disease as well some non-AIDS-defining malignancies such as non-Hodgkin's lymphoma. The key message for persons living with HIV is that if they stay in care and maintain adherence to ART, they can expect to live a relatively normal life.

Infections in the Immunocompromised Host

Staci A. Fischer

INTRODUCTION

With the development of increasingly complex and potent treatments for autoimmune, malignant, and chronic end-organ diseases, the spectrum of opportunistic infections continues to grow. Infections are the primary complication of many conditions causing immune deficiency, from congenital syndromes manifesting early in life to malignancy occurring in the elderly (Table 102-1). Success in challenging fields such as transplantation depends on preventing, quickly diagnosing, and effectively treating infections.

DEFINITION AND EPIDEMIOLOGY

The approach to the immunocompromised patient with possible infection should begin with an assessment of the arms of the immune system affected by the patient's underlying diseases and treatments.

Neutropenia

Neutropenia is a combined absolute neutrophil and band count of less than 500 cells/mm³. It is common after chemotherapy and may be prolonged in patients with hematologic malignancies and after hematopoietic stem cell transplantation (HSCT) (see Table 102-1). In these settings, patients may develop infections from their own microbial flora or from ubiquitous environmental organisms (Table 102-2). Because some chemotherapy agents cause mucositis and other breaches of protective barriers, bacterial infections predominate in this setting, most commonly as oral mucosal, skin, soft tissue, and sinopulmonary infections. Intravenous catheter-related infections and translocation of bacteria from the gastrointestinal tract may also occur. Because *Pseudomonas* species are associated with the highest mortality rate in this setting, empirical therapy for fever in the neutropenic patient should always include antibacterial therapy to cover this organism.

Neutropenic patients are at risk for invasive fungal infection, particularly in the setting of prolonged neutropenia. *Candida* species infections are common. Sinopulmonary infections caused by *Aspergillus* and the molds of the Mucorales order are associated with considerable morbidity and mortality.

Nonchemotherapy drugs may also cause neutropenia, with a less predictable risk of infection. Responsible agents include β -lactam antibiotics, carbapenems, amphotericin B, antipsychotics, antiepileptics (e.g., carbamazepine, valproic acid, phenytoin), hydralazine, sulfonamides, and nonsteroidal anti-inflammatory agents.

The risk of infection in patients with neutropenia is inversely related to their absolute neutrophil count (i.e., neutrophils plus bands); the lower the neutrophil count and the more prolonged the period of neutropenia, the higher the risk of infection. Because chemotherapeutic agents attack native cells with rapid turnover rates, mucosae in the oropharyngeal and gastrointestinal tracts are frequently interrupted, allowing commensal and colonizing bacteria (e.g., viridans streptococci, *Escherichia coli*, *Klebsiella*, *Enterococcus*, *Pseudomonas*), viruses (most commonly herpes simplex virus), and fungi (especially *Candida*) to escape and replicate. In patients on prophylactic antimicrobials while neutropenic, resistant organisms can break through, resulting in bloodstream infections and sepsis with multidrug-resistant organisms.

Cell-Mediated Immunity Defects

Cell-mediated immunity defects may result from infection with certain viruses (notably human immunodeficiency virus [HIV], hepatitis C virus, and cytomegalovirus [CMV]) or from immunosuppressive agents routinely used in solid organ transplantation and in the prophylaxis and treatment of graft-versus-host disease (GVHD) in allogeneic HSCT recipients (see Table 102-1). Cell-mediated immunity defects complicate T-cell lymphoma and primary immunosuppressive conditions such as common variable immune deficiency disease (CVID). CVID, the most common primary immunodeficiency, manifests with recurrent bacterial infections (notably pneumonia and bronchitis), usually between the ages of 20 and 50 years. Patients with T-cell dysfunction or deficiency are at risk for opportunistic infections such as *Listeria monocytogenes*, CMV, *Pneumocystis jirovecii*, and invasive fungal infections (see Table 102-2).

L. monocytogenes is the most common cause of bacterial meningitis in transplant recipients. CMV causes latent infection in T cells, and the seropositive patient with late-stage HIV infection or a transplant may reactivate CMV, causing viremia or focal infection of the gastrointestinal tract, liver, lungs, or retina. Seronegative recipients of seropositive organs are at high risk for developing donor-transmitted CMV infection, which can result in long-term allograft dysfunction in addition to symptomatic infection.

P. jirovecii, a fungal pathogen, causes hypoxemia and interstitial pulmonary infiltrates in those with advanced HIV infection or T-cell dysfunction from transplantation or GVHD. Reactivation, acquisition, or donor-derived transmission of endemic fungal infections, including *Blastomyces*, *Coccidioides*, and *Histoplasma*, can occur. Environmental fungi, including *Aspergillus*, Mucorales

COMPLEMENT DEFICIENCY

Recurrent sinopulmonary infections

*Streptococcus pneumoniae**Haemophilus influenzae**Neisseria gonorrhoeae**Neisseria meningitidis*

order fungi (which cause mucormycosis) and other molds, may be inhaled, causing sinopulmonary infections in neutropenic hosts. Infection may be complicated by dissemination to sites such as the skin and brain.

Bacterial infection with organisms such as *Nocardia* and *Legionella* and parasitic or protozoal infections such as *Strongyloides stercoralis* and *Babesia* are common in patients with cell-mediated immune defects.

Humoral Immunity

Humoral immunity is critical to control infection by encapsulated bacteria such as *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. Patients with hypogammaglobulinemia, protein-losing conditions such as enteropathy or nephrotic syndrome, splenectomy, or chronic lymphocytic leukemia have significant defects in humoral immunity, predisposing them to infection with these organisms (see Table 102-1). Transplant recipients on immunosuppressive therapy for many years may develop hypogammaglobulinemia, predisposing them to similar infections. The use of agents such as rituximab, a monoclonal antibody against CD20, in malignancy and transplantation may result in significant B-cell defects and infection with encapsulated bacteria.

Complement Deficiency

Patients deficient in complement factors have a higher risk of autoimmune disease and can develop recurrent infections. Sinopulmonary infections, particularly from *S. pneumoniae* and *H. influenzae*, are common. Patients with deficiencies of terminal

pathway components (C5 to C9) develop recurrent infections with *N. meningitidis* and *Neisseria gonorrhoeae*.

Although this chapter focuses on systemic immune deficiencies, it is important to consider local processes that increase the risk of focal infections in certain hosts. For example, the cystic fibrosis or chronic obstructive pulmonary disease patient with multiple bouts of pneumonia may develop localized bronchiectasis, in which normal mucociliary clearance mechanisms are inadequate to control and prevent infection. These areas are prone to recurrent bacterial infections, particularly with *Pseudomonas*. Similarly, the patient with lymphedema of a limb lacks the benefit of lymphatic drainage of early infections and is predisposed to recurrent cellulitis of the affected extremity.

PATHOLOGY

Infections in the immunocompromised host are often caused by organisms of low virulence that are able to cause infection due to impaired or absent normal defense mechanisms. Diagnosis of infection may be hampered by the small number of organisms required to cause disease and by the lack of inflammation associated with immunosuppressive conditions and therapies.

CLINICAL PRESENTATION

The clinical presentation of immunocompromised hosts with infection may be different from that seen in the immunocompetent patient. In the transplant population, typical signs and symptoms of infection such as fever, erythema, and leukocytosis may be absent as a result of the effect of immunosuppressive medications. Infections that are normally limited in scope may become disseminated in the immunocompromised host. For example, pyelonephritis involving the renal allograft may be complicated by bacteremia and acute kidney injury, both of which are uncommon in normal hosts.

Assessing the immunocompromised host with possible infection involves performing a detailed physical examination, including close inspection of the oral and periodontal tissues, perianal area, and skin. Even minor changes (e.g., faint erythematous rash, gum line erythema) may point to the source of a fever. Symptoms and signs of infection such as fever may not exist. On review of systems, subtle findings such as chills and sweats may be the only sign of an opportunistic infection. A classic finding is perianal or rectal pain without swelling or erythema, indicating a perirectal abscess in neutropenic patients. Laboratory clues to infection such as leukocytosis in the patient with systemic bacterial infection or eosinophilia in the patient with disseminated *Strongyloides* infection may be absent as a result of immunosuppressive therapy.

In many cases, the initial presentation of congenital or acquired immune deficiency states is the development of unusual or recurrent infections, and recognition of the immune defects associated with the infections can guide the diagnostic work-up. For example, the nonimmunosuppressed patient with *P. jirovecii* infection should undergo investigation for T-cell immune defects, most importantly HIV infection. The patient with recurrent *N. meningitidis* infections should be tested for possible late component complement deficiencies. Details on the manifestations of infection with the pathogens listed in [Table 102-2](#) are found elsewhere in this textbook.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnosis of infection in the immunocompromised host can be more difficult than in the normal host, and the differential diagnosis of infections can be quite broad. Because defects in humoral and cell-mediated immunity may limit the ability to develop antibody responses to infection, serologic tests have poor sensitivity for these patients. Cultures—including standard bacterial cultures and those facilitating growth of acid-fast bacilli and fungi—are often critical to making a diagnosis of infection. Because some of the pathogens causing infection in these settings are commensals or colonizers, interpretation of a positive culture result may be difficult. For example, the growth of *Candida* species in bronchoscopy specimens most likely reflects upper airway and pharyngeal colonization.

Sensitive assays to detect the DNA or RNA of opportunistic viruses—most commonly through quantitative polymerase chain reaction (PCR)—have become crucial diagnostic tests for infections such as CMV, human herpesvirus 6 (HHV-6), and BK virus, and they may help to guide the duration of antiviral therapy. Biologic markers of fungal infection such as serum galactomannan and β -D-glucan assays may suggest a diagnosis of invasive infection with molds such as *Aspergillus*.

In many cases, the diagnosis of infection may be elusive, requiring biopsy and histopathologic examination of involved tissues to determine the underlying pathogen. This process combined with tissue cultures may be needed to make a definitive diagnosis of infection in the immunocompromised host, and it can help differentiate colonization from infection with a particular organism. Biopsy of skin lesions, bone marrow, or liver may provide a diagnosis when cultures and other standard tests are unrevealing.

In neutropenic patients with fever, the procalcitonin level may be elevated in the setting of bacteremia, but it is normal in patients with fungal infections. 18-Fluorodeoxyglucose positron-emission tomography/computed tomography can help localize infection in the immunocompromised patient, in whom the sensitivity of nuclear medicine studies with indium-111, technetium-99m, or gallium may be limited.

TREATMENT AND PREVENTION OF INFECTIONS

Treatment of infections in the immunocompromised host requires rapid diagnosis and, when possible, improvement of the underlying immune disorder to help reconstitute natural immune function. In many cases, treatment must be broad spectrum and empirical while awaiting results of diagnostic testing. Delay of therapy for these patients is associated with a higher risk of dissemination and death. Details on the specific treatment recommendations for individual pathogens are found elsewhere in this textbook.

Neutropenia

For patients with neutropenic fever, empirical therapy should always include coverage for *Pseudomonas aeruginosa* because it is associated with a high mortality rate. Empirical therapy should also be guided by the individual patient's antimicrobial administration history, prior infections, colonization status (e.g., methicillin-resistant *S. aureus* [MRSA], vancomycin-resistant

Enterococcus [VRE]), and local susceptibility data. Broad-spectrum agents such as piperacillin-tazobactam and ceftazidime may be used. Carbapenems may be indicated in the patient with recent hospitalization, recent broad-spectrum antibacterial administration, or with a history of infection with extended-spectrum β -lactamase-producing Enterobacteriaceae. After a pathogen is identified in cultures and susceptibility data are available, antimicrobial therapy should be narrowed.

If a neutropenic patient remains febrile for 3 to 5 days without an identified locus or pathogen of infection, empirical glycopeptide therapy (e.g., vancomycin to cover *S. aureus*, particularly in the setting of an indwelling central catheter) and antifungal therapy are recommended to cover staphylococci and *Aspergillus* and other fungi common in this setting. Although amphotericin B products have been a mainstay of therapy for many years, voriconazole is the preferred agent to treat suspected aspergillosis because of its better efficacy in the neutropenic host.

Reconstitution of immune function in the patient with neutrophil deficiency or dysfunction can help prevent or treat infection. Administration of granulocyte colony-stimulating factor (G-CSF) (i.e., filgrastim or pegfilgrastim) with chemotherapy for solid tumors can prevent and treat absolute neutropenia and therefore reduce the risk of infection. For patients with drug-induced neutropenia, similar benefit can be attained. G-CSF usually is contraindicated in patients with myeloid malignancies and myelodysplasia due to the potential for stimulation of growth of dysplastic or malignant cells.

Several measures can help decrease the risk of infection in patients with neutropenia, including prevention of exposure to potential pathogens and antimicrobial prophylaxis. Periodontal care with oral rinses with sterile water or saline four to six times per day and gentle teeth brushing may help prevent periodontal infection and streptococcal bacteremia. Daily chlorhexidine bathing may decrease colonization with multidrug-resistant organisms that can be acquired while hospitalized. Ingestion of a low-microbial diet (e.g., no raw fruits or vegetables) and avoidance of dried or fresh flowers and potted plants may decrease exposure to fungi, including *Aspergillus*.

Housing in high-efficiency particulate air (HEPA)-filtered rooms with positive air pressure and adequate ventilation is the standard of care in HSCT units to decrease the risk of exposure to airborne pathogens. For patients at home, avoiding construction areas (including home renovation projects) while neutropenic may decrease the risk of invasive fungal infection. Patients visiting medical offices or hospitals should wear a mask, including when ambulating in the hallways or being transported for testing. Strict handwashing and hand hygiene are paramount to preventing infection. Avoidance of rectal thermometers, suppositories, enemas, and tampons while neutropenic has been recommended to prevent infection. Patients with well water should use filters to decrease the risk of *Cryptosporidium* infection. Minimization of mucositis with newer chemotherapeutic agents can help decrease the risk of infection in patients with malignancy.

Solid data support the use of quinolones (e.g., ciprofloxacin, levofloxacin) as prophylaxis for serious infection in patients with anticipated neutropenia for 7 or more days. Penicillin is often added to prevent infection with viridans streptococci in

patients on a mucositis-inducing chemotherapy regimen. Antifungal prophylaxis with voriconazole or posaconazole decreases the incidence of invasive fungal infections in patients undergoing HSCT and those with hematologic malignancies undergoing induction chemotherapy. Certain cancer patients, including those with acute lymphoblastic leukemia or those on high-dose corticosteroids, methotrexate, fludarabine, bleomycin, l-asparaginase, or cytarabine, have sufficient T-cell dysfunction to warrant prophylaxis against *P. jirovecii* (discussed later). Herpes simplex virus (HSV) prophylaxis with acyclovir is indicated for those with a history of symptomatic HSV infection or seropositivity.

Humoral Immunity Defects

Patients with hypogammaglobulinemia and CVID are at risk for infection with encapsulated organisms such as *S. pneumoniae*. Replacement of immunoglobulin G (IgG) with intravenous immune globulin (IVIG) at a dose of 400 to 600 mg/kg monthly can help prevent infections in these patients. Immunization may not be protective against *S. pneumoniae*, *H. influenzae*, or *N. meningitidis* due to poor seroconversion rates.

Hematopoietic Stem Cell Transplantation

Infection risk after HSCT depends on the source of stem cells, the type of conditioning chemotherapy regimen administered, and the risk and degree of GVHD (Fig. 102-1). Myeloablative regimens (including chemotherapy and total body irradiation) often result in severe mucositis, putting patients at risk for the infections detailed previously. Although the risk of infection in autologous transplants is relatively low due to earlier engraftment, recipients of matched unrelated donor allogeneic

Pre-engraftment Period (day 0 – day 30)

Neutropenia	}	Gram-negative bacilli (including <i>Pseudomonas</i>)
Breaks in cutaneous and mucosal barriers (e.g., IV catheters, mucositis and cystitis caused by chemotherapy)		Gram-positive cocci (<i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Enterococcus</i>)
		<i>Candida</i> species
		<i>Aspergillus</i> and other invasive molds
		HSV
		BK virus (hemorrhagic cystitis)
		Respiratory viruses

Early Post-engraftment Period (day 30 – day 100)

Cell-mediated immune suppression (acute GVHD prophylaxis and treatment)	}	<i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>N. meningitidis</i>

Chronic GVHD: prolonged risk of post-engraftment infections

FIGURE 102-1 Timing of infection after hematopoietic stem cell transplantation. CMV, Cytomegalovirus; GVHD, graft-versus-host disease; HHV, human herpesvirus; HSV, herpes simplex virus; IV, intravenous.

transplants are at significant and prolonged risk for opportunistic infections due to the high rate of GVHD associated with these allografts, resulting in prolonged T-cell-mediated immunosuppression and delayed immune reconstitution. Umbilical cord blood transplants are associated with prolonged neutropenia as a result of the small volume of cells available for transplantation, placing patients at risk for infection. The risk of GVHD, however, is lower with the use of umbilical cord cells.

Immediately after HSCT, stem cell recipients are neutropenic. During this pre-engraftment period, pathogens characteristic of prolonged neutropenia can cause infection. Prophylaxis with voriconazole or posaconazole, levofloxacin or ciprofloxacin, acyclovir, and penicillin is common to prevent infections during this vulnerable period.

After engraftment, the risk of GVHD is high for many allogeneic transplant recipients, resulting in administration of corticosteroids, methotrexate, cyclosporine, tacrolimus, sirolimus, or mycophenolate for prophylaxis. After GVHD develops, high-dose corticosteroids usually are given. In refractory cases, additional T-cell-active immunosuppressive agents, including antithymocyte globulin, tacrolimus, sirolimus, cyclophosphamide, and alemtuzumab, may be required. Patients on these agents are at risk for infections from CMV, *Nocardia*, HHV-6, *P. jirovecii*, adenovirus, invasive molds, and other opportunists. In some cases, patients require chronic immunosuppressive therapy to control GVHD, putting them at risk for infection indefinitely and requiring long-term antibiotic prophylaxis. If GVHD is successfully prevented, immunosuppressive therapy is discontinued after 6 to 12 months.

In uncomplicated HSCT cases without GVHD, functional humoral immunity takes 1 to 2 years to return to normal, and patients are at risk for encapsulated organisms despite being successfully engrafted. Standard immunizations are re-administered 1 to 2 years after transplantation because pretransplantation antibodies are often lost.

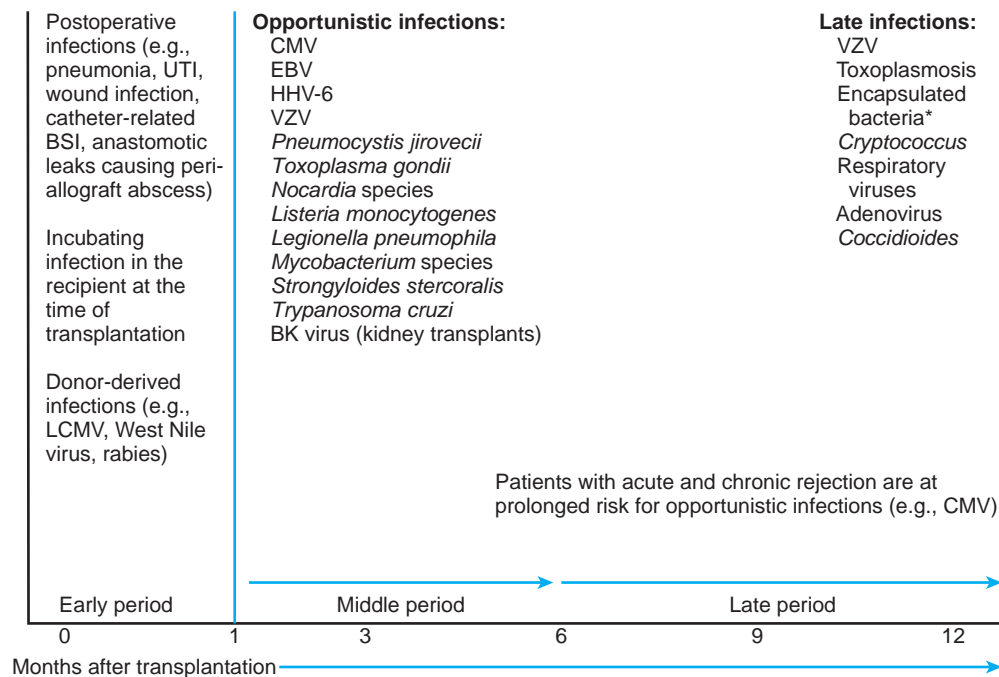

Human Immunodeficiency Virus Infection

Chapter 101 provides a detailed discussion of treatment and prophylaxis of infections occurring in HIV-infected patients.

Solid Organ Transplantation

Organ transplant recipients are at lifelong risk of infection, although the pathogens involved change over time (Fig. 102-2). In the first month after transplantation, patients develop infections related to the surgical procedures and hospitalization. Urinary tract infection in the renal transplant recipient, pneumonia in the lung transplant recipient, and sternal wound infection in the heart transplant recipient tend to manifest in the first 4 weeks postoperatively. Common nosocomial infections such as catheter-related bloodstream infection and *Clostridium difficile* may also occur. Anastomotic leaks in pancreas and liver transplant recipients may cause polymicrobial intra-abdominal abscesses.

Patients with incubating infection at the time of transplantation and induction immunosuppression can develop disseminated infection with viral or bacterial pathogens, which is associated with a high mortality rate. Careful evaluation of the recipient at the time of hospital admission for transplantation is

*Especially in patients with hypogammaglobulinemia complicating immune suppression

FIGURE 102-2 Timing of infections after solid organ transplantation. BSI, Bloodstream infection; CMV, cytomegalovirus; COPD, chronic obstructive pulmonary disease; EBV Epstein-Barr virus; HCV, hepatitis C virus; HHV-6, human herpesvirus 6; HIV, human immunodeficiency virus; LCMV, lymphocytic choriomeningitis virus; UTI, urinary tract infection; VZV, varicella-zoster virus.

essential for positive early outcomes. Rarely, donor-transmitted infections can occur, including viral pathogens such as rabies virus, West Nile virus, lymphocytic choriomeningitis virus (LCMV), HIV, and hepatitis B and C viruses. Organ banks and transplantation centers continue to work to improve the sensitivity and specificity of donor testing paradigms to prevent transmission of infection.

The most common time for opportunistic infections such as CMV, *Listeria*, *Legionella*, and invasive fungal infections such as *Aspergillus* is 1 to 6 months after transplantation. Later infection may be seen in those receiving lymphocyte-depleting induction agents (e.g., thymoglobulin, alemtuzumab) to prevent acute rejection at the time of transplantation or in those with episodes of acute rejection.

Because CMV causes symptomatic infection and is associated with chronic allograft dysfunction, prophylaxis or preemptive treatment of infection with valganciclovir is used. Seronegative recipients of a CMV-seropositive organ are at highest risk for infection. Lung transplant recipients, who are at significant risk for *Aspergillus* infection in the first 6 months after transplantation, receive prophylactic voriconazole to prevent invasive fungal infection. Lung recipients are at lifelong risk for respiratory viral infections. Lung transplant recipients may also receive azithromycin to improve the prognosis for bronchiolitis obliterans syndrome, the most common manifestation of chronic allograft dysfunction.

Heart transplant recipients are at particular risk for reactivation of donor-transmitted infection with *Toxoplasma gondii*, which can cause early myocarditis or late cerebral disease. Serologic (IgG) screening of the donor and recipient, with sulfamethoxazole-trimethoprim prophylaxis used in seropositive recipients or seronegative recipients of a seropositive heart, is the standard of care in cardiac transplantation centers.

P. jirovecii can cause infection in solid organ transplant recipients, which usually occurs 6 to 12 months after transplantation. Pneumonitis similar to that seen in patients with HIV is the most common manifestation, although extrapulmonary infection (particularly in the liver and spleen) can be seen in transplant recipients. Prophylaxis with sulfamethoxazole-trimethoprim (or atovaquone in sulfa-allergic patients) is indicated for 12 months after transplantation. If high-dose corticosteroids or antilymphocyte therapy is required for treatment of acute rejection, prophylaxis should be restarted.

Almost all liver transplant recipients with underlying active hepatitis B or C have reactivation of the infection. Treatment of hepatitis B with lamivudine or other antiviral agents is often successful in suppressing infection when started at the time of transplantation. Although more difficult, post-transplantation treatment of symptomatic hepatitis C with interferon, ribavirin, and protease inhibitors may prolong hepatic function. Newer direct acting agents are being studied in the post-transplant setting.

In patients with no episodes of acute rejection, the risk of opportunistic infections often declines with time. Late infections (≥ 12 months after transplantation) may still occur, with varicella-zoster virus (VZV), HSV (particularly encephalitis) *Cryptococcus neoformans*, JC virus (i.e., progressive multifocal leukoencephalopathy), and community-acquired infections such as influenza

and *S. pneumoniae* most commonly reported. Patients with hypogammaglobulinemia complicating long-term immunosuppressive therapy may benefit from IVIG to help prevent infections.

Although not always possible, especially with lifesaving heart, lung, or liver transplants, reduction of immunosuppression in the organ transplant recipient with invasive fungal infection, viral infection, or bacterial sepsis may assist in recovery. Reinstitution of immunosuppressive therapy may be indicated as infection resolves.

A significant challenge in treating infections in the patient with a solid organ transplant or GVHD complicating HSCT is the cytochrome P-450 metabolism of antimicrobial agents such as the azoles, macrolides, rifampin, echinocandins, nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, and non-nucleoside reverse transcriptase inhibitors (NNRTIs). Careful monitoring of levels of calcineurin inhibitors (e.g., cyclosporine, tacrolimus) is indicated for patients on these and other agents that can induce or inhibit P-450 metabolism.

Although the immunocompromised patient may not seroconvert from vaccinations such as the annual influenza vaccine, immunization of household contacts and health care workers can prevent exposure and therefore infection of the most vulnerable hosts. Immunocompromised patients should avoid live virus vaccines (e.g., measles/mumps/rubella, varicella, yellow fever) that can be associated with disseminated infection. Specialized protocols exist for immunization of immunocompromised children.

PROGNOSIS

The prognosis of infections in immunocompromised hosts relies on accurate and rapid diagnosis and early institution of appropriate antimicrobial therapy. Use of cidal therapies (versus static agents) is recommended. Manipulation of the immune response to infection through G-CSF administration (in neutropenic patients), administration of IVIG (in hypogammaglobulinemic patients), or decreasing immunosuppressive therapy (in kidney or pancreas transplant recipients) may improve survival.

The prognosis for infections in these settings is worse for older patients, those requiring intensive care unit (ICU) admission, and those in whom rapid immune reconstitution is not possible. Tumor lysis syndrome, acute respiratory failure, and sepsis increase mortality. Patients with underlying acute leukemia and those with other comorbidities, including cardiovascular disease, renal failure, liver disease, or lung disease have a significantly worse prognosis, particularly in the setting of invasive fungal infection. The attributable mortality rate for invasive aspergillosis is 20% to 50% when patients require ICU admission (Fig. 102-3).

CONCLUSIONS

Care of the immunocompromised host with infection requires meticulous monitoring of symptoms, detection of often subtle physical findings, and an understanding of the arms of the immune system involved in a particular patient's illness. With successes in treatment of malignancies and end-organ disease, the breadth of infections causing infection in these hosts continues to widen.

FIGURE 102-3 Invasive pulmonary aspergillosis in a kidney transplant recipient with myelodysplasia. At presentation, the patient was afebrile and had dyspnea on exertion without cough. **A**, Anteroposterior and lateral chest radiographs (top) and computed tomography scans (bottom) of the chest. **B**, Transbronchial lung biopsy demonstrates hyphae in tissue (hematoxylin and eosin stain, $\times 100$). **C**, Silver stain of biopsy tissue demonstrates acute-angle branching hyphae. Cultures grew *Aspergillus fumigatus*.

Infectious Diseases of Travelers: Protozoal and Helminthic Infections

Rebecca Reece, Aadia I. Rana, and Erna Milunka Kojic

INTRODUCTION

Medical advice for overseas travelers, recommended protective measures, and the diagnosis and treatment of common parasitic diseases endemic in the United States and abroad are reviewed in this chapter.

PREPARATION OF TRAVELERS

More than 27 million Americans travel internationally every year, and more than 60% of them travel to developing regions of the world. Increases in international travel are associated with exposures to infectious diseases worldwide and bring the issues of prevention and management of health problems in travelers into the office of every physician. The risk of becoming ill while traveling internationally depends on the destination and duration of the trip, the underlying health and age of the traveler, and activities undertaken while abroad. Major issues to be addressed before traveling include required and recommended immunizations, malaria prophylaxis, and traveler's diarrhea, as well as measures to prevent tick and mosquito bites. Information about health risks in specific geographic areas, updated weekly, can be obtained from the Centers for Disease Control and Prevention (CDC) through its publications or website (www.cdc.gov/travel/destinations/list).

Immunizations

All international travelers should ensure they are up-to-date on routine vaccinations. Only yellow fever vaccination may be required by law for international travel, but other immunizations are often strongly recommended, depending on the destination, type, and duration of travel. Before immunization, a thorough history should be obtained to determine the safety of immunizations and any allergies to eggs or chick embryo cells. Pregnant women and individuals who are immunocompromised by human immunodeficiency virus (HIV), malignancy, or chemotherapy pose specific and important concerns requiring review before receiving vaccinations.

Hepatitis A

In the United States, the most frequently identified risk for hepatitis A infection is travel. The risk varies with living

conditions, length of stay, and incidence of hepatitis A in the area visited. In some areas, the disease affects an estimated 1 of every 500 to 1000 travelers on a 2- to 3-week trip. Therefore, hepatitis A vaccination is recommended for all susceptible persons traveling to or working in countries with intermediate or high endemicity of infection. Hepatitis A vaccine should be given at least 2 weeks before departure but remains effective if given up until the time of travel. A single dose provides protection for 1 to 2 years; a booster 6 to 18 months later is required for long-lasting immunity (at least 20 years and possibly lifelong).

Influenza

Although influenza is not necessarily considered a travel-related illness, the influenza vaccine should be considered in the panel of vaccines offered to the traveler. Influenza seasons can occur at different times of the year in different parts of the world. If a patient cannot be immunized, a course of the antiviral medication oseltamivir can be provided to take at the first sign of a flu-like illness.

Japanese Encephalitis

Japanese encephalitis (JE) virus is closely related to the West Nile and Saint Louis encephalitis viruses and is transmitted to humans through the bite of an infected mosquito. JE virus is the most common vaccine-preventable cause of encephalitis in Asia. It occurs throughout most of Asia and parts of the western Pacific. The overall incidence of JE among people from non-endemic countries traveling to Asia is estimated to be less than 1 case per 1 million travelers. However, expatriates and travelers who stay for prolonged periods in rural areas with active JE virus transmission are likely to be at similar risk as the susceptible resident population (i.e., 5 to 50 cases per 100,000 children per year). Even during brief trips, travelers might be at increased risk if they have extensive outdoor or nighttime exposure in rural areas during periods of active transmission. Short-term (<1 month) travelers whose visits are restricted to major urban areas are at minimal risk for JE. A new inactivated JE vaccine, a two-dose series given 28 days apart, was approved in 2009 for use in people 17 years of age and older; pediatric clinical trials are being conducted to enable its licensure for use in children.

Measles

In the United States, most measles cases result from international travel, and measles remains a common disease in many parts of the world. Currently, measles vaccination is recommended at 15 months of age, with a second vaccination after age 5. Individuals born after 1956 who have no physician-documented record of immunization or who have not received a booster after early childhood should have a one-time booster before travel.

Meningococcal Meningitis

Vaccination for meningococcal disease is recommended to persons who travel to or reside in countries in which the bacterium *Neisseria meningitidis* is hyperendemic or epidemic, particularly if they will be in close contact with the local population. Vaccination is recommended for travelers to Saudi Arabia during the Hajj, along the meningitis belt of sub-Saharan Africa, and in other locations for which travel advisories have been issued (information available on the CDC website). The meningococcal conjugate vaccine (MCV4) is preferred for people age 9 months through 55 years, and the meningococcal polysaccharide vaccine (MPSV4) is the recommended vaccine for persons older than 55.

Polio

Polio remains endemic in some regions of Asia and Africa. Before traveling to areas where poliomyelitis cases are still occurring, travelers should ensure that they have completed the recommended age-appropriate polio vaccine series and have received a booster dose with the inactivated polio vaccine as an adult.

Typhoid

International travelers are at greatest risk for contracting typhoid in the Indian subcontinent, Central America, western South America, and sub-Saharan Africa. Vaccination is recommended for travel to endemic areas where exposure to contaminated food and water is likely. Both a live oral vaccine (four enteric-coated capsules given over 7 days) and an injectable vaccine (single-dose) are available; they are essentially equivalent in effectiveness, which ranges from 50% to 70%.

Yellow Fever

The yellow fever vaccine is a live, attenuated virus vaccine that is recommended for persons traveling to areas in South America and Africa where yellow fever is endemic. Vaccination is protective for at least 10 years and must be given at designated vaccination centers. Severe adverse events are rare and include yellow fever vaccine-associated viscerotropic and neurologic disease, both of which are more common in elderly persons and in those with thymus disease. Because the adverse events occur more commonly in people older than 60 years of age, a careful assessment of risks and benefits for these travelers should be made before vaccination.

Other Vaccines

Some individuals live for prolonged periods in developing countries or are at special risk for contracting certain highly contagious diseases. Consideration should be given to immunization against hepatitis B, plague, and rabies. Tetanus vaccinations

should be up to date: for travel, a tetanus booster within the previous 5 years is recommended. The cholera vaccine is not available in the United States. Worldwide, two oral cholera vaccines are available, but vaccination offers limited protection. Therefore, the vaccine is not recommended for travelers, but standard cholera prevention and control measures are emphasized.

Malaria Prophylaxis

Malaria infection is associated with significant morbidity and mortality, particularly if the causative agent is *Plasmodium falciparum*. The need for, as well as the type of, malaria prophylaxis depends on known resistance patterns and the exact itinerary within a given country because the risk of transmission is regional. In general, travelers to areas where chloroquine-sensitive *P. falciparum* strains are exclusively found (i.e., parts of Central America, the Caribbean, North Africa, and the Middle East) should take chloroquine phosphate (300-mg base or 500-mg salt) weekly, starting 1 week before travel to malarious areas and continuing during the trip and for 4 weeks after leaving the area.

Travelers to Southeast Asia, sub-Saharan Africa, South America, and South Asia, where chloroquine-resistant *P. falciparum* is common may take mefloquine (Lariam), atovaquone-proguanil (Malarone), or doxycycline. Mefloquine may be associated with neurologic side effects (dizziness, tinnitus, and vivid dreams) and, rarely, with significant neuropsychiatric side effects. A U.S. Food and Drug Administration (FDA) black box warning issued in 2013 indicated that the neurologic side effects can occur at any time and persist indefinitely; this has lent some caution to the prescription of mefloquine. Mefloquine is also not completely effective in Myanmar, rural Thailand, or some parts of East Africa, where resistance is a growing problem. Atovaquone-proguanil and doxycycline are effective in Southeast Asia and may be used in other areas of chloroquine resistance. Atovaquone-proguanil is well tolerated but must be taken every day. Daily doxycycline can be associated with photosensitivity, esophagitis, and, occasionally, vaginal candidiasis.

Where it is approved, primaquine can be used for primary prophylaxis in areas with higher rates of *Plasmodium vivax* or *Plasmodium ovale* infection. It has the advantage of both preventing acute infection from all malaria parasites and preventing the later recurrent infections of *P. vivax* and *P. ovale*. It cannot be used in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Emphasis must also be given to the use of mosquito bite prevention measures, including netting, screens, permethrin for clothing, and insect repellents.

Traveler's Diarrhea

Each year between 20% and 50% of international travelers develop diarrhea. Bacterial infections such as enterotoxigenic *Escherichia coli* are most common, but other causes include parasites and viruses. The average duration of an episode of traveler's diarrhea is 3 to 6 days, but about 10% of episodes last longer than 1 week. The diarrhea may be accompanied by abdominal cramping, nausea, headache, low-grade fever, vomiting, or bloating. Travelers with fever greater than 101° F (38° C), bloody stools, or both should see a physician at once (see [Chapter 96](#)).

Diarrheal illness can be avoided by taking precautions with regard to food and beverages. All water and ice should be presumed to be unsafe. Salads are often contaminated by protozoal cysts; along with street vendor foods, they are the most dangerous foods encountered by most travelers. Food should be well cooked, and unpasteurized dairy products should be avoided.

Prophylactic antibiotics are not generally recommended. Diphenoxylate (Lomotil) and loperamide (Imodium) may provide symptomatic relief of mild diarrhea. First-line treatment includes fluoroquinolones, taken orally for 3 days. In some countries, such as Thailand and Nepal, fluoroquinolone resistance, especially among *Campylobacter* species, has been on the rise; azithromycin is an alternative in these situations.

Special Problems

Pregnant Women

Although travel is rarely contraindicated during a normal pregnancy, complicated pregnancies require special consideration and may warrant a recommendation that travel be delayed. The risk of obstetric complications is highest during the first and third trimesters.

Most live-virus vaccines are contraindicated during pregnancy. Yellow fever vaccine, for which pregnancy is considered a precaution by the Advisory Committee on Immunization Practices (ACIP), should be avoided if possible. If travel is unavoidable and the risks for yellow fever virus exposure are believed to outweigh the risks of vaccination, a pregnant woman should be vaccinated. Pregnant women should avoid or delay travel to malaria-endemic areas because no prophylactic measures provide complete protection. If travel is unavoidable, pregnant women should take utmost precautions to avoid mosquito bites; for chemoprophylaxis, chloroquine and mefloquine are the drugs of choice for destinations with chloroquine-sensitive and chloroquine-resistant malaria, respectively.

Acquired Immunodeficiency Syndrome

Many countries bar entry to persons with acquired immunodeficiency syndrome (AIDS). Several countries require serologic testing for the human immunodeficiency virus (HIV) from all travelers applying for visa lasting longer than 3 months; official documentation is required well in advance of travel. Patients with HIV infection need special preparation before travel to developing countries because of their increased susceptibility to certain illnesses (e.g., pneumococcal infection, tuberculosis). Issues of HIV infection and other sexually transmitted diseases should be discussed, especially with young, sexually active adults.

The Returning Traveler

The most common medical problems encountered by travelers after their return home are diarrhea, fever, respiratory illnesses, and skin lesions. A detailed history should focus on the traveler's exact itinerary, including dates of travel, exposure history (e.g., food indiscretions, drinking-water sources, freshwater contact, sexual activity, animal contact, insect bites), style of travel (urban versus rural), immunization history, and use of antimalarial chemoprophylaxis.

Diarrhea

Traveler's diarrhea is an acute condition that usually resolves within 2 weeks. If the traveler's diarrhea is not responsive to empiric antibiotic treatment, a work-up should be performed to evaluate for *Giardia lamblia* (see later discussion). Three stool specimens for ova and parasites and a stool culture are indicated (E-Fig. 103-1). If *Giardia* tests are negative, an empirical trial of metronidazole for treatment of a possible infection with *Giardia* or other protozoan (e.g., amebiasis) should be considered. Non-infectious causes such as temporary lactose intolerance, irritable bowel syndrome, and, less commonly, inflammatory bowel disease should also be in the differential diagnosis.

Fever

Malaria should be the first diagnosis considered in a febrile traveler who has returned from a malarious area. *P. falciparum* malaria can be fatal if it is not diagnosed and treated promptly. Detection of the *Plasmodium* species on Giemsa-stained blood smears by light microscopy is the standard tool for diagnosis of malaria. Rapid diagnostic tests for detection of malaria parasite antigens are becoming increasingly important tools in resource-limited endemic settings because of their accuracy and ease of use.

Travelers with chloroquine-sensitive *P. falciparum* malaria should be treated with chloroquine. Reasonable agents for uncomplicated malaria caused by chloroquine-resistant *P. falciparum* include atovaquone-proguanil, artemisinin derivative combinations (if available), and mefloquine- or quinine-based regimens. Quinine- and mefloquine-based regimens are more frequently associated with adverse effects, and mefloquine should not be used to treat *P. falciparum* malaria acquired in the Thai-Myanmar-Cambodia area because of high resistance rates.

Severe malaria is defined as acute malaria with major signs of organ dysfunction or a high level of parasitemia (>5%) or both. It should be treated with intravenous quinidine for 7 days with close monitoring of the QTc interval. In many parts of the world, intravenous artesunate is used, but it may be associated with high rates of relapse.

Other important causes of fever after travel include viral hepatitis (hepatitis A and E), typhoid fever, bacterial enteritis, arboviral infections (e.g., dengue, chikungunya), rickettsial infections, and, in rare instances, leptospirosis, acute HIV infection, and amebic liver abscess.

Skin Diseases

Sunburn, insect bites, skin ulcers, and cutaneous larva migrans are the most common skin conditions affecting travelers after their return home. Persistent skin ulcers should prompt a work-up for cutaneous leishmaniasis, mycobacterial infection, or fungal infection. Careful, complete inspection of the skin is important in detecting the rickettsial eschar in a febrile patient or the central breathing hole in a "boil" caused by myiasis.

PROTOZOAL INFECTIONS

Protozoal infections, though endemic to certain regions, can be encountered all around the world, partly because of the increase in travel and migration (Table 103-1). They cause a tremendous burden of disease in the tropics and subtropics as well as more

E-FIGURE 103-1 *Giardia* wet preparation.

**TABLE 103-1** PROTOZOAL INFECTIONS

PROTOZOAN	SETTING	VECTORS	DIAGNOSIS	SPECIAL CONSIDERATIONS	TREATMENT
ENDEMIC IN THE UNITED STATES					
<i>Babesia microti</i>	New England	Ixodid ticks, transfusions	Thick or thin blood smear	Severe disease in asplenic persons	Quinine and clindamycin
<i>Giardia lamblia</i>	Mountain states	Humans, small mammals	Microscopic examination of stool or duodenal fluid	Common in homosexual men, travelers, children in daycare centers	Quinacrine, nitazoxanide, or metronidazole
<i>Toxoplasma gondii</i>	Ubiquitous	Domestic cats, raw meat	Clinical; serologic confirmation	Pregnant women, immunosuppressed host (AIDS)	Pyrimethamine and sulfadiazine
<i>Entamoeba histolytica</i>	Southeast	Human	Microscopic examination of stool or touch preparation from ulcer	Common in homosexual men, travelers, institutionalized persons	Metronidazole
<i>Cryptosporidium</i> species	Ubiquitous	Human	Acid-fast stain of stool	Severe in immunosuppressed hosts (AIDS)	Nitazoxanide
<i>Trichomonas vaginalis</i>	Ubiquitous	Human	Wet preparation of genital secretions	Common cause of vaginitis	Metronidazole
PRIMARILY SEEN IN TRAVELERS AND IMMIGRANTS					
<i>Plasmodium</i> species	Africa, Asia, South America	<i>Anopheles</i> mosquito	Thick and thin blood smears	Consider in returning travelers with fever	Dependent on regional resistance pattern (see text)
<i>Leishmania donovani</i>	Middle East	Sandfly	Tissue biopsy	Consider in immigrants with fever and splenomegaly	Sodium stibogluconate
<i>Trypanosoma</i> species	Africa, South America	Reduviid bugs, transfusion	Direct examination of blood or CSF	Very rare in travelers, transfusion associated	Dependent on species and stage of disease

AIDS, Acquired immunodeficiency syndrome; CSF, cerebrospinal fluid.

temperate climates. Immunosuppression associated with various conditions, particularly HIV infection, leads to more severe manifestations. Of all protozoal diseases, malaria causes the most deaths globally, approximately 1 million people each year.

Protozoal Infections in the United States

Giardiasis

Giardiasis is a common cause of nonbloody diarrhea in returning travelers. *G. lamblia* and *Giardia intestinalis* are found worldwide, including in the United States. However, giardiasis is most commonly diagnosed in travelers returning from Latin America, Southeast Asia, or the Middle East. Transmission is by the fecal-oral route in the setting of contaminated food or water or public swimming areas, or by person-to-person contact in certain risk populations such as men who have sex with men. It is usually a self-limited diarrheal illness that lasts 2 to 4 weeks but may persist longer. Rarely, individuals have associated fevers, nausea, or vomiting. The diagnosis is made by microscopic examination of stool for cysts or trophozoites or by an antigen detection test. Treatment options include metronidazole, tinidazole, or nitazoxanide.

Amebiasis

Amebiasis is another diarrheal illness that occurs in travelers. Like *Giardia*, *Entamoeba histolytica* is found worldwide, and transmission is by the fecal-oral route. However, most infected individuals (80%) are asymptomatic. The presentation in those acutely infected includes bloody or watery diarrhea with abdominal cramping lasting up to 4 weeks. In immunocompromised individuals, a severe invasive infection can occur with risk of necrotizing colitis or bowel perforation. Extraintestinal amebiasis can occur as well, particularly liver abscesses. The diagnosis can be made by microscopic examination of stool for ova and

parasites or by antigen detection tests of stool or serum. Treatment is with metronidazole or tinidazole in symptomatic individuals, followed by paromomycin or iodoquinol.

Protozoal Infections Common in Travelers and Immigrants

Leishmaniasis

Leishmaniasis is transmitted by the sandfly and can manifest with cutaneous, mucocutaneous, or visceral involvement. The skin finding is a persistent ulcer with raised edges in a traveler returning from the Middle East (Old World: *Leishmania major*, *Leishmania tropica*) or Latin America (New World: *Leishmania braziliensis*, *Leishmania peruviana*, others). Diagnosis is by tissue biopsy. Visceral leishmaniasis can have hepatic, splenic, or bone marrow involvement and is more commonly identified in immigrants from Asia (*Leishmania donovani*) or South America (*Leishmania chagasi*). Diagnosis is by tissue biopsy or culture of the involved organ.

Treatment varies based on severity of presentation and resistance characteristics. Most cutaneous lesions are self-limited, but treatment options include sodium stibogluconate (Pentostam) or paromomycin. For visceral involvement, treatment includes sodium stibogluconate, amphotericin B, or a combination of these two agents.

African Trypanosomiasis

African trypanosomiasis, or African sleeping sickness, is a protozoal infection caused by *Trypanosoma rhodesiense* (East Africa) or *Trypanosoma gambiense* (Central and West Africa), which is transmitted by the tsetse fly. Presenting symptoms include fever, headache, and central nervous system involvement. The disease is rarely reported in travelers returning from sub-Saharan Africa

**TABLE 103-2** HELMINTHIC INFECTIONS

HELMINTH	SETTING	VECTORS	DIAGNOSIS	TREATMENT
ENDEMIC IN THE UNITED STATES				
Pinworm (enterobiasis)	Ubiquitous	Human	Direct examination for ova	Mebendazole, albendazole
<i>Ascaris lumbricoides</i>	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
<i>Trichuris trichiura</i>	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
Hookworm	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
COMMON IN TRAVELERS AND IMMIGRANTS				
<i>Strongyloides stercoralis</i>	Developing world	Human	Stool examination for larvae	Thiabendazole, ivermectin
<i>Schistosoma</i> species	Developing world	Snails	Stool or urine examination for ova	Praziquantel
<i>Wuchereria</i> and <i>Brugia</i> species	Asia, some parts of Africa	Mosquitoes	Nocturnal blood examination	Ivermectin
<i>Onchocerca volvulus</i>	Africa, South and Central America	Black flies	Biopsy	Ivermectin
<i>Loa loa</i>	Africa	Tabanid flies	Blood examination, clinical setting	Diethylcarbamazine or ivermectin
<i>Clonorchis sinensis</i>	Asia	Undercooked fish and snails	Stool examination for ova, radiology	Praziquantel
<i>Echinococcus</i> species	Worldwide	Canines and livestock	Radiology, serology, biopsy	Surgery, supportive therapy
<i>Taenia solium</i> (cysticercosis)	Developing world	Humans, pigs	Radiology, serology	Surgery, albendazole
<i>T. solium</i> , <i>Taenia saginata</i> , <i>Diphyllobothrium latum</i> (tapeworms)	Worldwide	Pigs, bovine, fish	Stool examination for ova or proglottids	Praziquantel

but should be considered in immigrants from these areas. Frequently, the patient remembers a chancre at the site of the insect bite (E-Fig. 103-2). The diagnosis is made by microscopic examination of blood, lymph, or cerebrospinal fluid for the parasite (E-Figs. 103-3 and 103-4). Treatment varies by species and is highly toxic. Consultation with an expert in infectious disease or tropical medicine is recommended.

American Trypanosomiasis

American trypanosomiasis, or Chagas' disease, is caused by *Trypanosoma cruzi* and is endemic in Central and South America. Transmitted by contact with feces of reduviid bugs (kissing bugs) (E-Fig. 103-5), it can also be acquired through blood transfusion or organ transplantation from an infected individual. The risk to travelers is extremely low but increases with prolonged stays in poor-quality housing. The presentation has an acute phase of 3 months followed by a chronic infection for life. The classic acute presentation involves swelling and erythema of the eyelid and ocular tissue at the entry site of infection, known as the Romana sign. However, most individuals are asymptomatic throughout the infection and are identified only at the time of blood donation. Between 20% and 30% of individuals develop manifestations of chronic infection decades later that can include cardiomegaly and heart failure, megaesophagus, or megacolon.

Diagnosis in the acute phase is by microscopic examination of peripheral blood (E-Fig. 103-6). In the chronic phase, various serologic analyses are available to aid in diagnosis. Treatment is recommended early because it may prevent chronic manifestations. In the United States, antitrypanosomal drugs are available through the CDC in consultation with an expert in the field. For most chronic manifestations, however, treatment is supportive.

HELMINTHIC INFECTIONS

Infestation by nematodes, or roundworms, is the most common parasitic infection in the world. The intestinal nematodes *Ascaris* and *Trichuris* are the two most prevalent types. Other important

helminths include *Strongyloides*, *Enterobius*, schistosomes, and tapeworms (see later discussion). Although most helminths are found worldwide, they disproportionately affect the developing world and pose potential risk to travelers to those areas (Table 103-2).

Helminthic Infections Common in the United States

Pinworm

Enterobiasis is common in the United States and worldwide. Children are predominantly infected, and transmission is by the fecal-oral route. The clinical presentation is perianal pruritus. Diagnosis is made by the tape test, in which transparent tape is applied to the perianal skin overnight and then examined microscopically for ova on the tape. Treatment is with mebendazole.

Roundworm

Ascaris lumbricoides is found worldwide, including in the United States, but mostly affects people in the developing world. Although affected individuals are usually asymptomatic, some develop pulmonary infiltrates during the migration phase of the worm or obstruction of the biliary, pancreatic, or intestinal tract. These manifestations usually occur in the setting of high worm burden. Diagnosis is by stool examination for ova and parasites (E-Fig. 103-7). Treatment is with mebendazole.

Whipworm

Trichuris trichiura are called whipworms because of their characteristic shape in the adult form. Like *Ascaris*, this is an intestinal nematode that infects mostly children. It is usually asymptomatic except in the setting of heavy worm burden, which can lead to rectal prolapse and bloody diarrhea among children in the developing world. Diagnosis is made by stool examination for ova and parasites or by endoscopy revealing colitis and the presence of adult worms. The treatment of choice is mebendazole.

E-FIGURE 103-5 Reduviid bug ("kissing bug") on the skin.

E-FIGURE 103-6 Chagas disease blood smear.

E-FIGURE 103-7 *Ascaris* egg from wet preparation.

Hookworm

Ancylostoma duodenale and *Necator americanus* (hookworms) are similar to roundworms in their worldwide distribution and are common among immigrants from Asia and sub-Saharan Africa. Infection occurs through direct penetration of the skin by the larvae, which travel through the lymphatics and the bloodstream to the lungs and are then swallowed. Infected individuals may be asymptomatic, or they may develop pruritic dermatitis at the site of entry. As with the roundworm, pulmonary infiltrates can occur during the migration phase; this is known as Loeffler's syndrome. Chronic iron deficiency anemia associated with heavy hookworm infection can be severe and debilitating. Eosinophilia is common. The diagnosis is made by stool examination for ova and parasites (E-Fig. 103-8). The treatment is mebendazole.

Helminth Infections Common in Travelers and Immigrants

Strongyloidosis

Strongyloides stercoralis is a helminthic parasite that is found worldwide, although more commonly in the tropics. Infection occurs from contact with contaminated soil; the larva penetrates the skin, migrates to the lungs, and is then swallowed by the individual. The infection is usually asymptomatic, but infection can persist into the chronic phase decades later. Those with symptoms usually have gastrointestinal complaints of bloating, diarrhea, and abdominal pain. Eosinophilia is a common finding in these individuals. In immunocompromised individuals, a hyperinfection syndrome with dissemination of the organism can occur. Hyperinfection syndrome has a higher mortality rate and occurs usually in immigrants who become immunosuppressed as a result of chemotherapy, use of steroids, or illness. Diagnosis is made by stool examination (approximately 30% to 50% sensitivity) (E-Fig. 103-9) or by serology but does not distinguish between chronic and acute disease. Treatment is with ivermectin for 2 days; in the setting of hyperinfection, a longer course is required.

Schistosomiasis

Schistosomiasis is found throughout the tropics and the developing world. Also known as blood flukes, schistosomes use freshwater mollusks as their intermediate host and penetrate the skin of individuals, leading to infection. The three major species are: *Schistosoma mansoni* (Africa, Middle East, South America), *Schistosoma haematobium* (Africa, Middle East), and *Schistosoma japonicum* (China, Philippines, and Southeast Asia). Acute infection can manifest with dermatitis, although most cases are asymptomatic. Chronic infection develops from the immune response to egg deposition. *S. haematobium* can lead to urinary obstruction or hematuria, whereas *S. mansoni* and *S. japonicum* can lead to hepatosplenomegaly, hepatic fibrosis, obstruction of portal blood flow, and varices. *S. japonicum* can infect the central nervous system causing ring enhancing lesions and seizures. Diagnosis is by examination of stool or urine for schistosome eggs in individuals from endemic areas, who have a high egg burden; among travelers, in whom the egg burden is usually low, serology is used for diagnosis. The treatment of choice is praziquantel.

Lymphatic Filariasis (Elephantiasis)

Wuchereria bancrofti and *Brugia malayi* are found throughout the tropics; they are lymph-dwelling filariae that cause elephantiasis. The presentation can vary from acute lymphadenitis, to asymptomatic microfilaremia, filarial fevers, or tropical pulmonary eosinophilia. Lymphadenitis can involve both upper and lower extremities with both of these filarial species, but scrotal involvement only occurs with *W. bancrofti*. The diagnosis is made by examination of a peripheral blood smear for microfilariae obtained between 10 PM and 4 AM because these organisms are nocturnally periodic.

Diethylcarbamazine is used for lymphatic filariasis to eradicate the microfilariae and the adult worms. However, the management of chronic lymphatic obstruction remains a challenge because it is not fully reversible and requires supportive therapy.

Loa loa (Eyeworm)

Loiasis is caused by the eyeworm (*Loa loa*) and is found in West and Central Africa. Presentation can vary and may include pruritus, subcutaneous swellings, joint manifestations, or neurologic symptoms. In the rarest presentation, the adult worm can be seen in the anterior chamber of the individual's eye. Diagnosis is confirmed by the presence of microfilariae in blood samples or isolation of the adult worm. Treatment is as for lymphatic filariasis, with diethylcarbamazine.

River Blindness

Onchocerca volvulus infection mostly occurs in regions of West and Central Africa but also in South and Central America. Pruritic dermatitis is the most common presentation; but involvement of the eye is the most serious presentation. Ocular involvement occurs in endemic areas in individuals with heavy worm burden. The complications can begin with conjunctivitis and photophobia. Corneal involvement with the microfilariae causes an inflammatory reaction leading to sclerosing keratitis and blindness. River blindness is the most common cause of blindness in Africa. The diagnosis is made by examination of skin snips for microfilariae. Ivermectin is the drug of choice; an initial single dose is followed by a repeat dose at 3 or 6 months to suppress any further microfilariae.

Clonorchiasis

Clonorchis sinensis is the Chinese liver fluke. This is an important infection to consider in Asian immigrants who have symptoms consistent with biliary tract disease, including right upper quadrant pain, anorexia, and weight loss. Though the disease is uncommon, untreated infections can lead to cholangiocarcinoma. Treatment is curative with praziquantel in 85% of cases.

Cysticercosis

Cysticercosis is caused by the pork tapeworm, *Taenia solium*. Individuals report new-onset seizures or headaches. Head computed tomographic (CT) scans show ring-enhancing lesions. The diagnosis is usually based on the history and imaging findings, and confirmation can be made by immunoblot assay. Treatment depends on the site of infection and symptoms. It may include antiparasitic treatment, antiseizure medications, and surgical removal. The antiparasitic drug of choice is praziquantel.

E-FIGURE 103-8 Hookworm egg.

E-FIGURE 103-9 *Strongyloides* stool wet preparation.

or albendazole. Expert consultation before treatment is recommended because of the risk of increasing focal cerebral edema and seizure activity.

Intestinal Tapeworms

Tapeworms that commonly infect humans include *Taenia solium* (from raw pork), *Taenia saginata* (raw beef), and *Diphyllobothrium latum* (raw fish). Most infections are asymptomatic except in the case of invasive disease with *T. solium*, as discussed earlier (see Cysticercosis). Praziquantel is the treatment of choice for all three tapeworms.

Echinococcus

The tapeworm *Echinococcus granulosus* causes hydatid disease with production of a cystic liver mass. This occurs in immigrants from sheep-raising parts of the world such as South America, Central Asia, and the Middle East. The characteristic appearance of the cyst includes a calcified wall with a dependent hydatid on CT scans. This appearance and the supporting history help to make the diagnosis; the serologic testing available can be falsely negative. Treatment is surgical removal of the cyst without rupture or spillage of the contents. Albendazole is usually given before surgical removal.

Less common is *Echinococcus multilocularis*, which causes alveolar cyst disease. This more aggressive infection leads to liver

lesions as well as brain and lung involvement. Treatment includes resection of liver lesions in combination with antiparasitic therapy with mebendazole or albendazole. However, these agents are not parasitocidal, so the mortality rate remains high. Other potential therapies, such as amphotericin B and nitrazoxanide, are being explored.

Neurologic Evaluation of the Patient

Frederick J. Marshall

INTRODUCTION

To arrive at an accurate neurologic diagnosis, the clinician generates and tests hypotheses about the location and the mechanism of injury to the nervous system. Hypotheses are refined as the clinician progresses from the interview to the physical examination to the laboratory assessment of the patient. The focus is first placed on entities that are common, serious, and treatable. Typical clinical presentations of patients with common diseases account for 80% of cases, unusual presentations of patients with common diseases account for 15%, typical presentations of patients with rare diseases account for 5%, and unusual presentations of patients with rare diseases account for less than 1%.

TAKING A NEUROLOGIC HISTORY

The clinician must determine the location, quality, and timing of symptoms. He or she must ask the patient to report the progression of symptoms rather than a litany of diagnostic procedures and specialty evaluations. Establishing when the patient last felt normal is important. Ambiguous descriptors such as *dizzy* should be rejected in favor of evocative descriptors such as *light-headed* (which may implicate cardiovascular insufficiency) or *off balance* (which may implicate cerebellar or posterior column dysfunction).

Family members and other witnesses should corroborate historical information when appropriate. Historical information should include the medical and surgical histories; current medications; allergies; family history; review of systems; and social history, including the patient's level of education, work history, possible toxin exposures, substance use, sexual history, current life circumstance, and overall function.

Clues to localization are sought during the interview. For example, pain is usually caused by a lesion of the peripheral nervous system, whereas aphasia (i.e., disordered language processing) indicates an abnormality of the central nervous system. Because sensory and motor functions are anatomically relatively distant in the cerebral cortex but progressively closer together as fibers converge in the brain stem, spinal cord, roots, and peripheral nerves, the coexistence of sensory loss and motor dysfunction in a limb implies a large lesion at the level of the cortex or a smaller lesion lower down in the neuraxis. Small lesions in areas of high traffic such as the spinal cord or brain stem can result in widespread neurologic dysfunction, whereas small lesions elsewhere may be asymptomatic.

Table 104-1 lists the potential localizing values of common neurologic symptoms to help address the issue of lesion localization. Tables 104-2 and 104-3 list symptoms that are commonly associated with lesions at specific locations in the nervous system. Some symptoms can result from a lesion at any of several levels of the nervous system. For example, double vision can result from a focal lesion in the brain stem, peripheral nerves (cranial nerve III, IV, or VI), neuromuscular junction, or extraocular muscles; or it can be nonfocal and result from an increase in intracranial pressure. Associated symptoms (or their lack) may lead the interviewer to reject certain hypotheses that at first seemed most likely. Table 104-4 lists the most important types of neuropathologic conditions and provides examples of diseases in each category.

Some neuroanatomic locations point to a specific diagnosis or a limited number of diagnoses. For example, disease of the neuromuscular junction is usually caused by an autoimmune process such as myasthenia gravis (common) or Eaton-Lambert myasthenic syndrome (uncommon). The exceptions—botulism and congenital myasthenic disorders—are rare. Alternatively, some areas of the nervous system (e.g., the cerebral hemispheres) are vulnerable to practically any of the categories of disease outlined in Table 104-4.

The pace and temporal order of symptoms are important. Degenerative diseases usually progress gradually, whereas vascular diseases (e.g., stroke, aneurysmal subarachnoid hemorrhage) progress rapidly. Certain symptoms such as double vision almost invariably develop abruptly, even if the underlying disorder has been developing gradually over days to weeks.

TABLE 104-1 POTENTIAL LOCALIZING VALUE OF COMMON NEUROLOGIC SYMPTOMS

POTENTIAL LOCALIZING VALUE	SIGN OR SYMPTOM
High	Focal weakness, sensory loss, or pain Focal visual loss Language disturbance Neglect or anosognosia
Medium	Vertigo Dysarthria Clumsiness
Low	Fatigue Headache Insomnia Dizziness Anxiety, confusion, or psychosis

TABLE 104-2 SYMPTOM LOCALIZATION IN THE CENTRAL NERVOUS SYSTEM

SIGN OR SYMPTOM	LOCATION
CEREBRAL HEMISPHERES	
Unilateral weakness or sensory complaints	Contralateral cerebral hemisphere
Language dysfunction	Left hemisphere (frontal and temporal)
Spatial disorientation	Right hemisphere (parietal and occipital)
Anosognosia (lack of insight into deficit)	Right hemisphere (parietal)
Hemivisual loss	Contralateral hemisphere (occipital, temporal, and parietal)
Flattening of affect or social disinhibition	Bihemispheric (frontal and limbic)
Alteration of consciousness	Bihemispheric (diffuse)
Alteration of memory	Bihemispheric (hippocampus, fornix, amygdala, and mammillary bodies)
CEREBELLUM	
Limb clumsiness	Ipsilateral cerebellar hemisphere
Unsteadiness of gait or posture	Midline cerebellar structures
BASAL GANGLIA	
Slowness of voluntary movement	Substantia nigra and striatum
Involuntary movement	Striatum, thalamus, and subthalamus
BRAIN STEM	
Contralateral weakness or sensory complaints in the body with ipsilateral weakness or sensory complaints in the face	Midbrain, pons, and medulla
Double vision	Midbrain and pons
Vertigo	Pons and medulla
Alteration of consciousness	Midbrain, pons, medulla (reticular formation)
SPINAL CORD	
Weakness and spasticity (ipsilateral) and anesthesia (contralateral) below a specified level	Corticospinal and spinothalamic tracts
Unsteadiness of gait	Posterior columns
Bilateral (can be asymmetrical) weakness and sensory complaints in multiple contiguous radicular distributions	Central cord

TABLE 104-3 SYMPTOM LOCALIZATION IN THE MOTOR UNIT*

SIGN OR SYMPTOM	LOCATION
ANTERIOR HORN CELL	
Weakness and wasting with muscle twitching (fasciculation) but no sensory complaints	Anterior horn of spinal cord (diffuse or segmental)
SPINAL ROOT	
Weakness and sensory loss confined to a known radicular distribution (pain, a common feature, may spread)	Cervical, thoracic, lumbar, and sacral
PLEXUS	
Pain, weakness, and sensory loss in a limb; not limited to a single radicular or peripheral nerve distribution	Brachial and lumbosacral (may also be caused by polyradiculopathy)
NERVE	
Pain, distal weakness, and/or sensory changes confined to a single peripheral nerve distribution	Peripheral nerves (mononeuropathy)
Pain, distal weakness, and/or sensory changes affecting both sides symmetrically (usually starting in feet)	Peripheral nerves (polyneuropathy)
Pain, distal weakness, and/or sensory changes affecting scattered single peripheral nerve distributions	Peripheral nerves (mononeuropathy multiplex)
Unilateral special sensory loss	Cranial nerves I, II, V, VII, VIII, and IX
Unilateral facial weakness involving entire one half of face	Cranial nerve VII (ipsilateral)
NEUROMUSCULAR JUNCTION	
Progressive weakness with repeated use of a muscle; no sensory complaints	Ocular, pharyngeal, and skeletal
MUSCLE	
Proximal weakness; no sensory complaints	Diffuse and various patterns

*Anterior horn cell and the peripheral nervous system.

TABLE 104-4 CATEGORIES OF NEUROLOGIC DISEASE

DISEASE CATEGORY	EXAMPLE	DISEASE CATEGORY	EXAMPLE
GENETIC		DEGENERATIVE	
Autosomal dominant	Huntington's disease	Central	Parkinson's disease
Autosomal recessive	Friedreich's ataxia	Central and peripheral	Amyotrophic lateral sclerosis
X-linked recessive	Duchenne muscular dystrophy	AUTOIMMUNE	
Mitochondrial	Progressive external ophthalmoplegia	Central demyelinating	Multiple sclerosis
Sporadic	Down syndrome	Peripheral demyelinating	Guillain-Barré syndrome
NEOPLASTIC		Neuromuscular junction	Myasthenia gravis
Intrinsic	Glioblastoma	TOXIC AND METABOLIC	
Extrinsic	Metastatic melanoma	Endogenous	Uremic encephalopathy
Paraneoplastic	Cerebellar degeneration	Exogenous	Alcoholic neuropathy
VASCULAR		OTHER STRUCTURAL	
Stroke	Thrombotic, embolic, lacunar, hemorrhagic	Trauma	Spinal cord injury
Structural	Arteriovenous malformation	Hydrodynamic	Normal pressure hydrocephalus
Inflammatory	Cranial arteritis	Psychogenic	Hysterical paraparesis
INFECTIOUS			
Bacterial	Meningococcal meningitis		
Viral	Herpes encephalitis		
Protozoal	Toxoplasmosis		
Fungal	Cryptococcal meningitis		
Helminthic	Cysticercosis		
Prion	Creutzfeldt-Jakob disease		

NEUROLOGIC EXAMINATION

Performance of the main elements of a general screening neurologic examination is imperative (Table 104-5), but the examination should be tailored to confirm or disprove the clinical hypotheses generated from the patient's history. Unexpected signs must be explained, often with a return to the history for further clarification.

The examination is approached as if only one of two possible injuries has occurred—the final common pathway to a structure is disrupted, or the input to that pathway is disrupted (Fig. 104-1). In the case of the motor system, the *final common pathway* is the motor unit and includes the anterior horn cells giving rise to axons in a nerve, the nerve itself, the neuromuscular junction, and the muscle. Injury to any of these structures results in dysfunction of the muscle. Conversely, if these structures are intact, observing the muscle function may be possible under the

right circumstances. If all modes of engaging the final common pathway fail to elicit a response, the clinician can conclude that the lesion is located somewhere within the final common pathway.

For example, a man with paralysis of facial movement on one side that is caused by a lesion of cranial nerve VII cannot smile voluntarily, close his eye, or wrinkle his forehead on the affected side. Spontaneous laughter or smiling as an automatic response to a joke also fails to move the paretic side. If the problem is central, however, facial movement with involuntary (spontaneous) smiling may be preserved or increased. This observation is common in patients with facial weakness caused by a stroke.

Central input to a final common pathway in the nervous system is usually tonically inhibitory. Damage to this input typically results in overactivity of the involved muscle group. Signs of damage to central inhibitory systems include spasticity and hyperreflexia (i.e., motor cortex, subcortical white matter,

TABLE 104-5 ELEMENTS OF A GENERAL SCREENING NEUROLOGIC EXAMINATION

SYSTEMIC PHYSICAL EXAMINATION	Upper extremities: deltoids, biceps, triceps, wrist extension and flexion, finger extension and flexion, and interossei
Head (trauma, dysmorphism, and bruits)	Lower extremities: hip flexion, extension, abduction, and adduction; knee extension and flexion; ankle dorsiflexion, plantar flexion, inversion, and eversion; toe extension and flexion
Neck (tone, bruits, and thyromegaly)	
Cardiovascular (heart rate, rhythm, and murmurs; peripheral pulses and jugular venous distention)	SENSORY EXAMINATION
Pulmonary (breathing pattern, cough and cyanosis)	Light touch (posterior columns)
Abdomen (hepatosplenomegaly)	Pinprick (spinothalamic tract)
Back and extremities (skeletal abnormalities, peripheral edema, and straight-leg raising)	Temperature (spinothalamic tract)
Skin (neurocutaneous stigmata and hepatic stigmata)	Joint position sense (posterior columns)
MENTAL STATUS	Vibration (posterior columns)
Level of consciousness (awake, drowsy, and comatose)	Graphesthesia (cortical sensory)
Attention (coherent stream of thought, serial 7s)	Double simultaneous stimulation (cortical sensory)
Orientation (temporal and spatial)	Two-point discrimination (posterior columns and cortical sensory)
Memory (short and long term)	
Language (naming, repetition, comprehension, fluency, reading, and writing)	REFLEX EXAMINATION
Visuospatial skills (clock drawing and figure copying)	Standard reflexes (grades 0-4)
Judgment, insight, thought content (psychotic)	Biceps
Mood (depressed, manic, and anxious)	Triceps
CRANIAL NERVES	Brachioradialis
Olfactory (smell in each nostril)	Knee jerk
Optic (afferent pupillary function, fundoscopic examination, visual acuity, visual fields, and structural eye findings)	Ankle jerk
Oculomotor, trochlear, and abducens (smooth pursuit and saccadic eye movements, nystagmus, efferent pupillary function, and eyelid opening)	Pathologic reflexes
Trigeminal (jaw jerk, facial sensation, afferent corneal reflex, and muscles of mastication)	Babinski's sign (if present)
Facial (efferent corneal reflex, facial expression, eyelid closure, nasolabial folds, and power and bulk)	Myerson's sign (if present)
Vestibulocochlear (nystagmus, speech discrimination, Weber test, and Rinne test)	Snout (if present)
Glossopharyngeal and vagus (afferent and efferent gag reflex and uvula position)	Jaw jerk (if brisk)
Spinal accessory (power and bulk of sternocleidomastoid and trapezii muscles)	Palmomental (if present)
Hypoglossal (position, bulk, and fasciculations of tongue)	Hoffmann sign (if brisk)
MOTOR EXAMINATION	COORDINATION AND GAIT
Pronator drift (subtle corticospinal lesion)	Finger-nose-finger (action tremor suggesting cerebellar disease)
Tone and bulk of muscles (basal ganglia lesion yields rigidity, cerebellar lesion yields hypotonia, corticospinal lesion yields spasticity, nonspecific bihemispheric disease yields paratonia, hypertrophy indicates dystonia, pseudohypertrophy indicates muscle disease, and atrophy indicates lower motor neuron disease)	Rapid alternating movements (dysidiadochokinesia suggesting cerebellar disease)
Adventitious movements (tremor, tic, dystonia, and chorea indicate disease of the basal ganglia; asterix and myoclonus may indicate toxic metabolic process)	Fine motor movements (slowness and small amplitude suggesting basal ganglia or corticospinal tract abnormalities)
Power of major muscle groups (scale 0-5)	Heel-to-shin (ataxia suggesting cerebellar disease)
	Arising from chair with arms folded across chest (inability in advanced basal ganglia, cerebellar, corticospinal, or muscle disease)
	Walking naturally (look for decreased arm swing, spasticity, broad base, festination, waddle, footdrop, start hesitation, and dystonia)
	Tandem gait (look for ataxia)
	Walking with feet everted or inverted (look for latent dystonia)
	Hopping on each foot separately (look for latent dystonia)
	Stand with feet together and eyes open, eyes closed (sensory ataxia and cerebellar disease)
	Response to retropulsive stress (loss of postural righting mechanisms)

FIGURE 104-1 The nervous system can be conceptually reduced to a series of higher-order inputs that converge on final common pathways. For example, upper motor neurons converge on lower motor neurons, whose axons form the final common pathway to an effector muscle.

or corticospinal pathways in the brain stem and spinal cord); dystonia, rigidity, tremor, and tic (i.e., basal ganglia or extrapyramidal systems); and ataxia and dysmetria (i.e., cerebellum). An exception is hypotonia, which is caused by cerebellar disease.

TECHNOLOGIC ASSESSMENT

Laboratory investigations and special testing should be used to confirm a clinical suggestion and to finalize the diagnosis. Testing should be selectively performed because of expense, risk, and discomfort to the patient. Frequently helpful tests are discussed in subsequent sections. Diagnostic tests should never be ordered without a specific differential diagnosis firmly in mind. Many neurodiagnostic tests disclose incidental abnormalities unrelated to a patient's symptomatic disease process.

Lumbar Puncture

Investigation of the cerebrospinal fluid (CSF) is indicated in a small number of specific circumstances, usually meningitis and encephalitis (Table 104-6). When taken, a CSF specimen should be routinely sent for laboratory testing to determine cell and differential counts, protein and glucose levels, and bacterial cultures. The CSF should also be examined for its color and clarity. Cloudy or discolored CSF should be centrifuged and examined for xanthochromia in comparison with water. Additional, special studies may be obtained as appropriate, including Gram stain; fungal, viral, and tuberculous cultures; cryptococcal and other antigens; tests for syphilis; Lyme titers; malignant cytologic patterns; paraneoplastic and other specific protein antibodies; and oligoclonal bands. Polymerase chain reaction for specific viruses may also be appropriate. Assessment of specific CSF proteins such as tau, phosphorylated tau, and amyloid- β in patients at risk for dementia is considered more useful in research than clinical settings. The 14-3-3 protein may be found in patients with rapid-onset dementia.

Recording the opening and closing pressures is important. Tissue infection in the region of the puncture site is an absolute contraindication to lumbar puncture. Relative contraindications

TABLE 104-6 INDICATIONS FOR LUMBAR PUNCTURE

URGENT (DO NOT WAIT FOR BRAIN IMAGING)

Acute central nervous system infection in the absence of focal neurologic signs

LESS URGENT (WAIT FOR BRAIN IMAGING)

Vasculitis, subarachnoid hemorrhage, or cryptic process
 Increased intracranial pressure in the absence of mass lesion on magnetic resonance imaging or computed tomography
 Intrathecal therapy for fungal or carcinomatous meningitis
 Symptomatic treatment for headache from idiopathic intracranial hypertension or subarachnoid hemorrhage

include known or probable intracranial or spinal mass lesion, increased intracranial pressure as a result of mass lesions, coagulopathy caused by thrombocytopenia (usually correctable), anti-coagulant therapy, and bleeding disorders.

Rare but severe complications of lumbar puncture include transtentorial or foramen magnum herniation, spinal epidural hematoma, spinal abscess, herniated or infected disk, meningitis, and adverse reaction to a local anesthetic agent. More common and relatively benign complications include headache and backache.

Tissue Biopsies

In selected specialty centers, a diagnostic biopsy is performed on various tissues, including brain, peripheral nerve (see Chapter 121), muscle (see Chapter 121), and skin. Occasionally, biopsy provides the only means of arriving at a definitive diagnosis.

Electrophysiologic Studies

Electrophysiologic studies include electroencephalography, electromyography, nerve conduction studies, and evoked potentials. These studies are helpful in situations in which the patient cannot be examined or interviewed adequately.

Electroencephalography is most often used to investigate seizures (see Chapter 118). It can document encephalopathy, in which case the background electrical activity of the brain is slowed, and it is also used in the evaluation of brain death.

Electromyography is useful in the differential diagnosis of muscle disease, neuromuscular junction disease, peripheral nerve disease, and anterior horn cell disease (see Chapter 121). Nerve conduction studies (see Chapters 122 and 123) may show decreased amplitude (characteristic of axonal neuropathy) or decreased velocity (characteristic of demyelinating neuropathy).

Visual-evoked potential studies are commonly used in the evaluation of possible multiple sclerosis (see Chapter 120). Asymmetrical slowing of the cortical response to visual pattern stimulation suggests demyelination in the optic nerve or central optic pathways. Brain stem auditory-evoked potential studies are useful in the diagnosis of diseases affecting cranial nerve VIII or its central projections. Lesions at the cerebellopontine angle and the brain stem cause abnormal delay in conduction. Brain stem auditory-evoked potentials are helpful in the diagnosis of deafness in infants. Somatosensory-evoked potentials are used to identify a slowing of central sensory conduction that results from demyelinating disease, compression, or metabolic derangements.

TABLE 104-7 MAGNETIC RESONANCE IMAGING VERSUS COMPUTED TOMOGRAPHY

MAGNETIC RESONANCE IMAGING (MRI)

Resolution 1-2 mm (higher with newer 3-Tesla magnets)
 Gadolinium contrast relatively safe, except in severe renal insufficiency
 Unaffected by bone; multiple planes of imaging available; functional (physiologic) imaging capacity

COMPUTED TOMOGRAPHY

Resolution >5 mm
 Iodine contrast associated with anaphylaxis and rash
 Faster acquisition than MRI
 Metallic objects such as pacemaker or aneurysm clip preclude MRI
 Acute hemorrhage well visualized
 Better tolerated by patients who are severely ill or claustrophobic

They are also used to evaluate spinal cord–mediated sensory abnormalities.

Imaging Studies

Magnetic resonance imaging (MRI) and computed tomography (CT) are high-resolution imaging techniques that provide extraordinary diagnostic precision for central nervous system lesions. Most neurologic diseases, however, can have normal CT and MRI findings. Moreover, many abnormal findings on CT and MRI bear no relation to the diagnosis responsible for the patient's symptoms.

Table 104-7 compares CT with MRI. MRI is used for most purposes, although CT has the advantage of wider accessibility, greater speed of acquisition, and better tolerability by the patient. CT detects acute hemorrhage and is preferred for emergencies. MRI provides more detail and simultaneously obtains images in the horizontal, vertical, and coronal planes. Contrast media for CT or MRI are useful in the diagnosis of tumors, abscesses, and other processes that derange the blood-brain barrier. MRI can be used for functional imaging and spectroscopy; both techniques have great promise for the evaluation of cognitive and metabolic disorders, epilepsy, multiple sclerosis, and many other conditions.

MR- and CT-angiography allow noninvasive visualization of the major vessels of the head and neck. Conventional angiography with an intra-arterial injection of contrast agent is used for evaluation of many intracranial vascular abnormalities, including small aneurysms and arteriovenous malformations, and inflammation of small blood vessels.

Noninvasive ultrasonography of the carotid and vertebral arteries can define stenotic vessels. It has been supplemented by transcranial Doppler technology, which allows characterization of blood flow in intracranial arteries.

Single-photon emission CT (SPECT) is useful for the evaluation of intracranial blood flow. The development of iodine-123 ioflupane injection (DaTscan) makes it possible to visualize the dopamine transporter to follow cell loss in patients with Parkinson's disease.

Positron-emission tomography (PET) is a functional imaging technology that can demonstrate specific metabolic derange-

TABLE 104-8 NEUROLOGIC CONDITIONS FOR WHICH GENETIC TESTS ARE AVAILABLE

- Neuromuscular diseases: nerve (Charcot-Marie-Tooth disease); muscle (myotonic dystrophy, Duchenne-Becker muscular dystrophy; anterior horn cell (spinal muscular atrophy, familial amyotrophic lateral sclerosis)
- Movement disorders: spinocerebellar ataxia, multiple types; Friedreich's ataxia; dystonia (*DYT1* mutation); Huntington's disease
- Mental retardation (fragile X syndrome)
- Mitochondrial diseases: mitochondrial encephalomyelopathy, lactic acidosis, and strokelike symptoms (MELAS syndrome); myoclonus epilepsy with ragged red fibers (MERRF syndrome).

ments. It is useful for evaluating local abnormalities of glucose and oxygen metabolism. PET is of particular value in defining the site of origin of focal seizures. Customized ligands may be used to identify specific pathologic processes. Examples include florbetapir F-18 (Amyvid), a U.S. Food and Drug (FDA)–approved agent for estimating β -amyloid neurotic plaque density in Alzheimer's disease, and fluorodopa F18, which is under FDA review for diagnostic use in Parkinson's disease.

Genetic and Molecular Testing

There are more neurologic diseases than diseases of all other systems combined. Discoveries have revolutionized the diagnostic approach to many of these diseases, and new genetic tests are discovered every year. Table 104-8 outlines the tests that are commercially available.

Genetic testing for a disorder requires the clinician to perform a thoughtful and caring evaluation of the patient, usually with input from and evaluation of the patient's family. Important ethical issues surround the use of genetic tests, including the ability to ensure privacy, to ensure adequate psychological and social support for patients who may be given devastating news, and to address adequately the appropriateness of prenatal screening or presymptomatic testing when no treatment is available.

PROSPECTUS FOR THE FUTURE

Novel imaging techniques and molecular diagnostic studies are beginning to shed light on the pathogenesis of neurologic conditions that have been identifiable only by clinical phenomenology. Studies of previously untreatable neurodegenerative disorders are now targeting presymptomatic individuals in the hope that earlier intervention can modify disease outcomes. Despite these and foreseeable future advances, the clinical aspects of neurologic disease remain fundamentally important in understanding the impact of disease on patients and their families.

Disorders of Consciousness

Mohamad Chmayssani and Paul M. Vespa

INTRODUCTION

Coma is a sleeplike state in that the patient is unresponsive and the eyes remain closed even with vigorous stimulation. A poorly responsive state in which the eyes are open, or an agitated and confused state, or delirium is not coma but may represent early stages of the same disease processes and should be investigated in the same manner.

Consciousness requires that the brainstem reticular activating system and its cortical projections be intact and functioning. The reticular formation begins in the midpons and ascends through the dorsal midbrain to synapse in the thalamus; it then innervates higher centers through thalamocortical connections. Knowledge of this anatomic substrate provides the short list of regions to be investigated in the search for a structural cause of coma: Brainstem or bihemispheric dysfunction satisfies these anatomic requirements, whereas structural lesions elsewhere are not the cause of the patient's unconsciousness. In addition to structural lesions, meningeal inflammation, metabolic encephalopathy, and seizures diffusely affect the brain and complete the differential diagnosis for the patient in coma.

PATHOPHYSIOLOGIC FACTORS

Meningeal irritation caused by infection or blood in the subarachnoid space is an essential early consideration in coma evaluation because its cause requires immediate attention (especially with purulent meningitis) and may not be diagnosed by computed tomography (CT).

Hemispheric mass lesions result in coma either by expanding across the midline laterally to compromise both cerebral hemispheres or by impinging on the brainstem to compress the rostral reticular formation. These processes—*lateral herniation* (lateral movement of the brain) and *transtentorial herniation* (vertical movement of the brain)—most commonly occur together. At the bedside, clinical signs of an expanding hemispheric mass evolve in a level-by-level, rostral-caudal manner (Fig. 105-1). Hemispheric lesions of adequate size to produce coma are readily seen on CT.

Brainstem mass lesions produce coma by directly affecting the reticular formation. Because the pathways for lateral eye movements—the pontine gaze center, medial longitudinal fasciculus, and oculomotor (third nerve) nucleus—traverse the

	Pupillary light response	Reflex eye movements	Motor response to pain

FIGURE 105-1 The evolution of neurologic signs in coma from a hemispheric mass lesion as the brain becomes functionally impaired in a rostral-caudal manner. The terms *early diencephalic* and *late diencephalic* refer to levels of dysfunction just above and just below the thalamus, respectively. (From Aminoff MJ, Greenberg DA, Simon RP: Clinical neurology, Stamford, Conn., 1996, Appleton and Lange.)

**TABLE 105-1** MULTIFOCAL DISORDERS INDICATING METABOLIC COMA

Disseminated intravascular coagulopathy	Thrombotic thrombocytopenic purpura
Sepsis	Fat emboli
Pancreatitis	Hypertensive encephalopathy
Vasculitis	Diffuse micrometastases

reticular activating system, impairment of reflex eye movements is often the critical element of diagnosis of a brainstem lesion. A comatose patient without impaired reflex lateral eye movements does not have a mass lesion compromising brainstem structures in the posterior fossa. CT is not able to show some lesions in this region. Posterior fossa lesions may block the flow of cerebrospinal fluid from the lateral ventricles, resulting in the dangerous situation of *noncommunicating hydrocephalus*.

Metabolic abnormalities are caused by deficiency states (e.g., thiamine, glucose), by derangements of metabolism (e.g., hyponatremia), or by the presence of *exogenous toxins* (e.g., drugs) or *endogenous toxins* (e.g., organ system failure). Metabolic abnormalities result in diffuse dysfunction of the nervous system; therefore, with rare exceptions, they produce no localized signs such as hemiparesis or unilateral papillary dilation. The diagnosis of *metabolic encephalopathy* means that the examiner has found no focal anatomic features on examination or neuroimaging studies to explain coma but that a specific metabolic cause has not been established. Drugs have a predilection for affecting the reticular formation in the brainstem and for producing paralysis of reflex eye movement on examination. *Multifocal structural disorders* may simulate metabolic coma (Table 105-1).

In the late stages of status epilepticus, motor movements may be subtle even though *seizure activity* is continuing throughout the brain (nonconvulsive status epilepticus). Once seizures stop, the so-called *postictal state* can also cause unexplained coma.

DIAGNOSTIC APPROACH

The history and examination are essential in the diagnosis and are not replaced by brain imaging (Table 105-2). A history of a premonitory headache supports a diagnosis of meningitis, encephalitis, or intracerebral or subarachnoid hemorrhage. A preceding period of intoxication, confusion, or delirium points to a diffuse process such as meningitis or endogenous or exogenous toxins. The sudden apoplectic onset of coma is particularly suggestive of ischemic or hemorrhagic stroke affecting the brainstem or of subarachnoid hemorrhage or intracerebral hemorrhage with intraventricular rupture. Lateralized symptoms of hemiparesis or aphasia before coma occur in patients with hemispheric masses or infarctions.

The physical examination is critical, quickly accomplished, and diagnostic. The issues are three: (1) Does the patient have meningitis? (2) Are signs of a mass lesion present? and (3) Is this condition a diffuse syndrome of exogenous or endogenous metabolic etiology? Emergency management should then be instituted accordingly (Table 105-3).

Identification of Meningitis

Signs of meningeal irritation are not invariably present and have differing sensitivities depending on the cause: They are extremely

TABLE 105-2 CAUSES OF COMA WITH NORMAL COMPUTED TOMOGRAPHY SCAN

Meningeal disorders	Endogenous toxins, deficiencies, derangements
Subarachnoid hemorrhage (uncommon)	Hypoxia and ischemia
Bacterial meningitis	Hypoglycemia
Encephalitis	Hypercalcemia
Subdural empyema	Osmolar causes
Exogenous toxins	Hyperglycemia
Sedative drugs and barbiturates	Hyponatremia
Anesthetics and γ -hydroxybutyrate*	Hypertatremia
Alcohols	Organ system failure
Stimulants	Hepatic encephalopathy
Phencyclidine†	Uremic encephalopathy
Cocaine and amphetamine‡	Pulmonary insufficiency (carbon dioxide narcosis)
Psychotropic drugs	Seizures
Cyclic antidepressants	Prolonged postictal state
Phenothiazines	Spike-wave stupor
Lithium	Hypothermia or hyperthermia
Anticonvulsants	Brainstem ischemia
Opioids	Basilar artery stroke
Clonidine§	Pituitary apoplexy
Penicillins	Conversion or malingering
Salicylates	
Anticholinergics	
Carbon monoxide, cyanide, and methemoglobinemia	

*General anesthetic, similar to γ -aminobutyric acid; used as a recreational drug and body building aid. It has a rapid onset and rapid recovery, often with myoclonic jerking and confusion. It causes deep coma lasting 2 to 3 hours (Glasgow Coma Scale score = 3) with maintenance of vital signs.

†Coma associated with cholinergic signs: lacrimation, salivation, bronchorrhea, and hyperthermia.

‡Coma after seizures or status epilepticus (i.e., a prolonged postictal state).

§An antihypertensive agent that is active through the opiate receptor system; overdose is frequent when used to treat narcotic withdrawal.

TABLE 105-3 EMERGENCY MANAGEMENT

1. Ensure airway adequacy.
2. Support ventilation and circulation.
3. Obtain blood for glucose, electrolytes, hepatic and renal function, prothrombin and partial thromboplastin times, complete blood count, and drug screen.
4. Administer 100 mg of thiamine intravenously (IV).
5. Administer 25 g of dextrose IV (typically 50 mL of 50% dextrose) to treat possible hypoglycemic coma.*
6. Treat opiate overdose with naloxone (0.4-2 mg IV repeated every 2-3 minutes as needed).
7. The specific benzodiazepine antagonist flumazenil (0.2 mg IV every 1 min, x1-5 doses; max is 1 mg) should be given for reversal of benzodiazepine-induced coma or conscious sedation.†

*The glucose level is poorly correlated with the level of consciousness in hypoglycemia; stupor, coma, and confusion are reported with blood glucose concentrations ranging from 2 to 60 mg/dL.

†Not recommended in coma of unknown origin because seizures may be precipitated in patients with polydrug overdoses that include benzodiazepines with tricyclic antidepressants or cocaine.

common with acute pyogenic meningitis and subarachnoid hemorrhage and less common with indolent, fungal meningitis. Nevertheless, the presence of these signs on examination is the central clue to the diagnosis. Missing these signs results in time-consuming additional tests such as brain imaging and the potential loss of a narrow window of opportunity for directed therapy.

Passive neck flexion should be carried out (Fig. 105-2) in all comatose patients unless a history of head trauma exists. When the neck is passively flexed by attempting to bring the chin within

FIGURE 105-2 Elicitation of Brudzinksi's sign of meningeal irritation, as seen in infectious meningitis or subarachnoid hemorrhage. (From Aminoff MJ, Greenberg DA, Simon RP: Clinical neurology, Stamford, Conn., 1996, Appleton and Lange.)

a few fingerbreadths of the chest, patients with irritated meninges reflexively flex one or both knees. This sign, called *Brudzinksi's reflex*, is usually asymmetrical and not dramatic, but any evidence of knee flexion during passive neck flexion mandates that the cerebrospinal fluid be examined.

Is CT required before lumbar puncture in this setting? In the absence of lateralized signs (e.g., hemiparesis) supporting a superimposed mass lesion, a spinal puncture should be performed immediately. Although rare cases of herniation after lumbar puncture have been reported in children with bacterial meningitis, the urgency of diagnosis and treatment at the point of coma is paramount. The time required for CT may result in a fatal therapeutic delay. An alternative approach involves obtaining blood cultures and immediately initiating antibiotic therapy with subsequent lumbar puncture. With this approach, the cerebrospinal fluid cell count, glucose determination, and protein content are unchanged, and Gram stain and culture often remain positive despite a short period of antibiotic treatment. Bacterial antigens in the cerebrospinal fluid or blood can also be detected.

Separation of Structural from Metabolic Causes of Coma

The goal of this differential diagnosis is achieved by neurologic examination. Because the evaluation and potential treatments for structural and metabolic coma are widely divergent and the disease processes in both categories are often rapidly progressive, initiating prompt medical and surgical evaluation may be life-saving. Identification of a structural versus a metabolic cause is accomplished by focusing on three features of the neurologic examination: the *motor response* to a painful stimulus, *pupillary function*, and *reflex eye movements*.

Motor Response

Asymmetrical or reflex function of the motor system provides the clearest indication of a mass lesion. Elicitation of a *motor response* requires that a painful stimulus be applied, to which the patient will react. The patient's arms should be placed in a semiflexed posture, and a painful stimulus should be applied to the head or trunk. Strong pressure on the supraorbital ridge or pinching of the skin on the anterior chest or inner arm is the most useful method; finger nail bed pressure is also used, but it makes the interpretation of upper limb movement difficult.

The neurologic examination of a patient with an expanding hemispheric mass lesion is shown in [Figure 105-1](#). Hemispheric masses in their *early diencephalic* stage (i.e., compromising the brain above the thalamus), produce appropriate movement of one upper extremity—that is, movement toward the painful stimulus. The attenuated contralateral arm movement reflects a hemiparesis. This lateralized motor response in a comatose patient establishes the working diagnosis of a hemispheric mass. As the mass expands to involve the thalamus (*late diencephalic* stage), the response to pain becomes reflex arm flexion associated with extension and internal rotation of the legs (*decorticate posturing*); asymmetry of the response in the upper extremities is seen. With further brain compromise at the midbrain level, the reflex posturing in the arms changes such that both arms and legs respond by extension (*decerebrate posturing*); at that level, the asymmetry tends to be lost. At this point, the pupils become midposition in size, and the light reflex is lost, first unilaterally and then bilaterally. With further progression to the level of the pons, the most frequent finding is no response to painful stimulation, although spinal-mediated movements of leg flexion may occur.

The classic postures illustrated in [Figure 105-1](#), and particularly their asymmetry, strongly support the presence of a mass lesion. However, these motor movements, especially early in coma, are most frequently seen as fragments of the fully developed, asymmetrical flexion or extension of the arms (illustrated as decorticate and decerebrate postures in [Figure 105-1](#)). A small amount of asymmetrical flexion or extension of the arms in response to a painful stimulus carries the same implications as the full-blown postures of decortication or decerebration.

Metabolic lesions do not compromise the brain in a progressive, level-by-level manner as do hemispheric masses, and they rarely produce the asymmetrical motor signs typical of masses. Reflex posturing may be seen, but it lacks the asymmetry of decortication seen with a hemispheric mass, and it is not associated with the loss of pupillary reactivity at the stage of decerebration.

Pupillary Reactivity

In metabolic coma, one feature is central to the examination: Pupillary reactivity is present. This reactivity is seen both early in metabolic coma, when an appropriate motor response to pain may be retained, and late in coma, when no motor responses can be elicited. The pupillary reaction in metabolic coma is lost only when coma is so deep that the patient requires ventilatory and blood pressure support.

Reflex Eye Movements

The presence of inducible lateral eye movements reflects the integrity of the pons and midbrain. These reflex eye movements (see [Fig. 105-1](#)) are brought about with the use of passive head rotation to stimulate the semicircular canal input to the vestibular system (so-called *doll's eyes maneuver*) or by inhibiting the function of one semicircular canal by infusing ice water against the tympanic membrane (caloric testing).

In metabolic coma, reflex eye movements may be lost or retained. Lack of inducible eye movements with the doll's eyes maneuver, in the setting of preserved pupillary reactivity, is

virtually diagnostic of drug toxicity. With metabolic coma of non-drug-induced origin, such as organ system failure, electrolyte disorders, or osmolar disorders, reflex eye movements are preserved.

Brainstem mass lesions are most commonly caused by hemorrhage or infarction. Reflex lateral eye movements, the pathways for which traverse the pons and midbrain, are particularly affected, and the reflex postures of decortication and decerebration typical of brainstem injury are common. Lesions restricted to the midbrain (e.g., embolization from the heart to the top of the basilar artery) cause sluggish pupillary reflexes or their absence, with or without impaired medial eye movements; both are controlled by the third cranial nerve. With lesions restricted to the pons (e.g., intrapontine hypertensive hemorrhage), pupils are reactive but very small (pinpoint or pontine pupils), reflecting focal impairment of sympathetic innervations; pinpoint pupils are rare. Ocular bobbing (spontaneous symmetrical or asymmetrical rhythmic vertical ocular oscillations) is most often a manifestation of a pontine lesion.

Seizures occurring in a patient with acute brain injury (such as that resulting from encephalitis, hypertensive encephalopathy, hyponatremia, hypernatremia, hypoglycemia, or hyperglycemia) or chronic brain injury (such as dementia or mental retardation) often result in prolonged postictal coma. The examination shows reactive pupils and inducible eye movements (in the absence of overtreatment with anticonvulsants), and often up-going toes or focal signs are often observed (Todd's paresis).

Nonconvulsive status epilepticus should be considered as a diagnosis even if there are no obvious seizure movements. Nonconvulsive seizures can cause coma and also can complicate other etiologies of coma, including infectious and metabolic disorders. Nonconvulsive seizures should be suspected in patients with (1) a seemingly prolonged "postictal state" after generalized convulsive seizures or prolonged alteration of alertness after an operative procedure or neurologic insult; (2) acute onset of impaired consciousness or fluctuating mentation interspersed with episodes of normal awareness; (3) altered mental status or consciousness associated with facial myoclonus or nystagmoid eye movements; or (4) episodic blank staring, aphasia, automatism (e.g., lip-smacking, fumbling with fingers), or acute-onset aphasia without an acute structural lesion. The diagnosis is made by electroencephalography (EEG) (see [Chapter 118](#)). EEG provides information about brain electrical activity even when brain function is depressed and cannot be evaluated otherwise, as in comatose patients. EEG is essential to detect electrical seizures and document their duration as well as the response to therapy and to improve coma prognostication.

Current evidence suggests that the presence of nonconvulsive seizures or periodic discharges, delay to diagnosis, and duration of nonconvulsive status in patients with or without acute brain injury are independent predictors of worse outcome.

PROGNOSIS IN COMA

Therapeutic hypothermia has been demonstrated to improve neurologic outcomes in patients who have return of spontaneous circulation but remain comatose after cardiac arrest. Historically, prognostication after cardiac arrest was solely based on neurologic examination. Although this still holds true for the most part,

there has been extensive work using additional means besides the physical examination to better predict prognosis. Pupillary, corneal, and motor responses are the best clinical indicators of prognosis that can be assessed at bedside. Such responses give some indication of the functionality of the brainstem, which is the most resilient portion of central nervous system. Any signs of damage to the brainstem is strong evidence of cortical injury ([Fig 105-3](#)).

Current guidelines endorse the utility of EEG for predicting poor outcome in comatose survivors of cardiac arrest not treated with hypothermia. The early onset of generalized myoclonic status is an ominous sign. Serum biomarkers have been used in evaluating prognosis among comatose patients after cardiac arrest. Neuron-specific enolase (NSE) is the most promising biomarker and has been extensively studied. NSE levels of >30 ng/mL or higher have been found to predict persistent coma. Similarly, somatosensory evoked potentials (SSEPs), as electrophysiologic markers, are most helpful for predicting which patients will remain in a persistent coma. In particular, the bilateral absence of the N20 cortical response (a negative peak at 20 ms) to median nerve stimulation after 24 hours predicts a grave outcome. Despite tremendous potential, the role of neuroimaging as a prognostic tool after hypoxic-ischemic injury from cardiac arrest has yet to be clearly defined. Severe reductions in the apparent diffusion coefficient (ADC), as well as bilateral

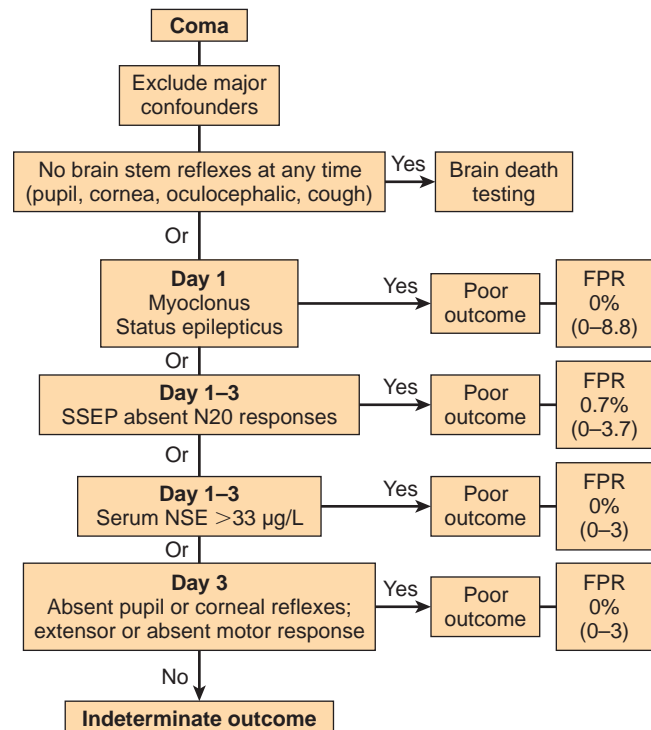

FIGURE 105-3 Decision algorithm for use in prognostication of comatose survivors after cardiopulmonary resuscitation (CPR). The numbers in parentheses show the exact 95% confidence intervals. FPR, False-positive rate; N20, a negative peak at 20 ms on SSEP; NSE, neuron-specific enolase; SSEP, somatosensory evoked potential. (Data from Wijdicks EFM, Hijdra A, Young GB, et al: Practice parameter: prediction of outcome in comatose survivors after CPR [an evidence-based review]: report of the Quality Standards Subcommittee of the American Academy of Neurology, *Neurology* 67:203-210, 2006.)

hippocampal hyperintensities on magnetic resonance imaging (MRI), suggests severe global damage and extensive ischemic injury and is highly indicative of poor outcome.

The use of therapeutic hypothermia quite likely influences the clinical examination and ancillary test findings. There is a scarcity of data about the utility of physical examination, EEG, and evoked potentials in predicting outcomes among cardiac arrest patients with induced hypothermia. It is well accepted that one should consider observation for longer than 72 hours before prognosticating outcome in patients treated with hypothermia.

COMA-LIKE STATES

Patients with *locked-in syndrome* have a lesion (usually a hemorrhage or an infarct) that transects the brainstem at a point below the reticular formation (thereby sparing consciousness) but above the ventilatory nuclei of the medulla (thereby maintaining cardiopulmonary function) (Table 105-4). Such patients are awake, with eye opening and sleep-wake cycles, but the descending pathways through the brainstem that are necessary for volitional vocalization or limb movement have been transected. Voluntary eye movement, especially vertically, is preserved, and patients can open and close their eyes or produce appropriate numbers of blinking movements in answer to questions. The EEG is usually normal, reflecting normal cortical function.

Psychogenic unresponsiveness is a diagnosis of exclusion. The neurologic examination shows reactive pupils and no reflex posturing in response to pain. Eye movements during the doll's eyes maneuver show volitional override rather than the smooth, uninhibited reflex lateral eye movements of coma. Ice water caloric testing either arouses the patient because of the discomfort produced or induces cortically mediated nystagmus rather than the tonic deviation typical of coma. The slow, conjugate roving eye movements of metabolic coma cannot be imitated and therefore rule out psychogenic unresponsiveness. Likewise, the slow, often asymmetrical, and incomplete eye closure seen after passive eye opening in a comatose patient cannot be feigned and also rules out psychogenic coma. In contrast, conscious patients usually exhibit some voluntary muscle tone in the eyelids during passive eye opening. The EEG in psychogenic unresponsiveness is that of normal wakefulness, with reactive posterior rhythms on eye opening and eye closing. In patients with catatonic stupor, lorazepam administration may produce awakening.

The vegetative state (VS), now also called *unresponsive wakefulness syndrome*, is exhibited by patients with eye opening and sleep-wake cycles. The reticular activating system of the brainstem is intact to produce wakefulness, but the connections to the cortical mantle are interrupted, precluding awareness.

A VS is termed *persistent* after 3 months if the brain injury was medical or after 12 months if the brain injury was traumatic. The determination as to when *persistent* equals *permanent* cannot be stated absolutely. Prediction early in VS of which patients will remain persistently vegetative is particularly difficult in cases of trauma. Lesions of the corpus callosum and dorsolateral brainstem seen on MRI 6 to 8 weeks after trauma correlated with persistence of VS at 1 year. A combined analysis of morphologic MRI studies and post-traumatic brainstem spectroscopy can be a predictor of persistent vegetative states (PVS) and minimally conscious states (MVS). In rare cases, patients show late improvement, but they do not return to normal. Bilateral absence of SSEPs in the first week predicts death or VS.

Patients in a PVS open their eyes diurnally and in response to loud sounds; blinking occurs with bright lights. Pupils react, and eye movements occur both spontaneously and with the doll's eyes maneuver. Yawning, chewing, swallowing, and, uncommonly, guttural vocalizations and lacrimation may be preserved. Spontaneous roving eye movements (very slow, with constant velocity) are particularly characteristic and distressing to the patient's visitors because the patient appears to be looking about the room. The brainstem origin of the eye movements is documented by their being readily redirected by the oculocephalic (doll's eyes) reflex. The limbs may move, but motor responses are only primitive; pain usually produces decorticate or decerebrate postures or fragments of these movements.

MCS is a newly described entity in which patients do not meet criteria for PVS. Both patients in PVS and those in MCS demonstrate severe alteration in consciousness. In contrast to PVS, subjects with MCS exhibit evidence of limited interaction with the environment by visually tracking, following simple commands, answering yes or no (not necessarily reliably), or having intelligible verbalization or restricted purposeful behavior. It is estimated that the rate of misdiagnosis between the VS and MCS is about 40%.

Novel applications of functional neuroimaging in patients with disorders of consciousness may aid in differential diagnosis, prognostic assessment, and identification of pathophysiologic mechanisms. In one study, authors prospectively evaluated cortical activation in response to a familiar voice in seven patients in VS and four subjects in MCS. All four of the MCS patients and only two of the VS patients showed activation that extended beyond the primary auditory cortex to hierarchically higher-order associative temporal areas. Over the course of 3 months, these two VS patients improved clinically to MCS.

Brain death characterizes the *irreversible cessation* of brain function. Therefore, death of the organism can be determined based on death of the brain. Although local laws may dictate some details, the standard definition permits a diagnosis of brain death based on documentation of irreversible cessation of all brain function, including function of the brainstem (Table 105-5). Documentation of *irreversibility* requires that the cause of the coma is known, that the cause is adequate to explain the clinical

TABLE 105-4 LOCKED-IN SYNDROME

Clinical features	Recovery possible
Eye opening	Onset over 1-12 wk (vascular)* or
Reactive pupils	Onset over 4-6 mo (nonvascular)*

*Implications for care.

TABLE 105-5 CRITERIA FOR CESSATION OF BRAIN FUNCTION*

ANATOMIC REGION TESTED	CONFIRMATORY SIGN
Hemispheres	Unresponsive and unresponsive to sensory stimuli including pain ¹
Midbrain	Unreactive pupils ²
Pons	Absent reflex eye movements ³
Medulla	Apnea ⁴

CO₂, Carbon dioxide; PCO₂, partial pressure of carbon dioxide.

*Sequential testing is necessary for a clinical diagnosis of brain death; it should be done at least every 6 hours in all cases and at least every 24 hours in the setting of anoxic-ischemic brain injury.

¹The patient does not rouse, groan, grimace, or withdraw limbs. Purely spinal reflexes (deep tendon reflexes, plantar flexion reflex, plantar withdrawal, and tonic neck reflexes) may be maintained.

²Most easily assessed by the bright light of an ophthalmoscope viewed through its magnifying lens when focused on the iris. Unreactive pupils may be either midposition, as they will be in death, or dilated, as they often are in the setting of a dopamine infusion.

³No eye movement toward the side of irrigation of the tympanic membrane with 50 mL of ice water. The oculoccephalic response (doll's eyes maneuver) is always absent in the setting of absent oculovestibular testing.

⁴No ventilatory movements in the setting of maximum CO₂ stimulation (≥60 mm Hg); with apnea, PCO₂ passively rises 2 to 3 mm Hg/min. Disconnect the ventilator from the endotracheal tube and insert a cannula with 6 L of oxygen per minute.

TABLE 105-6 EXCLUSIONARY CRITERIA FOR BRAIN DEATH

Seizures	Hypothermia (<32.2° C)
Decorticate or decerebrate posturing	Neuromuscular blockade
Sedative drugs	Shock

TABLE 105-7 CONFIRMATORY TESTS FOR BRAIN DEATH

EEG isoelectricity	Deep coma from sedative drugs or hypothermia (temperature <20° C) can produce EEG flattening.
Nuclear medicine	The most common radionuclide modality for brain imaging uses the tracer HMPAO. Absence of isotope uptake ("hollow skull phenomenon") indicates no brain perfusion and supports the diagnosis of brain death.
Transcranial Doppler	Findings of small systolic peaks without diastolic flow or a reverberating flow pattern suggest high vascular resistance and support the diagnosis of brain death. No cerebral blood flow is the most definitive confirmatory test.
CT angiography	Nonopacification of the cortical segments of MCAs and ICVs appears to be highly sensitive for confirming brain death, with a specificity of 100%. Lack of opacification of the ICVs is the most sensitive sign.

CT, Computed tomographic; EEG, electroencephalogram; HMPAO, ^{99m}Tc-labeled hexamethylpropyleneamineoxime; ICV, internal cerebral vein; MCA, middle cerebral artery.

findings of brain death, and that exclusionary criteria are absent (Table 105-6). Confirmatory tests are sometimes used but are not required for diagnosis (Table 105-7). Brain death results in asystole, usually within days (mean, 4 days), even if ventilatory support is continued. Recovery after appropriate documentation of brain death has never been reported. Removal of the ventilator results in terminal rhythms (most often complete heart block without ventricular response), junctional rhythms, or ventricular tachycardia. Purely spinal motor movements may occur in the moments of terminal apnea (or during apnea testing in the absence of passive administration of oxygen); these may include arching of the back, neck turning, stiffening of the legs, and upper extremity flexion.

Disorders of Sleep

Selim R. Benbadis

INTRODUCTION

Sleep disorders can be classified in various ways. The international classification uses an axial system to define three categories: dyssomnias, parasomnias, and sleep disorders associated with mental or neurologic diseases. From a practical point of view, sleep disorders are better classified by their clinical presentation, which is the approach taken here. This chapter focuses on primary sleep disorders rather than sleep disturbances that result from self-evident medical or psychiatric diseases.

DISORDERS OF EXCESSIVE DAYTIME SLEEPINESS

History

A careful sleep history is the starting point. It often uncovers likely causes of excessive daytime sleepiness (EDS), such as medications, systemic illnesses, sleep deprivation, or circadian rhythm disturbances. Most of the causes of EDS (e.g., insufficient sleep time, lifestyle, circadian rhythm disorders) do not require a specialized sleep evaluation. The history can elicit symptoms that suggest specific causes such as sleep-disordered breathing (i.e., sleep apnea) or narcolepsy.

To subjectively quantify EDS, various scales have been developed. The most useful in clinical practice is the Epworth Sleepiness Scale (ESS), which is an extension of the history. The ESS consists of a brief questionnaire on the likelihood of dozing off in eight situations. This yields a score between 0 and 24 (Table 106-1). Although there is no strict cutoff, scores above 10 or 11 indicate sufficiently severe EDS to warrant investigation. In addition to being disabling for the individual, EDS is a public health concern because it impairs performance and may cause motor vehicle and industrial accidents in a way comparable to alcohol intoxication.

Examination

The examination of patients with EDS should include a general neurologic examination. If sleep-disordered breathing is suspected, the upper airway should also be examined.

Sleep Studies

Polysomnography (PSG) is an all-night sleep study that measures multiple parameters such as sleep staging, respiration, leg movements, and electrocardiographic patterns. Portable or home adaptations of formal laboratory PSG are increasingly used.

The multiple sleep latency test (MSLT) and the maintenance of wakefulness test (MWT) are used to measure and quantify EDS. They consist of a series of daytime naps during which sleep

latency (i.e., latency to stage N1) is measured and sleep stages are determined. The MSLT is better standardized than the MWT. Normal sleep latency is greater than 12 minutes; latency of less than 5 minutes is evidence for severe sleepiness.

SLEEP-DISORDERED BREATHING

Definition and Epidemiology

Sleep-disordered breathing encompasses a spectrum of conditions typified by the most common: obstructive sleep apnea (OSA). The spectrum of obstructive disease extends from primary, isolated, or trivial snoring to upper airway resistance syndrome (i.e., compensated OSA) to OSA of mild, moderate, or severe degree. The degree is determined by PSG.

OSA has a prevalence of about 2% to 4%. It affects more men than women, and the incidence increases with age. Central sleep apnea is much less well defined. It has the same definitions but has no evidence of obstruction.

Pathophysiology

The pathophysiology of OSA is recurrent upper airway closure or collapse with resulting oxygen desaturation leading to arousals. Obstruction typically occurs at the level of the nasopharynx

TABLE 106-1 EPWORTH SLEEPINESS SCALE

How likely are you to doze off or fall asleep in the following situations in contrast to just feeling tired? The situations refer to your usual way of life.

Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = would never doze

1 = slight chance of dozing

2 = moderate chance of dozing

3 = high chance of dozing

What is your chance of dozing in the following situations?

Sitting and reading _____

Watching TV _____

Sitting and inactive in a public place
(theater or meeting) _____

As a passenger in a car for an hour
without a break _____

Lying down to rest in the afternoon
when possible _____

Sitting and talking to someone _____

Sitting quietly after lunch (without
alcohol) _____

In a car while stopped for a few
minutes in traffic _____

Total _____

Modified from Johns MW: A new method for measuring daytime sleepiness: the Epworth Sleepiness Scale, *Sleep* 14:540-545, 1991.

or oropharynx. The sleep fragmentation caused by arousal is responsible for sleep deprivation and EDS.

Clinical Manifestation

OSA typically manifests with a combination of EDS and snoring in a patient who is overweight. Other symptoms include apneic pauses or “choking” witnessed by the bed partner, and less specific symptoms such as morning headaches, depression, impaired cognition, and sexual dysfunction. On examination, the body mass index ($>10 \text{ kg/m}^2$) and neck circumference (>17 inches for men or 16 inches for women) predict OSA. If the patient is not obese, abnormalities of the craniofacial anatomy or upper airways (e.g., retromicrognathia, macroglossia, tonsillar hypertrophy) should be sought.

Diagnosis and Differential Diagnosis

Other causes of EDS should be considered, but in a typical case of OSA, the diagnosis is usually obvious and easily confirmed by overnight PSG. Apneas are defined as cessation (90% reduction) of airflow, whereas hypopneas are 30% to 90% reductions of airflow; both last 10 seconds or longer. These events are called *obstructive* if they occur with respiratory effort and *central* if they occur with no respiratory effort. The apnea-hypopnea index (AHI) is the total number of apneas plus hypopneas per hour, and an AHI score greater than 5 is considered abnormal. An AHI score of 5 to 10 is mild, 10 to 15 is moderate, and more than 15 is severe.

Respiratory effort–related arousals are episodes of decreased airflow with increased effort and crescendo snoring that result in arousals, and they define upper airways resistance syndrome. They represent a compensated degree of OSA. The PSG quantifies the severity in terms of event frequency (i.e., AHI), oxygen desaturation, sleep disturbances (i.e., arousals and fragmentation), and arrhythmias. With some limitations, diagnostic PSG can be performed at home with portable systems if OSA is the likely cause and there are no signs of underlying neurologic disease.

Treatment and Prognosis

Depending on severity, treatment modalities include weight loss, positional measures to prevent sleeping supine, oral appliances for mild disease, and positive airway pressure (PAP) modalities and surgery for moderate to severe disease. For patients with moderate to severe OSA, the initial treatment is PAP; its main limitation is patient compliance. Maximizing the patient’s comfort with nasal pillows, humidification, and attention to mask fit is important. PAP requires a titration study to determine the type continuous positive airway pressure (CPAP) (e.g., auto-CPAP, bilevel PAP) and pressure settings appropriate for each patient. When PAP modalities do not work, stimulants and wake-promoting agents can be used as adjuncts to help EDS.

Central sleep apnea is often associated with other cardiopulmonary abnormalities such as heart failure. It is also treated with CPAP initially, but it often requires specialized pulmonary care.

It is important to treat OSA because it has many complications. They include hypertension, coronary artery disease, stroke, diabetes mellitus, depression, and cognitive impairment.

NARCOLEPSY

Definition and Epidemiology

Narcolepsy affects at least 2 in 1000 individuals. Narcolepsy includes a tetrad of excessive sleepiness, cataplexy, sleep paralysis, and hypnagogic hallucinations. The full tetrad occurs in approximately 1 of 5000 people.

Pathophysiology

Narcolepsy is a disorder of rapid eye movement (REM) sleep regulation caused by disordered hypocretin neurotransmission, likely resulting from an autoimmune loss of hypocretin neurons in the lateral hypothalamus. It has a major genetic component, as evidenced by strong human leukocyte antigen (HLA) associations such as HLA-DQB1*0602 in black and white populations and HLA-DR2 in Japanese populations. The daytime symptoms of narcolepsy are accompanied by the intrusion of REM sleep into wakefulness.

Clinical Presentation

The mean age of onset of narcolepsy is in the mid-20s, but two peaks occur around 15 and 35 years of age. EDS is severe and almost constant, and the urge to sleep can be sudden and irresistible (i.e., sleep attacks).

Of the three accessory symptoms, cataplexy is the most specific and helpful for diagnosis. Cataplexy without narcolepsy is exceptional. Narcolepsy without cataplexy is more difficult to identify, and overlaps occur with idiopathic hypersomnia. Cataplexy is characterized by brief (seconds to a few minutes) loss of muscle tone (i.e., intrusion of REM atonia) triggered by emotions, most commonly laughter but also elation, surprise, and fear. If severe, the patient may fall. With milder attacks, a head nod or slurred speech can occur.

Hypnagogic hallucinations that are vivid and dreamlike and that occur at sleep onset are more specific for narcolepsy than hypnopompic (i.e., sleep offset) hallucinations. Sleep paralysis is the often frightening experience of inability to move while aware, usually on awakening. In addition to the tetrad, patients frequently have episodes of automatic behaviors with no recall, which can resemble complex partial seizures. Nocturnal sleep is often fragmented by frequent arousals, vivid dreams, or leg movements.

Diagnosis and Differential Diagnosis

Other causes of EDS, especially the more common OSA, should be sought. A PSG should be obtained the night before the MSLT. The PSG can exclude OSA as a cause of EDS, and an MSLT with a sleep latency of less than 8 minutes and two sleep-onset episodes of REM confirms the diagnosis. Alternatively, a CSF hypocretin level less than 110 pg/mL can confirm the diagnosis. HLA typing is more useful to exclude narcolepsy than to diagnose it because it is sensitive but not specific.

Treatment and Prognosis

Stimulants (e.g., amphetamines, methylphenidate) are still used for the treatment of EDS, but newer wake-promoting agents are more widely used. They include modafinil (100 to 400 mg twice daily) and the longer-acting, once-daily armodafinil (150 to

250 mg per day). Sodium oxybate (3 to 9 g each day) is also used to treat EDS, cataplexy, and disrupted nocturnal sleep. It is potent but short acting; it is typically administered at bedtime and again a few hours later. Sodium oxybate and modafinil may be synergistic in treating EDS. For cataplexy, antidepressants can be used (Table 106-2).

Prognosis is usually good with adequate treatment. However, narcolepsy, when severe, can remain disabling and require accommodations such as scheduled naps.

● IDIOPATHIC HYPERSONNIA

Definition and Epidemiology

Idiopathic hypersomnia is a poorly characterized syndrome with no known pathologic substrate. It is therefore a diagnosis of elimination. It is much less common than narcolepsy.

Clinical Manifestation

Patients have lifelong EDS with non-REM (long and unrefreshing) naps, and none of the REM-type accessory symptoms of narcolepsy. By definition, there must be no other cause of EDS. Patients also wake up unrefreshed (i.e., sleep inertia) from nocturnal sleep and long daytime naps, and they can have prolonged states of foginess (i.e., sleep drunkenness).

Diagnosis and Differential Diagnosis

Other causes of EDS must be excluded, and the PSG should be normal with no sleep-disordered breathing and no sleep fragmentation such as seen in narcolepsy. MSLT confirm sleep latency of less than 8 minutes but without sleep-onset REM.

Treatment and Prognosis

Treatment includes the same stimulants and wake-promoting agents as used for narcolepsy. The response is typically less satisfactory. The response to treatment is varies, and accommodation in the workplace is usually necessary.

● KLEINE-LEVIN SYNDROME

Kleine-Levin syndrome is a rare, recurrent or cyclic hypersomnia with a prevalence of 1 case per 1 million people. Its cause is unknown. Its onset is usually in the second decade, with episodes of hypersomnia lasting days to weeks and with associated hyperphagia, hypersexuality, confusion, and hallucinations. Episodes tend to recur every few months and at least once each year. Other symptomatic causes of EDS must be excluded.

Stimulants and wake-promoting agents and lithium are used for treatment. With time, episodes tend to become less severe, less prolonged, and less frequent.

TABLE 106-2 AGENTS PROMOTING WAKEFULNESS

DRUG	DOSE RANGE (MG)
Amphetamine (Dexedrine, Desoxyn, Adderall, Adderall XR)	5-60
Methylphenidate (Ritalin, Metadate, Methylin, Concerta)	10-60
Modafinil (Provigil)	200-400
Armodafinil	150-250

● PERIODIC LIMB MOVEMENT DISORDER

Definition and Epidemiology

Periodic limb movement disorder (PLMD) is characterized by repetitive movements (usually of the legs) that occur during sleep. This can be purely a PSG finding, but it is often associated with restless legs syndrome (RLS).

Pathophysiology

PLMD is caused by decreased dopamine neurotransmission.

Clinical Manifestations

Leg movements may be reported by the bed partner, and the patient may report EDS, insomnia, or symptoms of RLS (i.e., urge to move legs or walk due to unpleasant “creepy-crawly” sensations at rest). Most patients with RLS have PLMD, but the reverse is not true.

Diagnosis and Differential Diagnosis

RLS is diagnosed by the history. PLMD is diagnosed by PSG. Once established, the search for a cause of secondary PLMD should investigate the same causes as RLS: polyneuropathy, spinal cord disease, pregnancy, iron-deficiency anemia (i.e., ferritin levels), B₁₂ deficiency, uremia, medications, primary sleep disorders, narcolepsy, or OSA.

Treatment and Prognosis

Similar to RLS, pramipexole or ropinirole is used at lower doses than for treating Parkinson's disease (Table 106-3). Prognosis is usually good with treatment.

 For a deeper discussion of these topics, please see Chapter 410, “Other Movement Disorders,” in Goldman-Cecil Medicine, 25th Edition.

● INSOMNIA

Definition and Epidemiology

Insomnia is defined as difficulty initiating or maintaining sleep. Severe, chronic insomnia can have major health consequences, including depression, anxiety, drug or alcohol use, and overall higher mortality rates.

Insomnia is the most common sleep complaint in the general population. Up to one third of the population report at least occasional difficulties sleeping. Chronic insomnia (>1 month) affects about 10% of the population.

Pathophysiology

Insomnia can be caused by pain, medical conditions (e.g., chronic obstructive pulmonary disease), psychiatric conditions, and

TABLE 106-3 TREATMENTS FOR RESTLESS LEGS SYNDROME

DRUG	DOSE RANGE (MG)
Levodopa or carbidopa (Sinemet)	50-200
Ropinirole (Requip)	0.25-4.0
Pramipexole (Mirapex)	0.125-0.5

medications. Acute or short-term insomnia is caused by identifiable factors and can become a chronic, persistent problem. Chronic insomnia results from predisposing (genetic), precipitating (environmental), and perpetuating (behaviors) factors. With the exception of rare conditions such as the prion disease, fatal familial insomnia, insomnia alone is almost never the symptom of a neurologic disease.

Clinical Manifestations

Insomnia may manifest as the inability to fall asleep (i.e., onset insomnia) or to stay asleep (i.e., maintenance insomnia). In addition to nighttime symptoms, the diagnosis demands daytime symptoms considered to be the consequence of insomnia (e.g., fatigue, EDS, poor concentration, altered mood, headache).

Adjustment insomnia is an acute reaction to some type of stress. When the trigger combines with a propensity for poor or fragile sleep, the condition can become chronic (>1 month) and lead to maladaptive behaviors and a conditioned arousal associated with sleep. This is known as *psychophysiologic insomnia*, and it is by far the most common insomnia syndrome. A vicious cycle is created by poor sleep habits that worsen the insomnia. Because of its chronicity, it is typically associated with poor sleep habits, multiple treatment trials, and anxiety about sleep. If there was no trigger at onset, there may be a lifelong history of poor sleep (i.e., idiopathic insomnia) with the same end result of psychophysiologic insomnia.

Paradoxical insomnia and *sleep-state misperception* are terms applied to patients who claim to not sleep. However, when studied objectively, they have normal sleep amounts and architecture.

Diagnosis and Differential Diagnosis

The diagnosis is based on the history, which should include a sleep diary. Identifiable medical, psychiatric, or drug-related disease and other sleep disorders (e.g., OSA) require exclusion. Sleep studies (PSG and MSLT) are occasionally helpful.

Treatment and Prognosis

Nondrug treatments include common sense sleep hygiene recommendations (e.g., avoiding caffeine, exercising late in the day) (Table 106-4) and behavior modifications to avoid the conditioned arousal responses associated with sleep (e.g., using the

TABLE 106-4 SLEEP HYGIENE

1. Maintain a regular schedule each day.
2. Wake at the same time each morning.
3. Exposure to natural light entrains the circadian rhythm.
4. Exercise in the morning or early afternoon; avoid vigorous exercise in the evening.
5. Avoid napping during the day, especially after 3 P.M.
6. Avoid stimulants such as caffeine and nicotine and avoid alcohol close to bedtime.
7. Avoid large meals close to bedtime.
8. Maintain regular and relaxing routines at bedtime.
9. Maintain a comfortable sleep environment.
10. Reserve the bed for sleep; avoid other activities (e.g., TV, radio, reading).
11. Sleep only when sleepy.
12. Try to resolve worries (or list for future thought) before sleeping.
13. Get out of bed if not sleeping in 20 minutes.

bedroom only for sleep and sex). Other strategies include cognitive behavior therapy specifically for insomnia (CBT-I), relaxation techniques, biofeedback, and behavioral changes such as sleep restriction therapy and stimulus control therapy.

The principles of the pharmacologic treatment of insomnia include using the lowest effective dose, intermittent (not daily) use, using the appropriate (i.e., short or intermediate half-life) drug based on the type of insomnia (i.e., onset or maintenance), and limiting the duration of treatment. Treatment should be tapered to avoid rebound. Medications should be used only in combination with nondrug (i.e., behavioral) treatments. Behavioral treatment has been effective.

Over-the-counter sleep aids (usually antihistamines) are typically safe, but use is limited by anticholinergic and hangover effects. Melatonin may promote sleep and be used for circadian rhythm disorders, including jet lag. The selective melatonin agonist ramelteon is helpful for sleep-onset insomnia. Other treatments are listed in Table 106-1.

Prognosis is usually good with the combination of drug and nondrug treatments. Behavior modification may be limited by the willingness of patients to participate.

PARASOMNIAS

Parasomnias are undesirable phenomena that occur in sleep or during transition to or from sleep. They usually consist of complex and seemingly purposeful behaviors, sometimes dramatic, of which the patient is not aware. They are often classified by the sleep stage in which they arise.

Slow-Wave Sleep Parasomnias

Definition and Epidemiology

Slow-wave sleep parasomnias include disorders of arousals, including sleep talking, night terrors (i.e., pavor nocturnus), sleep walking (i.e., somnambulism), nocturnal wandering, and confusional arousals (i.e., sleep drunkenness), with considerable overlap among these entities.

Pathophysiology and Clinical Manifestations

Characterized by partial arousals and intermediate states between wakefulness and sleep, slow-wave sleep parasomnias tend to begin in childhood. A family history of similar symptoms is common.

Episodes are often triggered by precipitants such as fever, intercurrent illness, sleep deprivation, or alcohol. They tend to occur in the first third of the night, when delta sleep predominates. They are characterized by typical slow-wave sleep arousals. Patients appear confused, may have slurred speech, and take several minutes to regain orientation. Slow-wave sleep has a higher threshold for arousal.

Sleep talking usually consists of fragments of barely intelligible sentences. Sleep walking and nocturnal wandering typically include ambulation. Night terrors (i.e., sleep terrors or pavor nocturnus) are dramatic, with an abrupt arousal, a scream, and autonomic hyperactivity (e.g., mydriasis, diaphoresis, flushing, piloerection, tachycardia). The child appears terrified and is inconsolable. Episodes last a few minutes and are not recalled the next morning.

Diagnosis and Differential Diagnosis

The main differential diagnosis is nocturnal seizure, which occasionally requires epilepsy monitoring (video electroencephalogram) if the episodes are frequent. For episodic symptoms, the use of home video (by cell phone) is more reliable than description by witnesses. Nocturnal seizures tend to be more stereotyped than parasomnias, and they often include tonic or clonic motor activity.

Treatment and Prognosis

Reassurance and measures to avoid injuries usually are sufficient. For episodes with injurious behaviors, low-dose benzodiazepines (clonazepam, 0.5 to 1 mg) are often effective. Prognosis is good, and most patients do not require treatment.

Rapid Eye Movement Behavior Disorder

Definition and Epidemiology

REM behavior disorder (RBD) is a disorder of REM sleep regulation in which there is a dissociation of REM features with loss of the muscle atonia, leading to patients acting out their dreams. RBD typically affects patients after the age of 50 (usually older) and the male-to-female ratio is 10 : 1.

Pathophysiology

REM inhibition is lost due to bilateral degeneration of REM atonic neurons in the pons. RBD occurs with α -synucleinopathies (i.e., Parkinson's disease, multiple system atrophy, and dementia with Lewy bodies), and RBD typically heralds these neurodegenerative diseases, sometimes by 10 to 15 years.

Clinical Manifestations

Typically, the episodes are reported by the bed partner and consist of high-amplitude, flailing, injurious behaviors during

sleep. When awakened, the patient typically recalls the dream. As is typical of REM arousals, the patient is alert and coherent immediately (unlike slow-wave sleep arousal). Medications, especially psychotropics, can exacerbate RBD.

Diagnosis and Differential Diagnosis

The diagnosis can usually be made by the history alone, and PSG is not needed. When performed, PSG shows a lack of REM atonia or increased phasic and tonic REM. Like slow-wave parasomnias, the main differential diagnosis is nocturnal seizure, and this occasionally requires epilepsy monitoring. Home video (cell phones) recordings can be useful.

Treatment and Prognosis

Low-dose clonazepam (0.5 to 2 mg) is usually effective. Symptoms initially respond to treatment, but a neurodegenerative disease is likely to become evident.

 For a deeper discussion of these topics, please see Chapter 100, "Obstructive Sleep Apnea," and Chapter 405, "Disorders of Sleep," in Goldman-Cecil Medicine, 25th Edition.

Cortical Syndromes

Sinéad M. Murphy and Timothy J. Counihan

ANATOMY

The paired cerebral hemispheres are connected by a large band of white matter fibers, the *corpus callosum*. Each hemisphere consists of four anatomically and functionally distinct regions: the frontal, temporal, parietal, and occipital lobes (Fig. 107-1). The two cerebral hemispheres supplement each other functionally in a variety of behavioral and sensorimotor tasks; however, certain functions, particularly language, manual dexterity, and visuospatial perception, are strongly lateralized to one hemisphere. Language function is lateralized to the left hemisphere in 95% of the population; although 15% of people are left-handed, the right

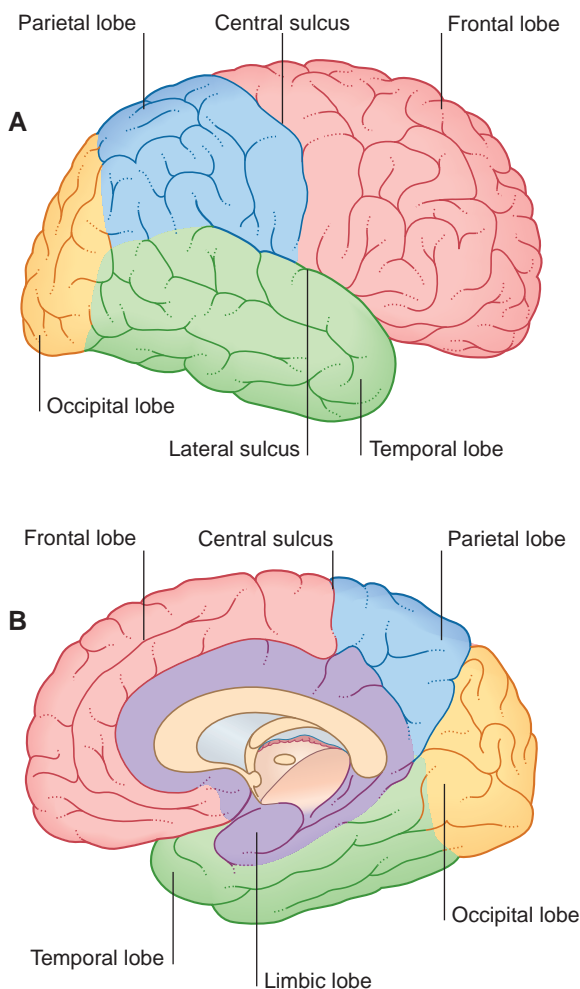

FIGURE 107-1 Lateral (A) and medial (B) views of the cerebral hemispheres. (From FitzGerald MJT, editor: *Clinical neuroanatomy and neuroscience*, ed 6, Philadelphia, 2011, Saunders, Fig. 2-1.)

hemisphere is dominant for language in only between 10% and 27% depending on the degree of left-handedness. Visuospatial functions are largely subserved by the right (nondominant) hemisphere. The Rolandic fissure separates the motor cortex (precentral gyrus) from the sensory cortex (postcentral gyrus). In these regions, cortical representations of the different parts of the body are arranged as the motor (frontal lobe) and sensory (parietal lobe) homunculi (Fig. 107-2).

CLINICAL ASSESSMENT

Symptoms and signs caused by cortical lesions may be less consistent than deficits caused by lesions of the spinal cord or more peripheral nerves, and patients may be unaware of the extent of their deficit. This makes a collateral history and careful examination (including cognitive assessment) important. In addition, there is substantial individual variability among patients. The rate of onset of symptoms and the tempo of progression influence the extent of the clinical deficit. The homuncular arrangement of cortical motor and sensory representation may allow for more precise localization of a lesion. For instance, motor or sensory signs confined to the lower extremities may suggest a parasagittal lesion, whereas signs involving the face and upper limb may originate in laterally placed cortical lesions.

REGIONAL SYNDROMES

Table 107-1 summarizes some of the eponymous syndromes and clinical features associated with damage to individual lobes.

Aphasia

Aphasia or *dysphasia* refers to a loss or impairment of language function as a result of damage to the specific language centers of the dominant hemisphere. It is distinct from dysarthria, which is a disturbance in the articulation of speech. The principal types of aphasia are summarized in Table 107-2.

Writing is almost invariably affected in patients with disturbances of language (Fig. 107-3). An exception to this occurs in the syndrome of *alexia without agraphia*, which results from a lesion in the dominant occipital lobe and splenium of corpus callosum (usually caused by infarction in the territory of the posterior cerebral artery). The patient's language center is "disconnected" from the contralateral (unaffected) visual cortex. Such patients can write a sentence but are unable to read what they have written.

Clinical assessment for aphasia requires testing of fluency, comprehension, repetition, naming, reading, calculation, and writing. *Anomia* (difficulty in recalling the names of objects) in isolation has little localizing value.

FIGURE 107-2 A, Homuncular arrangement shows the correlations with the primary motor cortex lying anterior to the central sulcus and the somatosensory cortex posteriorly (B). (Modified from Kretschmann HJ, Weinrich W: Neurofunctional systems: 3D reconstructions with correlated neuroimaging: text and CD-ROM, New York, 1998, Thieme.)

TABLE 107-1 CORTICAL SYMPTOMS AND SIGNS

DOMINANT HEMISPHERE	NONDOMINANT HEMISPHERE	EITHER HEMISPHERE
FRONTAL LOBE		
Broca's aphasia Transcortical motor aphasia Pure agraphia	Motor dysprosody	Contralateral spastic weakness Forced eye deviation Executive dysfunction, poor sequencing Akinetic mutism, urinary incontinence (bilateral lesions) Disinhibition, emotional lability, abulia Frontal lobe release signs (pout, grasp, snout, rooting, palmomental) Alien hand
PARIETAL LOBE		
Wernicke aphasia Transcortical sensory aphasia Apraxia Gerstmann's syndrome (acalculia, finger agnosia, right-left disorientation, agraphia) Conduction aphasia	Contralateral sensory neglect Constructional apraxia Anosagnosia Dressing apraxia	Contralateral sensory loss
TEMPORAL LOBE		
Anomic or sensory aphasia Verbal amnesia Transcortical sensory aphasia Pure word deafness	Impaired recognition of facial emotional expressions Visuospatial amnesia Sensory dysprosody/amusia	Contralateral superior quadrantanopia Amnesia Klüver-Bucy syndrome (oral-exploratory behavior, passivity, hypersexuality) bilateral lesions Auditory hallucinations Complex visual hallucinations Olfactory hallucinations Visual/experiential delusions
OCCIPITAL LOBE		
Alexia without agraphia		Anton's syndrome (visual agnosia, denial of blindness) Contralateral homonymous hemianopia Visual hallucinations Optic apraxia, absent optokinetic nystagmus, palinopsia Balint's syndrome (simultanagnosia, optic ataxia, oculomotor apraxia); bilateral lesions, usually occipitoparietal

TABLE 107-2 PRINCIPAL TYPES OF APHASIA

TYPE	LESION SITE	FLUENCY	COMPREHENSION	REPETITION	NAMING	OTHER SIGNS
Broca's (expressive)	Inferior frontal lobe	↓	Good	↓	↓	Contralateral weakness

Broca's aphasia is characterized by a severe disruption in the fluency of speech, with profound impairments of expression in both speech and writing. Comprehension may be mildly affected. The language disturbance is almost invariably accompanied by contralateral face and arm weakness as a result of the proximity of the motor homunculus to Broca's speech area.

Wernicke's aphasia is characterized by an inability to comprehend spoken or written language. Affected patients speak fluently, but the content is meaningless; they may use words that are close in meaning to the intended word (semantic paraphasias) or words that sound like the intended word (literal paraphasias). Patients may be misdiagnosed as having a psychiatric disorder because they lack an associated hemiparesis.

FIGURE 107-4 Attempts to draw a cube by a patient with a neurodegenerative disorder demonstrate constructional apraxia.

Conduction aphasia is characterized by normal comprehension and fluent speech but an inability to repeat. The responsible lesion lies in the arcuate fasciculus connecting Broca's and Wernicke's areas. *Global aphasia* results from large lesions of the frontal lobe; all aspects of language are affected. Lesions of the language areas of the nondominant hemisphere result in *dysprosody*. For instance, patients with lesions in the inferior frontal lobe of the nondominant hemisphere, analogous to Broca's area, speak with a monotonous voice, losing the natural cadence of speech.

In *dysarthria*, the language function is intact (which can be confirmed by having the patient write a sentence), but patients have difficulty articulating. Dysarthria can result from a lesion anywhere along the path from the cerebral cortex to the bulbar muscles.

Agnosia and Apraxia

Agnosia is the inability to recognize a specific sensory stimulus despite preserved sensory function. For instance, visual agnosia is the inability to recognize a visual stimulus despite normal visual acuity. Other agnosia syndromes include the inability to recognize sounds (auditory agnosia), color (color agnosia), or familiar faces (prosopagnosia). Usually, the responsible lesions are located in the occipitotemporal region.

Apraxia refers to an inability to perform learned motor tasks despite sufficient sensorimotor function to physically execute the movement; it is a disorder of motor planning (Fig. 107-4). The responsible lesions are usually in the dominant inferior parietal lobe. A simple test of apraxia is to ask the patient to perform a pantomime (e.g., combing his or her hair, blowing out a candle).

Lesions of the nondominant parietal lobe often result in *hemispatial neglect*: the patient does not attend to stimuli in the contralateral (usually the left) visual field or on the contralateral side of the body. In a milder form of neglect, called *extinction*, patients can attend to stimuli contralateral to the side of the brain with the lesion (and the lesion is usually on the right side), but when presented with bilateral stimuli simultaneously, they respond only on the ipsilateral (right) side. *Anosognosia*, or the lack of awareness of one's deficit, frequently accompanies hemispatial neglect. In severe cases, patients may even deny that the affected limb belongs to them.

PROSPECTUS FOR THE FUTURE

There have been many advances in neuroimaging technology that allow neuroscientists to study not only the structural and functional anatomy of a particular brain structure but also its metabolic activity. Functional magnetic resonance imaging (fMRI) permits mapping of the metabolic anatomy of subcortical gray and white matter structures, such as the basal ganglia, and their roles in conditions such as dystonia. These modalities allow one to study white matter tracts (tractography) in great detail, using a technique called diffusion tensor imaging.

Similarly, modern MRI technology is now able to discriminate brain tissue that is infarcted from tissue that is ischemic (and therefore potentially still viable) in the setting of acute stroke. Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are nuclear medicine imaging techniques that are increasingly used in the diagnosis of neurodegenerative disorders. It is likely that these techniques will become increasingly available in the acute hospital setting.

Dementia and Memory Disturbances

Frederick J. Marshall

MAJOR DEMENTIA SYNDROMES

Dementia is progressive loss of intellectual function coupled with loss of meaningful function in daily life. Memory loss is the central feature, and specific dementia syndromes characteristically cause particular forms of memory impairment. Dementia syndromes also produce specific abnormalities of cognition in language, spatial processing, praxis (i.e., learned motor behavior), and executive function (i.e., ability to plan and sequence events). *Cortical dementia* and *subcortical dementia*, although older terms, remain helpful for subdividing the dementias (Table 108-1).

Table 108-2 provides the differential diagnosis of neurodegenerative causes of dementia, and Table 108-3 outlines other causes of dementia. Neurodegeneration is the most common underlying cause of dementia and is seen in Alzheimer's disease (AD), frontotemporal dementia, and diffuse Lewy body disease.

Most causes of dementias are currently untreatable. Potentially correctable causes account for less than 5% of dementia cases. Structural processes or infections must be considered, along with metabolic and nutritional diseases. Every patient with dementia should have tests of serum electrolytes and vitamin B₁₂ and assessments of liver, renal, and thyroid function. Serologic studies for syphilis and Lyme exposure should be done if risk factors are identified. Chronic infections (see Chapter 90) and normal-pressure hydrocephalus should be considered. Brain imaging should be performed.

Neuropsychological testing characterizes the pattern of cognitive and memory impairments and is helpful in the differential

TABLE 108-1 DISTINGUISHING CHARACTERISTICS OF CORTICAL AND SUBCORTICAL DEMENTIAS

CORTICAL DEMENTIA

Symptoms: major changes in memory, language deficits, perceptual deficits, praxis disturbances

Affected brain regions: temporal cortex (medial), parietal cortex, and frontal lobe cortex

Examples: Alzheimer's disease, diffuse Lewy body disease, vascular dementia, frontotemporal dementias

SUBCORTICAL DEMENTIA

Symptoms: behavioral changes, impaired affect and mood, motor slowing, executive dysfunction, less severe changes in memory

Affected brain regions: thalamus, striatum, midbrain, striatofrontal projections

Examples: Parkinson's disease, progressive supranuclear palsy, normal-pressure hydrocephalus, Huntington's disease, Creutzfeldt-Jakob disease, chronic meningitis

diagnosis. The Montreal Cognitive Assessment (MoCA) (Table 108-4) is a standard test that can be used as a bedside or office screening tool for identifying patients with dementia. This examination is superior to the Mini-Mental Status Examination (MMSE) in that it is sensitive to abnormalities in a wider array of cognitive domains, including visual-spatial or executive

function, naming, attention, fluency; abstract reasoning, short-term memory encoding and retrieval, and orientation.

In addition to the MoCA, patients with dementia should have tests of praxis (e.g., show how you would comb your hair; show how you would blow out a match) and neglect (e.g., testing of double-simultaneous extinction to visual, tactile, and auditory stimuli). Depending on the results of these screening procedures, more detailed neuropsychological studies can be pursued.

Alzheimer's Disease

AD accounts for approximately 70% of dementia cases among older adults. Almost 5.3 million persons in the United States are affected, and this number may approach 18 million by 2050 as the population ages. AD places enormous burdens on the patient, family, and society. The annual direct and indirect expenditures are estimated to exceed \$150 billion. The disease occurs in 32% to 47% of persons older than 80 years of age. Incidence at age 65 is one in 200 people per year. Incidence at age 80 is one case per 10 people per year. More than 50% of caregivers develop depression or major medical illness.

AD has many causes, but none is fully defined. All causes produce similar clinical and pathologic findings. The disease is characterized by the progressive loss of cortical neurons and the formation of amyloid plaques and intraneuronal neurofibrillary

tangles. β -Amyloid ($A\beta$) is the major component of the plaques, and hyperphosphorylated tau protein is the major constituent of the neurofibrillary tangles. The process starts in the hippocampus and entorhinal cortex and spreads to involve diffuse areas of association cortex in the temporal, parietal, and frontal lobes. The relative deficiency of cortical acetylcholine (resulting from the loss of neurons in the nucleus basalis) provides the rationale for symptomatic treatment of the disease with centrally acting acetylcholinesterase inhibitors.

Pathogenesis

AD is often categorized as a young-onset, hereditary or familial form, which is rare and for which three specific genetic abnormalities have been determined, or as a common, sporadic form that typically occurs in persons older than 65 years of age (Table 108-5).

The autosomal dominant, early-onset forms of AD have in common abnormalities of $A\beta$ production and processing, which have provided clues to the molecular pathogenesis of sporadic AD. Abnormal processing of amyloid precursor protein into the amyloidogenic peptide $A\beta$ (1-42) is thought to be important in the pathogenesis of AD. It is thought to provoke downstream abnormalities of tau protein processing, with hyperphosphorylation of tau yielding intraneuronal tangles.

The apolipoprotein E (Apo E) gene (*APOE*) was found to be a susceptibility locus for sporadic AD in late-onset familial AD pedigrees. The gene is polymorphic ($\epsilon 2$, $\epsilon 3$, $\epsilon 4$), and first-degree relatives of AD patients, who inherit both $\epsilon 4$ alleles, have a more than 60% lifetime risk of developing AD. Apo E- $\epsilon 4$ interacts selectively with $A\beta$ and with tau protein, but how Apo E- $\epsilon 4$ increases the risk of AD remains unknown.

Clinical Features

AD begins gradually and affects memory, orientation, language, visuospatial processing, praxis, judgment, and insight. Depression is common early in AD, and psychosis with agitation and behavioral disinhibition often occur in advanced stages. Patients become dependent on others for all activities of daily living. The rate of progression of AD varies but usually takes 5 to 15 years to progress from presentation to advanced illness.

Diagnostic criteria are outlined in Table 108-6. Although a definitive diagnosis of AD requires biopsy (rarely done) or autopsy confirmation, these diagnostic criteria establish the diagnosis with more than 85% specificity in moderately demented patients. The positron emission tomography (PET) ligand

TABLE 108-4 ELEMENTS OF THE MONTREAL COGNITIVE ASSESSMENT

COGNITIVE DOMAIN	ITEMS	SCORE
Visual-spatial or executive	Complete a trail-making task, copy a cube, draw a clock	5
Naming	Name three depicted animals	3
Attention	Recall 5 digits forward, 3 digits backward, maintain letter vigilance, subtract 7s serially	6
Language	Repeat two phrases, generate a list of words starting with a specific letter	3
Abstraction	Identify the similarity between nouns (train/bicycle; watch/ruler)	2
Delayed recall	Recall five words rehearsed twice previously (face, velvet, church, daisy, red)	5
Orientation	Identify the date, month, year, day, place, and city	6
Total possible score		30

No single determinant gene‡	Usually >60	—	98

*Familial Alzheimer's disease (FAD) has early onset and is autosomal dominant.

†Sporadic Alzheimer's disease (SAD) has late onset and may be polygenetic and/or environmental.

‡Apolipoprotein E- $\epsilon 4$ allele on chromosome 19 increases the risk compared with the $\epsilon 2$ or $\epsilon 3$ allele.

TABLE 108-6 DIAGNOSTIC CRITERIA FOR PROBABLE ALZHEIMER'S DISEASE

Progressive functional decline and dementia established by clinical examination and mental status testing and confirmed by neuropsychological assessment
Insidious onset
Clear-cut history of worsening cognition by report or observation
Initial and most prominent cognitive deficits evident on history and examination in one of the following categories:
Amnesic presentation (plus at least one other domain)
Nonamnesic presentations (plus deficits in other domains): language, visuospatial, executive dysfunction
No evidence of vascular dementia, dementia with Lewy bodies, frontotemporal dementias, or other concurrent active neurologic or non-neurologic medical comorbidity or use of medication that could have a substantial effect on cognition

florbetapir F 18 (Amyvid), which binds to amyloid plaques, has been approved by the U.S. Food and Drug Administration (FDA) for use in the clinical diagnosis of AD. It can be positive in patients without clinical signs of dementia. Similarly, cerebrospinal fluid (CSF) assays for A β , tau, and phosphorylated tau protein loads have been commercialized as aids to diagnosis, but they are not universally used due to the invasive nature of the testing and the relatively good accuracy of the clinical diagnosis.

PET and CSF assays are in widespread use for stratification of subjects in emerging large-scale, prospective, randomized studies of individuals at risk for preclinical disease. Changes in brain morphometry are identifiable on structural imaging many years before onset of clinical symptoms.

Treatment

Although their benefits are modest, the cholinesterase-inhibiting drugs donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne) represent important advances. These drugs may be given in once-daily formulations. Rivastigmine is also available as a transdermal patch.

In clinical trials, cholinesterase inhibitors benefited less than 50% of patients. They have not been shown to prevent AD in patients with mild cognitive impairment (MCI), a condition in which the memory or another domain of cognition is impaired in the absence of meaningful dysfunction in daily life. Approximately 12% of patients with MCI go on to develop AD per year, with roughly two thirds of patients with MCI developing clinical AD within 5 years of symptom onset.

Ginkgo biloba has no role in the treatment or prevention of AD. The glutamate antagonist memantine (Namenda) has been shown to prolong daily function in patients with moderate to advanced AD.

Treatment strategies in clinical trials over the past decade have included decreasing A β peptide production by blocking α -secretase or β -secretase or upregulating cleavage of the amyloid precursor protein at the α -secretase site. Studies of active and passive immunization have been designed to lower brain A β levels. However, these approaches have failed to deliver on the promise of AD disease modification, necessitating a wide-reaching reassessment of current theories of disease pathogenesis.

There is an emerging concept of preclinical AD, with many biomarkers showing changes years before clinical manifestations.

Several large, prospective, interventional studies targeting this population are getting underway or are planned on the inference that intervening later in the disease process (when symptoms of dementia have manifested) may be too late. Novel molecular and immunologic approaches continue to hold promise for disease-modifying treatments in the future.

Nursing services provide oversight of hygiene, nutrition, and medication compliance. Antipsychotics, antidepressants, and anxiolytics are useful for patients with behavioral disturbances, which are the most common cause of nursing home placement. Patients and families can be referred to a local Alzheimer's Association chapter for further information on available community support.

Prevention

There is no high or even moderate level of evidence that any intervention decreases the risk of AD. There is a low level of evidence that a Mediterranean diet, folic acid, HMG-CoA reductase inhibitors (i.e., statins), higher levels of education, light alcohol intake, cognitively engaging activities, and physical activity (particularly at high levels) may decrease the risk of AD.

There is a moderate level of scientific evidence that conjugated equine estrogen with methyl-progesterone increases the risk of AD. There is a low level of scientific evidence that some nonsteroidal anti-inflammatory drugs, depressive disorder, diabetes mellitus, hyperlipidemia in midlife, current tobacco use, traumatic brain injury, pesticide exposure, and relative social isolation increase the risk of AD.

Diffuse Lewy Body Disease

Lewy bodies are pathologic inclusions that are the hallmark of Parkinson's disease when they are restricted to the brain stem (see [Chapter 114](#)). Patients with diffuse Lewy body disease have clinical parkinsonism (i.e., slow movement, rigidity, and balance problems) combined with early and prominent dementia. Pathologically, Lewy bodies are found in the brain stem, limbic system, and cortex. Visual hallucinations and cognitive fluctuations are common, and patients are unusually sensitive to the adverse effects of neuroleptic medication.

Diffuse Lewy body disease may represent the second most common cause of dementia after AD. However, the common concurrence of the pathologic features of diffuse Lewy body disease with the classic neuritic plaques and neurofibrillary tangles of AD complicates the identification of the cause of dementia in a given patient.

Vascular Dementia

Approximately 10% to 20% of older patients with dementia have radiographic evidence of focal stroke on magnetic resonance imaging (MRI) or computed tomography (CT), combined with focal signs on the neurologic examination. When the dementia syndrome begins with a stroke and progression of the illness is stepwise (suggesting recurrent vascular events), the diagnosis of vascular dementia is likely.

Patients typically develop early incontinence, gait disturbances, and flattening of affect. A subcortical dementing process attributed to small vessel disease in the periventricular white matter has been referred to as *Binswanger's disease*, but it may be a radiographic finding rather than a true disease. Appropriate

treatment of risk factors for vascular disease—blood pressure control, smoking cessation, diet modification, and anticoagulation (in select settings such as atrial fibrillation)—is mandatory and may be of benefit.

Frontotemporal Dementias

Patients with the behavioral variant of frontotemporal dementia (FTD) are frequently socially disinhibited, but they may also be lethargic and lack motivation and spontaneity. Patients with the progressive nonfluent aphasia variant of FTD have loss of speech fluency with poor articulation and syntactic errors but relative preservation of comprehension. Those with the semantic dementia variant of FTD remain fluent with normal phonation but have progressive difficulty with naming and word comprehension. Memory and spatial skills and praxis are relatively preserved early on in all of these forms, whereas executive function, emotional regulation, and conduct are relatively impaired.

There are several frontotemporal lobar degenerations (FTLDs), including Pick's disease (now referred to as FTLD-tau). In some families, a mutation in the microtubule-associated protein tau gene (*MAPT*) on chromosome 17 causes tau-positive frontotemporal dementia with parkinsonism (FTDP-17). Transactive response DNA-binding protein (TDP-43) pathology accounts for 40% of FTD with or without motor neuron disease. Although mutations in the fused in sarcoma gene (*FUS*) had previously been identified as a cause of familial amyotrophic lateral sclerosis (ALS), some also give rise to 5% to 10% of clinically diagnosed FTD (typically the behavioral variant). Hexanucleotide repeat expansions in *C9orf72* cause neurodegeneration in FTD and ALS. RNA processing is abnormal in both conditions.

As in AD, all forms of FTD progress for years. No intervention slows the inevitable decline of these patients. Approximately 50% of patients have a family history of the disease.

Parkinson's Disease

Almost 50% of patients with Parkinson's disease (see [Chapter 114](#)) become demented by the time they reach the age of 85 years. The dementia of Parkinson's disease affects executive function out of proportion to its impact on language and visuospatial processing. Thought processes appear to slow down (i.e., bradyphrenia), analogous to the slowing of movement (i.e., bradykinesia).

Because dementia occurs relatively late in the progression of Parkinson's disease, most patients are taking drugs to improve their movement disorder by enhancing dopaminergic neurotransmission. These drugs can induce psychosis. Dose reductions should be attempted before the diagnosis of underlying dementia is made for these patients. Acetylcholinesterase inhibition has been helpful for patients with dementia caused by Parkinson's disease, and the FDA has specifically approved rivastigmine for this indication.

Normal-Pressure Hydrocephalus

The triad of dementia (typically subcortical), gait instability, and urinary incontinence suggests the possibility of normal-pressure hydrocephalus. These patients appear to walk with their feet stuck to the floor, without lifting up the knees and with a broad base. Symptoms evolve over the course of weeks to months, and

brain imaging reveals ventricular enlargement out of proportion to the degree of cortical atrophy.

Numerous diagnostic tests have been described, including radionuclide cisternography and MRI flow studies. The most important test remains the clinical response to removal of large volumes of CSF through serial lumbar punctures or the temporary placement of a lumbar drain, followed by examination of the patient's gait and cognitive function. Neurosurgical placement of a permanent ventriculoperitoneal shunt may correct the problem. Patients likely to benefit from shunt placement have a clear response to the removal of 30 to 40 mL of spinal fluid, with improved gait and alertness within minutes to hours of the procedure. The cause of normal-pressure hydrocephalus is a derangement of the CSF hydrodynamics. Shunt placement is most likely to be effective if normal-pressure hydrocephalus occurs after severe head trauma or subarachnoid hemorrhage.

Prion Infection, Chronic Meningitis, and Dementia Related to Acquired Immunodeficiency Syndrome

Creutzfeldt-Jakob disease (CJD) is a subacute, dementing, transmissible illness with typical onset between 40 and 75 years of age and an incidence of one case per 1 million people (see [Chapter 90](#)). The disease causes spongiform degeneration and gliosis in widespread areas of the cortex. Clinical variants of the disorder are differentiated by the relative predominance of cerebellar symptoms, extrapyramidal hyperkinesias, or visual agnosia and cortical blindness (i.e., Heidenhain variant).

Ninety percent of patients with CJD have myoclonus, compared with 10% of patients with AD. Patients with all forms of the disease share a relentlessly progressive dementia and disruption of personality over weeks to months. The electroencephalogram shows characteristic abnormalities, including diffuse slowing and periodic sharp waves or spikes.

The transmissible agent, a prion protein, is invulnerable to routine modes of antiseptics. CSF can be tested for the 14-3-3 protein, although this test is not as sensitive or specific for CJD as once hoped (see [Chapter 90](#)). Diffusion-weighted MRI images show characteristic cortical ribbon changes.

Certain infectious agents can cause the subacute or chronic development of subcortical dementia. These chronic meningitides are discussed in [Chapter 90](#).

Human immunodeficiency virus accesses the central nervous system through monocytes and the microglial system and causes associated neuronal cell loss, vacuolization, and lymphocytic infiltration. The dementia associated with this infection is characterized by bradyphrenia and bradykinesia. Patients have executive dysfunction, impaired memory, poor concentration, and apathy. Treatment of the underlying viral infection with protease inhibitors and reverse transcriptase inhibitors may slow the progression of the dementia (see [Chapter 90](#)).

OTHER MEMORY DISTURBANCES

Structure of Memory

Memory function is divided into introspective processes (i.e., declarative, explicit, aware memories) and processes that are not accessible to introspection (i.e., nondeclarative, implicit, procedural memories). Short-term memory (e.g., words on a list) is

a form of declarative memory. Other forms include the conscious recall of episodes from personal experience (i.e., episodic memory), and factual knowledge (i.e., semantic memory) that can be consciously recalled and stated (i.e., declared). Declarative memory involves consciously *knowing that* ... Patients with amnesia resulting from lesions of the medial temporal lobes or midline diencephalic structures have deficits of declarative memory.

Nondeclarative memory encompasses several distinct and neuroanatomically less clearly localized functions related to the performance of specific learned motor, cognitive, or perceptual tasks. Nondeclarative (procedural) memories involve unconsciously *knowing how* ... Deficits in nondeclarative memory may involve various areas of association neocortex, depending on the nature of the task (e.g., parietal-temporal-occipital junction cortex for visual perceptual tasks, frontal association cortex for motor tasks). Patients with amnesia resulting from lesions of the medial temporal lobes tend to perform normally on tests of nondeclarative memory.

Anterograde amnesia is the inability to learn new information. It commonly occurs after brain injury or in association with dementia. The inability to recollect prior information is retrograde amnesia. Both types of amnesia usually occur together in brain injury syndromes, although the extent of one type or the other may vary. The degree of anterograde amnesia after head injury correlates with the severity of the injury.

Isolated Disorders of Memory Function

Memory can be impaired in relative isolation as a consequence of head injury, thiamine deficiency (i.e., Korsakoff's syndrome), benign forgetfulness of aging, transient global amnesia, or psychogenic disease.

Head injury typically results in retrograde amnesia in excess of anterograde amnesia, with both forms stretching out over time from the discrete event. As time passes, these disrupted memories gradually return, although rarely to the point at which the events immediately surrounding the trauma are recalled.

Korsakoff's syndrome is characterized by the near-total inability to establish new memory. Patients often confabulate responses when they are asked to convey the details of their current circumstance or to relay the content of a recently presented story. Deficiency of thiamine and other nutritional deficiencies in the context of chronic alcoholism are the most common underlying causes. Thiamine is a necessary cofactor in the metabolism of glucose, and thiamine must be replenished at the same time glucose is administered whenever a comatose patient is seen in the emergency department.

Aging is associated with mild loss of memory, exhibited by difficulty in recalling names and by forgetfulness for dates. Population-based assessments of neuropsychological function have demonstrated that poor performance on delayed-recall tasks is the most sensitive indicator of cognitive change with

advancing age. Verbal fluency, in contrast, remains intact with advancing age, and vocabulary may increase with time, even into old age.

Transient global amnesia is a dramatic memory disturbance that affects older patients (>50 years). Patients usually have only one episode; occasionally, episodes recur over the course of several years. Patients have complete temporal and spatial disorientation; orientation for person is preserved. Near-total retrograde and anterograde amnesia persists for various periods, typically 6 to 12 hours. Patients are often anxious and may repeat the same question over and over again. Transient global amnesia may be confused with psychogenic amnesia, fugue state, or partial complex status epilepticus. Transient global amnesia is thought to reflect underlying vascular insufficiency to the hippocampus or midline thalamic projections.

Unlike patients with organic memory disturbances, patients with psychogenic amnesia typically have inconsistent loss of recent and remote memory, relatively more loss of emotionally charged memory (rather than relatively less loss of such memory in organic disease), and an apparent indifference to their own plight; they ask few questions. Most characteristically, patients with psychogenic amnesia tend to express disorientation to person (asking, *Who am I?*), a phenomenon seldom seen in organic memory disturbance.

Patients with severe depression may exhibit pseudodementia. Vegetative signs, including changes in appetite, weight, and sleep pattern, are common, whereas signs of cortical impairment, such as aphasia, agnosia, and apraxia, are rare. Memory and bradyphrenia improve with antidepressant therapy. Depression often coexists with other causes of dementia, such as AD, Parkinson's disease, and vascular dementia.

 For a deeper discussion on this topic, please see Chapter 402, "Alzheimer's Disease and Other Dementias," in Goldman-Cecil Medicine, 25th Edition.

Major Disorders of Mood, Thoughts, and Behavior

Jeffrey M. Lyness

CLASSIFICATION OF MENTAL DISORDERS

Mental (psychiatric) disorders are alterations in thoughts, feelings, or behaviors that produce substantive subjective distress or affect the patient's functional status. Many mental disorders are caused by the direct effects of drugs, systemic disease, or neurologic disease on brain physiology. They may be broadly considered as secondary psychiatric disorders, as opposed to the primary or idiopathic psychiatric disorders. The distinguishing feature of neurocognitive disorders is impairment in intellectual functions such as level of consciousness, orientation, attention, or memory; however, these disorders also often include disruption of mood, thoughts, and behaviors similar to that seen in other psychiatric syndromes. Neurocognitive disorders are the focus of [Chapters 105 and 108](#).

The noncognitive secondary syndromes by definition cause psychiatric phenomena similar to their idiopathic counterparts. During the evaluation of any patient with new or worsened psychiatric symptoms, it is essential to conduct a thorough evaluation for other medical causes, including a careful history and physical examination (with a screening neurologic examination) that often are supplemented by laboratory evaluations. [Table 109-1](#) outlines important causes of psychiatric syndromes. Although some conditions are likely to produce certain psychiatric syndromes, many manifest as any of several psychiatric syndromes. Conversely, a psychiatric syndrome may be caused by any of a wide range of conditions.

Because the cause of primary psychiatric disorders is unknown, approaches to classification depend on reliable empirical observations of phenomena clustered into recognizable syndromes. [Table 109-2](#) shows the most important psychiatric syndromes

and the disorders in which they may manifest. [Table 109-3](#) shows the major idiopathic disorders, excluding addictive disorders (see [Chapter 126](#)). Many psychiatric disorders manifest with multiple syndromes. For example, major depression with psychotic features manifests with a depressive syndrome and a psychotic syndrome. In evaluating a patient with new or worsened psychiatric symptoms, the clinician must construct a differential diagnosis based on syndromes alongside the differential diagnosis based on potential secondary causes.

DEPRESSIVE AND BIPOLAR DISORDERS

Depressive and bipolar disorders are characterized by idiopathic episodes of depression alone (i.e., unipolar) or mania and depression (i.e., bipolar). The core symptoms of depressive episodes include emotional symptoms (e.g., dysphoria, irritability, anhedonia, loss of interests), ideational symptoms (e.g., thoughts with hopeless, worthless, guilty, or suicidal themes), and neurovegetative symptoms and signs (e.g., anergia; psychomotor slowing or agitation; decreased concentration; altered sleep, appetite, and weight).

Major depressive disorder is defined by episodes of a least five symptoms, including depressed mood, anhedonia, or loss of interests, that occur almost every day for at least 2 consecutive weeks, sufficient to cause significant distress and affect functional status. Other prominent symptoms may include associated anxiety, somatic worry, or new somatic symptoms, and in the most severe cases, psychotic symptoms, including nihilistic or self-deprecatory (i.e., mood-congruent) delusions.

Major depression is common, with a 12-month prevalence of approximately 7% and a lifetime prevalence of up to 10% among men and 20% to 25% in women. New depressive episodes have an annual incidence of approximately 3%. First onset may occur at any age but is most common in the third through fifth decades of life. Whereas most episodes of major depression fully remit spontaneously or with treatment, the lifetime risk of recurrence is at least 50% to 70%, and up to 20% of patients may experience chronic symptoms over many years. Major depression is a leading correlate of disability worldwide, is an important determinant of death by suicide, and is associated with increased risk of death from comorbid physical illnesses. Persistent depressive disorder (i.e., dysthymia) is a condition defined by chronic depressive symptoms, often of insufficient severity to meet criteria for major depression.

Depressive disorders are heterogeneous, with many potential pathogenic mechanisms. Genetic factors, such as polymorphisms

TABLE 109-1 IMPORTANT CAUSES OF PSYCHIATRIC SYNDROMES

CENTRAL NERVOUS SYSTEM CONDITIONS	SYSTEMIC DISEASES
Tumor	Cardiovascular diseases
Toxins	Pulmonary diseases
Vascular disorders	Cancer
Seizure	Infection
Infection	Nutritional disorders
Genetic disorders	Endocrine disorders
Congenital malformation	Metabolic disorders
Demyelinating conditions	DRUGS
Degenerative conditions	Drug intoxication
Hydrocephalus	Drug withdrawal

TABLE 109-2 IMPORTANT PSYCHIATRIC SYNDROMES

SYNDROME	MAIN SYMPTOMS AND SIGNS	DISORDERS
Neurocognitive	Impairment in intellectual functions (e.g., level of consciousness, orientation, attention, memory, language, praxis, visuospatial, executive functions)	Neurocognitive disorders Intellectual disability (if onset in childhood)
Mood	Depressive: lowered mood, anhedonia, negativistic thoughts, neurovegetative symptoms Manic: elevated or irritable mood; grandiosity; goal-directed hyperactivity with increased energy; pressured speech; decreased sleep need	Neurocognitive disorders Mood disorders (bipolar or depressive) (primary or secondary) Psychotic disorders (schizoaffective disorder)
Anxiety	All include anxious mood and associated physiologic signs and symptoms (e.g., palpitations, tremors, diaphoresis) May include various types of dysfunctional thoughts (e.g., catastrophic fears, obsessions, flashbacks) and behaviors (e.g., compulsions, avoidance behaviors)	Neurocognitive disorders Mood disorders (bipolar or depressive) (primary or secondary) Psychotic disorders (primary or secondary) Anxiety disorders (primary or secondary)
Psychotic	Impairments in reality testing: hallucinations, thought process derailments	Neurocognitive disorders Mood disorders (bipolar or depressive) (primary or secondary) Psychotic disorders
Somatic symptom syndromes	Somatic symptoms with associated distressing thoughts, feelings, or behaviors	Mood disorders (bipolar or depressive) (primary or secondary) Anxiety disorders (primary or secondary) Obsessive-compulsive and related disorders Trauma-related disorders Somatic symptom disorders
Personality pathology	Dysfunctional enduring patterns of emotional regulation, thought patterns, interpersonal behaviors, impulse regulation	Neurocognitive disorders Personality change due to another medical condition Personality disorders

Data from American Psychiatric Association: Diagnostic and statistical manual of mental disorders, ed 5, Washington, D.C., 2013, American Psychiatric Association.

of the serotonin transporter protein, affect vulnerability to depressive episodes in the face of psychosocial stressors. Depression is polygenic and multifactorial, with genetic factors accounting for about 40% of the risk. Alterations in the functioning of brain serotonergic and noradrenergic systems and of the hypothalamic-pituitary-adrenal axis are found in depression. Neuroimaging studies show smaller hippocampal volumes and altered metabolic activity in several regions, including the anterior cingulate cortex. However, the information in these studies is not sufficient for making the clinical diagnosis, which depends on identification of the clinical syndrome. Dysfunctional, negativistic patterns of thinking, impaired social relationships, and stressful life events also contribute to depression.

Mild to moderate forms of major depression respond to focused psychotherapies or antidepressant medications (level A evidence) (Table 109-4). More severe forms of depression do not respond to psychosocial interventions alone. Severe or refractory depression may be treated safely and effectively with electroconvulsive therapy (level A). Other evidence-based somatic therapies include light therapy (for depression with a seasonal component) and vagal nerve stimulation (levels B and C). Data suggest that the dissociative anesthetic ketamine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, may rapidly improve patients with treatment-resistant depression, although the general clinical applicability of ketamine remains to be determined.

Bipolar disorder (i.e., bipolar I) is characterized by recurrent episodes of mania, usually with episodes of major depression. Manic episodes include elevated (euphoric) or irritable mood, goal-directed hyperactivity (often for pleasurable activities with poor judgment leading to substantial adverse consequences such as sexual, spending, or gambling sprees), pressured speech, increased energy level with a decreased need for sleep, and distractibility.

Compared with unipolar depression, bipolar disorder has a lower 12-month prevalence (approximately 0.6%) and a younger average age of onset (typically late teens to 20s). Unlike unipolar depression, bipolar disorder is slightly more common among males. Most patients return to baseline functioning between acute mood episodes, but some have a deteriorating course, and others have frequent debilitating episodes (i.e., rapid cycling of four episodes per year).

Genetic factors play a greater role in the pathogenesis of bipolar disorder than in major depressive disorder, accounting for approximately 50% of the risk and representing a greater than 50-fold increase over the population base rate. Bipolar disorder is polygenic and has been linked in individual families to different loci. The pathogenesis is unclear but likely involves dysregulation of frontostriatal systems. Structural neuroimaging studies show increased ventricular-to-brain ratios, suggesting parenchymal atrophy. Psychosocial stressors often play a role in precipitating episodes of mania and depression.

The mainstay of treatment for bipolar disorder is mood stabilizer medications (e.g., lithium, anticonvulsants such as valproic acid and carbamazepine) for acute episodes and maintenance therapy (level A evidence). The anticonvulsant lamotrigine may be particularly useful for bipolar depression. Antipsychotic medications are useful for acute manic episodes and may have a role in maintenance therapy. Benzodiazepines may be used to treat acute agitation and aggression while waiting for more definitive antimanic therapies to take effect. Antidepressants have long been used for depressive episodes, although they may precipitate manic episodes.

Electroconvulsive therapy is effective for refractory mania (level B evidence) and depression (level A). Psychosocial treatments alone do not effectively treat mania and may be less effective for bipolar depression, but psychoeducation and support to

TABLE 109-3 MAJOR IDIOPATHIC (PRIMARY) DISORDERS OF MOOD, THOUGHTS, AND BEHAVIOR

MOOD DISORDERS	PERSONALITY DISORDERS
Depressive (Unipolar)	Cluster A: Odd Eccentric
Major depressive disorder Persistent depressive disorder (dysthymia)	Schizoid personality disorder (detachment from social relationships, restricted emotional expression)
Bipolar	Schizotypal personality disorder (social and emotional deficits, cognitive or perceptual distortions, eccentric behavior)
Bipolar disorder Cyclothymic disorder Bipolar II disorder (bipolar disorder not otherwise specified)	Paranoid personality disorder (pervasive distrust and suspiciousness)
ANXIETY DISORDERS	Cluster B: Dramatic or Emotional
Panic disorder (without or with agoraphobia) Generalized anxiety disorder Social phobia Specific phobia	Borderline personality disorder (instability of interpersonal relationships, self-image, and affects, and impulsivity)
OTHER CONDITIONS WITH ANXIETY AS A PROMINENT FEATURE	Narcissistic personality disorder (grandiosity, need for admiration, lack of empathy)
Obsessive-compulsive disorder Acute stress disorder, posttraumatic stress disorder	Antisocial personality disorder (disregard for and violation of the rights of others)
PSYCHOTIC DISORDERS	Histrionic personality disorder
Schizophrenia Schizophreniform disorder Brief psychotic disorder Schizoaffective disorder Delusional disorder	Cluster C: Anxious or Fearful
SOMATIC SYMPTOM DISORDERS	Avoidant personality disorder (social inhibition, feelings of inadequacy, hypersensitivity to criticism)
Somatic symptom disorder Illness anxiety disorder Conversion (functional neurologic symptom) disorder Psychological factors affecting physical condition Factitious disorder (i.e., Munchausen's syndrome)	Dependent personality disorder (pervasive and excessive need to be taken care of, leading to submissive and clinging behavior and fears of separation)
	Obsessive-compulsive personality disorder (preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency)

Data from American Psychiatric Association: Diagnostic and statistical manual of mental disorders, ed 5, Washington, D.C., 2013, American Psychiatric Association.

manage psychosocial stressors and encourage medication compliance improve longer-term outcomes.

A spectrum of less severe bipolar disorders includes conditions marked by episodes of hypomania (i.e., low-level manic symptoms without psychosis or significant impairment in functioning). They include bipolar II disorder, characterized by episodes of hypomania and major depression, and cyclothymic disorder, characterized by hypomania and low-level depression not meeting criteria for major depression. Because patients with bipolar II disorder are most likely to seek care during depressive episodes, it is important to inquire about a history of manic symptoms to avoid precipitating mania with the use of antidepressant medications. The pathogenesis of these less severe mood disorders is unclear.

DISORDERS WITH ANXIETY AS A PROMINENT FEATURE

The idiopathic anxiety disorders manifest with troublesome thoughts and somatic symptoms (Table 109-5) along with the

TABLE 109-4 PSYCHOTHERAPIES FOR DEPRESSION AND ANTIDEPRESSANT MEDICATIONS

NAME	APPROACH OR MECHANISM OF ACTION
PSYCHOTHERAPY	
Cognitive psychotherapy	Identify and correct negativistic patterns of thinking
Interpersonal psychotherapy	Identify and work through role transitions or interpersonal losses, conflicts, or deficits
Problem-solving therapy	Identify and prioritize situational problems; plan and implement strategies to deal with top-priority problems
COMMONLY USED ANTIDEPRESSANTS	
Selective serotonin reuptake inhibitors (SSRIs) Citalopram and escitalopram Fluoxetine Paroxetine Sertraline	Inhibit presynaptic reuptake of serotonin
Serotonin and norepinephrine reuptake inhibitors (SNRIs) Duloxetine Venlafaxine and desvenlafaxine	Inhibit presynaptic reuptake of serotonin and norepinephrine
Tricyclic antidepressants (TCAs) Amitriptyline Desipramine Doxepin Imipramine Nortriptyline	Inhibit presynaptic reuptake of serotonin and norepinephrine (in various proportions depending on the specific TCA)
Monoamine oxidase inhibitors (MAOIs) Isocarboxazide Phenelzine Selegiline Tranylcypromine	Inhibit monoamine oxidase, the enzyme that catalyzes oxidative metabolism of monoamine neurotransmitters
Other drugs Bupropion	Selective MAO-B inhibitor
Mirtazapine	Unknown, although it is weak inhibitor of presynaptic reuptake of norepinephrine and dopamine
Trazodone	Serotonin (5-hydroxytryptamine [5-HT]) antagonist at α_2 and 5-HT ₂ receptors
Vilazodone	Inhibits presynaptic reuptake of serotonin; antagonist at 5-HT ₂ and 5-HT ₃ receptors
	Inhibits presynaptic reuptake of serotonin; agonist at 5-HT _{1A} receptors

emotional sensation of anxiety. A panic attack is a transient episode of crescendo anxiety, catastrophic thoughts (e.g., fears of dying, going insane, losing self-control), and somatic symptoms. If panic attacks or other clinically significant anxiety symptoms occur only in predictable response to environmental stimuli, the anxiety disorder is known as a *phobia*, which may further be classified as agoraphobia (i.e., anxiety about being in places from which escape may be difficult or embarrassing such as being alone, in crowds, in tunnels, or on bridges), social phobia (i.e., anxiety in interpersonal situations); and specific phobia (i.e., anxiety provoked by other situations or objects such as blood, animals, or heights). Panic disorder manifests with recurrent panic attacks, some of which are unexpected and unpredictable, along with anticipatory anxiety (i.e., fear of having another attack) and avoidance behaviors (i.e., avoiding situations that

TABLE 109-5 COMMON SOMATIC SYMPTOMS OF ANXIETY

CARDIORESPIRATORY	GENITOURINARY
Palpitations	Urinary frequency or urgency
Chest pain	NEUROLOGIC OR AUTONOMIC
Dyspnea or sensation of being smothered	Diaphoresis
GASTROINTESTINAL	Warm flushes
Sensation of choking	Dizziness or presyncope
Dyspepsia	Paresthesia
Nausea	Tremor
Diarrhea	Headache
Abdominal bloating or pain	

may provoke a panic attack or in which having an attack is perceived to be embarrassing or dangerous).

Other disorders may not cause discrete panic attacks. Obsessive-compulsive disorder is characterized by recurrent obsessions (i.e., thoughts, impulses, or mental images that are anxiety-producing, perceived as intrusive and inappropriate, and resistant to attempts to suppress or neutralize them) and compulsions (i.e., repetitive behaviors or mental acts performed in response to obsessions or other rigid rules). Recognizing its distinct pathogenesis involving striatofrontal function and central serotonergic systems, it has been classified separately from the anxiety disorders.

Individuals exposed to severely stressful events (typically involving the actual or threatened loss of life or limb) may experience any of a wide variety of psychiatric sequelae. If the sequelae include symptoms of intrusion (e.g., intrusive memories, dreams, flashbacks, intense distressing responses to reminders of the trauma), avoidance of distressing memories or external reminders, negative cognitions and mood (e.g., amnesia for aspects of the event, negativistic thoughts about oneself in general or self-blame for the event, diminished interests or activities, feelings of detachment), and alterations in arousal and reactivity, the disorder is called *acute stress disorder* (duration up to 1 month) or *posttraumatic stress disorder* (duration is more than 1 month). Enduring anxiety symptoms that are not captured by these diagnoses or by diagnoses of cognitive, mood, or psychotic disorders may be diagnosed as *generalized anxiety disorder*.

These disorders are common, with point prevalence of 1% to 2% each for panic disorder and obsessive-compulsive disorder and up to 10% for phobias. Although there are fewer data on long-term outcome than for mood disorders, many of these disorders tend to have a chronic waxing and waning course. Most of these disorders have a first onset in the teens, 20s, and 30s, although new-onset anxiety is common in later life. The cause is rarely a primary anxiety disorder (see [Table 109-2](#)).

The pathogeneses of most anxiety disorders may be understood as inappropriate activation of the stress response system involving a variety of neuroendocrine and autonomic outputs and coordinated by the central nucleus of the amygdala and other brain structures. The amygdala receives excitatory glutamatergic inputs from cortical sensory areas and the thalamus and has outputs to the major monoaminergic centers (e.g., noradrenergic neurons of the locus coeruleus, dopaminergic neurons of the ventral tegmental area, and serotonergic neurons of the raphe

nuclei), which project to the many brain regions subserving the symptoms of anxiety.

The identification and correction of dysfunctional patterns of thinking (i.e., cognitive therapy) and the extinction of pathologic behaviors and positive reinforcement of more functional behaviors (i.e., behavior therapy) are evidence-based psychotherapies useful in most anxiety disorders (level A evidence). They are the sole therapies for specific phobias and may be the sole or primary therapy for most other anxiety disorders or combined with pharmacotherapy.

Antidepressant, anxiolytic, and other drug therapies are used in treatment. Increasingly, antidepressant medications have replaced anxiolytics as the mainstay of pharmacotherapy for panic disorder, posttraumatic stress disorder, generalized social phobia, and generalized anxiety disorder. For obsessive-compulsive disorder, only antidepressant agents with pronounced activity on the serotonergic system (i.e., clomipramine and selective serotonin reuptake inhibitors [SSRIs]; see [Table 109-4](#)) are efficacious.

PSYCHOTIC DISORDERS

Psychosis is a loss of reality testing, manifested as hallucinations (i.e., false sensory perceptions), delusions (i.e., fixed false beliefs), and thought process derailments. Schizophrenia is the prototypic psychotic disorder; it includes acute episodes of psychosis (i.e., positive symptoms) and often declining overall functioning over time related to the negative symptoms such as affective flattening, abulia, apathy, and social withdrawal.

The lifetime prevalence of schizophrenia is slightly less than 1%, and its chronic, debilitating course takes a considerable toll on patients, families, and society. Peak onset is in late adolescence to young adulthood, with slightly younger ages for males than females. The annual incidence is approximately 15 cases per 100,000 people, but with marked variability across study samples and populations. The condition is slightly more common in males than females.

The pathogenesis of schizophrenia remains unknown, but it is clearly multifactorial. Genetic factors account for up to 50% of the risk, with multiple loci implicated. Studies of postmortem brains indicate a nongliotic neuropathologic process with subtle disruptions of cortical cytoarchitecture. It is likely that psychosocial factors and neurodevelopment interact with a nonlocalizable brain lesion present at birth or acquired early in life. Dopaminergic mesocortical and mesolimbic pathways are important in the production of psychotic symptoms.

Antipsychotic medications, often with adjunctive benzodiazepines, are used to treat acute psychotic episodes. Although maintenance antipsychotic medications help reduce the severity and frequency of acute psychotic episodes (level A evidence), comprehensive psychosocial rehabilitation programs are required to help patients manage interpersonal and other stressors and to improve overall clinical outcomes. Adjunctive cognitive-behavioral therapy also may improve outcomes for some patients (level A). Second-generation (atypical) antipsychotic medications have replaced first-generation antipsychotics in common U.S. practice because of their lower rates of extrapyramidal side effects, including tardive dyskinesia. However, second-generation drugs contribute to an increase in obesity and metabolic syndrome.

Schizoaffective disorder is a chronic, recurrent disorder with a prevalence slightly lower than that of schizophrenia. It is characterized by episodes of nonmood psychosis and mood episodes (i.e., manic or depressed) with psychotic features. Its diagnosis therefore cannot be based on the patient's clinical findings at any one point in time but requires knowledge of the overall course. The outcomes of schizoaffective disorder are heterogeneous but on average are intermediate between schizophrenia and mood disorders. Treatment is symptomatic, using antipsychotic, mood stabilizing, and antidepressant medications to target specific psychotic and mood symptoms.

Delusional disorder is characterized by delusions in the absence of thought process disorder, prominent hallucinations, or the negative symptoms of schizophrenia. The delusions may be potentially plausible (i.e., not bizarre). Delusional disorder has a lifetime prevalence of approximately 0.2%. It often is only partially responsive to antipsychotic medications, but patients' functioning may be largely unimpaired if they are able with the aid of antipsychotics and psychotherapy to avoid acting on their delusions. The pathogenesis of the nonschizophrenic primary psychotic disorders remain largely unknown.

SOMATIC SYMPTOM DISORDER AND RELATED DISORDERS

Formerly called *somatoform disorders*, these conditions include somatic symptoms and associated thoughts, feelings, or behaviors that are distressing and disabling. Prominent types include somatic symptom disorder (i.e., excessive thoughts, feelings, or behaviors associated with one or more somatic symptoms), illness anxiety disorder (i.e., illness preoccupation and health-related behaviors disproportionate to somatic symptoms), conversion (i.e., functional neurologic symptom) disorder (i.e., neurologic somatoform symptoms incompatible with recognized neurologic or general medical conditions), and psychological factors affecting physical conditions. Factitious disorder (i.e., Munchausen's syndrome) is a mental disorder in which patients consciously produce stigmata of disease (e.g., simulated or artificially induced fever or hypoglycemia) for the unconscious gain of assuming the sick role.

Although identifiable physical disease is insufficient to fully explain the patient's presentation, in all these conditions other than factitious disorder, the patient's distress and dysfunction are *not* consciously produced and are just as distressing to patients as would be similar symptoms produced by other medical conditions. Malingering is the conscious feigning of illness for conscious gain and therefore is not a mental disorder.

PERSONALITY DISORDERS

Personality is defined as the repertoire of enduring patterns of inner mental experience and behavior, including affect and impulse regulation, defense and coping mechanisms, and interpersonal relatedness. Personality traits must be distinguished from time-limited states. For example, a patient who exhibits dependent features solely while acutely depressed does not have a dependent personality.

A personality disorder is diagnosed when personality traits lead to pervasive (if variable) subjective distress or dysfunction in a broad range of situations. The major personality disorders are listed in [Table 109-3](#). Personality and personality disorders are

the result of complex interactions among genetic, environmental, and developmental factors. Approaches to patients with personality disorders depend on the specific type, but in most clinical circumstances other than long-term psychotherapy, the realistic goal is not to alter fundamental personality structure but to help the patient maximize use of personality strengths (e.g., optimal defense mechanisms) while minimizing the harmful effects of emotional dysregulation, unhelpful defenses, and destructive behaviors.

Although not the mainstay of most treatments for personality disorders, pharmacotherapy can be useful in selected patients (e.g., antipsychotics to target escalating paranoia in paranoid personality disorder, mood stabilizers or antidepressants to target emotional dysregulation in borderline personality disorder). Patients with personality disorders are also prone to mood, anxiety, eating, addictive, and other treatable psychiatric disorders.

PROSPECTUS FOR THE FUTURE

Advances in neuroscience will lead to better pharmacologic or other somatic therapies. One example, deep brain stimulation, is being studied for severe refractory mood and anxiety disorders. In the future, regimens tailored for each individual may be based on genomic or proteomic profiles. These same advances may help identify patients for whom evidence-based psychotherapies or other psychosocial interventions are most likely to be effective. Identification of more specific and powerful risk markers may lead to the development of preventive interventions for at-risk individuals or groups. The current U.S. health care system, however, provides barriers that often prevent implementation of mental health treatments, although this may change in light of recent incentives to improve the health of populations.

Autonomic Nervous System Disorders

William P. Cheshire, Jr.

DEFINITION AND EPIDEMIOLOGY

The autonomic nervous system reaches throughout the body and governs all visceral activity. Its central network and peripheral sympathetic and parasympathetic divisions integrate complex organ functions, maintain internal homeostasis in response to environmental change, modulate the flight-or-fight physiologic response to stress, and enable circulation, digestion, and procreation.

Benign dysautonomias are common. Neurally mediated syncope and situational reflex syncope in response to emotional distress, carotid sinus stimulation, micturition, defecation, coughing, straining, or other factors occur in about 20% of people during a lifetime and account for 1% to 3% of all emergency room visits. Hyperhidrosis of the palms and soles affects about 1% of the population. Anhidrosis can contribute to increased mortality rates during severe heat stress.

One of the most disabling manifestations of autonomic failure is orthostatic hypotension, the prevalence of which increases with age, physical inactivity, and in diseases that impair sympathetic adrenergic nerves. Orthostatic hypotension affects about 5% to 20% of the elderly.

Diabetes mellitus is the most common cause of autonomic neuropathy in industrialized nations. About 30% of diabetics develop autonomic neuropathy, and symptomatic orthostatic hypotension occurs in 5% of patients. Other features of autonomic neuropathy include constipation in 40% to 60% of diabetics, gastroparesis in 20% to 40%, bladder dysfunction in 30% to 80%, and erectile impotence in more than 30% of men.

For a deeper discussion of these topics, please see Chapter 25, "Common Clinical Sequelae of Aging," and Chapter 229, "Diabetes Mellitus," in Goldman-Cecil Medicine, 25th Edition.

PATHOLOGY

Many brain, spinal cord, peripheral nerve, and systemic disorders that impair autonomic nerves can cause autonomic dysfunction or failure. They include a wide range of degenerative, traumatic, cerebrovascular, autoimmune, genetic, metabolic, toxic, and pharmacologic conditions.

Small-caliber peripheral autonomic nerves are unmyelinated or thinly myelinated, and small-fiber peripheral neuropathies that cause distal sensory loss may also involve sympathetic

or parasympathetic nerves. Diabetic autonomic neuropathy results from microvascular damage to autonomic nerves. Several hereditary, infectious, metabolic, toxic, and drug-induced sensory and autonomic neuropathies are recognized causes.

Accumulation of abnormal proteins distinguishes some of the degenerative dysautonomias. Oligodendroglial cytoplasmic inclusions composed of aggregates of misfolded α -synuclein are pathognomonic of multiple system atrophy. Abnormally folded sympathetic neuronal accumulation of α -synuclein occurs in Lewy body disorders such as Parkinson's disease. Peripheral autonomic nerve deposition of β -pleated sheet amyloid protein causes a severe autonomic neuropathy, which is frequently seen in primary amyloidosis, immunoglobulin light chain-associated disease, and hereditary amyloidosis, although rarely in reactive amyloidosis.

Other dysautonomias have an autoimmune basis. Autonomic instability has long been recognized in Guillain-Barré syndrome, which is an acute inflammatory, demyelinating polyradiculoneuropathy associated with antiganglioside antibodies (e.g., anti-GM₁, anti-GM₃). The list of autoimmune autonomic neuropathies includes acute autonomic ganglionopathy; patients with acute pandysautonomia have antibodies against the nicotinic acetylcholine receptor in autonomic ganglia, which is sometimes associated with lung cancer or thymoma. Additional paraneoplastic autonomic neuropathies include those associated with antineuronal nuclear antibody type 1 (i.e., ANNA-1 or anti-Hu) and antibodies against collapsing response mediator proteins (i.e., CRMP-5 or anti-CV2). Lambert-Eaton myasthenic syndrome is associated with antibodies to voltage-gated calcium channels. Antibodies to voltage-gated potassium channels cause autoimmune neuromyotonia and dysautonomia with hyperhidrosis and orthostatic intolerance.

Pharmacologic agents frequently alter autonomic function. Diuretics, sympatholytic drugs, α -adrenoreceptor blockers, and vasodilators can cause or contribute to orthostatic hypotension. Anticholinergics and carbonic anhydrase inhibitors decrease sweating, whereas opioids and selective serotonin reuptake inhibitors increase sweating. Opioids slow intestinal transit. Anticholinergics, tricyclic antidepressants, and antihistamines may cause urinary retention.

Functional dysautonomias are medical conditions in which autonomic function is impaired in the absence of a known structural neurologic deficit. Some psychological disorders may

manifest with autonomic symptoms because emotional and autonomic centers are closely linked in the limbic system.

 For a deeper discussion of these topics, please see Chapter 420, “Peripheral Neuropathies,” Chapter 188, “Amyloidosis,” and Chapter 47, “Mechanisms of Immune-Mediated Tissue Injury,” in Goldman-Cecil Medicine, 25th Edition.

CLINICAL PRESENTATION

Clinical manifestations of autonomic disorders vary according to which nerves are involved and how severely. Autonomic signs and symptoms may be benign or serious, paroxysmal or continuous, or localized or generalized, and they may represent hypo-function or hyperfunction.

Afferent autonomic lesions that separate central autonomic nuclei from incoming information needed to gauge an appropriate response may cause excessive or erratic autonomic outflow. An example of afferent dysautonomia is the volatile hypertension in carotid arterial baroreceptor failure after irradiation to treat laryngeal carcinoma. Spinal cord injuries above the level of sympathetic outflow at T5 can cause autonomic dysreflexia, a condition of paroxysmal sympathetic surges with hypertension, diaphoresis, flushing, and headache. Catastrophic brain disorders such as subarachnoid hemorrhage, trauma, or hydrocephalus may also cause autonomic storms if hypothalamic circuits are released from cortical inhibition.

More common are efferent autonomic lesions, which cause failure of outflow to neuroeffector junctions, resulting in inadequate excitatory or inhibitory autonomic responses. An example of efferent dysautonomias is autonomic peripheral neuropathy, which may accompany distal sensory loss and decreased Achilles tendon jerks.

Adrenergic failure impairs the cardiac and peripheral vascular response needed to maintain blood pressure during orthostatic stress. Typical symptoms of adrenergic failure include lightheadedness or fatigue on standing that is relieved by sitting.

Vagal failure impairs cardiac parasympathetic tone that may protect against arrhythmogenic sympathetic activity. Patients have a fixed heart rate that does not vary with respiration.

Sudomotor failure with extensive anhidrosis may coexist with tonic pupils and areflexia (i.e., Ross syndrome), and it can increase the risk of heat exhaustion or heat stroke. A dramatic example of regional sudomotor failure is harlequin syndrome, in which hemifacial cutaneous sympathetic denervation divides the pale and dry denervated half of the face from the intact half that flushes red in response to heat stress. Horner’s syndrome (i.e., unilateral ptosis, miosis, and anhidrosis) may be identified.

The clinical hallmark of generalized autonomic failure is severe orthostatic hypotension without pulse acceleration. In at least one half of patients, it is accompanied by supine and nocturnal hypertension, a reversal of the normal diurnal decrease in blood pressure during sleep. In addition to vagal and sudomotor failure, patients with generalized autonomic failure may have constipation, gastroparesis, bladder dysfunction, male erectile dysfunction, drymouth, or dry eyes. Some have postprandial hypotension, in which a large meal high in carbohydrate content causes a reduction in blood pressure.

One of the most severe autonomic disorders is multiple system atrophy, which is a sporadic, progressive, ultimately fatal neurodegenerative disorder in which autonomic failure occurs in combination with parkinsonism or cerebellar ataxia. Bladder hypotonia with overflow incontinence and nocturnal respiratory stridor may occur. The parkinsonian phenotype (i.e., Shy-Drager syndrome) tends to respond poorly to levodopa. Orthostatic hypotension is also common in Lewy body disorders such as Parkinson’s disease. Pure autonomic failure consists of widespread autonomic failure without other neurologic features.

In contrast to autonomic failure, neurally mediated syncope occurs in patients with a functioning autonomic nervous system in which there is a reversal of normal autonomic outflow. Prodromal features typically include pallor, sweating, nausea, abdominal discomfort, mydriasis, increased respiratory rate, and cognitive slowing, which may progress to transient loss of consciousness if the patient continues in an upright posture. Withdrawal of peripheral sympathetic vasomotor tone (i.e., vasodepressor syncope) or an increase in parasympathetic tone (i.e., vasovagal syncope) causes a fall in blood pressure, heart rate, and cerebral perfusion.

Orthostatic intolerance refers to a heterogeneous group of conditions in which patients have difficulty sustaining the autonomic outflow needed to maintain blood pressure during the gravitational stress of prolonged standing. Some patients experience a gradual decline in blood pressure, but others experience an abnormal increase in heart rate without a drop in blood pressure.

 For a deeper discussion of these topics, please see Chapter 62, “Approach to the Patient with Suspected Arrhythmia,” Chapter 67, “Arterial Hypertension,” Chapter 136, “Disorders of Gastrointestinal Motility,” and Chapter 409, “Parkinsonism,” in Goldman-Cecil Medicine, 25th Edition.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A careful history and discerning physical examination are essential for reaching a diagnosis. The astute clinician inquires about the time course of symptoms and the circumstances that provoke or modify them. How long have they been present? Are they stable, improving, or worsening? Do they occur consistently or episodically? Orthostatic disorders are typically worse in the early morning, in heat, and after physical exercise or a large meal. How well the patient tolerates standing in line or taking a warm shower are helpful clues to identifying orthostatic intolerance.

Physical signs of autonomic dysfunction may include pupillary asymmetry or sluggishness, ptosis, or mucosal dryness. An acutely distended bladder may be suspected by percussion. Asymmetrical sweating may be visible or palpable.

The most important part of the examination, but one that is frequently omitted, is measurement of orthostatic blood pressure (Fig. 110-1). Blood pressure and heart rate should be assessed when the patient is resting supine and again after standing for 1 to 3 minutes or longer. Correlation with symptoms is key. Patients with orthostatic hypotension may appear less alert, or they may shift weight from one leg to the other to improve venous return, lower the head to bring the cerebral circulation closer to the level

FIGURE 110-1 Orthostatic blood pressure profiles. **A**, The normal response to standing or head-up tilt is no change or a small decrease in blood pressure that recovers within one-half minute and a small increase in heart rate. **B**, Dehydration causing intravascular hypovolemia may cause a fall in blood pressure accompanied by reflex tachycardia. **C**, Neurogenic orthostatic hypotension may cause a more profound drop in blood pressure. Hypotension occurs immediately and is sustained without recovery during standing and often without adequate compensatory tachycardia. **D**, Postural tachycardia syndrome and other forms of orthostatic intolerance are characterized by an abnormal increase in heart rate without orthostatic hypotension. **E**, Neurally mediated syncope develops after standing for some time, may be preceded by oscillations in blood pressure, and may be accompanied by bradycardia with loss of consciousness in about 7 seconds if cerebral perfusion is not restored.

of the heart, or exhibit lower extremity rubor if cutaneous vasomotor function is impaired.

Orthostatic hypotension is a reduction in systolic blood pressure of at least 20 mm Hg or a reduction in diastolic blood pressure of at least 10 mm Hg, with or without symptoms, within 1 to 3 minutes of assuming an erect posture. Neurogenic orthostatic hypotension is typically sustained with continued standing and lacks the reflex tachycardia that may be seen if hypotension is caused by blood loss, dehydration, or excessive venous pooling.

Orthostatic intolerance is a sustained increase in postural heart rate of more than 30 beats per minute in adults (40 in adolescents). In postural tachycardia syndrome, the standing heart rate consistently exceeds 120 beats per minute.

Laboratory testing of autonomic responses under controlled conditions is useful to determine the presence, severity, and distribution of autonomic failure. Clinical autonomic testing typically evaluates beat-to-beat blood pressure and heart rate responses to the Valsalva maneuver, upright tilt, and periodic deep breathing, along with quantitative assessment of sweating responses. Ambulatory blood pressure testing is useful for the assessment of episodic or postprandial hypotension, nocturnal hypertension, and the volatile hypertension of autonomic storms.

TREATMENT

Treatment options for orthostatic hypotension are outlined in Table 110-1. The goal is to enable the patient to stand long enough to engage in daily activities without symptoms. Medication is not always needed and can potentially exacerbate recumbent hypertension. Orthostatic intolerance was shown in a randomized controlled trial to improve after endurance exercise training (level A evidence).

Generalized hyperhidrosis may be reduced by oral anticholinergic agents such as 1 to 2 mg of glycopyrrolate taken one to three times daily (level B evidence). Topical glycopyrrolate reduces regional gustatory sweating (level A). Subdermal botulinum toxin injections are helpful for some forms of focal hyperhidrosis (level A), and palmar hyperhidrosis may respond to tap water iontophoresis (level B) or, in severe cases, to endoscopic thoracic sympathectomy (level A).

For a deeper discussion of these topics, please see Chapter 418, "Autonomic Disorders and Their Management," in Goldman-Cecil Medicine, 25th Edition.

PROGNOSIS

Orthostatic intolerance and neurally mediated syncope are frequently benign, manageable, and improve or recover with time. Autonomic failure, in contrast, can signify a more serious prognosis, depending on the nature and extent of its pathophysiology. Persistent or severe orthostatic hypotension carries a worse prognosis.

Diabetic cardiovascular autonomic neuropathy doubles the risk for silent myocardial ischemia and overall mortality. Amyloid autonomic neuropathy is especially grave, with a median survival of less than 1 year if the patient has orthostatic hypotension. Pure autonomic failure may remain stable for many years, although some patients with this phenotype eventually develop signs of multiple system atrophy, which denotes a life expectancy of 7 to 9 years after diagnosis.

Regular physical exercise can reverse the autonomic deconditioning that comes from inactivity. In the elderly, it may compensate for some age-associated decline in autonomic function (level B evidence).

For a deeper discussion of these topics, please see Chapter 418, "Autonomic Disorders and Their Management," in Goldman-Cecil Medicine, 25th Edition.

TABLE 110-1 TREATMENT OF ORTHOSTATIC HYPOTENSION

INTERVENTION	RATIONALE	DOSAGE	EVIDENCE LEVEL
CONSERVATIVE			
Avoid prolonged bed rest and increase time spent upright	Reverses physiologic deconditioning		B
Liberalize fluid intake	Expand plasma volume	2-2.5 L/day	B
Increase sodium intake	Expand plasma volume	Salt 10-20 g/day	A
Compressive leg garments and abdominal binder	Reduce venous pooling	15-20 mm Hg	B
Physical counter-maneuvers	Tensing limb muscles augments venous return	Isometric contractions for 30 sec	A
Water bolus treatment	Sympathetic reflex increases blood pressure for 1-2 hr	16 oz. plain water	A
Elevate heads of bed 4 inches	Decrease nocturnal natriuresis and nocturnal hypertension		C
Avoid large meals high in carbohydrate content	If patient is subject to postprandial hypotension		B
PHARMACOLOGIC			
Discontinue or decrease dose of blood pressure-lowering drugs			A
Midodrine	α -Adrenergic agonist, constricts capacitance vessels	5-10 mg tid	A
Fludrocortisone	Retains sodium and sensitizes peripheral vascular α -adrenergic receptors	0.1-0.4 mg/day	B
Pyridostigmine	Stimulates sympathetic ganglionic transmission	30-60 mg bid or tid	B

Headache, Neck and Back Pain, and Cranial Neuralgias

Timothy J. Counihan

HEADACHE

Definition and Epidemiology

Headache is caused by irritation of pain-sensitive intracranial structures, including the dural sinuses; the intracranial portions of the trigeminal, glossopharyngeal, vagus, and upper cervical nerves; the large arteries; and the venous sinuses. Many structures are insensitive to pain, including the brain parenchyma, the ependymal lining of the ventricles, and the choroid plexuses. The insensitivity of the brain parenchyma to pain accounts for the common clinical observation of patients who, despite having large intracerebral lesions (such as a hematoma or a brain tumor), complain of little or no headache. The term “cervicogenic” headache is sometimes used to indicate that the source of headache (usually occipital in location) arises from an abnormality in the cervical spine.

Classification of Headache

Headache is generally classified into primary, secondary, and cranial neuralgia syndromes (Table 111-1; Table 111-2; Table 111-3). It is essential that the clinician make every effort to make an accurate clinical diagnosis of the presenting headache syndrome; Table 111-4 provides some key questions in the assessment of the patient with headache.

Migraine

Definition

Migraine is a common episodic neurologic disorder characterized by disabling headache preceded in one third of patients by various combinations of neurologic, gastrointestinal, and autonomic phenomena (termed the “aura”). The diagnosis is based on the headache’s characteristics and associated symptoms. Results of the physical examination as well as the laboratory studies are usually normal.

- Central facial pain syndromes (e.g., cold-stimulus headache)

TABLE 111-4 KEY QUESTIONS IN THE ASSESSMENT OF HEADACHE

1. For how long have you been having headaches?
2. What were they like when they first began? Were they intermittent, daily persistent, or progressive from the beginning?
3. What is the length of time from the start of the headache until its peak intensity?
4. Are there any warning symptoms (e.g., aura)?
5. Does the headache interfere significantly with normal activity (e.g., work, school)?
6. What aggravates the headache (e.g., light, noise, odors)?
7. What do you do for relief from the headache (e.g., rest, move around, take medication)?
8. What time of day are the headaches most likely to occur? Do they regularly awaken you from sleep?
9. Are you aware of any specific triggers (e.g., foods, stress, lack of sleep, menstrual cycle)?
10. Does anyone else in the family have headaches?

TABLE 111-5 CLASSIFICATION OF MIGRAINE

Migraine without aura	Migraine variants
Migraine with aura	<ul style="list-style-type: none"> • Hemiplegic migraine • Migraine with basilar aura • Vestibular Migraine • Retinal Migraine

The prevalence of migraine is up to 18% in women and 6% in men. It is estimated that 28 million Americans have disabling migraine headaches. All varieties of migraine may begin at any age from early childhood on, although peak ages at onset are adolescence and early adulthood.

Several subtypes of migraine are described (Table 111-5). The two most common are migraine without aura and migraine with aura; migraine without aura accounts for 70% of patients. Migraine auras are focal neurologic symptoms that precede, accompany, or, rarely, follow an attack. The aura usually develops over 5 to 20 minutes, lasts less than 60 minutes, and can involve visual, sensorimotor, language, or brainstem disturbances. The most common aura is typified by positive visual phenomena (such as scintillating scotomata) that often precede the headache. The differential diagnosis of an aura includes a focal epileptic seizure arising from the visual cortex of the occipital lobe, or a transient ischemic attack (TIA). In the latter, there is no evolution of symptoms, and the symptoms themselves are typically “negative” (such as a hemianopia) rather than the “positive” visual phenomenon of phosphenes that is characteristic of the migrainous aura. The pain of migraine is often pulsating, unilateral, and frontotemporal in distribution and usually accompanied by anorexia, nausea, and, occasionally, vomiting. In characteristic attacks, patients are markedly intolerant of light (photophobia) and seek rest in a dark room. There may also be intolerance to sound (phonophobia) and occasionally to odors (osmophobia). The diagnosis of migraine requires the presence of at least one of these features, particularly in the absence of gastrointestinal symptoms. The presence of these symptoms results in a syndrome that is invariably disabling for the patient, to the extent that for the duration of the attack he or she is unable to function normally. In children, migraine is often associated with episodic abdominal pain, motion sickness, vertigo, and sleep disturbances. Onset of typical migraine late in life (older than age 50) is rare, although recurrence of migraine that had been in remission is not uncommon. Recurrent migraine headache associated with transient hemiparesis or hemiplegia occurs rarely as a clearly genetically determined (Mendelian) disease (*familial hemiplegic migraine*).

Migraine with basilar aura is unusual and occurs primarily in childhood. Severe episodic headache is preceded, or accompanied by, signs of bilateral occipital lobe, brainstem, or cerebellar dysfunction (e.g., diplopia, bilateral visual field abnormalities, ataxia, dysarthria, bilateral sensory disturbances, other cranial nerve signs, and occasionally coma). *Vestibular migraine* is characterized by symptoms of vertigo with or without the other typical migraine symptoms.

Complications of Migraine

Status Migrainosus refers to a severe migraine lasting greater than 72 hours. *Migrainous infarction* is a rare complication of migraine

with aura. The term *migrainalepsy* has been suggested for patients in whom an aura triggers a seizure.

Pathophysiology of Migraine

A migraine attack is the end result of the interaction of a number of factors of varying importance in different individuals. These factors include a genetic predisposition, a susceptibility of the central nervous system to certain stimuli, hormonal factors, and a sequence of neurovascular events. A positive family history is reported in 65% to 91% of cases. Three distinct ion channel gene mutations have been identified in patients with familial hemiplegic migraine (FHM), including a mutation in the P/Q type calcium channel on chromosome 19 (FHM 1) and a gene encoding a Na/K- ion pump on chromosome 1 (FHM 2). These findings lend support to the theory that migraine may be a true channelopathy in which mutations of diverse channels result in a common phenotype. The etiology of migraine in the majority of patients remains unknown.

The migrainous aura is likely caused by a “cortical spreading depression,” corresponding to a wave of neuronal depolarization spreading over the cortex from posterior to anterior. One of the key structures in the mechanism of pain in migraine is the trigeminal vascular system. Stimulation of the trigeminal nucleus caudalis can activate serotonin receptors and nerve endings on small dural arteries and result in a state of neurogenic inflammation. It is postulated that these processes, in turn, stimulate perivascular nerve endings, with resultant orthodromic stimulation of trigeminal nerve and pain referred to its territory. Furthermore, positron emission tomographic (PET) studies have demonstrated activation of brainstem neuromodulatory structures, including the periaqueductal grey matter, locus coeruleus, and raphe nuclei during a migraine attack.

Treatment of Migraine

The goals of treatment are (1) making an accurate and confident diagnosis of migraine to reassure the patient that there is no more sinister cause for the headache; (2) relieving acute attacks; and (3) preventing pain and associated symptoms of recurrent headaches. The first step is to inform the patient that he or she has a migraine. The benign nature of the disorder and the patient’s central role in the treatment plan should be emphasized. It is important that the patient keep a headache diary, which serves to help identify covert headache triggers, assists in monitoring headache frequency and response to treatment, and actively involves the patient in the management of the condition. A sustained pain-free therapeutic response should aim to have the patient pain-free at two hours with no recurrence and no need for subsequent rescue medication.

Acute Migraine Attack

Acute attacks are best alleviated using a stratified, rather than stepped care approach, using single agents or varying combinations of drugs as well as with behavioral modification therapy. Many attacks of migraine respond to simple analgesics, such as acetaminophen, aspirin, or nonsteroidal anti-inflammatory agents (NSAIDs). Opioid drugs and butalbital should not be used in the routine management of patients with migraine. Overuse of analgesics is particularly frequent in headache

patients; therefore, one of the most important aspects of therapy is the monitoring of amounts of analgesic used. In patients who are nauseated, it is often helpful to prescribe an anti-emetic agent early in an attack. Phenothiazine drugs have antiemetic, prokinetic, and sedative properties, but they can produce involuntary movements as an acute adverse effect (acute dystonic reaction) or with prolonged use (tardive dyskinesias).

A number of *migraine-specific* serotonin agonist drugs have become available. These agents, commonly referred to as “triptans,” are useful in the acute treatment of migraine, having a rapid onset of action. The increasing availability of non-oral (parenteral, inhaled, and transdermal) preparations has largely circumvented the problem of emesis and gastroparesis in migraine patients resulting in greater efficacy. For instance, sumatriptan, available as a subcutaneous preparation, results in a headache response rate of close to 70% (Fig. 111-1). Although triptans are highly effective in alleviating migraine, patients must be carefully instructed in their appropriate use. Moreover, a response to these medications does not confirm a diagnosis of migraine.

Treating Acute Migraine in the Emergency Room

Migraine is one of the most common reasons for emergency room visits and presents some treatment challenges; typically migraine is more difficult to treat once it is fully established. It is essential to confirm that the diagnosis is accurate, even in patients with an established history of migraine. Patients will usually be aware that the headache will have started as their typical migraine, although it may be more severe than usual. In patients who state that the new headache is different to their usual headache, consideration should be given to exclude a more sinister cause.

Thereafter the core principles of treatment include reassurance that the headache can be treated effectively, hydration, pain control, and relief of accompanying symptoms such as nausea and photophobia. The majority of patients presenting with acute migraine as an emergency will have already tried some form of abortive therapy, and they are likely to be dehydrated. In this setting parenteral therapy with an NSAID, a triptan, and an anti-emetic is often effective (Fig. 111-1)

Migraine Prevention

Several agents have a strong evidence base for efficacy in the prevention of migraine (Table 111-6). The use of these agents should be restricted to patients who have frequent attacks (usually more than four per month) and who are willing to take daily medication. With any of the medications, an adequate trial period should be given, using adequate doses, before it is declared ineffective. Combination therapy is occasionally required but is not routinely prescribed. For a preventative drug to be considered successful, it should reduce the headache frequency rate by at least 50%. Other medications commonly used for migraine prevention include gabapentin, cyproheptadine, methysergide, and clonidine, but these have limited evidence to support their use as first line therapy. Magnesium supplementation, the plant extract feverfew, butterbur, and high-dose riboflavin (vitamin B₂) have been effective in some patients.

Future of Migraine Treatment

The most significant recent advance in acute migraine treatment relates to calcitonin gene-related peptide (CGRP) receptor antagonists. Stimulation of trigeminal ganglia neurons results in

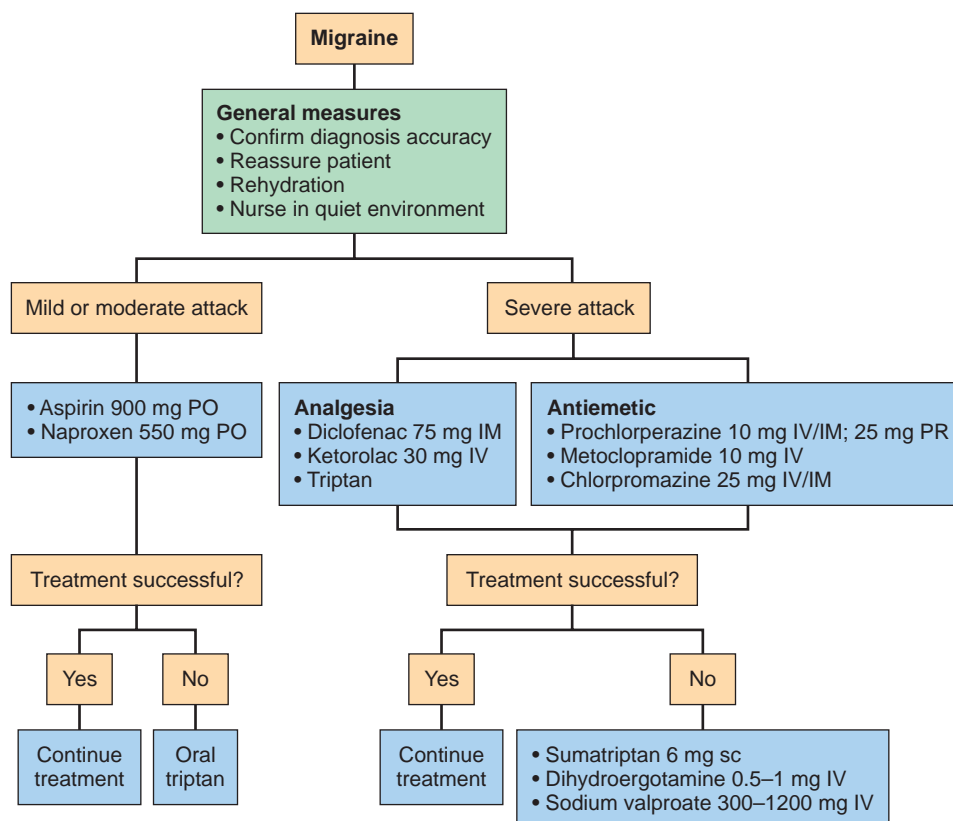

FIGURE 111-1 Algorithm for the treatment of migraine. DHE, Dihydroergotamine; IM, intramuscular; IV, intravenous; NS, normal saline; NSAIDs, nonsteroidal anti-inflammatory drugs; SC, subcutaneous.

TABLE 111-6 PREVENTIVE THERAPIES FOR MIGRAINE

DRUG CLASS	AGENT	DOSE RANGE	EVIDENCE LEVEL	ADVERSE EFFECTS
β-adrenoceptor blockers	Propranolol	80-240 mg	A	Contraindicated in asthma, syncope
	Metoprolol	50-150 mg	A	
	Timolol	10-20 mg	A	
Antiepileptic drugs	Divalproex sodium	200-1500 mg	A	Weight gain, thrombocytopenia, tremor Renal calculi, weight loss, amnesia, glaucoma, dysequilibrium
	Topiramate	25-150 mg	A	
	Gabapentin	300-1800 mg	U	
Antidepressants	Amitriptyline	10-150 mg	B	Somnolence Insomnia, hypertension
	Nortriptyline	25-100 mg	N/A	
	Venlafaxine	37.5-150 mg	B	
Calcium channel blockers	Verapamil	180-480 mg	U	Constipation, hypotension, edema Weight gain, depression
	Flunarizine*	5-10 mg	N/A	
Other	Onabotulinum toxin A	Variable	N/A	Discomfort, ecchymosis

Level of Evidence A, Medication with established efficacy; Level B, medication probably effective; Level U, inadequate data to support use; N/A, not considered in recent evidence review.

release of CGRP; telcagepant, a CGRP receptor antagonist has been found to have similar efficacy to oral triptan therapy. Greater insights into the genetic basis for migraine has enhanced our understanding of ion channel dysfunction in this disorder, and are likely to lead to new therapeutic targets.

Cluster Headache

Clinical Features

Cluster headache is the prototypic trigeminal autonomic cephalgia, entirely distinct from migraine, although there may be some clinical overlap. It is uncommon, occurring in less than 10% of all patients with headache. Unlike migraine, it is much more common in men than in women, and the mean age at onset is later in life. Also, unlike migraine, cluster headache rarely begins in childhood, and there is less often a family history. The pain in cluster headache is of extreme intensity, is strictly unilateral, and is associated with congestion of the nasal mucosa and injection of the conjunctiva on the side of the pain. Increased sweating of the ipsilateral side of the forehead and face may occur. There may be associated ocular signs of Horner syndrome: miosis, ptosis, and the additional feature of eyelid edema. Attacks often awaken patients, usually 2 to 3 hours after the onset of sleep (“alarm-clock headache”). In contrast to migraineurs, the pain is not relieved by resting in a dark, quiet area; on the contrary, patients sometimes seek activity that can distract them. The duration of headache is usually around 1 hour, although it may recur several times in a day, paroxysmally (in *clusters*) for several weeks.

These periods of frequent headaches are separated by headache-free periods of varying duration, often several months or years. Attacks have a striking tendency to be precipitated by even small amounts of alcohol. There are rare variants of cluster headache: a “chronic variety” in which remissions are brief (less than 14 days); “*chronic paroxysmal hemicrania*,” in which attacks are shorter and strikingly more prevalent in women; and “*hemicrania continua*,” in which there is continuous, moderately severe, unilateral headache. The cause of all these syndromes is unknown, although the distribution of the pain suggests dysfunction of the trigeminal nerve.

Treatment

Therapy for cluster headache may be abortive for acute headache or prophylactic to prevent headache. Acute headache may respond to oxygen by mask (7 to 10 L/min for 15

minutes), which is effective within several minutes in 70% of patients. Sumatriptan and dihydroergotamine are also effective. Preventive medications include lithium, divalproex sodium, verapamil, methysergide, and corticosteroids. Paroxysmal hemicrania and related syndromes are often strikingly responsive to indomethacin.

Tension-Type Headache

In contrast to migraine, tension-type headache is featureless. The pain is usually not throbbing, but rather steady and often described as a “pressure feeling” or a “viselike” sensation. It is usually not unilateral and may be frontal, occipital, or generalized. There is frequently pain in the neck area, unlike in migraine. Pain commonly lasts for long periods of time (days) and does not rapidly appear and disappear in attacks. There is no “aura.” Photophobia and phonophobia are not prominent. Although tension-type headache may be related by the patient to occur or be exacerbated at times of particular emotional stress, the pathophysiology may relate to sustained craniocervical muscle contraction; hence, a more useful term for this syndrome is *muscle-contraction headache*.

A careful evaluation should be made of the patient’s psychosocial milieu and the presence of anxiety or depression. The tricyclic antidepressant drugs in low doses have proven the most useful for prevention of tension-type headache. Although the best documented is amitriptyline, newer agents with fewer side effects may be equally effective. Nonpharmacologic therapies such as relaxation therapy, massage, physiotherapy, or acupuncture may be useful in refractory cases. Intramuscular botulinum toxin injections have been used both in migraine and tension-type headache, but are of established benefit only in patients with chronic migraine.

Other Defined Primary Headache Syndromes

Other acute short-lasting headache syndromes need to be differentiated from migraine, cluster, or tension headache. These include primary “thunderclap” headache, *primary stabbing headache*, *primary exertional headache*, and coital headache. The latter may be indistinguishable from the headache of intracranial aneurysm rupture and requires computed tomography (CT) and lumbar puncture to exclude subarachnoid hemorrhage (SAH). All of these headache syndromes are more common in migraineurs. Two additional rare, short-lasting headache

syndromes deserve mention: short-lasting unilateral neuralgiform headache with conjunctival tearing (SUNCT); and *hypnic* headache. The latter refers to multiple episodes of very brief headache that awaken the patient (typically an older woman) from sleep. The syndrome of SUNCT causes multiple very brief (seconds to minutes) episodes of cluster-like headache and autonomic disturbance.

Chronic daily headache is defined arbitrarily as headache lasting for more than 4 hours on more than 15 days in the month for more than 3 months. In clinical practice this means that the patient has a headache more often than not. In these cases it is important to establish whether the headache syndrome began as an episodic disorder (as in migraine or tension-type headache) or whether it consists of new daily persistent headaches.

New Daily Persistent Headache

New daily persistent headache needs to be distinguished from tension-type or migraine headaches that have transformed into chronic daily headache, and necessitates investigation to exclude a secondary cause.

Headache may be a manifestation of underlying structural brain disease (Table 111-2). Headache can be seen in all forms of cerebrovascular disease, including infarction, intracerebral hemorrhage, and SAH, although headache is rarely prominent in cerebral infarction. In contrast, the headache in SAH is usually extremely severe and often described by the patient as “the worst headache of my life.” Nuchal rigidity, third nerve palsy (usually involving the pupil), and retinal, preretinal, or subconjunctival hemorrhages may be found. CT of the head usually shows subarachnoid, intraventricular, or other intracranial blood.

Certain symptoms raise suspicion for a structural brain lesion (Table 111-7).

The patient with headache and fever presents a common diagnostic problem in the emergency department. Neck stiffness is a common symptom. Meningismus is confirmed by eliciting Brudzinski and Kernig signs. Vomiting occurs in about 50% of patients. Suspicion for meningitis should prompt immediate investigation, including a lumbar puncture. If the patient shows focal signs, papilledema, or profound alteration in level of consciousness, CT of the head before lumbar puncture is required to rule out focal disease such as an abscess or subdural empyema. These lesions, however, are rare.

Acute Sinusitis

Head and face pain is the most prominent feature of sinusitis. Malaise and low-grade fever are usually present. The pain is dull, aching, and nonpulsatile; is exacerbated by movement, coughing, or straining; and is improved with nasal decongestants. The pain

is most pronounced on awakening or after any prolonged recumbency, and is diminished with maintenance of an upright posture.

The location of the pain depends on the sinus involved. Maxillary sinusitis provokes ipsilateral malar, ear, and dental pain with significant overlying facial tenderness. Frontal sinusitis produces frontal headache that may radiate behind the eyes and to the vertex of the skull. Tenderness to frontal palpation may be present with point tenderness on the undersurface of the medial aspect of the superior orbital rim. In ethmoidal sinusitis, the pain is between or behind the eyes with radiation to the temporal area. The eyes and orbit are often tender to palpation, and, in fact, eye movements themselves may accentuate the pain. Sphenoidal sinusitis causes pain in the orbit and at the vertex of the skull and occasionally in the frontal or occipital regions. Given that the trigeminal nerve mediates pain perception from the sinuses, many patients who complain of “sinus headaches” are probably suffering from the trigeminovascular disturbance of migraine, rather than sinusitis. Chronic sinusitis is seldom a cause of headache.

Brain Tumors

Posterior fossa tumors (particularly of the cerebellum) frequently produce headache, especially if hydrocephalus occurs because cerebrospinal fluid (CSF) flow is partially obstructed. Supratentorial tumors, however, are less likely to cause headache and are more frequently heralded by altered mental status, focal deficits, or seizures. Although increased intracranial pressure is often associated with headache, it is usually not the primary mechanism because uniform pressure elevations do not usually produce distortions of pain-sensitive structures.

Idiopathic Intracranial Hypertension

Idiopathic intracranial hypertension (IIH), also called *benign intracranial hypertension*, is defined as a syndrome of elevated intracranial pressure without evidence of focal lesions, hydrocephalus, or frank brain edema. It usually occurs between the ages of 15 and 45 years and is more frequent in obese women. The disorder is characterized by headache with features of raised intracranial pressure. The headache is usually insidious in onset, is typically generalized, is relatively mild in severity, and is often worse in the morning or after exertion (e.g., straining or coughing).

At times, patients have visual disturbances, such as restricted peripheral visual fields, enlarged blind spots, visual blurring (*obscurations*), or diplopia secondary to abducens nerve palsies. Funduscopic examination shows papilledema, which is often more impressive than the clinical picture. IIH is usually a benign and self-limited disorder, but it may lead to visual loss, including blindness.

The condition has been associated with drugs—vitamin A intoxication, nalidixic acid, danazol (Danocrine), and isotretinoin (Accutane)—as well as corticosteroid withdrawal and systemic disorders such as hypoparathyroidism and lupus.

CT scans are usually normal but can show small ventricles and an “empty sella” in some cases. CSF opening pressure is elevated, usually in the range of 250 to 450 mm of water, with the pressure fluctuating markedly when monitoring occurs over a prolonged period. Some cases of IIH are caused by cerebral venous sinus

TABLE 111-7 DIFFERENTIAL DIAGNOSIS OF ACUTE HEADACHE—MAJOR CAUSES

Migraine	Acute hydrocephalus
Cluster headache	Meningitis or encephalitis
Stroke	Giant cell arteritis (often chronic)
• Subarachnoid hemorrhage	Tumor (usually chronic)
• Intracerebral hemorrhage	Trauma
• Cerebral infarction	
• Arterial dissection (carotid or vertebral)	

occlusion. These cases can occur in hypercoagulable states, including peripartum, in association with the combined oral contraceptive pill, and in association with antiphospholipid antibody syndrome. After secondary causes of IHH have been eliminated, the patient should have dietary counseling for weight loss. Carbonic anhydrase inhibitors (acetazolamide) and corticosteroids have proved useful in headache control. As a second-line agent, furosemide also acts to lower CSF production. Serial lumbar punctures are understandably unpopular with patients even though transient headache relief is obtained. CSF shunting procedures (ventriculoperitoneal shunt) are occasionally necessary. For patients with progressive visual loss, optic nerve sheath fenestration preserves or restores vision in 80% to 90% of cases and provides headache relief in a majority.

Idiopathic Intracranial Hypotension

Also known as *low pressure headache*, idiopathic intracranial hypotension is commonly encountered as a sequela of lumbar puncture, resulting from leakage of CSF through the dural sac. Low pressure headaches may also occur spontaneously as a result of rupture of subarachnoid cysts. The headache is initially characteristically positional, being severe on standing but relieved rapidly on lying down. Occasionally the headache is associated with focal or “false localizing” signs, especially abducens nerve palsies.

Post-Traumatic Headache

Headache following trauma has no specific quality and is associated with irritability, concentration impairment, insomnia, memory disturbance, and light-headedness. Anxiety and depression are present to variable degrees. Multiple treatment options are available, and amitriptyline and nonsteroidal anti-inflammatory agents are useful. Occasionally, muscle relaxants and anxiolytics are beneficial. Training is occasionally associated with the onset of typical migraine.

Giant Cell Arteritis

Headache occurs in 60% of patients with giant cell arteritis, a granulomatous vasculitis of medium and large arteries. Over 95% of patients are 50 years of age or older. Malaise, fever, weight loss, and jaw claudication occur early, in addition to headache. Poly-myalgia rheumatica, a syndrome of painful stiffness of the neck, shoulders, and pelvis, is found in half the patients (Chapter 131). Visual impairment secondary to ischemic optic neuritis may occur. The headache is usually described as aching and is exacerbated at night and after exposure to cold. The superficial temporal artery is frequently swollen, tender, and may be pulseless. The erythrocyte sedimentation rate is usually elevated; the mean is 100 mm/hr. Anemia is frequently present. Temporal artery biopsy usually confirms the diagnosis, but, because the arteritis is segmental, large or multiple sections may be required. Prednisone therapy is often dramatically effective and must be given promptly to preserve vision on the affected side.

Evaluation of the patient with acute headache

It is important to distinguish benign from ominous causes of headache. A detailed history (the quality, location, duration, and

time course of the headache) helps in determination of which patients have a symptomatic structural intracranial lesion (Table 111-7; Table 111-8; Table 111-4)). Pain intensity is not of much diagnostic value, except for the patient who complains of the acute onset of the worst headache of his or her life). The quality of pain (“throbbing,” “pressure,” “jabbing”) and the location may also be helpful, especially if the pain is of extracranial origin, such as temporal in temporal arteritis. Posterior fossa lesions cause occipitocervical pain, occasionally associated with unilateral retro-orbital pain. In general, multifocal pain usually implies a benign cause. It is most important to clarify the acuity of onset of the headache; patients who describe the onset of pain as “like being hit on the head with a bat” should be suspected of having the sentinel headache of subarachnoid headache. Equally important is to establish the time course of the headache. Is this paroxysmal, nonprogressive headache (typical of migraine or tension-type headache)? Or is the headache daily persistent (such as in temporal arteritis) or progressive (suggesting the presence of a structural brain lesion)? Patients should be asked about any known triggers for the headache, such as menses, particular foods, caffeine, alcohol, or stress. Positional headache (headache that is maximal in the upright position and disappears rapidly on lying down) is characteristic of intracranial hypotension (low pressure headache). Diurnal variation in headache severity may give a clue to cause; morning headache or headache that awakens a patient from sleep may indicate raised intracranial pressure or sleep apnea as a cause. The presence of associated symptoms such as visual disturbances, nausea, or vomiting should be noted. The history should include inquiries about medications, especially use of analgesics and over-the-counter remedies. Information regarding the patient’s past medical history as well as family history should also be taken into consideration. In the majority of patients with headache, the physical and neurologic examination findings are normal, although special attention may be directed toward examination of the eyes for papilledema, as well as the temporal arteries for a palpable nonpulsatile artery. Assessment of the patient with acute nontraumatic headache in the emergency room can be challenging; it is essential to establish how the headache evolved. Acute-onset severe headache should prompt investigation to exclude SAH, intracranial hemorrhage, acute obstructive hydrocephalus, and meningitis (Table 111-7). Appropriate initial investigations should include brain imaging with CT or magnetic resonance imaging (MRI). Patients with suspected meningitis without focal neurologic signs or impaired consciousness should not have their lumbar puncture delayed unnecessarily before imaging. All patients should have standard

TABLE 111-8 CLINICAL FEATURES OF HEADACHES SUGGESTING A STRUCTURAL BRAIN LESION

SYMPTOMS	SIGNS
Worst of the patient’s life	Nuchal rigidity
Progressive	Fever
Onset >50 years of age	Papilledema
Worse in early morning—awakens patient	Pathologic reflexes or reflex asymmetry
Marked exacerbation with straining	Altered state of consciousness
Focal neurologic dysfunction	

blood tests, including blood cultures if bacterial meningitis is suspected.

A wide variety of systemic diseases have headache as a prominent symptom; some of the more prevalent disorders are summarized in [Table 111-2](#).

CRANIAL NEURALGIAS

Neuralgias are differentiated from other head pains by the brevity of the attacks (usually 1 to 2 seconds or less) and by the distribution of the pain ([Table 111-3](#)).

Trigeminal Neuralgia

In trigeminal neuralgia (tic douloureux), stabbing, spasmodic pain occurs unilaterally in one of the divisions of the trigeminal nerve. It lasts seconds, but it may occur many times a day for weeks at a time. It is characteristically induced by even the lightest touch to particular areas of the face, such as the lips or gums. Trigeminal neuralgia is the most frequent neuralgia of the elderly and is thought to be caused by compression of the trigeminal nerve root in the pons by an aberrant arterial loop. A small minority of cases are caused by multiple sclerosis, cerebellopontine angle tumors, aneurysms, or arteriovenous malformations, although in these cases (unlike “true” trigeminal neuralgia) there are usually objective signs of neurologic deficit, such as areas of diminished sensation. In these cases of “symptomatic” neuralgia, the pain is often atypical. MRI is indicated in patients who have sensory loss, those who are under 40, and those with bilateral or atypical symptoms. Trigeminal neuralgia may be life threatening when it interferes with eating. Neuralgic pain is often responsive to treatment with standard doses of an anticonvulsant such as phenytoin, carbamazepine, gabapentin, pregabalin, and, occasionally, baclofen. Antidepressant drugs such as amitriptyline and, more recently, duloxetine may also be useful in this setting. Combination therapy, including an antidepressant, anticonvulsant, and opiate analgesic has been shown to have synergistic effects.

If medical treatments are unsuccessful, surgical treatment may be indicated: microvascular decompression or radiofrequency lesioning of the sensory portion of the trigeminal nerve.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is less common than trigeminal neuralgia. Brief paroxysms of severe, stabbing, unilateral pain radiate from the throat to the ear or vice versa and are frequently initiated by stimulation of specific “trigger zones” (e.g., tonsillar fossa or pharyngeal wall). Swallowing often provokes an attack; yawning, talking, and coughing are other potential triggers. Microvascular decompression is necessary if medical treatment is ineffective.

Postherpetic Neuralgia

Herpes zoster produces head pain by cranial nerve involvement in one third of cases. In some cases a persistent intense burning pain follows the initial acute illness. The discomfort may subside after several weeks or persist (particularly in the elderly) for months or years. The pain is localized over the distribution of the affected nerve and associated with exquisite tenderness to even the lightest touch. The first division of the trigeminal nerve is the most frequent cranial nerve involved (ophthalmic herpes) and is

occasionally associated with keratoconjunctivitis. When the seventh nerve is affected (“geniculate herpes”), the pain involves the external auditory meatus and pinna. Occasionally, concomitant facial paralysis may occur (Ramsay Hunt syndrome).

Occipital Neuralgia

Occipital neuralgia is a syndrome that includes occipital pain starting at the base of the skull and often provoked by neck extension. Physical examination shows tenderness in the region of the occipital nerves and altered sensation in the C2 dermatome. Treatment includes the use of a soft collar, muscle relaxants, physical therapy, and local injections of analgesics and anti-inflammatory agents. The term *cervicogenic headache* is often used to describe headache associated with myofascial trigger points in the neck. Importantly, cervical spondylosis (discussed below) is not usually typically associated with headache.

CERVICAL SPONDYLOSIS

Cervical spondylosis is a degenerative disorder of the cervical intervertebral disks leading to osteophyte formation and hypertrophy of adjacent facet joints and ligaments. In contrast to the lumbar spine, herniation of cervical intervertebral disks (nucleus pulposus) accounts for only 20% to 25% of cervical root irritation. Cervical spondylosis one of the most common pathologies seen in office practice and is present radiographically in over 90% of the population older than 60 years of age. For unknown reasons, the degree of anatomic abnormality is not directly correlated with the clinical signs and symptoms. Clinical disease may represent a combination of normal, age-related, degenerative changes in the cervical spine and a congenital or developmental stenosis of the cervical canal; the process may be aggravated by trauma. Cervical spinal myelopathy results from a combination of degenerative disc disease, spondylosis aggravated by biomechanical instability, as well as stiffening and buckling of the ligamentum flavum. It may manifest as a painful stiff neck, with or without symptoms or signs of cervical root irritation or spinal cord compression. Patients with root irritation (cervical radiculopathy) complain of pain and paresthesias radiating down the arm roughly in the dermatomal distribution of the affected nerve root. More typically, the pain radiates in a myotomal pattern, whereas numbness and paresthesias follow a dermatomal distribution. Discrete sensory loss is uncommon and less prominent than symptoms ([Table 111-9](#)). For relief, patients often adopt a position with the arm elevated and flexed behind the head. Pain is exacerbated by turning the head, ear down, to the side of the pain (Spurling maneuver). Objective neurologic findings may be limited to reflex asymmetry because weakness may be obscured by pain. Patients who have some degree of spinal cord compression demonstrate gait and bladder disturbances and evidence of spasticity on examination of the lower extremities. These patients require investigation with MRI. Plain radiographs of the cervical spine add little information except in patients with rheumatoid arthritis in whom basilar invagination or atlantoaxial subluxation is suspected.

Cervical spondylosis is so common in the general population that it may be present coincidentally in a patient with another disease of the spinal cord. Among other diseases that may mimic cervical spondylosis are multiple sclerosis, amyotrophic lateral

TABLE 111-9 COMMON CERVICAL ROOT SYNDROMES

DISK SPACE	ROOT AFFECTED	MUSCLES AFFECTED	DISTRIBUTION OF PAIN	DISTRIBUTION OF SENSORY SYMPTOMS	REFLEX AFFECTED
C4-5	C5	Deltoid, biceps	Medial scapula; shoulder	Shoulder	Biceps
C5-6	C6	Wrist extensors	Lateral forearm	Thumb; index finger	Triceps
C6-7	C7	Triceps	Medial scapula	Middle finger	Brachioradialis
C7-T1	C8	Hand intrinsic	Medial forearm	Fourth and fifth fingers	Finger flexion

sclerosis, and, less commonly, subacute combined system disease (vitamin B₁₂ deficiency). Conservative treatment includes the use of anti-inflammatory medication, cervical immobilization, and physical therapy for isometric strengthening of neck muscles once pain has subsided. Surgery should be considered if there is progression of the neurologic deficit, especially the emergence of signs of cervical cord compression. There is some evidence to suggest that cervical spondylosis is an active degenerative disease rather than simply the process. Furthermore, early studies with the glutamate antagonist riluzole suggest a potential role in reducing disease progression.

ACUTE LOW BACK PAIN

Low back pain without sciatica (radiating radicular pain) is common, with a reported point prevalence of up to 33%. Acute low back pain lasting several weeks is usually self-limiting, with a low risk for serious permanent disability. Risk factors for prolonged disability include psychological distress, compensation conflict over work-related injury, and other coexistent pain syndromes. The evaluation of patients with acute low back pain should focus on distinguishing pain of mechanical origin from neurogenic pain caused by nerve root irritation. The same pathologic changes that affect the cervical spine may also affect the lumbar spine. Because the spinal cord ends at the level of the first lumbar vertebra, lumbar canal stenosis from intervertebral disk disease and degenerative spondylosis will affect the roots of the cauda equina. The most common levels for lumbar degenerative disk disease are at L4 to L5 and L5 to S1, resulting in the common complaint of sciatica caused by irritation of the lower lumbar roots. Pain tends to improve with sitting or lying down, in contrast to the pain from spinal or vertebral tumors, which is aggravated by prolonged recumbency. Examination shows loss of the normal lumbar lordosis, paraspinal muscle spasm, and exacerbation of pain with straight leg rising, owing to stretching of the lower lumbar roots. About 10% of disk herniations occurs lateral to the spinal canal, in which case the more rostral root is compressed. Percussion of the spine may elicit focal tenderness of one of the vertebrae, suggesting bony infiltration by infection or tumor.

Spinal stenosis of the lumbar region may manifest as “neurogenic claudication,” which is usually described as unilateral or bilateral buttock pain that is worse on standing or walking and relieved by rest or flexion at the waist. Patients may have pain that is worse when walking downhill, in contrast to patients with vascular claudication, whose pain is maximal when walking up an incline.

MRI in many patients with isolated low back pain shows non-specific findings; MRI assessment early in the course of an episode of low back pain does not improve clinical outcome. MRI should be limited to patients with back pain who have associated neurologic symptoms or signs, especially new onset disturbances of bladder or bowel continence or perineal sensory symptoms suggestive of a *cauda equina syndrome*. Patients with risk factors for malignancy, infection, or osteoporosis, as well as those with pain maximal at rest (or nocturnal pain) require imaging. Patients with primary and metastatic tumor can present with acute back pain (Chapter 119). Moreover, developmental anomalies are often associated with pain (Chapter 115).

Treatment strategies for lumbar pain are similar to those for cervical pain, with surgery reserved for patients with neurologic signs and clear pathologic processes seen on imaging studies. Most cases of acute low back pain, even with rupture of an intervertebral disk, can be treated conservatively with a short period of rest, muscle relaxants, and analgesics. Prolonged bed rest is recommended only for patients in severe pain. Patient education regarding proper posture and appropriate back exercises is helpful, as is a formal physical therapy program. Chiropractic manipulation should not be performed for patients who have evidence of neurologic injury or spine instability.

 For a deeper discussion on this topic, please see Chapter 398, “Headaches and Other Head Pain,” in Goldman-Cecil Medicine, 25th Edition.

Disorders of Vision and Hearing

Eavan McGovern and Timothy J. Counihan

DISORDERS OF VISION AND EYE MOVEMENTS

Examination of the Visual System

Acuity

The clinical examination of visual function should begin with testing visual acuity. Patients who wear corrective lenses should wear them during testing, and testing should be performed using a Snellen chart at a distance of 20 feet (Fig. 112-1). The smallest line the patient can read is documented as the visual acuity; for instance, acuity of 20/40 refers to letters that the patient sees maximally at 20 feet, which a normal individual can see at 40 feet. When errors of refraction are responsible for decreased visual acuity, vision may be improved by having the patient look through a pinhole. Corrected vision in one eye of less than 20/40 suggests damage to the lens (cataract) or retina or a disorder of the anterior visual (prechiasmal) pathway. Color vision in each eye

should also be tested using Ishihara color plates; even when visual acuity is normal, patients with lesions of the optic nerve may complain that colors appear “washed out” in the affected eye.

Visual Fields

Thorough examination of the visual fields can often localize lesions interrupting the afferent (sensory) visual system (Fig. 112-2). Visual fields in all four quadrants should be tested by comparing the patient’s field with that of the examiner (confrontation). The examiner’s head should be level with that of the patient’s, and a white pin used to map peripheral visual fields and a red pin to assess for the presence of a scotoma. Asking the patient to count the number of the examiner’s extended fingers is more sensitive than presenting moving objects in detecting visual field deficits. The field should be tested first unilaterally and then bilaterally because uncovering a defect (particularly in the left hemifield) with bilateral testing only (extinction) suggests a lesion in the contralateral parietal lobe.

Partial or complete visual loss in one eye only implies damage to the retina or optic nerve anterior to the optic chiasm, whereas a visual field abnormality involving both eyes implies a defect at or posterior to the optic chiasm. *Scotomas* are areas of partial or complete visual loss and may be central or peripheral. Central scotomas result from damage to the macula. A scotoma affecting one half of a visual field is known as a *hemianopia*. Field defects are said to be *homonymous* if the same part of the visual field is affected in both eyes; a homonymous hemianopia implies a post-chiasmatal lesion. A homonymous defect may be *congruous* (the visual defect is identical in each hemifield) or *incongruous* (the visual defect is not identical in each hemifield).

Quadrantanopias are smaller defects in the visual field and may be superior (which suggests a temporal lobe lesion) or inferior (which suggests a parietal lobe lesion). Bitemporal hemianopia implies a lesion at the chiasm, such as a pituitary tumor. An altitudinal hemianopia occurs with vascular damage to the retina. Scintillating scotomas are hallucinations of flashing lights. If they are monocular, they may be caused by retinal detachment; binocular scintillations suggest occipital oligemia (as in migraine) or seizure. Any suspicious findings on bedside confrontation testing warrant formal visual field testing using perimetry (Fig. 112-3).

Pupils

Examination of the pupils should begin with observation of pupillary size and shape at rest. Pupil constriction is mediated by the parasympathetic system of the oculomotor (third cranial) nerve,

FIGURE 112-1 Snellen Chart.

FIGURE 112-2 Visual fields that accompany damage to the visual pathways. **1**, Optic nerve: unilateral amaurosis. **2**, Lateral optic chiasm: grossly incongruous, incomplete (contralateral) homonymous hemianopia. **3**, Central optic chiasm: bitemporal hemianopia. **4**, Optic tract: incongruous, incomplete homonymous hemianopia. **5**, Temporal (Meyer) loop of optic radiation: congruous partial or complete (contralateral) homonymous superior quadrantanopia. **6**, Parietal (superior) projection of the optic radiation: congruous partial or complete homonymous inferior quadrantanopia. **7**, Complete parieto-occipital interruption of optic radiation: complete congruous homonymous hemianopia with psychophysical shift of foveal point often sparing central vision, giving “macular sparing.” **8**, Incomplete damage to visual cortex: congruous homonymous scotomas, usually encroaching at least acutely on central vision. (From Baloh RW: Neuro-ophthalmology. In Goldman L, Bennett JC, editors: Cecil textbook of medicine, ed 21, Philadelphia, 1998, WB Saunders, p 2236).

whereas dilation is mediated by the sympathetic system. If the balance of these systems is disrupted, *anisocoria* (unequal pupil size) results. The pupils should be examined in both dim and bright light. If the anisocoria increases going from dim to bright light, a lesion of the parasympathetic system is likely. *Physiologic anisocoria* is characterized by pupillary asymmetry that is unchanged irrespective of the ambient light intensity; this occurs in approximately 20% of the population.

Both the direct and consensual light responses should be noted for each eye; in the latter, when the light is shone in one eye, both pupils should constrict. This is best tested using the “swinging light test,” in which the light is moved quickly from one eye to the other. When light is shone into one eye, both eyes should constrict simultaneously. If there is dilation of one pupil as the light is moved to it from the other side, an abnormality of the optic nerve in that eye should be

FIGURE 112-3 Humphrey visual fields demonstrating an incongruous homonymous hemianopia.

suspected. This abnormality is referred to as an *afferent pupillary defect*. The accommodative pupillary response is tested by asking the patient to look first in the distance and then at the examiner’s finger, held 12 inches away. The pupils should constrict symmetrically and rapidly. *Argyll-Robertson pupils* are small, irregular pupils that constrict to near vision (accommodation reflex) but not in response to light. They are associated with neurosyphilis, diabetes, and other disorders. This so-called *light-near dissociation* may also occur in rostral dorsal midbrain lesions, in which there may be associated abnormalities of vertical gaze, eyelid retraction, and convergence retraction nystagmus (Parinaud Syndrome). This uncommon constellation of clinical findings is frequently noted in patients with lesions of the pineal gland.

The presence of ptosis should be noted. A large, unreactive pupil with ptosis indicates a lesion of the oculomotor nerve (*third cranial nerve palsy*) interrupting the parasympathetic nerve supply to the pupil. The associated paralysis of the medial and inferior rectus and inferior oblique muscles (see later discussion) results in distortion of the eye (inferolaterally, “down and out”) and a subjective complaint of diplopia by the patient. Common causes of a third nerve palsy include compression by an aneurysm of the posterior communicating artery by transtentorial herniation, or from ischemia, usually in the setting of diabetes or vasculitis. A third nerve palsy caused by ischemia often spares the pupil but results in complete paralysis of the oculomotor and eyelid levator muscles. Acute painful third nerve palsy should be treated as an emergency, with the need to investigate for an intracranial aneurysm.

A small, poorly reactive pupil with associated ptosis is known as *Horner syndrome* and results from damage to the sympathetic fibers to the pupil, which may occur anywhere along their course from the hypothalamus, brainstem, and ascending sympathetic chain from the superior cervical ganglion to the orbit. There may be associated unilateral anhidrosis resulting from damage to sympathetic fibers. Horner syndrome may be the first sign of an apical lung tumor (Pancoast) or may occur in diseases affecting the carotid artery.

Tonic (Adie) pupils constrict slowly and incompletely in response to light. This is usually an incidental finding on examination but may be associated with areflexia (Holmes-Adie syndrome). Reaction to accommodation is preserved, and it has been suggested that the disorder is a result of parasympathetic denervation. *Hippus* refers to pupillary unrest with synchronous oscillation of the pupil size; it is considered a normal

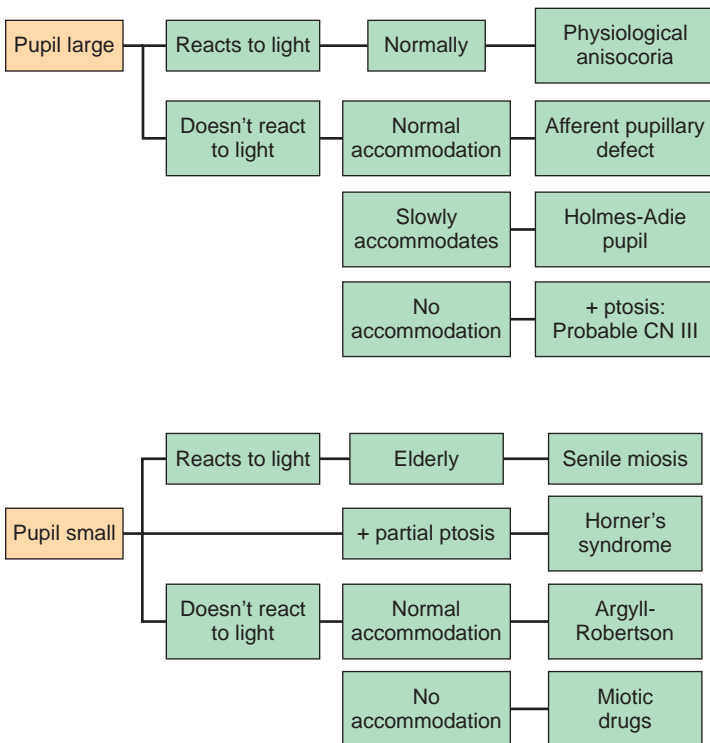

FIGURE 112-4 Algorithm for the approach to unequal pupils (anisocoria).

phenomenon. [Figure 112-4](#) summarizes common pupillary abnormalities and their associated features.

Eye Movements

The history helps in evaluating the patient with diplopia. Is the diplopia primarily horizontal or vertical, or is it greater looking to the right or to the left? Double vision that varies during the day suggests myasthenia gravis. Is the diplopia maximal with near or distant vision? Greater difficulty with near vision suggests impairment of the medial rectus, oculomotor nerve, or convergence system, whereas abducens nerve weakness results in horizontal diplopia when objects are viewed at a distance. Diplopia that worsens on going down stairs may suggest a fourth nerve lesion. Monocular diplopia is usually caused by diseases of the retina or lens and is corrected by having the patient look through a pinhole, unless the cause is psychogenic.

The examination should begin by determining the position of the head and eyes with the eyes in primary gaze. There are four components to oculomotor function:

1. Pursuit eye movements: Smooth pursuit eye movements allow fixation on a moving object. Ask the patient to follow a moving target such as a pin in all directions of gaze.
2. Saccadic eye movements: These movements allow rapid switching of gaze from one target to another. Both horizontal and vertical saccadic movements should be checked.
3. Vestibulo-ocular reflex: This reflex enables fixation on an object even if the head is moving. It is assessed by using the *Doll's Eye Maneuver*.
4. Convergence Response: This tests the ability of the eyes to track an object as it is brought close to the limit of accommodation. Ask the patient to look into the distance and then at your finger held close to their eyes.

Both smooth pursuit and (voluntary) saccadic eye movements in horizontal and vertical directions are checked to determine whether the movements are conjugate or disconjugate. Disconjugate eye movements suggest a disorder of the brainstem (at the level of the ocular motor nuclei or their connections), the peripheral nerves (cranial nerves III, IV, or VI), individual eye muscles (ocular myopathy), or the neuromuscular junction (myasthenia gravis or botulism). A large deficit in the range of eye movements may provide sufficient diagnostic information. However, in many cases, although the patient complains of diplopia, no clear misalignment is visible on testing eye movements. The corneal reflection test may help identify misalignment in these cases. The patient is instructed to look at a light shining directly at the eyes. If the eyes are normally aligned, the light reflection will be about 1 mm nasal to the center of the cornea. If one eye is deviated medially, the reflection will be displaced outward; the reflection will be displaced inward if the eye is deviated outward.

The abducens (sixth cranial) nerve supplies the lateral rectus muscle. The trochlear (fourth cranial) nerve subserves the superior oblique muscle, which intorts the eye as well as depresses the eye in adduction (such as when a patient tries to look down stairs). All other muscles are supplied by the oculomotor nerve ([Fig. 112-5](#)). Abnormalities of the cranial nerves in the brainstem are usually accompanied by other signs, such as weakness, ataxia, or dysarthria. The abducens nerve has a long ascending course through the posterior fossa, where it is prone to compression at multiple sites and as a result of raised intracranial pressure; hence, a sixth nerve palsy may be a false localizing sign. Conjugate eye movement is regulated by supranuclear pathways from the cerebral hemisphere to the medial longitudinal fasciculus in the brainstem. A lesion in the cerebral hemisphere resulting from hemorrhage, infarction, or tumor disrupts conjugate gaze to the contralateral side, so that the eyes “look away” from the

FIGURE 112-5 Movements of eye muscles and their innervation.

FIGURE 112-6 A normal optic disk on fundoscopic examination.

TABLE 112-1 MAJOR CAUSES OF ACUTE OPHTHALMOPLEGIA

CONDITION	DIAGNOSTIC FEATURES
BILATERAL	
Botulism	Contaminated food; high-altitude cooking; pupils involved
Myasthenia gravis	Fluctuating degree of paralysis; responds to edrophonium chloride (Tensilon) IV
Wernicke encephalopathy	Nutritional deficiency; responds to thiamine IV
Acute cranial polyneuropathy	Antecedent respiratory infection; elevated CSF protein level
Brainstem stroke	Other brainstem signs
UNILATERAL	
P Comm aneurysm	Third cranial nerve, pupil involved
Diabetic-idiopathic	Third or sixth cranial nerve, pupil spared
Myasthenia gravis	As above
Brainstem stroke	As above

CSF, Cerebrospinal fluid; IV, intravenous; P Comm, posterior communicating artery.

hemiplegia. Lesions of the brainstem cause conjugate paralysis to the ipsilateral side (eyes looking toward the side of the hemiplegia). Lesions of the medial longitudinal fasciculus, which connects the nuclei of the oculomotor and abducens nerves, lead to *internuclear ophthalmoplegia*. In this case, horizontal gaze results in failure of adduction in one eye and nystagmus in the abducting eye. The lesion is on the side of failed adduction; bilateral lesions are frequently seen in multiple sclerosis. Table 112-1 lists the major causes of acute ophthalmoplegia.

Funduscopy

The retina should be carefully examined in each patient by direct ophthalmoscopy, which provides a magnified view of the fundus without the necessity for dilation of the pupil (Fig. 112-6).

Monocular Visual Loss

Loss of vision in one eye may be caused by lesions of the cornea, lens, vitreous, retina, or optic nerve. Careful fundoscopic examination will usually reveal ocular and retinal lesions, but acute lesions of the optic nerve (optic neuritis) may not be associated with abnormalities of the optic nerve head. *Optic neuritis* is characterized by inflammation of the optic nerve accompanied by

non-homonymous visual defects. The term *papillitis* refers to ophthalmoscopically observable changes in the optic nerve; *retrobulbar neuritis* refers to this condition without observable changes in the fundoscopic examination findings (“the doctor sees nothing and the patient sees nothing”).

The patient with optic neuritis complains of difficulty with vision in the affected eye. Loss of vision may be insidious and recognized only when the unaffected eye is accidentally occluded. Patients often complain of periorbital pain on eye movement on presentation. The evolution of visual loss is highly variable, progressing over a period ranging from less than a day to several weeks, although most patients will have reached their maximal visual deficit in 3 to 7 days. Patients may describe their vision as blurred or dim, and colors may appear less bright than usual or “gray.” Red desaturation may occur with optic neuritis and may be detected using Ishihara color plates. At the time the patient is first examined, visual acuity may range from almost 20/20 to the extreme of total blindness. Examination of the visual field shows defects within the central 25 degrees, with central and paracentral scotomas being the most common types. An afferent pupillary defect is frequently present. The fundoscopic examination is abnormal in only about one half of the cases. The disc may appear hyperemic with blurred margins, and hemorrhages, when present, are few and found only on the disc or in the area immediately surrounding the disc. Optic neuritis should be treated acutely with high-dose intravenous corticosteroids because this is proven to shorten time to recovery. The most common cause of optic neuritis is multiple sclerosis. Bilateral optic neuritis is much less common and may coincide with longitudinally extensive transverse myelitis, known as *neuromyelitis optica* (NMO) or *Devic disease*. The recent discovery of antibodies directed toward aquaporin 4 (a water channel present on astrocytes and vascular endothelial cells), associated with NMO, has identified this as a separate disease entity, with a different treatment regimen emerging for it. The NMO antibody is the first sensitive and specific biomarker associated with a central demyelinating disorder.

The optic nerve may be compressed by tumors that originate in the nerve itself or in the region of the optic chiasm. Pathologic processes that appear acutely as optic disc edema frequently result in a secondary optic atrophy, including papilledema, optic neuritis, and ischemic optic neuropathy. Glaucoma is responsible

for more cases of optic atrophy in the adult population than any other cause. In young patients with inherited optic atrophy, Leber hereditary optic neuropathy is often the cause; it is usually bilateral. *Foster-Kennedy* syndrome is optic atrophy in one eye with papilledema in the other eye, secondary to a tumor compressing the atrophied optic nerve and causing raised intracranial pressure to produce papilledema in the opposite eye.

Ischemic optic neuropathy occurs in two forms. The *atherosclerotic* variety occurs mostly between the ages of 50 and 70 years, and no evidence of systemic disease is present. The *arteritic* form is usually a manifestation of giant cell arteritis; there may be systemic manifestations of the disease, including headache, scalp tenderness, and generalized myalgias. Laboratory evaluation shows anemia and elevated erythrocyte sedimentation rate in almost every case. Patients with arteritis should be treated with high doses of corticosteroids to prevent permanent loss of vision.

Acute transient monocular blindness is usually the result of embolization to the central retinal artery from an atheromatous plaque in the carotid artery (*amaurosis fugax*). Any complaint of transient visual loss constitutes an emergency, and steps must be taken to prevent permanent loss of vision by making a prompt diagnosis and initiating appropriate therapy. Examples of sight-saving procedures include corticosteroid therapy for cranial arteritis, reduction of intraocular pressure for acute glaucoma, and carotid surgery, anticoagulation, or antiplatelet therapy for embolic cerebrovascular disease.

Binocular Visual Loss

Gradual bilateral visual loss caused by optic nerve lesions is rare. Causes include Leber hereditary optic neuropathy and a toxic nutritional–deficiency state. Acute transient bilateral visual loss (visual obscuration) may be a symptom of raised intracranial pressure caused by a brain tumor or idiopathic intracranial hypertension (IIH); papilledema is often severe. IIH, formerly known as *pseudotumor cerebri*, requires prompt investigation and treatment to prevent potential bilateral visual failure. It is often associated with a high body mass index (BMI) and is more common in young females. Vitamin A and tetracycline ingestion have been associated with the condition. Unilateral or bilateral lateral rectus palsy may be present. It is one of the few situations in which, after imaging, performance of a lumbar puncture is safe in the setting of marked bilateral papilledema. Cerebral venous sinus thrombosis may mimic IIH and should be screened for with neuroimaging.

Bilateral damage to the optic radiations or visual cortex results in cortical blindness. The pupillary light reflex is normal, as are the fundoscopic examination findings, and the patient may occasionally be unaware that he or she is blind (*Anton syndrome*). Patients are often misdiagnosed as having a conversion reaction. Transient cortical blindness occurs most often in basilar artery insufficiency but is also seen in hypertensive encephalopathy. Positive visual phenomena (e.g., phosphenes, scintillating scotomas) are characteristic of migrainous aura and probably reflect oligemia to the occipital lobes from vasoconstriction. Arteriovenous malformations, tumors, and seizures may produce similar symptoms and should be distinguished from migraine with aura by a careful history and examination as well as by imaging in appropriate cases.

Visual hallucinations are visual sensations independent of external light stimulation; they may be either simple or complex, may be localized or generalized, and may occur in patients with a clear or clouded sensorium. Visual illusions are alterations of a perceived external stimulus in which some features are distorted. The simplest visual phenomena consist of flashes of light (photopsias), blue lights (phosphenes), or scintillating zigzag lines, which last a fraction of a second and recur frequently or which appear to be in constant motion. These can arise from dysfunction within the optic pathways at any point from the eye to the cortex. Glaucoma, incipient retinal detachment, retinal ischemia, or macular degeneration can cause simple visual hallucinations based on dysfunction in the eye. Lesions of the occipital lobe are often associated with simple hallucinations; classic migraine is by far the most common condition of this type. Complex visual hallucinations such as seeing objects as people, animals, landscapes, or various indescribable scenes occur most frequently with temporal lobe lesions or parieto-occipital association areas. Visual hallucinations of epileptogenic origin are typically stereotyped.

HEARING AND ITS IMPAIRMENTS

Symptoms of Auditory Dysfunction

The main symptoms of lesions within the auditory system are hearing loss and tinnitus. Hearing loss can be classified as conductive, sensorineural, mixed, or central, based on the anatomic site of pathology (Figs. 112-7 and 112-8). Tinnitus can be either subjective or objective. Conductive hearing loss results from lesions involving the external or middle ear. Patients with a conductive hearing loss can hear speech in a noisy background as well as in a quiet background, because they can understand loud speech as well as anyone. The ear often feels full, as if it is blocked. The Weber test localizes to the deaf ear, if the deafness is unilateral.

Sensorineural hearing loss usually results from lesions of the cochlea or the auditory division of the vestibulocochlear (eighth cranial) nerve. Patients with sensorineural hearing loss often have difficulty hearing speech that is mixed with background noise and may be annoyed by loud speech. They usually hear low tones better than high-frequency ones. Distortion of sounds is common with sensorineural hearing loss. Central (retrocochlear) hearing disorders are rare and result from bilateral lesions of the central auditory pathways, including the cochlear and dorsal olivary nuclear complexes, inferior colliculi, medial geniculate bodies, and auditory cortex in the temporal lobes. Damage to both auditory cortices may result in pure word deafness, in which patients are selectively unable to discriminate language but may be able to hear nonverbal sounds.

Tinnitus is the perception of a noise or ringing in the ear that is usually audible only to the patient (subjective), although, rarely, an examiner can hear the sound as well. The latter, so-called *objective tinnitus*, can be heard when the examining physician places a stethoscope against the patient's external auditory canal. Tinnitus that is pulsatory and synchronous with the heartbeat suggests a vascular abnormality within the head or neck (see Fig. 120-7). Aneurysms, arteriovenous malformations, and vascular tumors can produce this type of tinnitus.

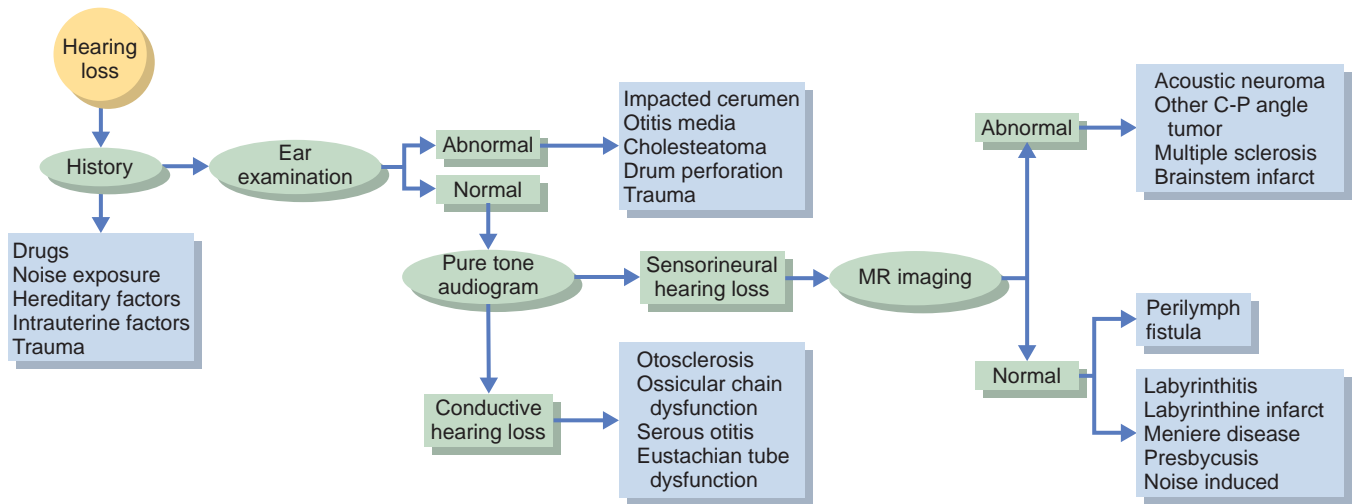

FIGURE 112-7 Evaluation of deafness (unilateral and bilateral). C-P, Cerebellopontine; MR, magnetic resonance. (Modified from Baloh RW: Hearing and equilibrium. In Goldman L, Bennett JC, editors: Cecil textbook of medicine, ed 21, Philadelphia, 1998, WB Saunders, p 2250).

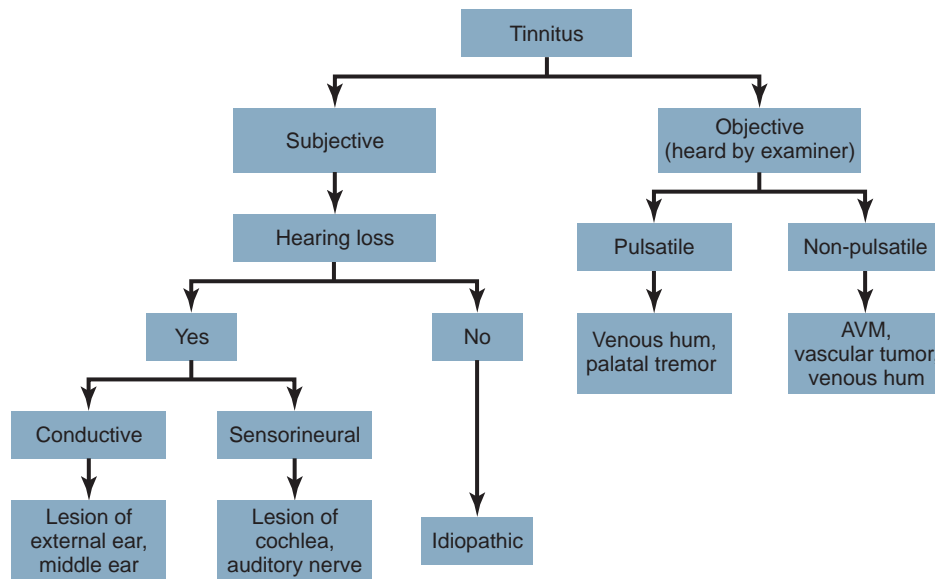

FIGURE 112-8 Algorithm for the approach to the patient with tinnitus. AVM, Arteriovenous malformation.

Subjective tinnitus, heard only by the patient, can result from lesions involving the external ear canal, tympanic membrane, ossicles, cochlea, auditory nerve, brainstem, and cortex. The character of the tinnitus does not usually aid in determining the site of the disturbance. For this, one must rely on associated symptoms and signs. When tinnitus results from a lesion of the external or middle ear, it is usually accompanied by a conductive hearing loss. The patient may complain that his or her voice sounds hollow and that other sounds are muffled. Because the masking effect of ambient noise is lost, the patient may be disturbed by normal muscular sounds such as chewing, tight closure of the eyes, or clenching of the jaws. The characteristic tinnitus associated with Meniere's syndrome is low pitched and continuous, although fluctuating in intensity. Often the tinnitus becomes very loud immediately preceding an acute attack of vertigo and then may disappear after the attack. Tinnitus resulting from lesions within the central nervous system is usually not

associated with hearing loss but is nearly always associated with other neurologic symptoms and signs. High-dose salicylates frequently result in tinnitus.

Examination of the Auditory System

A quick test for hearing loss in the speech range is to observe the response to spoken commands at different intensities (whisper, conversation, and shouting). The examiner must be careful to prevent the patient from reading his or her lip movement. A high-frequency stimulus such as a watch tick should also be used because sensorineural disorders often involve only the higher frequencies. Tuning fork tests permit a rough assessment of the hearing level for pure tones of known frequency. The Rinne test compares the patient's hearing by air conduction with that by bone conduction. A 512-cps tuning fork is first held against the mastoid process until the sound fades. It is then placed 1 inch from the ear. Normal subjects can hear the fork about twice as

long by air conduction as by bone conduction. If hearing by bone conduction is longer than by air conduction, a conductive hearing loss is suggested. The Weber test compares the patient's hearing by bone conduction in the two ears. The fork is placed at the center of the forehead, and the patient is asked where he or she hears the tone. Normal subjects hear it in the center of the head, patients with unilateral conductive loss hear it on the affected side, and patients with unilateral sensorineural loss hear it on the side opposite the loss. Otoloscopic examination may reveal impacted cerumen as a cause of conductive hearing loss.

Causes of Hearing Loss

The bilateral hearing loss commonly associated with advancing age is called *presbycusis*. Presbycusis is not a distinct disease entity but rather represents multiple effects of aging on the auditory system. Presbycusis may include conductive and central dysfunction, although the most consistent effect of aging is on the sensory cells and neurons of the cochlea; as a result, higher tones are lost early.

Otosclerosis is a disease of the bony labyrinth that usually manifests itself by immobilizing the stapes and thereby producing a

conductive hearing loss. Seventy percent of patients with clinical otosclerosis notice hearing loss between the ages of 11 and 30. There is a family history of otosclerosis in approximately 50% of cases. *Stapedectomy*, a procedure in which the stapes is replaced with a prosthesis, is effective in correcting the conductive component of hearing loss.

A lesion of the cerebellopontine angle, such as a vestibular schwannoma, often causes unilateral hearing loss that progresses slowly (Table 112-2); symptoms are caused by compression of the nerve in the narrow confines of the canal (Fig. 112-9). The most common symptoms associated with vestibular

TABLE 112-2 CAUSE OF ACUTE UNILATERAL SENSORINEURAL DEAFNESS

COCHLEAR	RETROCOCHLEAR
Idiopathic (85%)	Demyelination
Trauma	Vestibular schwannoma (usually gradual onset)
Meniere's disease	Stroke
Lyme's disease	
Syphilis	
Autoimmune disease	

FIGURE 112-9 Magnetic resonance imaging scan of the brain showing coronal and axial views of a tumor of the left cerebellopontine angle, consistent with a schwannoma.

schwannomas are slowly progressive hearing loss and tinnitus from compression of the cochlear nerve. Vertigo occurs in fewer than 20% of patients, but approximately 50% complain of imbalance or disequilibrium. Next to the auditory nerve, the cranial nerves most commonly involved by compression are the seventh (facial weakness) and fifth (sensory loss). Loss of the corneal reflex on the affected side is often the first clinical sign. Treatment in most cases is surgical removal.

Meniere's syndrome (endolymphatic hydrops) is characterized by fluctuating hearing loss and tinnitus, episodic vertigo, and a sensation of fullness or pressure in the ear. Typically the patient develops a sensation of fullness and pressure, along with decreased hearing and tinnitus in one ear. Vertigo rapidly follows, reaching a maximum intensity within minutes and then slowly subsiding over the next several hours. The patient is usually left with a sense of unsteadiness and dizziness for days after the acute vertiginous episode. In the early stages the hearing loss is completely reversible, but in later stages a residual hearing loss remains. Up to 50% of patients with idiopathic Meniere's syndrome frequently have a positive family history, suggesting genetic predisposing factors. The key to the diagnosis of Meniere's syndrome is to document fluctuating hearing levels in a patient with the characteristic clinical history. Medical therapy for endolymphatic hydrops includes dietary sodium restriction and oral diuretics.

Acute unilateral deafness usually results from damage to the cochlea and may be caused by viral or bacterial labyrinthitis or vascular occlusion in the territory of the anterior inferior cerebellar artery. Perilymphatic fistulas may also cause abrupt unilateral deafness, usually in association with tinnitus and vertigo.

Drugs that cause acute irreversible bilateral hearing loss include aminoglycosides, cisplatin, and furosemide. Salicylates may cause reversible hearing loss and tinnitus.

Treatment of Hearing Loss

The best treatment is prevention, particularly by the appropriate use of earplugs for those working in a noisy environment. Hearing aids help patients with conductive hearing loss, and developments with cochlear implants may help patients with sensorineural hearing loss.

Prospectus for the Future

Optical coherence tomography (OCT) is an emerging technology in the assessment of retinal layer thickness. This technology has been used in multiple sclerosis research. It has been used to correlate retinal layer thickness with severity of multiple sclerosis. This may have important implications for future research in this field.

 For a deeper discussion on this topic, please see Chapter 423, "Diseases of the Visual System," and Chapter 424, "Neuro-Ophthalmology," in *Goldman-Cecil Medicine, 25th Edition*.

Dizziness and Vertigo

Kevin A. Kerber

DEFINITION/EPIDEMIOLOGY

Dizziness is a common term that is used by patients and providers to group a variety of different symptoms including a spinning sensation, lightheadedness, disorientation, or imbalance. Other more vague symptoms are also often labeled as “dizziness.” Vertigo is the term used for a false sense of movement, typically spinning. The problem with defining the type of dizziness is that patients are often inconsistent when describing dizziness. In addition, the type of dizziness generally does not adequately discriminate among disorders. Approximately 30% of the general population reports having had some type of bothersome dizziness.

PATHOLOGY

Pathology that causes dizziness can stem from many systems of the body. Understanding the vestibular system and common peripheral vestibular disorders is of central importance in the evaluation of patients with dizziness. This is because the dilemma is often discriminating a benign peripheral vestibular disorder from a focal brain lesion. The vestibular system is a common source of confusion. Many clinicians assume a “peripheral” cause in the absence of motor, sensory, or language deficits, but this approach is flawed. A more effective approach is to aim to “rule in” a *specific* peripheral vestibular disorder. The three common peripheral vestibular disorders all have highly characteristic history and examination features, thus enabling this approach. When a specific peripheral vestibular disorder does not fit, then one must consider other potential etiologies.

BASIC VESTIBULAR SYSTEM CONCEPTS

The peripheral vestibular system maintains a balanced tonic input to the brain. The input represents the circuitry that links the inner ear to eye movements, the vestibulo-ocular reflex

(VOR). A normal functioning VOR is important for balance and maintaining clear vision when moving. Vertigo ensues when an imbalance is caused by a lesion (e.g., vestibular neuritis) or aberrant stimulation (e.g., benign paroxysmal positional vertigo). A characteristic sign of vestibular system imbalance is nystagmus: rhythmic slow and fast movements of the eyes in opposite directions. The location of pathology determines the pattern of nystagmus (Table 113-1). Dysfunction at the semicircular canal level leads to nystagmus in the plane of the affected canal. Therefore problems in the vertical canals (i.e., posterior and anterior canals) lead to vertical and torsional nystagmus, whereas problems in the horizontal canal lead to horizontal nystagmus. At the vestibular nerve level a mixed horizontal-torsional nystagmus is generated because input from all the semicircular canals converge at this level and the signals from the vertical canals mostly cancel each other out. The pathways and thus the patterns of eye movements become less predictable with lesions of the central vestibular pathways, although some general rules apply. Pure vertical (downbeat or upbeat) spontaneous nystagmus, bidirectional gaze-evoked nystagmus (look left, beats left; look right, beats right) (Video 113-1), and persistent downbeat-positional nystagmus are signs of central dysfunction (see Table 113-1).

Another characteristic sign of vestibular disturbance is a positive head-thrust test (Video 113-2). A person with an intact VOR will maintain gaze on a stationary, straight-ahead target after a brief, small-amplitude, high-acceleration movement of the head to one side. A person with vestibular impairment on one side loses this reflex on the ipsilateral side and therefore, after the quick head movement, will need to make a re-fixation voluntary eye movement (i.e., a “saccade”) back to the target because the eyes moved with the head. This so-called “catch-up” or “corrective” saccade is easily appreciated at the bedside and indicates vestibular deafferentation.

TABLE 113-1 COMMON TYPES AND PATTERNS OF NYSTAGMUS

TYPES	PATTERNS	LOCALIZATION	PRINCIPAL CAUSES
Spontaneous	Unidirectional horizontal >>> torsional Downbeat, upbeat, or pure torsional	Vestibular nerve, or less commonly the brainstem Brain	Vestibular neuritis, or less commonly stroke Stroke
Gaze-evoked	Unidirectional Bidirectional	Vestibular nerve Brain	Vestibular neuritis (recovery pattern) Stroke, cerebellar syndrome, medication side effect*
Positional	Burst of upbeat torsional with DH Horizontal with supine positional testing Persistent downbeat	Posterior SCC Horizontal SCC or less commonly the brainstem Brain	BPPV BPPV, brainstem lesion Chiari malformation, cerebellar degeneration

BPPV, Benign paroxysmal positional vertigo; DH, Dix-Hallpike positional test; SCC, semicircular canal; >>>, greater than.

*Most common with antiepileptic drugs.

CLINICAL PRESENTATION

Patients usually present with acute constant dizziness, recurrent spontaneous attacks, or recurrent positional attacks. Less commonly, patients present with chronic constant dizziness. The physical examination is a critical part of the assessment. If the general examination is unrevealing, then the focus should shift to the ocular motor examination because vestibular disorders have highly characteristic findings, particularly regarding the presence and pattern of nystagmus (see Table 113-1). Hearing should be tested one ear at a time with either tuning forks or finger rub.m

DIFFERENTIAL DIAGNOSIS

The differential diagnosis can generally be categorized as follows: a peripheral vestibular disorder, a central nervous system disorder, a general medical disorder (e.g., anemia, metabolic derangement, anxiety disorder), or a chronic otherwise undefined disorder. There are three common peripheral vestibular disorders: vestibular neuritis, Meniere's disease, and benign paroxysmal positional vertigo (BPPV). An understanding of these three disorders is important because each one is the primary consideration for the cause of one of the three common dizziness presentation categories (Table 113-2). In addition, these disorders are the prototypes for most pathology that involves the peripheral vestibular system.

Vestibular neuritis manifests with the abrupt onset of severe vertigo, nausea, and imbalance without other neurologic symptoms. The disorder is caused by a viral disturbance of the vestibular nerve, analogous to Bell's palsy. On examination, the acute peripheral vestibular pattern of nystagmus is seen (see Table 113-2; Video 113-3). A positive head-thrust test in the direction of the affected ear (but in the direction opposite the fast phase of nystagmus) further supports vestibular nerve localization. If the nystagmus changes direction with gaze (i.e., look left, beat left; then look right, beat right), then vestibular neuritis is not the diagnosis because these findings localize to the central nervous system. Small strokes of the cerebellum or brainstem can closely mimic vestibular neuritis.

Meniere's disease is characterized by recurrent episodes of vertigo, nausea, and imbalance typically lasting hours; prominent auditory features must be present to make the diagnosis. Early in the course, auditory symptoms fluctuate along with vertigo attacks, but later they become a fixed symptom. The auditory symptoms are nearly always unilateral at the onset and consist of hearing loss, roaring tinnitus, or severe fullness in one ear. If attacks are brief (i.e., minutes rather than hours), then transient ischemic attacks should be considered. The dizziness of migraine can also closely mimic Meniere's disease.

Patients with BPPV report very brief episodes (<1 minute) of vertigo triggered by head movement; most often tilting the head back to look up, getting in or out of bed, or rolling over in bed. Dizziness from any cause may worsen after certain movements, but the dizziness of BPPV is *triggered* by certain movements. The most common form of BPPV occurs when otoliths enter the posterior canal. Posterior canal BPPV is identified at the bedside using the Dix-Hallpike test (Fig. 113-1). In response to the Dix-Hallpike test, otoliths move in the canal and lead to a burst of upbeat-torsional nystagmus lasting about 20 to 30 seconds (Video 113-4). BPPV is less commonly caused by otoliths in the horizontal canal and very rarely the anterior canal. When the otoliths are in one of these other canals, the pattern of nystagmus is different from that of posterior canal BPPV, as are the repositioning maneuvers used to treat BPPV. Positional vertigo and nystagmus are common in patients with migraine. If a persistent downbeating nystagmus is seen during the Dix-Hallpike test, then a central nervous system cause (e.g., Chiari malformation, cerebellar tumor, or cerebellar degeneration) should be considered.

If the patient reports imbalance as the principal symptom and has a gait disorder, then the following causes should be considered: stroke (if the onset was acute), a musculoskeletal disorder, peripheral neuropathy, bilateral vestibulopathy (frequently attributable to ototoxicity, particularly from gentamicin), or a neurodegenerative disorder involving the cerebellum.

If a specific peripheral vestibular disorder is not identified and the neurologic examination is normal, then general medical causes should be considered. The list of medications should be

TABLE 113-2 COMMON CATEGORIES OF DIZZINESS PRESENTATIONS

	ACUTE CONSTANT DIZZINESS	RECURRENT SPONTANEOUS ATTACKS	RECURRENT POSITIONAL ATTACKS
Primary consideration	Vestibular neuritis	Meniere's disease	BPPV
Key features	Constant vertigo, unidirectional horizontal nystagmus,* positive head-thrust test [†]	Vertigo lasting hours, unilateral auditory symptoms	Positionally triggered, brief (<1 min) attacks Upbeat-torsional burst of nystagmus in DH position, cured by Epley maneuver [‡]
Red flags	Other CNS features, other patterns of nystagmus, imbalance as the principal symptom, chest pain, cardiovascular risk factors	Other CNS features, CNS patterns of nystagmus, imbalance as the principal symptom, attacks lasting only minutes, chest pain, cardiovascular risk factors, recent onset, crescendo pattern	Other CNS features, CNS patterns of nystagmus
Other considerations	Stroke, myocardial infarction, metabolic disturbances, demyelinating attack	TIA, cardiac arrhythmia, migraine, panic attacks	Horizontal or anterior canal BPPV, migraine, Chiari malformation, posterior fossa tumor, orthostatic hypotension

BPPV, Benign paroxysmal positional vertigo; CNS, central nervous system; DH, Dix-Hallpike; TIA, transient ischemic attack.

*This nystagmus never changes direction. Gaze in the direction of the fast phase will increase the velocity of the nystagmus, whereas gaze in the opposite direction will decrease the velocity of the nystagmus.

[†]The head-thrust test will be positive in the direction of the affected ear, which is opposite the direction of the fast phase of nystagmus.

[‡]These features apply to BPPV stemming from the posterior canal.

FIGURE 113-1 Repositioning treatment for benign paroxysmal positional vertigo designed to move endolymphatic debris out of the posterior semicircular canal (PSC) of the right ear and into the utricle (UT). The patient is seated, and the patient's head is turned 45 degrees to the right (**A**). The head is then lowered rapidly to below the horizontal (**B**). The examiner shifts hand positions (**C**), and the patient's head is rotated rapidly 90 degrees in the opposite direction, so it now points 45 degrees to the left, where it remains for 30 seconds (**D**). The patient then rolls onto the left side without turning the head in relation to the body and maintains this position for another 30 seconds (**E**) before sitting up. The treatment is repeated until nystagmus is abolished. The procedure is reversed for treating the left ear. (Modified from Foster CA, Baloh RW: Episodic vertigo. In Rakel RE, editor: *Conn's Current Therapy*, Philadelphia, 1995, WB Saunders.)

carefully scrutinized because dizziness is a common medication side effect. Dizziness can be a prominent symptom of anxiety and panic disorders. Vestibular migraine should be on the differential diagnosis of any dizziness presentation. When none of these seem to fit, the examination findings are normal, and the symptom has been present for more than several months, then the patient likely has chronic dizziness—typically considered a benign hypersensitivity disorder.

TREATMENT

Vestibular rehabilitation is the treatment of choice for patients with vestibular neuritis. If Meniere's disease is diagnosed, then a low-salt diet or a diuretic may alleviate the frequency of episodes. However, neither of these treatments is of established efficacy. Ablative surgical procedures are appropriate in refractory Meniere's disease. The treatment of BPPV involving the posterior canal is the highly effective and guideline-supported repositioning maneuver described by Epley (see Fig. 113-1). Patients with chronic dizziness may benefit from lifestyle modifications (e.g., exercise, optimizing sleep and diet, and stress management).

Migraine prophylactic agents are reasonable to initiate, but their effectiveness for dizziness has not been established. Acute symptoms can be effectively managed with an antihistamine, a benzodiazepine, or an antiemetic. However, these are not appropriate long-term treatment regimens.

PROGNOSIS

The prognosis in patients with dizziness is generally favorable. The main goals are to identify the patients at significant probability of having a dangerous disorder, to relieve the acute symptoms, and to take appropriate steps to reduce the likelihood of recurrent events.

Disorders of the Motor System

Kevin M. Biglan

INTRODUCTION

The motor system is broadly divided into the pyramidal and extrapyramidal systems. The pyramidal system is a single neuron system, which originates in the primary motor cortex of the frontal lobes and, with white matter projections, coalesces to form the internal capsule; it then traverses the brainstem (as the cerebral peduncles in the midbrain, the basis pontis in the pons and the pyramids in the medulla where the majority of neurons decussate to form the corticospinal tracts), and ultimately synapses on the lower motor neurons in the anterior horn of the spinal cord (Fig. 114-1). The extrapyramidal system consists primarily of the basal ganglia and the cerebellum, and provides coordinating and integrating information to the pyramidal tract system under the influence of various afferent feedback loops. The components and pathways of the basal ganglia (Fig. 114-2) and cerebellum (Fig. 114-3) influence and modulate voluntary motor activity of the motor cortex.

Disorders of the motor system affect the components of the pyramidal and extrapyramidal systems. The approach to the patient with motor dysfunction depends on the ability to accurately localize the neuroanatomical region affected through a careful history and focused examination.

SYMPTOMS AND SIGNS OF MOTOR SYSTEM DISORDERS

Table 114-1 summarizes the neuroanatomic localization of diseases and the associated symptoms and signs characteristic of dysfunction at those levels. While “weakness” is a frequent complaint, it does little to help with the localization of the problem because it can occur with any disorder of the motor system and does not always reflect weakness on examination. In addition, weakness of insidious onset may be completely overlooked by the patient. Some patients may complain of feeling numb, or that the limb is asleep, uncoordinated, or fatigued. Symptoms referable to impaired balance and gait are common. Patients with distal weakness may complain of impairment in fine motor tasks, buttoning buttons, opening jars/doors, handwriting, stumbling, or tripping with walking. Proximal weakness of the upper extremities will result in difficulty performing tasks over their heads, including washing their hair or applying makeup. Proximal weakness of the lower extremities is often manifested as difficulty with stairs or getting up from sitting. Bulbar weakness with dysarthria and dysphagia may be referable to a variety of diseases of the motor system and can often provide important clues to the differential diagnosis. Involuntary movements may reflect diseases of the basal ganglia but, similar to weakness, may not be appreciable to

the patient; therefore, information from a secondary observer is beneficial. Complaints of diffuse motor incoordination including deficits in speech, fine motor coordination, and gait imbalance suggest cerebellar dysfunction.

SIGNS OF CENTRAL MOTOR SYSTEM DYSFUNCTION

Central nervous system diseases affecting the motor system are divided into abnormalities of pyramidal tract (upper motor neuron), basal ganglia, and cerebellum. Each presents with distinct clinical signs; however, overlapping syndromes may occur, which suggests more diffuse disease processes.

Upper motor lesions affecting the motor cortex and the subcortical white matter prior to the medullary decussation are associated with contralateral weakness, whereas lesions of the medulla and corticospinal tracts in the spinal cord post-decussation cause ipsilateral weakness. Both are associated with upper motor neuron signs. Lesions of the spinal cord may cause mixed upper motor neuron dysfunction below the lesion and lower motor neuron dysfunction at the level of the lesion due to involvement of descending corticospinal tracts and peripheral motor neurons originating in the anterior horn. Dysfunction of upper motor neurons traditionally causes distal greater than proximal weakness, increased muscle tone with spasticity, increased muscle stretch reflexes with clonus, and pathologic reflexes (Babinski’s sign). There is little or no muscle atrophy. Acute lesions of the spinal cord can initially cause a flaccid paralysis with areflexia that eventually evolves into a typical upper motor neuron syndrome.

The basal ganglia are important for the planning, initiation, and execution of movements. They facilitate desired movements while inhibiting unwanted movements through pathways that ultimately interact with primary motor cortex. Disorders of basal ganglia function often cause movement disorders characterized by heterogeneous and mixed impairments in voluntary movement not associated with muscle weakness, and often involuntary movements. Disorders of tone are common and variable. Speech and posture are often affected. Patients may have involuntary movements when awake but, with rare exceptions, the involuntary movements are abolished during sleep. Gait dysfunction with postural instability may be seen.

The cerebellum constantly monitors afferent input from muscles, joints, and motor cortex and integrates planned movements to fine tune motor control through efferent projections that regulate motor cortex activity. Disorders causing cerebellar signs may result from direct impairment of cerebellar function or impairment in afferent and efferent pathways of the cerebellum. Cerebellar disorders result in signs that reflect difficulty with

FIGURE 114-1 Normal human voluntary motor system.

FIGURE 114-2 Anatomy of the basal ganglia and their connections. The feedback loop proceeds from cerebral prefrontal areas to the basal ganglia and eventually back from the basal ganglia to the thalamus to the motor cortex. This ultimately regulates the descending corticospinal motor system. ACH, Acetylcholine; DA, dopamine; GABA, γ -aminobutyric acid; GLU, glutamate; GP, globus pallidum (e, external; i, internal); SN, substantia nigra (c, compacta; r, reticulate); VL, ventrolateral. (From Jankovic J: The extrapyramidal disorders: Introduction. In Goldman L, Bennett JC, editors: Cecil Textbook of Medicine, ed 21, Philadelphia, 2000, Saunders, p 2078).

FIGURE 114-3 Corticocerebellar loop. The major cerebellar input is from the spinocerebellar tract. Outflow is to the motor cortex via the mesencephalon and thalamus.

monitoring and regulating motor actions. Eye movement abnormalities include square wave jerks on ocular fixation, jerky slow pursuit movements, hypo- and hyper-metric point-to-point saccades, and nystagmus. The characteristic speech pattern, a scanning dysarthria, displays an abnormal modulation of speech volume and velocity. Speech prosody is also affected. Voluntary movements are irregular and uncoordinated with irregularities in amplitude, velocity, and rhythm. With sustained posture a tremor may develop and increase in amplitude with prolonged sustention. On directed movements there is an irregular placement of the limb (i.e. dysmetria) with voluntary movements, such as finger to nose or heel to shin testing. An intention tremor (increasing amplitude of tremor as one approaches target) is characteristic of cerebellar dysfunction. Patients have difficulty regulating muscle contractions with an increase in rebound when the examiner pushes against a limb and the patient is asked to keep the limb still, or a reduced ability to check a movement when resistance to muscle contraction is suddenly removed.

● SIGNS OF PERIPHERAL MOTOR SYSTEM DYSFUNCTION

Disorders affecting the peripheral motor system reflect disease of the motor unit: the anterior horn cell, peripheral nerve, neuromuscular junction, and muscles. All may be associated with weakness, muscle atrophy, hypotonia, hyporeflexia, fasciculations, and fibrillations. Anterior horn cell diseases cause a pure motor disorder with profound atrophy and prominent fasciculations. Paradoxically, the most common cause of anterior horn cell disease, amyotrophic lateral sclerosis, is associated with both upper and lower motor neuron syndrome: individuals have weakness, muscle wasting with spasticity, and increased muscle stretch reflexes. The motor neuron exits the spinal cord via a nerve root,

in the limb multiple roots combine to form a plexus, and then individual peripheral nerves innervate specific muscles. Lesions of nerve roots, plexus, and peripheral nerves are often associated with both weakness and sensory symptoms in the regions innervated by the specific roots, plexus, or nerves. Muscle stretch reflexes are reduced or absent. The distribution of weakness, sensory, and reflex findings assists in accurate localization. Peripheral nerve disorders may affect single nerves, such as median nerve in carpal tunnel syndrome, or multiple nerves, such as polyneuropathy in diabetes. In the former setting combined motor and sensory findings are the rule, whereas in the latter, occasional pure motor neuropathies occur. Polyneuropathy is usually associated with a distal gradient of both motor and sensory abnormalities that can be slowly or rapidly ascending depending on the underlying etiology.

Neuromuscular junction disorders are characterized by fluctuating weakness and fatigability. Tone and reflexes are usually unaffected with the exception of Lambert-Eaton Syndrome, in which muscle stretch reflexes are reduced or absent. Muscle mass and sensation are preserved. On examination, an individual may demonstrate fatigable weakness with strength recovery after rest. Bulbar symptoms and signs may be prominent with a nasal speech pattern, various abnormalities of eye movements, ptosis, and neck weakness.

Disorders of the muscle classically result in proximal greater than distal limb weakness with some exceptions, such as inclusion body myositis and myotonic dystrophy, in which distal weakness predominates. Muscle diseases, especially toxic or inflammatory conditions, may be associated with myalgia and tenderness to muscle palpation. Muscle stretch reflexes are normal to slightly reduced. Sensation is preserved.

● DIFFERENTIAL DIAGNOSIS OF PYRAMIDAL TRACT DISORDERS

Any disease affecting the nervous system can cause pyramidal tract dysfunction. Structural lesions due to stroke, tumor, infection, trauma, inflammatory and demyelinating diseases can cause pyramidal tract dysfunction with variable presentations depending on the underlying disease process and the variable involvement of non-motor systems. These disorders are discussed elsewhere.

Hereditary spastic paraplegia (HSP) is a rare and heterogeneous group of inherited disorders that causes progressive pyramidal tract dysfunction manifest clinically by spastic paraparesis.

● DIFFERENTIAL DIAGNOSIS OF PERIPHERAL MOTOR SYSTEM DISORDERS

Similar to pyramidal tract dysfunction, lesions resulting from direct tumor involvement, infection, trauma, and inflammatory and demyelinating processes may all affect the peripheral motor system. In addition, specific inherited and acquired degenerative disorders may affect the peripheral motor system ([Chapters 121, 122, and 123](#)).

● MOVEMENT DISORDERS

Movement disorders are a heterogeneous group of disorders associated with basal ganglia dysfunction. Movement disorders refer to the involuntary or abnormal movement, known as the

TABLE 114-1 SYMPTOMS AND SIGNS APPROACH TO NEUROANATOMIC LOCALIZATION OF MOTOR SYSTEM DYSFUNCTION

NEUROANATOMIC LOCALIZATION	SYMPTOMS	SIGNS
CENTRAL NERVOUS SYSTEM		
PYRAMIDAL TRACT		
Cortical	Weakness Cortical symptoms (e.g. aphasia)	Hemiparesis or focal weakness Spasticity Babinski's sign Other cortical findings
Subcortical	Isolated weakness/clumsiness	Hemiparesis of face and body Spasticity Babinski's sign Absence of cortical findings
Brainstem	Weakness Bulbar symptoms Somnolence	Crossed facial and body paresis Spasticity Babinski's sign Cranial nerve findings (e.g. INO) Cerebellar signs
Spinal Cord	Weakness Sensory loss, paresthesia/dysesthesia Gait imbalance and falls Back pain Bowel and bladder dysfunction	Impaired arousal Paraparesis > hemiparesis Sensory level Absence of bulbar signs Babinski's sign Hoffman's sign
BASAL GANGLIA	Changes in gait, gait imbalance, and falls Changes in voice Impairment in voluntary motor actions Involuntary movements Behavioral changes	Tone abnormalities (rigidity) Postural abnormalities Postural instability Gait disorders Akinesia/hypokinesia Tremor Chorea/ballism/athetosis Dystonia Tics
CEREBELLAR	Gait imbalance and falls Slurred speech Tremor with intentional tasks Incoordination	Oculomotor abnormalities Hypotonia Gait ataxia Titubation Scanning dysarthria Dysmetria Intention tremor Past pointing Dysdiadokinesis Excessive rebound Impaired check
PERIPHERAL NERVOUS SYSTEM		
ROOTS (RADICULAR)	Pain radiating into limb/trunk Localized sensory loss, parasthesias, dysesthesias Localized weakness	Combined motor and sensory deficits in a radicular distribution Reduced MSR in region subserved by root(s) Muscle atrophy
PLEXUS	Localized sensory loss, parasthesias, dysesthesias in a single limb Localized weakness in a single limb Bowel and bladder symptoms in lumbosacral plexus	Combined motor and sensory deficits involving multiple roots and subserving multiple nerves Reduced MSR in region subserved by multiple roots Muscle atrophy
PERIPHERAL NERVE	Polyneuropathy Distal/bilateral sensory loss, parasthesias, dysesthesias Distal/ascending and bilateral weakness Mononeuropathy Localized pain and sensory symptoms	Distal predominant weakness Stocking-glove sensory loss Reduced MSR Hypotonia Muscle atrophy
NEUROMUSCULAR JUNCTION	Fluctuating weakness Worsening weakness over the course of the day or with physical activity Diplopia Slurred speech Absence of sensory symptoms	Bulbar weakness Normal MSR Normal muscle bulk Fatigable weakness Normal sensory exam
MUSCLE	Proximal greater than distal weakness Myalgias Absence of sensory symptoms	Proximal weakness Normal muscle tone and bulk Normal to reduced MSR

INO, Intranuclear ophthalmoplegia; MSR, muscle stretch reflexes.

movement phenomenon, or may be used to describe a syndromic disorder in which involuntary or abnormalities of movement are cardinal features of the disease. In contrast to most seizures, the involuntary movements occur when the patient is conscious, but are absent during sleep.

Movement disorders can be classified as either hyperkinetic or hypokinetic. Hyperkinetic phenomena include tremor, chorea, dystonia, tics, myoclonus, and other involuntary movements. Hypokinetic disorders encompass the Parkinsonian disorders characterized by a paucity of spontaneous movement (akinesia) and low amplitude slow movements (bradykinesia). While this classification strategy is a valuable means for approaching the patient with abnormal movements, many movement disorders include both hyperkinetic and hypokinetic phenomena. Idiopathic Parkinson's disease is the prototypical hypokinetic movement disorder, but it is associated with the hyperkinetic phenomenon of tremor in over 60% of patients. Similarly, Huntington disease, a traditionally hyperkinetic disorder, is associated with bradykinetic voluntary movements.

Parkinsonism

Parkinsonism is the most common of the extrapyramidal disorders and is characterized by akinesia, rigidity, tremor, and postural instability. Parkinsonism is caused by a wide variety of degenerative disorders, medication and toxins, and systemic diseases. [Table 114-2](#) summarizes the differential diagnosis of Parkinsonism.

Idiopathic Parkinson's Disease

Idiopathic Parkinson's disease (PD) accounts for most individuals with Parkinsonism and is the second most common adult onset neurodegenerative disease after Alzheimer's disease. The average age of onset is around 60 years with an increasing prevalence associated with aging and a slight male preponderance. The motor symptoms of PD result from the selective loss of dopaminergic neurons in the substantia nigra-pars compacta that project to the striatum. The pathological hallmark of PD is the presence of eosinophilic cytoplasmic neuronal inclusions known as Lewy bodies containing α -synuclein.

TABLE 114-2 DIFFERENTIAL DIAGNOSIS OF PARKINSONISM

DEGENERATIVE/ INHERITED CAUSES	Idiopathic Parkinson's disease
	Multiple system atrophy
	Progressive supranuclear palsy
	Dementia with Lewy body
	Corticobasal degeneration
	Frontotemporal dementia with Parkinsonism
	Huntington's disease
	Wilson's disease
	Dopa-responsive dystonia
	Pantothenate kinase-associated neurodegeneration
	SECONDARY CAUSES
Dopamine receptor blocking medications (e.g. antipsychotics, metoclopramide, prochlorperazine)	
Presynaptic dopamine depleting medications (tetraabenazine)	
Cerebrovascular disease	
Toxins (MPTP, manganese, carbon monoxide)	

MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

Clinically, PD is characterized by its motor phenomenon with asymmetric rigidity, bradykinesia, rest tremor, and postural instability. However, PD is also characterized by secondary, non-motor manifestations (facial hypomimia, hypophonia, dysphagia, micrographia, and flexed posture), autonomic dysfunction (orthostatic hypotension, constipation, hyperactive bladder, and impaired temperature regulation), behavioral symptoms (depression, anxiety, psychosis), cognitive impairment and dementia, sleep disorders (impaired sleep architecture, restless legs syndrome, REM sleep behavior disorder), and sensory phenomena.

Until recently the diagnosis of PD was made based on the findings of an adult onset disorder of unilateral onset, persistent asymmetry of motor findings, and responsiveness of motor features to levodopa therapy. In addition, a number of "red flags" on history or examination might suggest an atypical or secondary cause of Parkinsonism ([Table 114-3](#)). However, Dopamine Transporter (DAT) SPECT imaging has recently been approved to assist in distinguishing PD from PD mimics, notably drug-induced Parkinsonism and essential tremor with parkinsonian features. The dopamine transporter is responsible for re-uptake of dopamine into presynaptic terminals and is, therefore, an indirect measure of nigro-striatal neuronal density. In PD, nigro-striatal neurons are lost asymmetrically; on dopamine transporter imaging, this is characterized by asymmetric reduction in dopamine transporter signal in the striatum. Unfortunately, this imaging method does not distinguish atypical Parkinsonism from PD.

A number of monogenic causes of Parkinsonism have been identified. Mutations in α -synuclein (*SNCA*), leucine-rich repeat kinase 2 (*LRRK2*), vacuolar protein sorting 35 (*VPS35*), and eukaryotic translation initiation factor 4- γ (*EIF4G1*) are associated with autosomal dominant Parkinsonism. Autosomal dominant causes account for less than 2% of all adult onset Parkinson's disease cases with higher frequencies in certain populations due to founder effects. Autosomal recessive monogenic causes include parkin, PTEN-induced kinase 1 (*PINK1*), and Parkinson protein 7 (*DJ-1*) and are relatively common in familial cases with onset before the age of 45. An improved understanding of these genetic causes suggests an important role of impairment in lysosomal pathways and protein degradation in PD pathogenesis.

PD is a slowly progressive disorder associated with accumulating disability. No treatments have been proven to slow progression; however, ongoing efforts continue to identify putative

TABLE 114-3 "RED FLAGS" IN THE DIAGNOSIS OF PARKINSON'S DISEASE

CLINICAL OR HISTORICAL "RED FLAG"	SUGGESTED DIAGNOSIS
Early postural instability and falls	PSP, MSA, CBD, DLB, Vascular
Early dysphagia	PSP, CBD
Early or spontaneous hallucinations	DLB
Early dementia or dementia predating PD	DLB
Early or severe dysautonomia	MSA
Pyramidal tract and/or Cerebellar signs	MSA
Antipsychotic exposure	Tardive or drug-induced
Acute onset and/or non-progressive	Vascular

CBD, Corticobasal degeneration; DLB, dementia with Lewy body; MSA, multiple system atrophy; PSP, progressive supranuclear palsy.

Table 114-4 MEDICATIONS FOR PARKINSON'S DISEASE**ANTICHOLINERGIC AGENTS**

Trihexyphenidyl (Artane)
 Benztropine (Cogentin)

DOPAMINE PRECURSORS (COMBINED WITH PERIPHERAL AROMATIC AMINO ACID DECARBOXYLASE INHIBITORS)

Carbidopa-levodopa (Sinemet, Sinemet-CR, Parcopa) (regular, controlled-release, and orally disintegrating)
 Benserazide-levodopa (Madopar) (marketed in Europe)

DOPAMINE AGONISTS

Apomorphine (Apokyn) (injectable short acting), bromocriptine (Parlodel)
 Pramipexole (Mirapex)
 Rotigotine (Neupro) (transdermal patch)
 Ropinirole (Requip, Requip XR)

MONOAMINE OXIDASE TYPE B (MAO-B) INHIBITORS

Selegiline (deprenyl) (Carbex, Eldepryl, Zelapar)
 Rasagiline (Azilect)

CATECHOL O-METHYLTRANSFERASE (COMT) INHIBITORS

Tolcapone (Tasmar)
 Entacapone (Comtan)

CATECHOL O-METHYLTRANSFERASE (COMT) INHIBITORS COMBINED WITH CARBIDOPA-LEVODOPA

Entacapone-carbidopa-levodopa (Stalevo)

disease modifying therapies. Treatments of the motor symptoms can reduce disability and improve function (Table 114-4). The mainstay of treatment is levodopa, the precursor to dopamine, given with a dopa-decarboxylase inhibitor to maximize CNS penetration of levodopa and minimize systemic side effects. Other symptomatic treatments stimulate dopamine receptors in the brain or inhibit the breakdown of levodopa and dopamine (Table 114-4). This approach to symptom management is effective early in the course of the disease; however, as the disease continues to progress, it may be complicated by the development of motor fluctuations, drug-induced dyskinesias, and psychosis.

Atypical Parkinsonism

Atypical Parkinsonism or “Parkinson plus” disorders refer to a heterogeneous group of inherited and sporadic neurodegenerative disorders characterized by Parkinsonism and a reduced or absent response to dopaminergic therapy. The most common are multiple system atrophy (MSA), progressive supranuclear palsy (PSP), dementia with Lewy bodies (DLB), and corticobasal degeneration (CBD).

MSA is a sporadic neurodegenerative disorder characterized clinically by the variable combination of Parkinsonism, autonomic dysfunction, cerebellar dysfunction, and extrapyramidal motor signs. The term MSA was coined to encompass three previously distinct clinical entities: striatonigral degeneration with prominent parkinsonism, olivopontocerebellar atrophy with prominent cerebellar dysfunction, and Shy-Drager syndrome with prominent autonomic dysfunction, particularly profound orthostatic hypotension. The identification of a shared neuropathological correlate of neuronal inclusions consisting of α -synuclein bolstered the shared nomenclature of these disorders. Currently, the preferred classification refers to either MSA-parkinsonism type or MSA-cerebellar type depending on the

predominant clinical symptoms and signs. An MSA-autonomic type is proposed for those with an overwhelmingly autonomic presentation. Although relatively rare, MSA is among the most frequently encountered of the atypical Parkinsonisms with an overall incidence of 0.6/100,000 and an increasing incidence with age. It is universally fatal with a mean survival of 7 to 9 years, though longer disease duration is sometimes seen. Treatment is challenging and largely symptomatic. Some patients may be partially responsive to dopaminergic therapy and levodopa is recommended for individuals with prominent parkinsonism. Autonomic manifestations can be managed with symptomatic treatments to address orthostatic hypotension, constipation, and bladder symptoms (see Chapter 110).

Progressive supranuclear palsy is a relentlessly progressive disorder characterized by early gait instability and falls, prominent and early dysphagia, early speech difficulties progressing to a non-fluent aphasia, dementia, and supranuclear gaze palsy; death occurs on average 5 years after diagnosis. Supranuclear gaze palsy, in its fully realized form, is characterized by vertical greater than horizontal gaze palsy with preserved oculocephalic reflexes. Early, the gaze palsy may manifest by the presence of square wave jerks, difficulty initiating saccades, and loss of the fast phase on optokinetic nystagmus testing. Patients have a wide-eyed stare and lid lag may be present. Opposed to the flexed posture and asymmetry of PD, individuals with progressive supranuclear palsy have extensor trunk posturing and greater axial rigidity with relatively appendicular symmetry. Up to 20% of patients may have a modest response to levodopa therapy.

Dementia with Lewy bodies is the second most common degenerative cause of dementia after Alzheimer's disease. It is characterized clinically by Parkinsonism, dementia preceding or within 1 year of the motor symptoms, propensity for psychosis, early falls, and fluctuations in cognition and arousal. Motorically, it may be indistinguishable from Parkinson's disease. Patients have a high risk for psychosis associated with dopaminergic therapy and antipsychotics may cause worsening of Parkinsonism and even death making management of these patients challenging.

Corticobasal degeneration is a rare and heterogenous disorder. The characteristic Parkinsonian disorder presents with marked asymmetric Parkinsonism, focal limb dystonia, cortical sensory findings, alien limb phenomenon, and myoclonus. However, it may present with primary cortical cognitive symptoms and have features of progressive supranuclear palsy. It is a relentlessly progressive and fatal illness. Treatment is symptomatic.

Secondary Parkinsonism

There are many causes of secondary Parkinsonism, including medications, toxins, and cerebrovascular disease. Medications associated with Parkinsonism include any medication that reduces dopaminergic tone in the brain, either through direct blockade of post-synaptic dopamine receptors (e.g. antipsychotics) or through depletion of pre-synaptic dopamine stores (e.g. tetraabenazine). Metoclopramide, a medication commonly used to treat gastroparesis, is a frequent cause because its dopamine blocking effects may be overlooked. Drug-induced Parkinsonism can be indistinguishable from Parkinson's disease and is frequently asymmetric. Treatment consists of withholding the

offending agent, recognizing that it may take months for the symptoms to resolve. Even then, patients exposed to dopamine blocking agents may develop a tardive Parkinsonism (i.e., a drug-induced Parkinsonism that persists even after the offending agent is removed). DAT SPECT imaging can be useful in distinguishing drug-induced or tardive Parkinsonism from Parkinson's Disease.

Cerebrovascular disease is a common cause of secondary Parkinsonism. Tremor is uncommon in vascular Parkinsonism; lower extremity bradykinesia and gait difficulties dominate the clinical picture. Patients may have a history of clinical strokes with acute deteriorations followed by plateaus; however, many patients have vascular risk factors and a history of gradual decline.

Tremor

Tremor is a rhythmic, oscillatory movement of a body part. Tremor is classified by its distribution (e.g., voice, limb) and whether it is present at rest, with sustained posture (sustention), or with action. Action tremor can further be classified as an intention tremor, in which the tremor worsens as one approaches target. Intention tremor is characteristic of cerebellar disease. Tremor has multiple etiologies, including medications, alcohol and drug withdrawal, systemic disease (e.g. hyperthyroidism), structural brain lesions, or as a component of a neurodegenerative disease.

Essential tremor is among the most common movement disorders and the most common cause of tremor. Essential tremor has a worldwide prevalence of 2% to 4% with increasing incidence with aging. Clinically it is characterized by postural tremor of the upper extremities. An intention tremor develops with disease progression and may be disabling. Involvement of the head and voice are common. Mild Parkinsonian features (e.g., tremor at rest, rigidity with activation) may develop and can make distinguishing incipient Parkinson's disease challenging. The condition is often familial with an autosomal dominant pattern of inheritance and tends to improve with alcohol ingestion. Propranolol and primidone are of similar benefit (Table 114-5).

Chorea

Chorea is characterized by brief, irregular, random, non-rhythmic movements that flow from one body part to another. It is often associated with athetosis and ballism. These conditions lie on a spectrum of choreic phenomenon with ballism characterized by proximal large amplitude flinging movements on one end, chorea in the middle with lower amplitude random flowing movements

and athetosis characterized by slower distal writhing movements on the other. Chorea is often associated with a variety of secondary clinical features detailed in Table 114-6.

There are many etiologies of choreic disorders reflecting a wide variety of processes affecting the basal ganglia and specifically the striatum. Generally, chorea either represents the primary manifestation of an inherited disorder or is acquired secondary to basal ganglia insults due to various comorbid medical conditions, medications or toxins, or structural abnormalities. Table 114-7 summarizes the differential diagnosis of chorea categorized by genetic and acquired causes.

Huntington's Disease

Huntington's disease (HD) is an autosomal dominant, progressively disabling, and fatal neurodegenerative disease; it is and the most common cause of inherited adult onset chorea. The causative mutation is an expansion of an unstable cytosine-adenine-guanine (CAG) trinucleotide repeat of the IT-15 gene on the short arm of chromosome 4.

HD may emerge at any age, with the peak incidence between 35 and 40 years of age with death occurring 10 to 20 years after onset. Age of onset and rate of progression of the disease are inversely associated with CAG repeat length with the longest repeats associated with juvenile onset disease and a more rapid disease progression.

HD is characterized clinically by the triad of an extrapyramidal movement disorder, progressive cognitive decline (dementia), and an array of behavioral disturbances. Chorea is the prototypical motor manifestation of HD occurring in 90% of patients. Cognitive impairment is invariable in HD and typically progresses from selective deficits in psychomotor, executive, and visuospatial abilities to more global impairment with higher cortical functions usually spared. Psychiatric illness has been recognized as an important feature of HD since George Huntington reported on the "tendency to insanity and suicide."

The juvenile variant of HD, in which age of onset occurs before 20, typically has an akinetic-rigid phenotype and paternal inheritance and only rarely chorea. Paternal inheritance of the HD gene is the rule for onset before the age of 10 and paternal inheritance predominates (about 3 : 1 paternal : maternal) for onset before the age of 20.

TABLE 114-5 TREATMENT OPTIONS FOR ESSENTIAL TREMOR

FIRST LINE	Propranolol Primidone
SECOND LINE	Topiramate Zonisamide Benzodiazepines Other beta-blockers
MEDICATION FAILURE	Gabapentin/Pregabalin Botulinum toxin injections Deep brain stimulation

TABLE 114-6 SECONDARY FEATURES ASSOCIATED WITH CHOREA

ATHETOSIS	Slow, writhing movements of distal limbs
BALLISM	Rapid, flinging movements of proximal limbs
PARAKINESIS	Incorporation of an involuntary movement into a voluntary movement (e.g. crossing and uncrossing of legs, adjusting glasses)
MOTOR IMPERSISTENCE	Inability to maintain tongue protrusion, "milk maid's grip"
PARTIALLY SUPPRESSIBLE	Brief ability to voluntarily reduce the severity of movements
DEEP TENDON REFLEX CHANGES	"hung up" or "pendular" reflexes
GAIT DISORDERS	Irregular or dance like gait

TABLE 114-7 DIFFERENTIAL DIAGNOSIS OF CHOREA

GENETIC DISORDERS	Autosomal dominant	Huntington's disease Spinocerebellar ataxia (SCA 17 >1-3) DRPLA Neuroferritinopathy Benign hereditary chorea
	Autosomal recessive	Neuroacanthocytosis Wilson's disease Ataxia (Friedreich's, ataxia-telangiectasia, ataxia with oculomotor apraxia) Disorders associated with brain iron accumulation (PKAN)
	X-linked	McLeod's syndrome Lesch-Nyan's syndrome
ACQUIRED/SPORADIC	Medications	Direct side effects Tardive dyskinesia
	Immune mediated	Sydenham's chorea Systemic lupus erythematosus Anti-phospholipid antibody syndrome Vasculitis Paraneoplastic (CRMP5 gene, anti-Hu)
	Infectious	HIV/AIDS Variant CJD Neurosyphilis
	Endocrine	Hyperthyroidism Chorea gravidarum
	Metabolic	Hyperglycemia Electrolyte disturbances Acquired hepatocerebral degeneration
	Vascular	Basal ganglia infarcts/hemorrhage
	Miscellaneous	Polycythemia vera Post-cardiac bypass pump Multiple sclerosis Sporadic neurodegenerative disorders

CJD, Creutzfeldt-Jakob disease; DRPLA, dentatorubropallidolusian atrophy; PKAN, pantothenate-kinase-associated neurodegeneration; SCA, spinocerebellar ataxia.

The neuropathology of HD is characterized by selective neuronal vulnerability, particularly involving the caudate and putamen of the corpus striatum. Microscopically, the pathological hallmark of the disease is the preferential loss of medium-sized spiny neurons projecting from the striatum to the external pallidum. While HD is associated with a variety of motoric phenotypes, it remains the prototypical choreiform disorder and the most common cause of inherited adult onset chorea. In addition, HD represents one of the most important genetic disorders of adulthood. HD was the first disease recognized to arise from a trinucleotide expansion and serves as a model for the experimental therapeutics of adult-onset neurodegenerative diseases.

Huntington's Disease Phenocopies

Approximately 10% of individuals with an autosomal dominant HD-like disorder will not carry the causative mutation for HD. Among these "phenocopies," only a small minority will have an identifiable genetic mutation. The most common genetic causes in the Caucasian population include spinocerebellar ataxia (SCA) 17, Friedreich's ataxia, HD-like 2, and familial prion disease (HD-like 1). Alternative diagnoses include dentatorubropallidolusian atrophy (DRPLA), SCA 1-3, and neuroferritinopathy. A benign form of an autosomal dominant chorea, benign familial chorea, without significant behavioral or cognitive impairment can occur.

Wilson's Disease

Wilson's disease is a rare, autosomal recessive disorder of impaired copper metabolism with copper accumulation and neurological and hepatic dysfunction. It causes heterogenous movement

disorder including chorea, dystonia, Parkinsonism, and tremor; dystonia and tremor tend to predominate. Onset with movement disorder occurs in about 50% of individuals, the others presenting with liver disease. The mean age of onset is 20; it rarely occurs after the age of 40. Untreated it is invariably fatal; early treatment is associated with better clinical outcomes; therefore, a high level of suspicion should be maintained. Diagnosis is confirmed by the presence of Kayser-Fleischer corneal rings in the setting of increased urinary copper excretion or elevated copper on liver biopsy. Although ceruloplasmin is usually low in symptomatic patients, it is not definitive, and confirmatory testing with ophthalmologic screen, 24-hour urinary copper or liver biopsy is necessary. Treatment consists of drugs that facilitate copper excretion, such as zinc, trientine, tetrathiomolybdate, penicillamine (the latter falling from favor because of its toxicities).

Sydenham's Chorea

Sydenham's chorea is one of the most common causes of childhood onset chorea and is an immune complication of group A streptococcal infection. It presents acutely months after the streptococcal infection, is frequently asymmetric, and may cause behavioral symptoms in addition to chorea. Other features of rheumatic fever may also be present and echocardiography should be performed on any child with suspected Sydenham's. Treatment of the underlying infection, management of complications of rheumatic fever, and supportive care are generally sufficient with the majority of patients having resolution of symptoms by 1 year. A history of Sydenham's may predispose a female patient to adult onset chorea during pregnancy (chorea gravidarum) or in response to estrogen treatment.

Medications and Tardive Dyskinesia

Numerous medications have been associated with chorea. The most common direct cause of drug-induced chorea is levodopa-induced dyskinesias in individuals with Parkinson's disease. Tardive dyskinesia is a late complication of treatment with dopamine receptor blocking agents, usually neuroleptic antipsychotics, and may have chorea as a prominent feature. Advancing age, female gender, and use of high potency antipsychotics are associated with an increased risk for this complication. While removal of the offending agent is critical to prevent worsening, symptoms persist in approximately two thirds of patients and treatment can be challenging.

Dystonia

Dystonia is a heterogeneous class of movement disorders characterized by sustained muscle contractions that lead to twisting movements, abnormal postures, and repetitive movements. The classification of dystonia is challenging, having undergone numerous revisions over time, and is based on age of onset, distribution (focal versus generalized), association with neurological signs other than dystonia, and cause, if known. Mutations in at least 23 different genes are associated with dystonia. In general, the specific mutation does not reliably predict the phenotype. Childhood onset dystonia often has an underlying genetic cause, tends to generalize, and has a more severe course; while adult onset focal dystonia of the neck (e.g. cervical dystonia) tends to be non-progressive without a defined genetic cause.

Adult onset focal dystonias are by far the most common dystonias encountered clinically. Cervical dystonia is the most common dystonia, followed by focal dystonias involving the face and jaw muscles (blepharospasm, oromandibular dystonia or the combination); laryngeal and limb dystonias are rare. Adult onset limb dystonias are usually task-specific; dystonic contraction only occurs during specific voluntary actions (e.g., writer's cramp, musician's dystonia). This task specificity may be lost over time and occur even at rest. Focal adult onset limb dystonia that is not task specific can be the earliest manifestation of Parkinsonism and Parkinson's disease.

A mutation in the *TOR1A* gene is the most common cause of early onset generalized dystonia. *DYT1* is an autosomal dominant disorder with reduced penetrance (30%). Onset is usually during childhood (10 to 15 years of age) with focal limb dystonia with action that rapidly generalizes often sparing the craniocervical muscles. It accounts for less than 50% of childhood onset dystonia in non-Jews and approximately 80% in children of Ashkenazi Jewish descent.

Dopa-responsive dystonia is a rare but important cause of childhood onset dystonia. It is inherited in autosomal dominant fashion with reduced penetrance (30%) with females more commonly affected than males. It is characterized by lower extremity dystonia, Parkinsonism, and diurnal variability with the symptoms worsening as the day progresses and improving with sleep. As the name suggests, it is exquisitely sensitive to levodopa therapy. The condition is often misdiagnosed and untreated; therefore, patients with childhood onset dystonia should have a trial of levodopa.

Myoclonus dystonia syndrome is an autosomal dominant disorder with alcohol responsive myoclonic jerks and dystonia. Dystonia is often focal with cervical dystonia and writer's cramp predominating. Onset is usually prior to the age of 20 years and psychiatric symptoms are common.

Rapid-onset dystonia Parkinsonism is a rare autosomal dominant condition with reduced penetrance that presents over hours or weeks with craniofacial and limb dystonia, dysarthria, bradykinesia, and postural instability. After initial progression the disorder stabilizes. The rapid onset and triggers, including emotional trauma or physical exertion, often result in it being misdiagnosed as a somatoform disorder.

Treatment of dystonia consists of a combination of oral medications and focused botulinum toxin injections. Oral medications include anticholinergics, benzodiazepines, and muscle relaxants. Deep brain stimulation has shown recent benefit in treating dystonia resulting from multiple causes.

Tics and Tourette's Syndrome

Tics are rapid, stereotyped, non-rhythmic movements or vocalizations. They can mimic many normal motor activities and movement disorders and occur on a background of otherwise normal activity and motor function. The key differentiating characteristics of tics are that they are associated with an irresistible urge or sensation that is temporarily relieved with performance of the tic. Tics are voluntarily suppressible but suppressing them results in increasing urge and rebound exacerbation of tics. Tics of childhood are extremely common and if transient, require no treatment.

Tourette's syndrome (TS) is a tic disorder, beginning in childhood with both motor and vocal tics persisting for more than one year. Approximately 50% of individuals with TS will also have features of obsessive compulsive disorder and/or attention deficit disorder. These other features are often more disabling than the tics themselves. In the majority of individuals there is partial or complete resolution of symptoms by adulthood. Treatment of tics and associated comorbidities should be reserved only for functionally disabling symptoms. A combination of behavioral approaches (comprehensive behavioral intervention for tics), oral medications, and botulinum toxin injections can be effective at minimizing the impact of symptoms. Extreme cases with persistence in adulthood may respond to deep brain stimulation.

CEREBELLAR ATAXIAS

The ataxias are a heterogeneous group of conditions reflecting impaired cerebellar function or impairment in cerebellar afferent and efferent pathways. Structural lesions due to abnormalities of brain development, stroke, tumor, infection, trauma, and inflammatory and demyelinating diseases can frequently affect cerebellar function and result in cerebellar symptoms and signs. [Table 114-8](#) summarizes the differential diagnosis of the ataxic disorders divided by genetic and acquired causes.

Inherited/Genetic Ataxias

Progressive ataxia in coordination and gait disturbance are the cardinal features of the inherited ataxias. Autosomal dominant spinocerebellar ataxias (SCA) may present with a pure cerebellar syndrome or be associated with other extrapyramidal, pyramidal,

TABLE 114-8 DIFFERENTIAL DIAGNOSIS OF CEREBELLAR ATAXIA

GENETIC DISORDERS	Autosomal dominant	Spinocerebellar Ataxias Episodic ataxia DRPLA	
	Autosomal recessive	Friedreich's ataxia Ataxia-telangiectasia Ataxia with oculomotor apraxia Ataxia with vitamin E deficiency	
	X-linked	Fragile X-associated tremor/ataxia syndrome

Miscellaneous	MSA-cerebellar Multiple sclerosis		

CJD, Cruetzfeldt-Jakob disease; DRPLA, dentatorubropallidolusian atrophy; MSA, multiple system atrophy; PML, progressive multifocal leukoencephalopathy.

cognitive, or behavioral features. They are usually adult onset with variable genetic mutations, including trinucleotide repeats, mutations in noncoding regions, and point mutations. Genetic testing is available for many of the common spinocerebellar ataxias and new mutations are being identified in a rapid and ongoing basis. Currently there are no treatments to address disease progression and symptomatic treatment is limited.

The fragile X mental retardation (FMR1) gene contains a CCG trinucleotide repeat expansion of greater than 200 in the fully penetrant mutation associated with mental retardation in boys. Recently a pre-mutation associated with repeats of 55-200 in the FMR1 gene has been found to be the cause of the adult onset neurodegenerative disorder, fragile X-associated tremor/ataxia syndrome (FXTAS). Clinically, affected males have a progressive cerebellar tremor and ataxia. Fragile X-associated tremor/ataxia syndrome has been under-recognized and may be the most common genetic cause of late onset ataxia. Treatment is largely symptomatic and the disease results in progressive disability.

Autosomal recessive ataxias are rare conditions with onset in childhood. Friedreich's ataxia (FA) is the most common and best characterized of these disorders. It results from an unstable GAA expansion on chromosome 9. Clinically it is characterized by childhood onset gait ataxia and clumsiness. The ataxia reflects a combination of spinocerebellar degeneration and peripheral sensory loss. Frank weakness secondary to

pyramidal tract dysfunction is a late complication. Non-neurological manifestations include cardiomyopathy, diabetes mellitus, and skeletal deformities, which add to the morbidity and mortality of the disease. Since identification of the mutation, late onset forms of the disease with less systemic involvement and milder symptoms have been identified. Therefore, Friedreich's ataxia should be considered in the differential of adult onset sporadic ataxias.

Ataxia with vitamin E deficiency is a childhood onset ataxia with a Friedreich's ataxia phenotype. Treatment with high dose vitamin E may slow the progression of neurological symptoms. Ataxia with vitamin E deficiency should be considered in any child with signs and symptoms of Friedreich's ataxia that do not carry the Friedreich's ataxia mutation.

Sporadic/Acquired Ataxias

Insidious onset of cerebellar ataxia without a family history can be a diagnostic challenge. Alcohol abuse, toxins, multiple system atrophy, and mitochondrial disorders are diagnostic considerations.

Acute or subacute onset ataxia is most often associated with cerebrovascular disease, demyelinating illness, or direct or indirect effects of cancer. Paraneoplastic cerebellar degeneration is one of the more common paraneoplastic syndromes usually associated with gynecological, breast, lung cancer, or lymphoma. A variety of anti-neuronal antibodies have been implicated; however, anti-Hu/Yo/Ri are most frequently seen. The cerebellar syndrome often predates the identification of the cancer. Treatment of the underlying cancer and plasma exchange are sometimes beneficial.

Vitamin B12 and vitamin E deficiency secondary to malabsorption can present with ataxic gait as a result of posterior column sensory deficits. In the appropriate clinical situation, Wernicke's encephalopathy due to thiamine deficiency needs to be considered as an acute cause of gait ataxia.

Congenital, Developmental, and Neurocutaneous Disorders

Maxwell H. Sims and Jennifer M. Kwon

This chapter describes some of the most important congenital nervous system malformations and neurodevelopmental disorders. Advances in imaging and molecular genetic diagnostic technology have improved our understanding of these disorders. Neuroimaging facilitates diagnosis and informs early management of malformations of the brain and spinal cord. The remarkable advances in genetic sequencing and microarray technology are improving our understanding of the etiology and pathogenesis of neurodevelopmental disorders due to single genes, like Fragile X syndrome, Rett syndrome, tuberous sclerosis, and neurofibromatosis, as well as the genetically heterogeneous disorders autism and ADHD.

CONGENITAL MALFORMATIONS

Malformations of the central nervous system develop during fetal life. [Table 115-1](#) summarizes the timeline of early neural and cortical development and the defects that may occur during these stages. Malformations developing early in embryogenesis can be more severe than those arising later, after the basic structures of the nervous system are in place.

Brain Malformations

Disorders of Ventral Induction

Definition/Epidemiology

Ventral induction is the early stage of brain development where brain vesicles and the face begin to form. Malformations that arise during this time include holoprosencephaly (HPE), agenesis of the corpus callosum (ACC), and septo-optic dysplasia

(SOD). In clinical practice, ACC is the most commonly seen, with an estimated prevalence in the general population of greater than 0.5%, higher in those with developmental disabilities. The estimated prevalence of HPE is 1/10,000, and SOD is even rarer, occurring in 3/100,000.

Pathology

During ventral induction, the prosencephalon forms and undergoes cleavage and midline formation. Abnormal prosencephalon cleavage leads to HPE, a spectrum of abnormalities ranging from alobar HPE (cortex with a single ventricle) to semi-lobar and lobar HPE (cerebral hemispheres are mostly separated except for the frontal lobes) ([Figure 115-1](#)). In all cases, there is some fusion between the two cerebral hemispheres, often accompanied by facial anomalies. ACC and SOD represent more discrete abnormalities localized to specific midline structures and occur later in prosencephalic development.

Clinical Presentation

Children with HPE, ACC, and SOD have varying degrees of developmental disability and other congenital anomalies. In HPE, especially, the close timing of this defect with facial development may lead to midline anomalies like cleft lip, hypotelorism, or cyclopia. Children with SOD will have vision problems and optic nerve hypoplasia on examination; they can also have pituitary dysfunction. The clinical presentations range from severe—where individuals develop multiple complications related to their severe neurologic impairments—to nearly normal, as in the case of ACC associated with no other defects.

TABLE 115-1 STAGES OF PRENATAL NEURAL DEVELOPMENT (SIMPLIFIED)

	STAGE	STRUCTURES FORMING	POST-CONCEPTUAL AGE	ANOMALIES SEEN*
NEURAL TUBE, BRAIN VESICLE DEVELOPMENT (KANEKAR)	Dorsal induction	Neural tube closure	18-26 days (3-5 weeks)	Anencephaly, spina bifida, myelomeningocele, Chiari 2 malformation
	Ventral induction (ref Kanekar)	Brain vesicle and face development	5-10 weeks	Holoprosencephaly, agenesis of the corpus callosum, septo-optic dysplasia
CORTICAL DEVELOPMENT (REF BARKOVICH, OSBORNE)	Proliferation	Development of neuroblasts and glioblasts	2-4 months (neuroblasts)	Microcephaly, megalencephaly
	Migration	Formation of 6 cortical layers	Peak occurrence at 2-4 months, though occurs from 8 weeks to 8 months	Lissencephaly, periventricular heterotopias
	Post-migrational organization	Cortex formed		Polymicrogyria, schizencephaly

*NB: Some anomalies (such as microcephaly, polymicrogyria) can arise from different stages. So even though it may seem intuitive to think of microcephaly as a disorder of neuronal proliferation, there are some forms of microcephaly that develop well after migration.

FIGURE 115-1 Semilobar HPE. MRI (sagittal T1 image taken at midline paired with and the axial FLAIR image whose location is indicated by the scout line) of 13 day old with hypotelorism and microcephaly. There is presence of partial fusion of the frontal lobes with lack of interhemispheric fissure/falx and septum pellucidum. The body and genu of corpus callosum is likewise poorly formed. There is appropriate separation of the thalami.

Diagnosis/Differential

Neuroimaging is the primary method of diagnosing HPE, ACC, and SOD. MRI allows for specific anatomic diagnoses and for delineating the full extent of brain malformations. Ophthalmology examination can also detect hypoplastic optic nerves. HPE, ACC, and SOD are associated with a number of genetic syndromes, including trisomies and familial disorders.

Treatment

Surgical treatment can improve associated craniofacial anomalies (e.g., cleft lip) and hormone replacement is needed for pituitary dysfunction (seen in SOD). These patients can present with a wide range of medical problems related to their underlying disabilities, including the development of joint contractures, hip dislocations, impaired swallowing, and respiratory insufficiency.

Prognosis

Survival has improved for these children thanks to aggressive treatment and management of associated medical problems. Long-term outcome depends on the degree of neurologic impairment and associated medical comorbidities.

Disorders of Neuronal Migration and Organization

Definition/Epidemiology

These disorders, including lissencephaly, schizencephaly, polymicrogyria and pachygyria, are caused by disrupted migration of neuronal progenitor cells, resulting in the abnormal appearance of cortical sulci and gyri. The more severe forms of lissencephaly occur in approximately 1/100,000 births. Other migrational disorders have a more variable presentation and, while their true incidence is unknown, they are more common than lissencephaly.

Pathology

Neuronal migration is a complex, highly-regulated process integral to formation of normal cortical architecture that occurs throughout gestation but peaks from 2 to 4 months. In the case of lissencephaly and pachygyria, the brain appearance is smoother because there are fewer convolutions of the cortical surface. In polymicrogyria syndromes, the brain is more irregular in appearance due to an increased number of abnormally small gyri. In schizencephaly, clefts form from the surface of the brain to the lateral ventricle; the clefts are often lined by polymicrogyri.

Clinical Presentation

Lissencephaly has a severe presentation with marked motor disability and seizures. Polymicrogyria and schizencephaly, depending on the extent and location, often result in less severe developmental disabilities. All neuronal migration disorders are associated with high risk of seizures.

Diagnosis/Differential

Neuroimaging is the primary method of diagnosing the neuronal migration disorders. Further diagnostic evaluation is often done because these disorders are heterogeneous in etiology and may be associated with other genetic syndromes or environmental factors, such as teratogens or intrauterine infections. Single gene mutations are responsible for many malformation syndromes and identification of these genes can aid in counseling and prognosis.

Treatment

The most common medical issue in this population is intractable epilepsy which is treated with medications and possibly by surgical resection of the abnormal epileptogenic cortex. In the case of severe neurologic impairment, a number of medical complications can arise: orthopedic complications from immobility and spasticity; failure to thrive and aspiration from poor oromotor coordination; vulnerability to pulmonary infections; and complications due to respiratory insufficiency.

Prognosis

Long-term outcome depends on the degree of neurologic impairment and, to a lesser extent, the etiology of the migration disorder. Genetic evaluation is useful for prognostic counseling and management.

Chiari Malformation, Type 1 (CMI)

Definition/Epidemiology

Chiari malformation, type 1 (CMI) is cerebellar tonsillar ectopia with displacement of the cerebellar tonsils more than 5 mm below the foramen magnum, usually accompanied by deformity of tonsils and evidence of altered CSF flow (indicated by loss of peritonsillar CSF space or impaired CSF flow dynamics.) It is common, likely occurring in 0.5 % of the population.

Pathology

The cerebellar tonsils are inferiorly displaced, elongated, and compressed by the foramen magnum. This displacement can cause increased intracranial pressure and change CSF flow dynamics, leading to development of syringomyelia.

Clinical Presentation

In CMI cases with severe displacement, there may be lower cranial neuropathies, disordered sleep, headaches, and vertigo, among other symptoms. If there is an associated syringomyelia, this may also result in symptoms (see discussion of [syringomyelia](#).) Rarely, patients may experience difficulty with balance and gait.

Diagnosis/Differential

MRI is most useful for making the diagnosis. CSF flow studies may be helpful to establish clinical significance of the Chiari malformation. Since any cause of increased intracranial pressure can lead to tonsillar herniation, it is important to exclude idiopathic intracranial hypertension and CNS mass lesions.

Treatment

Surgical decompression by removing suboccipital bone and posterior C1 vertebrae may be necessary when the symptoms are severe and when syringomyelia is present, symptomatic, and worsening. Otherwise, conservative management is sufficient.

Prognosis

CMI is generally not disabling. Surgical decompression is generally effective and prognosis is good.

Spinal Cord Malformations

Spina Bifida

Definition/Epidemiology

Failure to completely close the neural tube during the 24th to 26th days post conception can result from defects anywhere along the neuroaxis. These abnormalities are termed neural tube defects (NTDs), the most common of which occur caudally, and are collectively termed spina bifida. Spina bifida occurs in about 1 in 2800 births in the United States. The prevalence of NTDs varies by geography and is influenced by genetic and environmental factors. Use of folic acid at the time of conception and during pregnancy can significantly reduce NTD rates.

Pathology

The neural plate folds and seals itself to form the neural tube in a process, called neurulation, from gestation day 18 to 28. The central portion of the neural tube closes first, then the cranial and caudal portions. Abnormal caudal closure can be associated with overlying bony and skin defects, leading to “open” NTDs, such as myelomeningocele (MMC). The severe neuropathology seen in MMC may not be due only to the lack of caudal tube closure, but also to exposure of neural tube contents to amniotic fluid, trauma, and the leakage of CSF leading to downward herniation of the cerebellum. In cases of “closed” spina bifida where the abnormal caudal cord tissue is covered by fat or skin, neurologic function is less impaired.

Clinical Presentation

The more severe and disabling the defect, the earlier it will present. A large MMC is clinically obvious at birth. MMC can be diagnosed prenatally as well. MMC causes severe distal spinal cord dysfunction, including paralysis and sensory loss in the

legs, and loss of bladder control. Nearly all children with MMC have an associated Chiari malformation, “type II” (CM2, also called an Arnold-Chiari malformation). CM2 is characterized by displacement of the cerebellum and lower brainstem through the foramen magnum, usually causing obstructive hydrocephalus. Spina bifida does not have to be associated with an open defect. In cases of closed NTD, patients may present with leg spasticity, foot deformities, and bladder abnormalities, and the overlying skin may show nevi, lipomas, abnormal dimples, or hairy tufts.

Diagnosis/Differential

MRI is the method of choice for evaluation of NTDs. In the case of a child with an open caudal defect, the imaging should look for other associated nervous system abnormalities, such as CM2 and hydrocephalus. Closed NTDs are definitively diagnosed by MRI, but patients may present with symptoms later. Other disorders that can present with gait abnormalities and deformities include spastic diplegia, vitamin B12 deficiency, multiple sclerosis, and other conditions presenting with spastic paraparesis.

Treatment

Treatment is surgical repair of the MMC with subsequent shunting of the hydrocephalus. Bladder dysfunction may necessitate intermittent catheterization and treatment of urinary tract infections and genitourinary reflux. A recent clinical trial indicated that fetal surgery before 26 weeks gestation to repair the MMC defect resulted in better neurologic outcomes, possibly by preventing the spinal cord injury and CSF leakage that can occur during the third trimester with an open defect.

Prognosis

Infants with open NTDs such as MMC have a much more severe presentation and course than those born with closed defects. Fetal surgery at qualified centers may improve MMC outcome.

Syringomyelia

Definition/Epidemiology

Syringomyelia or syrinx is a cystic cavitation of the central portion of the spinal cord. The estimated prevalence of 8/100,000 is likely an underestimate.

Pathology

The central canal cysts are most commonly located in the cervical spine and consist of CSF-filled space lined by glial cells, in contrast to hydromyelia, where the dilated central canal is lined with ependymal cells. The syrinx can be septated and irregular, and it may develop in association with Chiari malformations (CM1 and CM2), trauma, tumor, or a tethered cord.

Clinical

The classic presentation is a dissociated sensory loss (pain and temperature loss with preservation of light touch and proprioception) in the neck, arms, or legs. A cervical lesion produces a cape-like dissociated sensory loss of the arms and shoulder, along with atrophy of the hands and arms with increased tone and hyperreflexia in the legs. Extension into the medulla (syringobulbia) may cause lower cranial neuropathies.

Diagnosis/Differential

Diagnosis is confirmed by MRI, which will also differentiate the cysts from neoplasms, infections, and other spinal cord lesions.

Treatment

If the syrinx is associated with CM1 or CM2, then posterior fossa decompression or shunting of the hydrocephalus may improve the symptoms. Direct evacuation or shunting of the syrinx itself is less frequently done and not of established benefit.

Prognosis

Syringomyelia can be slowly progressive but spontaneous resolution has been seen. Therefore, conservative treatment has been advocated, especially in children.

DEVELOPMENTAL DISORDERS

Autism Spectrum Disorder

Definition/Epidemiology

Autism spectrum disorder (ASD) is characterized by 1) impaired social communication and interactions and 2) restricted and repetitive behaviors. The prevalence of ASD is 1/88 and is four times higher in boys than girls.

Pathology

The marked social impairments that characterize ASD are not associated with specific pathology or physical findings.

Clinical Presentation

ASD presents in early childhood with lack of interest or inclination to relate to others. Young children with autism may be physically healthy with good motor skills, but they are hard to engage, do not reliably respond to their name being called, and are slow to develop social and communicative gestures such as pointing and waving.

Diagnosis/Differential

The lack of a clear biologic marker or simple clinical test means that the diagnosis of ASD relies on careful evaluation of the child by experienced examiners. (See [Table 115-2](#) for DSM-V criteria for ASD). ASD may be difficult to diagnosis or distinguish from other forms of mental retardation and psychiatric disorders. ASD should be distinguished from acquired encephalopathies (e.g., epilepsy or encephalitis).

Treatment

The mainstay of treatment is prompt initiation of appropriate behavioral and early enrichment services. The treatments for ASD are aimed at improving social interactions and communication; not surprisingly, there is no set treatment that works for all. Rather, treatment of this disorder often requires coordination of medical, educational, and community services.

Prognosis

Patients with ASD respond to appropriate treatments over time, but these may be highly resource intensive. Some children with ASD, especially those who have normal verbal and intellectual

skills and a higher level of adaptive functioning, may develop skills for independent living and work.

Attention Deficit/Hyperactivity Disorder (ADHD)

Definition/Epidemiology

ADHD is a common neurodevelopmental disorder occurring in about 5% of children and 2.5% of adults, worldwide. ADHD is

marked by inappropriate inattention, impulsivity, and hyperactivity that, in turn, cause impaired functioning, as compared to typical same-age peers.

Pathology

Despite extensive neuroimaging studies, there are no consistent pathologic brain findings or neurotransmitter abnormalities in ADHD. ADHD appears to be highly heritable. The behaviors of ADHD likely are a common phenotype caused by multiple etiologies.

Clinical Presentation

ADHD presents before age 12 years with developmentally inappropriate inattention, hyperactivity, and impulsivity resulting in significant impairment in at least two different settings (e.g., home, school, work, with friends), by multiple observers, and the disruptive symptoms should have persisted for at least 6 months. [Table 115-3](#) lists the symptoms of inattention and hyperactivity/impulsivity that fulfill diagnostic criteria for ADHD.

Diagnosis/Differential

ADHD is a primary disorder of attention and should be distinguished from attentional deficits that are secondary to other disorders. Causes of secondary inattention include learning disability, hearing impairment, and psychiatric disorders. ADHD can also coexist with autism spectrum disorders. [Table 115-3](#) outlines the criteria used for diagnosis of ADHD.

Treatment

Stimulant medications such as methylphenidate and amphetamines are the primary class of medication used in ADHD. Other nonstimulant medications such as atomoxetine and guanfacine are also used. All children with ADHD benefit from behavioral interventions designed to help children re-focus and stay on task.

TABLE 115-2 DSM-5 CRITERIA FOR AUTISM SPECTRUM DISORDER

REQUIRED DOMAIN	CRITERIA
Deficits in social communication/interaction (must have all three criteria)	<p>Problems reciprocating social or emotional interaction, including difficulty establishing or maintaining back-and-forth conversations and interactions, inability to initiate an interaction, and problems with shared attention or sharing of emotions and interests with others.</p> <p>Severe problems maintaining relationships—ranges from lack of interest in other people to difficulties in pretend play and engaging in age-appropriate social activities, and problems adjusting to different social expectations.</p> <p>Nonverbal communication problems such as abnormal eye contact, posture, facial expressions, tone of voice and gestures, as well as an inability to understand these.</p>
Restricted and Repetitive Behavior (at least 2 criteria must be met)	<p>Stereotyped or repetitive speech, motor movements or use of objects.</p> <p>Excessive adherence to routines, ritualized patterns of verbal or nonverbal behavior, or excessive resistance to change.</p> <p>Highly restricted interests that are abnormal in intensity or focus.</p> <p>Hyper or hypo reactivity to sensory input or unusual interest in sensory aspects of the environment.</p>
Symptoms must be present in early childhood, but may not become fully manifest until social demands exceed capacities.	
Symptoms need to be <i>functionally impairing</i> and not better described by another DSM-5 diagnosis.	

TABLE 115-3 DSM-5 CRITERIA FOR ADHD

Inattention: 6 or more symptoms of inattention for children up to age 16, or 5 or more symptoms in those 17 years or older; symptoms present for at least 6 months.

- Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or with other activities.
- Often has trouble holding attention on tasks or play activities.
- Often does not seem to listen when spoken to directly.
- Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., loses focus, side-tracked).
- Often has trouble organizing tasks and activities.
- Often avoids, dislikes, or is reluctant to do tasks that require mental effort over a long period of time (such as schoolwork or homework).
- Often loses things necessary for tasks and activities (e.g. school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).
- Is often easily distracted
- Is often forgetful in daily activities.

In addition, the following conditions must be met:

- Several inattentive or hyperactive-impulsive symptoms were present before age 12 years.
- Several symptoms are present in two or more settings, (e.g., at home, school or work; with friends or relatives; in other activities).
- There is clear evidence that the symptoms interfere with, or reduce the quality of, social, school, or work functioning.
- The symptoms do not happen only during the course of schizophrenia or another psychotic disorder. The symptoms are not better explained by another mental disorder (e.g. Mood Disorder, Anxiety Disorder, Dissociative Disorder, or a Personality Disorder).

Hyperactivity and Impulsivity: 6 or more symptoms of hyperactivity-impulsivity inattention for children up to age 16, or 5 or more symptoms in those 17 years or older; symptoms present for at least 6 months.

- Often fidgets with or taps hands or feet, or squirms in seat.
- Often leaves seat in situations when remaining seated is expected.
- Often runs about or climbs in situations where it is not appropriate (adolescents or adults may be limited to feeling restless).
- Often unable to play or take part in leisure activities quietly.
- Is often “on the go” acting as if “driven by a motor.”
- Often talks excessively.
- Often blurts out an answer before a question has been completed.
- Often has trouble waiting his/her turn.
- Often interrupts or intrudes on others (e.g., butts into conversations or games)

Prognosis

ADHD generally responds to treatment, but there are often residual school difficulties. Improvement depends on age at diagnosis, associated intelligence, and the effectiveness of clinical follow-up.

Rett Syndrome**Definition/Epidemiology**

Rett Syndrome is an X-linked dominant disorder caused by a mutation of the methyl-cytosine binding protein (MECP2), a transcriptional repressor. The prevalence in girls is 1/10,000. In boys, MECP2 mutations are lethal or result in severe encephalopathy.

Pathology

Girls with Rett syndrome have a characteristic constellation of behaviors, but there are no specific pathologic hallmarks. Microcephaly is typically seen, with reduced frontotemporal brain volume. The loss of MECP2 function prevents the protein from regulating gene expression during critical developmental periods in infancy.

Clinical Presentation

Patients with Rett syndrome develop normally during their first year then lose communication skills with deceleration of head growth. A classic feature is loss of hand function and stereotypic hand wringing. Seizures are common.

Diagnosis/Differential

Diagnosis is confirmed by mutational testing of the MECP2 gene. Other conditions that can cause a similar presentation include Angelman syndrome, mitochondrial disorders, and neuronal ceroid lipofuscinosis.

Treatment

Girls usually required ongoing medical management of seizures, along with therapy for their gross and fine motor delays. They receive long-term enrichment and support for their intellectual disability.

Prognosis

While girls survive into adulthood, most will not acquire speech or functional skills; they will remain dependent for their care.

Fragile X Syndrome (FX)**Definition/Epidemiology**

X-linked disorder caused by expanded CGG triplet repeats (>200 CGG repeats) in the first exon of the fragile X mental retardation gene (*FMR1*). Considered an X-linked recessive disorder, females can be symptomatic though they may have milder intellectual disability compared with male. FX is the most common genetic cause of mental retardation, affecting 1/4000 males and 1/8000 females.

Pathology

Boys with FX have a characteristic constellation of behaviors and clinical findings on examination, but there are no specific pathologic hallmarks.

Clinical Presentation

Children with FX syndrome present with mild-to-moderate social anxiety, shyness, distractibility, hyperactivity, stereotypic movements, and intellectual disability. They are generally diagnosed before school age. Children have a distinctive appearance: relative macrocephaly with a long narrow face, and prominent ears, pubertal macro-orchidism, soft skin, and joint laxity. Individuals with 55 to 200 CGG repeats (the “pre-mutation” range) develop ataxia and tremor and cognitive dysfunction (Fragile X associated tremor/ataxia syndrome, FXTAS) in adulthood, at a median age of onset of 60 years.

Diagnosis/Differential

Diagnosis is confirmed by testing for increased repeats in the *FMR* gene. Other etiologies of intellectual disability and autism can be mistaken for FX. Adults with FXTAS are often diagnosed with a variety of other conditions which may present similarly (e.g., parkinsonism, other ataxia syndromes, tremor).

Treatment

Treatment focuses on appropriate behavioral and educational services. In older individuals with movement disorders, the treatment is supportive.

Prognosis

Patients with FX respond to training and education over time, but their intellectual disability may make it difficult for them to live independently. FXTAS tends to cause, gradual, progressive neurologic deterioration over many years.

NEUROCUTANEOUS DISORDERS

Neurocutaneous disorders are congenital, often hereditary disorders characterized by pathognomonic cutaneous and central nervous system lesions that uniquely distinguish each disease. The most important of these syndromes are neurofibromatosis 1 and 2, tuberous sclerosis complex, and Sturge-Weber syndrome. One disorder, von Hippel-Lindau disease, is often included with the neurocutaneous syndromes though skin findings are generally absent. Many neurocutaneous disorders are associated with abnormal, non-cancerous growth of tissues often in a disorganized manner. There is considerable variability in the spectrum of clinical manifestations.

Neurofibromatosis 1 (NF1)**Definition/Epidemiology**

Autosomal dominant disorder caused by mutation of the gene, *NF1*, that encodes the protein, neurofibromin. NF1 is characterized by altered skin pigmentation, tumors, and abnormalities of bones, connective tissue, and brain. This is a relatively common disorder occurring in 1/3500 individuals.

Pathology

Neurofibromin is a tumor suppressor gene, and loss of function can lead to dysregulated cell growth and differentiation, accounting for the variety of tumors—cutaneous neurofibromas, plexiform neurofibromas, and gliomas—that can occur in NF1.

Malignant tumors can also occur, likely due to malignant transformation.

Clinical Presentation

Patients can present with NF1 in a variety of ways. All NF1 patients can be identified by clinical criteria before 20 years of age, but those with mild symptoms may not realize they have the disorder. Diagnosis is based on clinical criteria, having two or more of the following: (1) six or more café-au-lait macules larger than 5 mm in prepubertal patients or more than 15 mm in postpubertal individuals (Fig. 115-2), (2) two or more neurofibromas of any type or one plexiform neurofibroma, (3) axillary or inguinal freckling, (4) sphenoid bone dysplasia, (5) optic nerve glioma, (6) iris Lisch nodules, and (7) a family history of NF1. Other comorbid conditions frequently seen are learning disabilities, macrocephaly, and epilepsy. Important complications of NF1 include scoliosis, gastrointestinal neurofibromas, pheochromocytomas, and renal artery stenosis.

Diagnosis/Differential

The diagnostic criteria outlined above are highly sensitive and specific. Neuroimaging and DNA testing can be useful as well. There are many other disorders that present with hyperpigmented skin macules. Schwannomatosis and neurofibromatosis type 2 (see [Neurofibromatosis type 2](#)) may also be mistaken for NF1.

Treatment

Most individuals with NF1 do not require specific treatment though ongoing periodic surveillance is recommended. Many identified tumors can be followed without surgery. Painful subcutaneous neurofibromas can be excised, though they may recur. Genetic counseling should be provided to all patients and families.

Prognosis

There is as much variability in disease course as there is in clinical presentation. Even within families, some individuals

FIGURE 115-2 Multiple café-au-lait spots in a child with neurofibromatosis type 1. (From Shah KN: The diagnostic and clinical significance of café-au-lait macules, *Pediatr Clin N Am* 57:1131-1153, 2010, Fig. 3.)

may have only skin findings with no symptoms, while others have more complications including malignant transformation of plexiform neurofibromas. While it is an autosomal dominant condition, about half of the cases are sporadic due to new mutations.

Neurofibromatosis 2 (NF2)

Definition/Epidemiology

Neurofibromatosis type 2 (NF2) is an autosomal-dominant adult onset disease characterized by bilateral vestibular schwannomas and brain tumors. It is caused by mutations in the gene, *NF2*, whose protein product is merlin (schwannomin). It affects approximately 1/30,000 individuals.

Pathology

Despite the name, the primary tumor types seen in NF2 are schwannoma and meningioma. Merlin behaves as a tumor suppressor gene.

Clinical Presentation

The diagnosis is generally made when bilateral VIII nerve tumors are identified (often by MRI). The diagnosis can be made based on other clinical criteria (some combination of family history of NF2; presence of characteristic tumors—meningioma, schwannoma, neurofibroma, or posterior subcapsular lenticular opacities.) Symptoms of NF2 begin in the second to fourth decades usually with onset of hearing loss. Skin lesions are present in a minority of patients with NF2.

Diagnosis/Differential

NF2 is frequently misdiagnosed as NF1, especially if there are café-au-lait spots. Patients with NF2 may be misdiagnosed as having isolated meningioma or unilateral vestibular schwannoma if other findings are not sought. Schwannomatosis can be distinguished by the absence of vestibular schwannomas.

Treatment

Eventual removal of the schwannomas and other tumors is usually indicated, though later in life when the tumors are larger and causing significant symptoms. There may be post-surgical complications and tumors may recur.

Prognosis

The vestibular tumors, leading to deafness and vestibular symptoms contribute greatly to the morbidity of this condition. Mortality is related to tumor growth.

Tuberous Sclerosis Complex (TSC)

Definition/Epidemiology

Tuberous Sclerosis Complex (TSC) is an autosomal dominant disorder of early cellular differentiation, proliferation, and migration, which results in hamartomatous lesions involving multiple organs at different stages. Sporadic cases are frequent because of spontaneous mutations. The incidence is 1/6000. Two genes, *TSC1* and *TSC2*, are known to cause TSC and account for

approximately 85% of cases. *TSC1* for approximately 30% and *TSC2* 69% of confirmed cases.

Pathology

The gene product for *TSC1* is hamartin and for *TSC2*, tuberin. Both gene products interact with the mammalian target of rapamycin (mTOR), which is essential in cell growth, proliferation, and angiogenesis. Hamartin and tuberin join to form a combined tumor suppressor complex (*TSC1:TSC2* complex) that acts to inhibit mTOR signaling. Mutations that impair function of the *TSC1:TSC2* complex lead to unregulated growth and proliferation.

Clinical Presentation

Like NF1, TSC has variable presentation depending on the location and extent of lesions. The organs most affected include the brain (cortical tubers, subependymal giant cell astrocytomas [SEGAs]), heart (cardiac rhabdomyomas), skin (facial angiofibromas, hypomelanotic skin macules or “ash leaf spot,” shagreen patches, and subungual fibromas), kidney (renal angiomyolipoma), eye (retinal hamartoma), and lung (pulmonary lymphangioleiomyomatosis). Seizures, most commonly infantile spasms, are the usual early clinical presentation.

Diagnosis/Differential

The spectrum of tumors seen in TSC patients can also be seen in isolation. Biopsy may be needed to distinguish facial angiofibromas from acne and other skin lesions.

Treatment

Treatment is directed toward the epilepsy, especially for infantile spasms. A surgical approach may be necessary for intractable epilepsy. SEGAs are slow growing tumors that may enlarge and cause obstruction, especially during adolescence and early adulthood. Surgical treatment of SEGAs causing hydrocephalus can be effective but associated with significant morbidity. Everolimus is a pharmacologic mTOR inhibitor that is effective at reducing the size and growth of SEGAs and is useful for delaying the need for surgery or in those cases where surgery is not an option. Renal angiomyolipomas are prone to hemorrhage and may need to be resected, and pulmonary lymphangioleiomyomatosis may cause life-threatening complications. These renal and pulmonary tumors may also respond to the mTOR inhibitors, everolimus and sirolimus. Cognitive disability may require special education.

Prognosis

The variability in outcome depends on the extent and type of presenting symptoms. Refractory seizures, developmental delays, and CNS lesions have poor prognoses. The development of renal angioliomas, especially multiple tumors, is also associated with poorer outcome.

Sturge-Weber Syndrome (SWS)

Definition/Epidemiology

SWS is variably characterized by an upper facial vascular nevus (port-wine stain), leptomeningeal angiomas (cerebral

venous malformation), and glaucoma with ocular capillary malformations. The disorder occurs sporadically in less than 1 in 20,000 births.

Pathology

The port-wine stain represent a collection of congested capillaries of subepidermal tissue. If there is an associated leptomeningeal vessel abnormality, it tends to be ipsilateral to the port-wine stain. The leptomeningeal vascular malformation makes the underlying brain susceptible to injury, possibly from venous stasis and abnormal perfusion. Cortical injury can lead to increased susceptibility to seizures, which in turn can increase the metabolic demands of already poorly perfused tissue.

Clinical Presentation

Clinical features include focal epilepsy, cognitive impairment, and, less frequently, hemiparesis, hemianopia, and glaucoma.

Diagnosis/Differential

The diagnosis is usually made by observing a port-wine stain in the cranial nerve V1 distribution with neuroimaging confirmation of the intracranial abnormality. Magnetic resonance imaging is a more reliable tool for diagnosis because calcifications on computed tomographic scans are classic but unnecessary for the diagnosis. However, 80% of people with a facial port-wine stain have no associated brain involvement. SWS should be distinguished from other disorders involving abnormal intracranial vessels and intractable seizures and neurologic dysfunction. These include moyamoya disease, other vascular malformations, and tuberous sclerosis.

Treatment

Aspirin (3-5 mg/kg/day) may reduce the frequency of stroke-like events. Aggressive treatment of seizures is indicated as well. If antiepileptic drugs do not control seizures, surgical excision of epileptogenic areas may be indicated. Laser treatment of the port-wine stain is of cosmetic benefit. Patients require regular ophthalmologist visits to screen for and surgically treat glaucoma.

Prognosis

Prognosis depends on the degree of underlying intellectual and developmental disability and control of seizures.

Von Hippel-Lindau Disease (Central Nervous System Angiomatosis)

Definition/Epidemiology

Von Hippel-Lindau (VHL) disease is an autosomal-dominant disorder caused by a defective tumor suppressor gene, *VHL*, associated with a variety of vascular tumors in multiple organs, including cerebellar and retinal hemangioblastomas and renal cell carcinomas. Incidence is 1/36,000.

Pathology

VHL is a tumor suppressor gene and increases susceptibility to various vascular tumors.

Clinical Presentation

VHL disease is variably associated with retinal angiomas, brain and spinal cord hemangioblastomas, renal cell carcinomas, pheochromocytomas, angiomas of the liver and kidney, and cysts of the pancreas, kidney, liver, and epididymis. Symptoms typically begin during the third or fourth decade. Retinal inflammation with exudates, hemorrhage, and retinal detachment may antedate cerebellar symptoms (headache, vertigo, and vomiting) or signs (incoordination, dysmetria, and ataxia).

Diagnosis/Differential

The diagnosis of VHL disease is suspected in individuals with characteristic lesions such as hemangioblastomas, multiple renal cysts and renal cell carcinoma, pheochromocytoma, and endolymphatic sac tumors. Clinical diagnostic criteria have been established. Molecular genetic testing of *VHL* detects mutations in 90% to 100% of those meeting clinical criteria.

Treatment

Early evaluation and repeated imaging studies are indicated once the diagnosis has been made, and genetically at-risk relatives should also be evaluated. Retinal detachments and tumors are treated by laser therapy. Surveillance for brain tumors, renal cell carcinomas, pheochromocytomas, and epididymal tumors is instituted and appropriated medical and surgical interventions are provided.

Prognosis

Survival depends on management of tumors. Aggressive surveillance has increased survival (where the median had been less than 50 years).

 For a deeper discussion on this topic, please see Chapter 417, "Congenital, Developmental, and Neurocutaneous Disorders," in Goldman-Cecil Medicine, 25th Edition.

Cerebrovascular Disease

Mitchell S.V. Elkind

INTRODUCTION

Stroke is a major public health problem throughout the world due to its high prevalence and mortality, and its association with significant disability even among survivors. Stroke is the fourth leading cause of death in the United States, and a leading cause of death in other countries, particularly in Asia. It is the leading cause of serious disability, and results in enormous costs measured in both health care dollars and lost productivity. Major strides have been made in understanding the epidemiology, etiology, and pathogenesis of cerebrovascular disease, which have led to new approaches to diagnosis and treatment.

DEFINITION AND EPIDEMIOLOGY

The term *cerebrovascular disease* encompasses a host of disorders that share pathology localized to the vessels of the brain and spinal cord, including ischemic stroke, transient ischemic attack (TIA), intracerebral hemorrhage (ICH), subarachnoid hemorrhage (SAH), cerebral venous and sinus thrombosis, and disorders of the vessels themselves unassociated with cerebral injury (Table 116-1). Strokes may also be classified as either ischemic (i.e., due to lack of blood flow) or hemorrhagic. With widespread use of sensitive brain imaging, such as diffusion-weighted MRI (DWI), cerebral injury from ischemia can be seen among patients whose symptoms last only a few minutes. A definition from an expert panel in 2013 defines an *ischemic stroke* as “an episode of neurological dysfunction caused by focal cerebral, spinal, or retinal infarction.” A *stroke due to ICH* was defined as “rapidly developing clinical signs of neurologic dysfunction due to a focal collection of blood within the brain parenchyma or ventricular system which is not due to trauma.” Importantly, the pathology, and not the duration of the symptoms, is considered paramount.

Ischemic strokes may be further classified into etiologic subgroups, based on the mechanism of the ischemia and the type and localization of the vascular lesion. Cardioembolism as the source occurs in 15% to 30% of cases, large vessel atherosclerotic infarction varies from 14% to 40%, and small-vessel lacunar infarcts account for 15% to 30%. Stroke from other determined causes, such as arteritis or dissection, account for less than 5% of cases. In 30% to 40% of ischemic infarcts the cause cannot be determined. Intracranial hemorrhage may also be subdivided into subtypes, based on the site and vascular origin of the blood: subarachnoid, when the bleeding originates in the subarachnoid spaces surrounding the brain; and intracerebral, when the hemorrhage is into the brain parenchyma. Other forms of intracranial bleeding, such as subdural hemorrhage and epidural hemorrhage,

are generally associated with trauma and not usually manifestations of stroke.

A further complicating issue is that advanced imaging techniques permit the detection of abnormalities consistent with infarction or microhemorrhage that are unassociated with any clinical symptoms. Therefore, current definitions distinguish between “stroke,” which involves clinical symptoms, and “cerebral infarction,” which need not be associated with symptoms of cerebral injury. However, these so-called “silent infarcts” are not so silent; they are associated with cognitive decline, dementia, gait disorders, functional disability, and an increased risk of clinical strokes. Because these subclinical infarcts are approximately five times more common than clinically evident strokes, including them (and microbleeds) within the rubric of *cerebrovascular disease* substantially increases the recognized burden of cerebrovascular disease.

In the United States, there are 6.4 million stroke survivors (prevalence of 3%), and there are approximately 600,000 new (incident) and 200,000 recurrent strokes per year. Of these

TABLE 116-1 COMMON FORMS OF CEREBROVASCULAR DISEASE

Ischemic cerebrovascular disease
Symptomatic
• Ischemic stroke
• Cerebral infarction
• Spinal cord infarction
• Retinal infarction
• Transient ischemic attack
• Transient monocular blindness (<i>amaurosis fugax</i>)
Asymptomatic
• Cerebral infarction/spinal cord infarction/retinal infarction
Hemorrhagic cerebrovascular disease
• Intracerebral hemorrhage
• Subarachnoid hemorrhage
• Intraventricular hemorrhage
• Subdural hemorrhage
• Epidural hemorrhage
• Cerebral microbleeds
Other forms of cerebrovascular disease
• Cerebral vein thrombosis
• Dural sinus thrombosis
Disorders of cerebral autoregulation
• Posterior reversible encephalopathy syndrome
• Hypertensive encephalopathy
• Reversible cerebral vasoconstriction syndrome
Vascular abnormalities
• Aneurysms
• Arteriovenous malformations
• Cavernous malformations
• Fibromuscular dysplasia

strokes, about 87% are ischemic infarctions, 10% primary hemorrhages, and 3% SAHs. Among adults age 35 to 44, the incidence of stroke is 30 to 120/100,000 per year, and for those age 65 to 74, the incidence is 670 to 970/100,000 per year. Stroke incidence rates are approximately twice as high for African Americans as for whites. In northern Manhattan, Caribbean Hispanics had an incidence rate intermediate between that of whites and blacks. Temporal trends in stroke incidence suggest that stroke incidence rates have been declining since 1950; however, disparities in stroke incidence and mortality have increased.

Stroke incidence increases with age, but strokes do occur in young adults and children, and may be missed if the diagnosis is not considered. Although stroke incidence rates are higher for men than women at most ages, among young adults the rates are similar or higher among women, probably related to pregnancy, hormonal contraception, and other hormone-related differences. At older ages, incidence rates among women are again greater, and because women tend to live longer than men, overall about 60,000 more women than men have a stroke each year.

MODIFIABLE RISK FACTORS

Well-established modifiable stroke risk factors include hypertension, cardiac disease (particularly atrial fibrillation), diabetes, hyperlipidemia, cigarette use, physical inactivity, alcohol abuse, asymptomatic carotid stenosis, and a history of TIAs (Table 116-2).

Hypertension is the most powerful modifiable stroke risk factor and is associated with both ischemic and hemorrhagic

strokes. Risk of stroke decreases with lower systolic and diastolic blood pressures, and this graded decrement in risk persists down to levels as low as 115/75. There is no clearly defined threshold level below which stroke risk levels off.

Cardiac disease is associated with an increased risk of ischemic stroke. Atrial fibrillation accounts for up to 24% of cerebral infarction in the elderly. Atrial fibrillation (AF) is the most important cardiac cause of embolic stroke, but other cardiac diseases, including valvular heart disease, myocardial infarction (MI), coronary artery disease (CAD), congestive heart failure (CHF), and electrocardiographic evidence of left-ventricular hypertrophy are also associated with stroke risk. Recent evidence also suggests that other atrial abnormalities, such as paroxysmal supraventricular tachycardia, may also increase risk of stroke, even in the absence of atrial fibrillation. Other possible sources of cardiac emboli include patent foramen ovale, aortic arch atherosclerotic disease, atrial septal aneurysms, and valvular strands.

Hyperlipidemia is a stroke risk factor, though its relationship to stroke is more complicated than for heart disease, primarily because of the many types of stroke. Lipid abnormalities, such as elevations in low density lipoprotein (LDL) and decreased levels of high density lipoprotein, are strongly associated with atherosclerotic stroke.

The role of alcohol as a stroke risk factor depends on stroke subtype and quantity consumed. Alcohol consumption has been shown to be a risk factor for both ICH and SAH in a linear fashion, whereas a J-shaped relationship exists between alcohol and ischemic stroke, such that modest consumption (up to two drinks daily in men, and one daily in women) is protective against stroke and heavy consumption (five or more drinks per day) increases risk.

Asymptomatic carotid artery disease, particularly with 75% or greater stenosis, is associated with increased stroke risk (approximately 2% per year). The risk of stroke also depends, however, on the rate of progression of the stenosis, collateral circulation, and the stability of the atherosclerotic plaque.

TIAs are a strong predictor of subsequent stroke. The first several days after a TIA have the greatest stroke risk, with recent series demonstrating a 5% risk at 2 days and 10% risk at 90 days. Patients with transient monocular blindness (*amaurosis fugax*) have a better outcome than those with hemispheric ischemic attacks. The stroke risk after TIA depends on the underlying cause of the ischemia, including the presence and severity of underlying atherosclerotic disease or atrial fibrillation. Age, hypertension, the presence of diabetes, clinical syndromes, including aphasia and hemiparesis, and duration of at least 10 minutes predict patients at higher risk of stroke. Patients with TIA with evidence of infarction on MRI are also at higher risk. Other potential stroke risk factors include migraine, oral contraceptive use, drug abuse, sleep apnea, infection, and inflammation.

PATHOLOGY

Understanding the pathology of cerebrovascular disease requires an appreciation of the vascular anatomy of the brain, the vascular pathologies that can affect brain vessels, and the response of brain tissue to ischemia and hemorrhage.

TABLE 116-2 STROKE RISK FACTORS

NON-MODIFIABLE RISK FACTORS	Age Sex Race/ethnicity Family history Genetic disorders
WELL-ESTABLISHED MODIFIABLE RISK FACTORS	Hypertension/blood pressure Diabetes mellitus/hyperglycemia Cardiac disorders Atrial fibrillation Valvular heart disease Recent myocardial infarction Cardiomyopathy/heart failure Bacterial endocarditis Hyperlipidemia Cigarette smoking Carotid stenosis TIAs Physical inactivity Hypercoagulable states (e.g., antiphospholipid antibody syndrome, cancer-associated) Alcohol abuse Substance abuse (e.g., cocaine, IV drug abuse)
OTHER POTENTIAL RISK FACTORS	Migraine Sleep apnea Cardiac disorders Paroxysmal supraventricular tachycardia Patent foramen ovale/atrial septal aneurysm Aortic atheroma Infections (e.g. varicella zoster virus, influenza) Inflammation Others

Clinical Implications of Vascular Anatomy

The brain is perfused by four major vessels, the paired carotid and vertebral arteries. These originate extracranially as branches off the aorta and great vessels and course through the neck and base of the skull to reach the intracranial cavity (Fig. 116-1). The carotid and its branches constitute the anterior circulation, and the vertebral arteries and its branches the posterior circulation. Anterior and posterior circulations communicate with one another through the posterior communicating arteries. The left and right sides of the anterior circulation communicate with each other through the anterior communicating artery. The major vessels at the base of the brain and these communicating vessels constitute the Circle of Willis, the anastomotic network that allows for collateral blood flow when individual vessels are stenotic or occluded. Because variants in the circle of Willis are common, collateral flow may not be sufficient in many cases of blockage, and the risk of ischemic stroke, therefore, depends on a patient's individual anatomy.

The right common carotid artery usually begins as a branch from the innominate artery, whereas the left common carotid artery originates directly from the aortic arch. The common carotid arteries bifurcate into the internal and external carotid arteries, usually at the level of the fourth cervical vertebrae. The

FIGURE 116-1 Coronal view of the extracranial and intracranial arterial supply to the brain. Vessels forming the circle of Willis are highlighted. A, Artery; ACA, anterior cerebral artery; AICA, anterior inferior cerebellar artery; Ant Comm, anterior communicating artery; CCA, common carotid artery; ECA, external carotid artery; ICA, internal carotid artery; MCA, middle cerebral artery; PCA, posterior cerebral artery; PICA, posterior inferior cerebellar artery; Post Comm, posterior communicating artery; SCA, superior cerebellar artery. (Modified from Lord R: Surgery of occlusive cerebrovascular disease, St. Louis, 1986, Mosby.)

internal carotid arteries have no branches in the neck and face, and enter the cranium through the carotid canal. There are four main segments of each internal carotid artery: cervical, petrous, cavernous, and supraclinoid. The siphon is the term used to describe the hairloop turn made by the cavernous and supraclinoid segments, and it is at this level that the ophthalmic artery originates, providing the first major branch of the internal carotid artery and supplying blood flow to the optic nerve and retina. Thus, internal carotid artery disease commonly causes ocular ischemia, leading to a transient ischemic attack (*amaurosis fugax*) or infarction of the optic nerve or retina, a warning sign of impending cerebral stroke. The internal carotid arteries then give off the superior hypophyseal, posterior communicating, and anterior choroidal arteries, before terminating intracranially by dividing into the middle and anterior cerebral arteries. In addition to the eye, the paired carotid systems supply approximately 80% of the hemispheric blood flow, including the frontal, parietal, and anterior temporal lobes. In up to 15% of individuals, the posterior cerebral artery (PCA) also arises directly from the internal carotid artery (the so-called fetal origin PCA), so that the entire hemisphere including the occipital lobe is supplied by the internal carotid artery. The anterior choroidal artery supplies a number of structures in addition to the choroid plexus, including the inferior portion of the posterior limb of the internal capsule, the hippocampus, and portions of the globus pallidus, posterior putamen, lateral geniculate, amygdala, and ventrolateral thalamus.

The middle cerebral artery (MCA) is the largest branch of the internal carotid artery. Its first portion, or stem, is often referred to as the M1 segment, and this usually bifurcates into superior and inferior divisions or, less often, trifurcates into three major divisions (upper, middle, and lower). The MCA stem gives rise to the medial and lateral lenticulostriates, which supply the extreme capsule, claustrum, putamen, most of the globus pallidus, part of the head and the entire body of the caudate, as well as the superior portions of the anterior and posterior limbs of the internal capsule. The divisions of the MCA supply almost the entire lateral cortical surface of the brain, including the insula, operculum, and frontal, parietal, temporal, and occipital cortices.

The anterior cerebral artery (ACA) also has a proximal, or A1, segment, which ends at the junction with the anterior communicating artery. The ipsilateral ACA then continues as the distal, or A2, segment. An important branch is the recurrent artery of Heubner, which supplies the head of the caudate nucleus, and several cortical branches supply the medial and orbital surfaces of the frontal lobe.

The vertebral arteries generally originate from the subclavian arteries, course through the transverse foramina of the cervical vertebrae, pierce the dura, and enter the cranial cavity through the foramen magnum. The two vertebral arteries join to form the basilar artery at the level of the pontomedullary junction. Anterior and posterior spinal arteries and the posterior inferior cerebellar artery (PICA), which supplies the inferior surface of the cerebellum, arise from the distal segments of the vertebrals. The lateral medulla is supplied by the multiple, perforating branches of PICA or the direct penetrating branches of the vertebral artery. Occlusion of the distal vertebral artery may, therefore, cause

infarction of the lateral medulla (Wallenberg syndrome), characterized by vertigo, imbalance, Horner syndrome, dysphagia, and sensory loss.

After originating as the union of the right and left vertebral arteries, the basilar artery travels up the ventral pons. Paramedian and circumferential penetrating arteries exit the basilar to dive into the pontine parenchyma. Proximally, the basilar gives off the paired anterior inferior cerebellar arteries (AICA), and more distally the superior cerebellar arteries (SCA); these perfuse the ventrolateral aspect of the cerebellar cortex. An internal auditory (labyrinthine) artery arises either directly from the basilar or from the anterior cerebellar artery to supply the cochlea, labyrinth, and part of the facial nerve. Ischemia in the basilar territory may, therefore, cause hearing loss and vertigo, sometimes as an isolated symptom.

The basilar artery terminates in the right and left posterior cerebral arteries (PCAs). A series of penetrators arise from the posterior communicating and posterior cerebral arteries to supply the hypothalamus, dorsolateral midbrain, lateral geniculate, and thalamus. The posterior cerebral artery supplies the inferior temporal lobe, and the medial and inferior surfaces of the occipital lobe. In some patients a single large penetrating vessel at the midline of the terminal basilar artery may supply medial aspects of both thalami (the artery of Percheron); emboli occluding this vessel may, therefore, cause bilateral thalamic infarcts, with a decrease in alertness and vertical gaze abnormalities, without significant motor deficit.

The brain's anastomotic network includes not only the connections through the Circle of Willis, but also intercommunicating systems extracranially and more distal connections intracranially through meningeal anastomoses that cover the cortical and cerebellar surfaces (pial-pial collaterals). These networks all protect the brain from ischemia by providing alternate routes to circumvent obstructions in the main arteries.

Venous anatomy is more variable than arterial. Superficial veins drain into the transverse, superior sagittal, and cavernous sinuses. The deep venous drainage is via the great vein of Galen, which drains into the straight sinus, and in turn drains into the torcula along with the sagittal sinus. Blood drains from the torcula to the transverse sinus, then to the sigmoid sinus, and thereafter the jugular vein. Anterior venous drainage is via the cavernous sinus, which communicates with the contralateral cavernous sinus, the transverse sinus via the superior petrosal sinus, and the inferior petrosal sinus, which drains directly into the jugular bulb.

Vascular Pathogenesis

There are multiple mechanisms leading to brain ischemia. Hemodynamic infarction occurs as a result of reduced perfusion, usually in the setting of arterial stenosis due to atherosclerosis. In some cases, stenosis may be due to arterial dissection, vasculitis, fibromuscular dysplasia, or other arteriopathies. Embolism occurs when a thrombus originating from a more proximal source (e.g., arterial or cardiac) travels through the arteries and occludes a cerebral artery. Paradoxical embolism occurs when a thrombus crosses from the venous circulation to the left side of the heart through a patent foramen ovale or, less commonly, an intrapulmonary arteriovenous shunt. Other particles that may embolize include neoplasm, fat, air, or other foreign substances.

Air emboli can follow injuries or procedures involving the lungs, the dural sinuses, or jugular veins. Fat embolism usually results from a bone fracture. Septic emboli arise from bacterial endocarditis.

Intracranial hemorrhage results from the rupture of a vessel anywhere within the cranial cavity. Intracranial hemorrhages may be classified by location (e.g., extradural, subdural, subarachnoid, intracerebral, intraventricular), by the nature of the ruptured vessel (e.g., arterial, capillary, venous), or by cause (e.g., primary, secondary). Trauma is often involved in the generation of extradural hematoma from laceration of the middle meningeal artery or vein, and subdural hematomas from traumatic rupture of veins that traverse the subdural space.

Intracerebral hemorrhage is characterized by bleeding into the substance of the brain, usually originating from a small penetrating artery. Hypertension has been implicated as the cause of weakening in the walls of arterioles and the formation of microaneurysms (i.e., Charcot-Bouchard aneurysms). The most common sites for hypertensive arterial hemorrhage are the putamen, pons, cerebellum, and thalamus. Blood under arterial pressures destroys or displaces brain tissue. Amyloid angiopathy, due to the vascular deposition of β -amyloid protein similar to that seen in Alzheimer disease has been implicated as an important cause of lobar hemorrhage in elderly patients. Other causes of hemorrhage include arteriovenous malformations, aneurysms, moyamoya disease, bleeding disorders or anticoagulation, trauma, tumors, cavernous angiomas, and illicit drug abuse.

Subarachnoid hemorrhage occurs when blood is localized to the surrounding membranes and cerebrospinal fluid. It is most frequently caused by leakage of blood from a cerebral aneurysm. The combination of congenital and acquired factors leads to a degeneration of the arterial wall and the release of blood, under arterial pressures, into the subarachnoid space and cerebrospinal fluid. Aneurysms may be distributed at different sites throughout the base of the brain, particularly at the origin or bifurcations of arteries of the circle of Willis. Other secondary causes that may lead to SAH include trauma, arteriovenous malformations, bleeding disorders or anticoagulation, amyloid angiopathy, or cerebral sinus thrombosis.

The most common intrinsic disorder of the cerebral blood vessels is atherosclerosis, which shares similarities in pathology with atherosclerosis throughout the body. Arteriosclerotic plaques may develop at any point along the carotid artery and the vertebrobasilar system, but the most common sites are the bifurcation of the common carotid artery, the origins of the MCAs and ACAs, and the origins of the vertebral from the subclavian arteries (Fig. 116-2). In the past it was thought that intracranial atherosclerotic disease required significant stenosis (>50%) to cause symptoms. However, recent pathological and radiological studies provide evidence that substenotic lesions can also cause strokes due to plaque rupture and acute thrombosis, as is the case elsewhere in the body.

Small-vessel disease refers to the occlusion of a penetrant branch of a larger artery, usually due to microatheroma or to lipohyalinosis, a degenerative disorder of the vessel characterized by deposition of fatty and proteinaceous material. Hematological disorders and coagulopathies, including leukemia, Waldenstrom macroglobulinemia, polycythemia, primary and secondary

FIGURE 116-2 Sites of predilection for atheromatous plaque. (From Caplan LR: *Stroke: a clinical approach*, ed 2, Boston, 1993 Butterworth-Heinemann.)

antiphospholipid antibody syndrome, and genetic defects of the coagulation cascade, may also lead to occlusive thrombi and emboli.

The cerebral circulation differs from the systemic circulation. The brain is protected by the anastomoses described above. In addition, *cerebral autoregulation* maintains a constant cerebral perfusion pressure over a range of systemic blood pressures (Fig. 116-3). Cerebral arterioles have a well-developed muscular coat that allows constriction in response to increased blood pressure, and dilation with hypotension. The arterioles are also exquisitely sensitive to changes in peripheral arterial concentrations of carbon dioxide (PaCO_2) and oxygen (PaO_2). When the partial pressure of CO_2 decreases, such as after hyperventilation, the arterioles constrict and blood flow is reduced. In healthy individuals, cerebral autoregulation maintains a constant cerebral blood flow over mean arterial pressures of 60 to 140 mm Hg. In patients with chronic hypertension, the autoregulatory curve is shifted to the right, so that even minor reductions in blood pressure levels may not be tolerated. At blood pressures above these limits, moreover, as in severe hypertension, autoregulatory capacity may be overwhelmed, leading to breakthrough edema and hemorrhage. In the setting of infarction or hemorrhage, cerebral autoregulation is also impaired, resulting in cerebral dependence on systemic blood pressure to maintain adequate perfusion. Thus, decreasing the blood pressure in the setting of acute ischemia is hazardous.

FIGURE 116-3 Autoregulatory cerebral blood flow (CBF) response to changes in mean arterial pressure in normotensive and chronically hypertensive persons. Note the shift of the curve toward higher mean pressures with chronic hypertension. (From Pulsinelli WA: *Cerebrovascular diseases-principles*. In Goldman L, Bennett JC, editors: *Cecil textbook of medicine*, ed 21, Philadelphia, 2000, Saunders, p 2097.)

Specific disorders may originate from autoregulatory dysfunction: posterior reversible encephalopathy syndrome (PRES) and the reversible cerebral vasoconstriction syndrome (RCVS). In posterior reversible encephalopathy syndrome, there is loss of autoregulatory control with leakage of fluid across the blood-brain barrier, primarily in the posterior regions of the brain. Patients present with elevated blood pressures, headaches, seizures, and loss of visual function. Reversible cerebral vasoconstriction syndrome, a recently recognized syndrome, remains incompletely characterized, and shares features with posterior reversible encephalopathy syndrome. The two disorders overlap in 10% or more of cases. Patients with reversible cerebral vasoconstriction syndrome are typically young women who present with acute, severe headache, have minimal or no neurological deficits, and may have evidence of non-aneurysmal, superficial SAH as well as vasospasm of the cerebral arteries. Sympathetic innervation of the vessels is also less in the posterior circulation than anteriorly, leading to a reduced ability of the posterior circulation to adapt to changes in blood pressure, and may contribute to the propensity for edema to form in the occipital lobes during hypertensive crises.

In addition, focal cerebral activity, such as occurs when activating brain regions responsible for moving a limb, is accompanied by accelerated metabolism in the appropriate region, and is accommodated by slight increases in local blood flow and oxygen delivery. Exploitation of this increased local energy demand and delivery is what allows imaging of functional brain activity using MRI, which can detect subtle changes in regional cerebral blood flow.

Intracerebral capillaries also lack adventitia, with astrocytes serving as the vascular component of the neurovascular unit. Tight junctions at the capillary level play an important role in the blood-brain barrier, which limits permeability between the vascular compartment and the brain tissue.

Injury to Brain Tissue

The adult brain weighs about 1500 g, or 2% of total body weight, but accounts for 20% of the total body oxygen consumption. Because the brain cannot store much energy, dysfunction results after only a few minutes of deprivation when either oxygen or glucose content is reduced below critical levels. In the resting state, normal total cerebral blood flow is 50 mL/min per 100 g of brain tissue.

Neuronal dysfunction occurs at cerebral blood flow levels below 50 mg/dL, and irreversible neuronal injury begins at levels below 30 mg/dL. Both the degree and duration of reductions in cerebral blood flow are related to the likelihood of permanent neuronal injury. When blood supply is completely interrupted for 30 seconds, brain metabolism is altered; after 1 minute, neuronal function may cease. After 5 minutes, anoxia initiates a chain of events that may result in cerebral infarction; however, if oxygenated blood flow is restored quickly enough, the damage may be reversible, as with a TIA.

Research into the cellular basis of cerebral ischemia has led to the concept of the “ischemic cascade.” As perfusion of the brain decreases, a chain of events at the neuronal level begins with failure of the membrane sodium/potassium (Na/K) pump, the depolarization of the neuronal membrane, the release of excitatory neurotransmitters such as glutamate and glycine that hyperstimulate their receptors, and the opening of calcium channels. Calcium enters the neuron through various voltage-sensitive and receptor-mediated channels (e.g., the *N*-methyl-D-aspartate receptor). The influx of calcium is at the root of further neuronal injury, with damage to organelles and further destabilization of neuronal metabolism and normal function resulting. These events may lead to delayed neuronal death, even after restoration of blood flow, and are a target of experimental neuroprotective strategies.

Recent research has distinguished between the “core” infarct and an “ischemic penumbra,” or shadow. The core represents a central region of necrosis, or tissue that dies very quickly after blood flow ceases. The penumbra represents the surrounding region of brain tissue, in which neurons are dysfunctional but potentially salvageable. Recanalization of occluded vessels with blood flow into infarcted tissue, particularly when delayed, results in “reperfusion injury.” Increased use of MRI has shown that petechial hemorrhagic infarction is very common, occurring in the majority of strokes, even when not suspected clinically.

CLINICAL PRESENTATION

The signs and symptoms of strokes are varied, and depend on the type of stroke, the region of the nervous system affected by the lack of flow or hemorrhage, and the patient’s handedness (Table 116-3). In general, embolic ischemic strokes are characterized by the sudden onset of a neurological deficit, generally painless. Thrombotic strokes may have a stuttering or progressive course due to fluctuating hypoperfusion and gradual occlusion. Arterial dissections, as well as hemorrhages, are more often associated with headaches than ischemic stroke. Hemorrhagic strokes and large hemispheric infarcts can lead to decrease in consciousness due to increased intracranial pressure.

TABLE 116-3 CLINICAL MANIFESTATIONS OF ISCHEMIC STROKE

OCCLUDED VESSEL	CLINICAL SIGNS
ICA	Ipsilateral blindness (variable) MCA syndrome
MCA	Contralateral hemiparesis, hemisensory loss (face or arm more than leg) Aphasia (dominant) or anosognosia (nondominant) Homonymous hemianopsia (variable)
ACA	Contralateral hemiparesis, hemisensory loss (leg more than arm) Abulia (especially if bilateral)
VA or PICA	Ipsilateral facial sensory loss, hemiataxia, nystagmus, Horner syndrome Contralateral loss of temperature or pain sensation Dysphagia
SCA	Gait ataxia, nausea, vertigo, dysarthria
BA	Quadriparesis, dysarthria, dysphagia, diplopia, somnolence, amnesia
PCA	Contralateral homonymous hemianopsia, amnesia, sensory loss

ACA, Anterior cerebral artery; BA, basilar artery; ICA, internal carotid artery; MCA, middle cerebral artery; PCA, posterior cerebral artery; PICA, posterior inferior cerebellar artery; SCA, superior cerebellar artery; VA, vertebral artery.

Most emboli occur in the territory of the MCAs. Lesions of the dominant (almost always left) hemisphere are characterized by variable combinations of right hemiparesis, right hemisensory loss, right visual loss, impaired gaze to the right side of space, and language disturbance. When the superior division of the middle cerebral artery is affected, the language impairment is predominantly motor: the patient either cannot speak or produces sparse, agrammatic speech, despite an ability to fully comprehend spoken and written material. When the inferior division is affected, the patient may produce fluent, prosodic, but nonsensical speech and be unable to follow instructions. Larger infarcts of the dominant hemisphere produce a total loss of language function, leaving the patient mute and uncomprehending.

Lesions of the non-dominant (right) hemisphere produce deficits of the left side of the body. Language is preserved but the patient may demonstrate impaired attention, particularly to the left side of space and fail to appreciate the presence of people or objects to their left, and may even fail to recognize the left side of their own body (asomatagnosia). This neglect phenomenon may extend even to an awareness of any deficit of functioning on their part, and they may be unaware there is a problem (anosagnosia). These patients may be found at home, lying on the floor paralyzed yet unaware that anything is the matter; their unawareness can delay their presentation to the hospital for treatment and similarly limit their participation in rehabilitation. Lesions in the right hemisphere may also cause dysprosody, the non-dominant equivalent of aphasia, which is characterized by a lack of the emotional and gestural components of speech, despite preservation of its semantic content; many of these patients have a flat affect or appear to be depressed.

Infarcts in the territory of the anterior cerebral arteries often cause weakness limited to the legs, due to location of the representation of the legs in the medial part of the hemispheres. They may have incontinence, lack initiative (abulia), and have gaze

palsies. In some cases their deficits may be more extensive and mimic those of middle cerebral artery infarctions. Posterior cerebral artery infarcts lead to visual loss, often without any motor deficit. With involvement of the medial temporal lobes supplied by the PCAs, there may also be behavioral disturbances, including delirium and amnesia.

Brainstem infarcts cause specific syndromes due to the affected neural pathways and nuclei. Midbrain infarcts often produce vertical gaze deficits and impaired consciousness if the reticular activating system is involved.

Many cerebral infarctions do not cause weakness, such as fluent (or Wernicke's) aphasia, cortical visual loss, and Wallenberg syndrome. Because the inferior division of the MCA supplies the lateral temporal lobe and parietal lobes, including Wernicke's area, occlusion of that vessel may cause a prosodic, fluent speech with multiple paraphasic errors and poor comprehension, while sparing the motor strip in the frontal lobe. Emboli traveling up the basilar artery may cause significant infarction in the territory of both posterior cerebral arteries, causing complete blindness, sometimes without awareness of the deficit on the part of the patient, due to infarction of both occipital lobes (the "top of the basilar syndrome"). Behavioral abnormalities, memory loss, and eye movement abnormalities may also occur, due to the involvement of the medial temporal lobe structures and the midbrain eye movement centers. Small emboli to branches of the superior division of the MCA may cause focal weakness of the hand, particularly fine finger movements, simulating a peripheral compression neuropathy.

In patients presenting with dizziness, it is particularly difficult to distinguish stroke from vestibular neuronitis or Ménière's disease (see Chapter 113). The presence of a normal head-thrust test, skew deviation, or direction-changing nystagmus are all signs of stroke, rather than a peripheral cause. Patients should be followed until they can walk without imbalance; patients with nausea and vomiting due to cerebellar infarction may develop fatal brainstem compression due to swelling.

The signs and symptoms of *subarachnoid hemorrhage* differ from other stroke types due to the absence of focal deficits. Instead, patients present with abrupt onset of severe headache (i.e., "the worst headache of my life"), vomiting, altered consciousness, and sometimes coma, typically without localizing signs.

Thrombosis of cerebral veins or the larger draining dural sinuses present with a combination of headache due to elevated intracranial pressure, seizures, and focal deficits due to hemorrhage. Rarely the syndrome of *thunderclap headache*, or sudden severe headache without any focal signs similar to that occurring in SAH, may be due to venous thrombosis. Occlusion of the cerebral venous sinuses may occur in association with a hyperviscosity or hypercoagulable state, including pregnancy or hormonal contraceptive use. Imaging findings include bilateral hemorrhagic infarctions in a parasagittal distribution and extensive white matter edema. Contrast-enhanced CT may demonstrate the *empty delta* sign, indicating a filling defect in the sagittal sinus. Magnetic resonance venography (MRV) and T1 weighted MRI images confirm the presence of thrombus; cerebral angiography is seldom needed to confirm the diagnosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The benefit of thrombolytic therapy within 3 hours of onset of acute ischemic stroke requires urgent differentiation of ischemic stroke from hemorrhage and other causes of sudden neurological symptoms. Headache, vomiting, seizures, and coma, are more common in hemorrhagic stroke, though these are never reliable enough to preclude imaging. The distinction is straightforward in most cases once a head CT is performed. The hyperdense signal of blood in the parenchyma on CT almost invariably distinguishes hemorrhage from ischemia. In exceptional cases the typical hyperdensity of ICH is absent owing to severe anemia or to its subacute state, during which blood may be indistinguishable from brain tissue. Certain imaging findings on initial CT further support a presumed diagnosis of infarction, such as a hyperdense vessel sign indicative of thrombus in the vessel, or loss of the gray-white junction and sulci in the cortex, and loss of the demarcation of the insular cortex and deep gray nuclei, both of which are early indicators of ischemia and edema (Fig. 116-4). CT angiography often identifies the site of vascular occlusion.

Imaging in the setting of suspected acute ischemia does not definitively diagnose ischemia, but rather excludes hemorrhage; if clinical symptoms are consistent with cerebral ischemia, then thrombolytic treatment is indicated. Primary stroke centers must perform and interpret CT scans within 30 minutes of the arrival of a patient with suspected stroke. MRI can also effectively exclude acute hemorrhage, and diffusion-weighted imaging sequences are more sensitive to the earliest changes of ischemia (Fig. 116-5), but the speed and availability of CT make it the initial imaging modality of choice at most centers. MRI scanning may then be used to provide additional information. Specific MRI sequences have greater sensitivity to blood than CT, and many identify hemorrhagic infarction missed by CT.

Clinical features at stroke onset may suggest a subtype of cerebral infarction but require confirmatory laboratory data. Cerebral embolism is suggested by sudden onset and a syndrome of circumscribed focal signs attributable to cerebral surface infarction, such as pure aphasia or pure hemianopia. Unless the source of embolization is obvious on hospital admission, blood cultures, electrocardiographic monitoring, and echocardiography are indicated.

A diagnosis of atherosclerotic infarction is suggested if there were previous TIAs, particularly when the symptoms are stereotypical. Doppler ultrasonography or MRA can usually identify the stenosis. In equivocal cases, CT angiography or conventional angiography may be needed. Small penetrating vessel infarcts, *lacunar infarcts*, usually spare cortical functions, such as language and cognition, but cause loss of elementary neurologic function, such as strength, sensation, and coordination. Up to 25% of patients with lacunar infarcts have large-vessel disease or a cardioembolic source, so it is important to carry out a complete etiologic evaluation in all stroke patients.

Up to 50% of patients with transient deficits lasting less than 24 hours have evidence of infarction on imaging, and the risk of stroke and other vascular events is as high after TIA as after completed stroke. In the acute setting, when decisions about thrombolysis must be made, it is virtually impossible to know which

FIGURE 116-4 Early signs of infarction on computed tomography of the brain. **A**, Hyperdense middle cerebral artery sign (red arrow), and **B**, hypoattenuation of the left caudate and lentiform nuclei, loss of the insular ribbon, and sulcal effacement (outlined in red).

FIGURE 116-5 Magnetic resonance imaging scan of the brain of the same patient shown in Figure 116-4. **A**, Diffusion-weighted image shows bright signal in the left middle cerebral artery territory. **B**, Apparent diffusion coefficient shows dark signal in the same area, confirming acute infarction.

patients with ischemia will have symptoms resolve without infarction (thus, having a TIA) and which will have a completed infarction. Patients with either stroke or TIA need immediate attention to secondary prevention strategies. In terms of choosing treatments, the important issue is to identify the cause of the cerebral ischemia, rather than its duration. Entities other than cerebral ischemia can masquerade as strokes and TIAs. Among patients diagnosed with stroke in emergency departments, 20% or more have a stroke *mimic*, including seizure, migraine, systemic

infection, brain tumor, and toxic-metabolic encephalopathy. Other sources of misdiagnosis are listed in Table 116-4.

In patients with a prior history cerebral infarct or hemorrhage, new *metabolic derangements*, including infections, may precipitate a recrudescence of the original stroke syndrome. Hypoglycemia, hyponatremia, urinary tract infection, pneumonia, and starting initiation of a psychotropic medication can each precipitate this phenomenon. The patient returns to normal over hours to days when the new insult is treated or reversed. Such

TABLE 116-4 STROKE MIMICS AND DIFFERENTIAL DIAGNOSIS

COMMON MIMICS
Metabolic encephalopathy (hypoglycemia, hyponatremia, etc.)
Systemic infection
Seizure
Migraine
Brain tumors
OTHER MIMICS
Transient focal neurological symptoms associated with amyloid angiopathy
Positional vertigo
Cardiac events
Syncope
Trauma (especially acceleration-deceleration without evidence of external injury)
Subdural hematoma
Herpes simplex virus encephalitis
Transient global amnesia
Dementia
Demyelinating disease

Parkinsonism
Hypertensive encephalopathy
Conversion disorder
Intoxication/substance abuse

metabolic and infectious causes of neurologic deterioration must be excluded in patients with a history of earlier brain injury before diagnosing a new stroke. Focal signs may also occur with metabolic disturbances in patients without a prior history of stroke.

External signs of injury are usually present in brain *trauma*, but they need not be present after acceleration-deceleration injury, such as from a motor vehicle accident. The most frequent sites of brain contusions are the frontal and temporal poles, which are not typical locations for strokes.

Seizures may occasionally complicate acute stroke, but they may also mimic stroke. Unlike stroke, seizures are often characterized by obtundation, an amnesic state, clonic activity, incontinence, or tongue biting. The postictal deficit, often called a *Todd's paralysis*, resembles stroke and weakness or language and other cortical deficits may occur. The deficits after seizure usually resolve within hours after the seizure, but occasionally persist for up to a week, making the distinction from stroke difficult. Seizures may also develop months or years after an infarct or hemorrhage, and the postictal state in these patients may recapitulate the initial stroke syndrome.

Migraine with persistent aura often mimics stroke or TIA. Aura alone, without headache (i.e., acephalgic migraine), is sometimes experienced by those who previously suffered from migraine with aura. Migraine aura typically produces a visual disturbance that marches across the vision of both eyes as an advancing, enlarging blind spot that takes 20 to 30 minutes to resolve. Subsequent unilateral, pounding headache suggests the diagnosis, but may not occur. Less often, migrainous auras take the form of sensory symptoms. The speed of the march is generally slower than the rapid spread of symptoms in stroke.

As many as 10% of *brain tumors* present with acute transient symptoms reflecting intratumoral hemorrhage or focal seizures. Seizures often precede focal signs. CT scan usually demonstrates an enhancing mass even when symptoms are mild.

TABLE 116-5 EVIDENCE-BASED PRIMARY PREVENTION OF ISCHEMIC STROKE

RISK FACTOR	TREATMENT
Hypertension	Anti-hypertensives
Myocardial infarction	HMG-CoA reductase inhibitors
Hyperlipidemia	HMG-CoA reductase inhibitors
Atrial fibrillation	Anticoagulation (warfarin, other agents)
Diabetes mellitus/vascular disease	ACE inhibitor
Diabetes mellitus type II, obesity	Metformin
Asymptomatic carotid stenosis (60-99%)	Carotid endarterectomy
High vascular risk populations	Antiplatelet therapy

TREATMENT

Stroke prevention and treatment are directed toward: (1) preventing the first stroke (primary prevention); (2) limiting damage from the stroke; (3) optimizing functional recovery following stroke; and (4) avoiding recurrence (secondary prevention). Specific measures for treatment and prevention depend on the patient's risk factors and stroke mechanism. The diagnostic evaluation of the stroke patient dictates optimal therapy.

Primary Prevention of Stroke

Randomized trials have demonstrated that specific interventions prevent first stroke among patients with specific risk factors (Table 116-5). Treatment of hypertension, for example, is associated with up to a 45% reduction in the risk of stroke (Level A). Among patients with atrial fibrillation, the use of warfarin is associated with a 60% to 70% relative reduction in risk of stroke, though younger patients without any accompanying heart disease, hypertension, or diabetes may be managed with antiplatelet agents alone (Level A). Hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, or statins, have been shown in some primary prevention studies, and in studies of patients with heart disease, to reduce the risk of a first stroke as well as that of heart disease (Level A). The effects on stroke risk are more modest than the effects on heart disease, possibly reflecting the greater heterogeneity among causes of stroke compared to heart disease. For patients with asymptomatic carotid stenosis of at least 60%, carotid endarterectomy reduces the risk of stroke, though the effect is much more modest than in symptomatic patients, and the number of patients needed to treat to prevent one stroke is greater. Because many of the large randomized trials of endarterectomy for asymptomatic patients were conducted in the era before the current recommended use of statins and antiplatelet agents, it is no longer clear that surgery is superior to medical therapy. New trials are addressing medical versus surgical treatment.

Antiplatelet therapy is not of established benefit for prevention of a first stroke. In a large primary prevention study, for example, aspirin use was associated with an increased risk of both ischemic and hemorrhagic stroke, despite reducing the risk of ischemic heart disease. However, other studies have shown that aspirin reduces the risk of ischemic stroke among women over the age of 45 (Level B).

Observational studies provide evidence that certain behaviors prevent stroke. Smoking cessation leads to a reduction by 5 years in stroke risk to levels similar to non-smokers. Consumption of alcohol in moderation, up to 2 drinks daily for men and one daily for women is associated with a lower level of stroke risk than in those who do not drink. Physical activity, weight loss when appropriate, and management of diabetes are recommended.

Acute Treatment of Ischemic Stroke

For patients with ischemic stroke evaluated within 3 hours of symptom onset with no evidence of hemorrhage on a brain CT or MRI, recombinant tissue plasminogen activator (rt-PA), a thrombolytic agent, improves functional outcomes at 3 months compared to placebo. Among the 624 ischemic stroke patients treated within 3 hours in the original landmark study, the proportion of patients achieving normal or near-normal neurological and functional status by 3 months was significantly higher among those receiving rt-PA, though there was no definite benefit at 24 hours. The proportion of patients who achieved independence in their performance of activities of daily living was increased from 38% to 50%, an absolute benefit of 12%. The absence of an immediate (24-hour) benefit, coupled with the finding of a benefit at 3 months, is consistent with the hypothesis that thrombolytic treatment works to reduce the size of the infarct penumbra by reperfusing tissue before permanent infarction of the entire territory occurs, despite some irreversible injury to a core component.

Patients treated with rt-PA had a tenfold increase in incidence of hemorrhagic conversion of the infarction (from 0.6% in placebo-treated patients to 6.0% in rt-PA-treated patients). Overall, the rates of neurological deterioration and mortality within the first day after stroke were similar between the groups. Rt-PA was approved for patient use by the FDA in 1996, and it is now considered standard of care for ischemic stroke patients presenting within 3 hours (Level A). Specific guidelines for eligibility and exclusion must be met when using rt-PA to reduce the risk of complications (Table 116-6).

Because of the potential to reduce cerebral perfusion below the limits permitted by autoregulation in the setting of acute brain injury, current guidelines recommend that blood pressure not be reduced acutely after ischemic stroke, and systolic blood pressure levels as high as 220 mm Hg are allowed. Before and following thrombolytic treatment, however, systolic blood pressure should be kept below 180 mm Hg to reduce the risk of hemorrhagic conversion. In addition, antiplatelet and anticoagulant medications must be withheld for 24 hours after rt-PA.

Subsequent meta-analyses and individual trials have demonstrated that the benefit of thrombolytic therapy decreases as the time interval between symptom onset (the presumed beginning of ischemia) and treatment increases, but that the therapeutic time window may persist as long as 4.5 hours after stroke. Advanced imaging techniques, such as diffusion-weighted (DWI) and perfusion-weighted images (PWI), that can distinguish irreversibly injured versus underperfused or “at risk” tissue have been investigated as a means to identify ischemically viable tissue that may respond to revascularization. Recent trial results, however, have not confirmed their value, at least using the imaging parameters under study.

TABLE 116-6 ELIGIBILITY AND EXCLUSION CRITERIA FOR TREATMENT OF ACUTE ISCHEMIC STROKE WITH INTRAVENOUS RT-PA

ELIGIBILITY

Age \geq 18 years
Diagnosis of ischemic stroke causing measurable neurological deficit
Well-documented onset of symptoms $<$ 4.5 hours before beginning treatment

MAJOR EXCLUSION CRITERIA

Stroke or head trauma within the preceding 3 months
Major surgery within the preceding 2 weeks
History of intracerebral hemorrhage
Systolic blood pressure $>$ 185 mm Hg
Diastolic blood pressure $>$ 110 mm Hg
Rapidly improving or minor neurological symptoms and signs
Symptoms suggestive of subarachnoid hemorrhage
Gastrointestinal or urinary tract bleeding within 3 weeks
Arterial puncture at a noncompressible site within 1 week
Platelet count $<$ 100,000/mm³
INR $>$ 1.7

RELATIVE EXCLUSION CRITERIA (MUST WEIGH RISKS AND BENEFITS)

Seizure at stroke onset
Myocardial infarction within 6 weeks
Infective endocarditis
Hemorrhagic eye disorder
Blood glucose $<$ 30 mg/dL (2.7 mmol/L)
Blood glucose $>$ 400 mg/dL (21.6 mmol/L)
Patients requiring very aggressive therapy for blood pressure reduction

Interventional techniques to revascularize occluded vessels has promise in the management of patients with ischemic stroke. For patients with MCA occlusions presenting up to 6 hours after symptom onset, there is evidence that intra-arterial thrombolytic agents delivered via catheter into the face of the occluding thrombus can improve functional outcomes, despite an increase in risk of hemorrhage similar to that seen with intravenous rt-PA (Level B). More recently, the FDA has approved the use of mechanical devices specifically engineered to facilitate clot extraction and dissolution in the setting of ischemic stroke. These devices are promising in that they are associated with higher recanalization rates of occluded vessels than occurs spontaneously, but they have not yet been demonstrated to lead to better clinical outcomes than standard treatment with intravenous rt-PA in randomized trials. There is evidence, however, that earlier treatment (within 2 hours) may lead to better outcomes, and further studies are ongoing to test whether other devices used quickly enough will improve clinical outcomes.

Treatment with heparin and various heparinoids for acute stroke are not of benefit and are not recommended in acute stroke. In some patients with massive hemispheric strokes, surgical decompression (hemicraniectomy) can be lifesaving with acceptable functional outcomes, particularly for younger patients (Level A).

Since stroke is characterized by a cascade of events that can cause further neuronal injury for hours or days after stroke, experimental animal stroke studies have tested strategies that might limit this injury (i.e., neuroprotection), including drugs targeting N-Methyl-D-Aspartate (NMDA)-receptors, glycine receptors, calcium channels, adhesion molecules, free radicals, albumin, inflammation, and membrane constituents. However, none of these have been of benefit in human clinical trials.

Treatment of Intracerebral Hemorrhage

Treatment of ICH is primarily supportive. Many patients require management in the intensive care setting to manage elevated blood pressure and secondary complications, such as respiratory failure, aspiration, and hemodynamic instability in severely neurologically compromised patients. In many cases, patients also require management of intracranial pressure using osmotic agents, such as mannitol or hypertonic saline, or therapeutic hyperventilation. In some patients, surgical evacuation of hematomas may be lifesaving, although trials have thus far failed to show that most ICH patients benefit from surgical decompression. Among more than 1000 participants randomized in a large international study, there was no evidence of benefit of surgical over medical therapy, apart from a potential benefit in the subgroup of patients with small superficial hemorrhages. Most hemorrhages that occur deep within the hemispheres probably cause the majority of their damage immediately after the ictal hemorrhage, so that evacuation does not save tissue and may introduce further damage.

One of the major recent insights into the pathogenesis of cerebral injury associated with ICH has been the recognition that a large proportion of hemorrhages continue to expand during the early hours after onset. As a result, there has been increased interest in the use of prothrombotic agents to reduce this expansion and to limit secondary cerebral injury. Though preliminary studies on the potential benefits of infusing factor VII as a prothrombotic agent showed promise, subsequent and more definitive studies did not confirm a benefit in the majority of patients, although it remains possible that subgroups of patients, including those with warfarin-associated hemorrhage, may benefit.

For cerebellar hemorrhages, surgical decompression may be lifesaving, and it is essential to recognize the signs and symptoms of incipient brainstem compression and herniation (i.e., headache, vertigo, nausea, vomiting, and truncal ataxia without focal weakness, declining sensorium, and gaze-palsy). Neuroimaging studies that support the need for surgical decompression include hematoma greater than 3 cm, fourth ventricular shift, cisternal obliteration, and ventricular enlargement. Lumbar puncture is contraindicated with ICH, particularly with cerebellar hemorrhages because life-threatening tonsillar herniation and midbrain compression may occur. Great caution must be taken in these patients subjected to ventriculostomy for the purposes of reducing intracranial pressure because upward cerebellar herniation may occur.

The management of aneurysmal SAH is complicated. Recurrent bleeding risks and mortality are high; therefore, definitive therapy is elimination of the ruptured aneurysm. This may be accomplished surgically or with interventional embolization techniques, such as with coils deposited in the aneurysm. Even after securing the aneurysmal site of bleeding, however, several other complications may ensue, including vasospasm, cerebral infarction, cerebral edema, seizures, ventricular dilatation, the syndrome of inappropriate ADH secretion (SIADH), and cardiac failure. Antifibrinolytic agents, such as epsilon-amino-caproic acid, used to preserve the thrombus around an aneurysm, and thereby preventing rebleeding, have been unsuccessful.

Transcranial Doppler screening may be used daily to detect early changes of vasospasm; continuous EEG monitoring and multimodality monitoring of vital signs are other emerging ways to detect cerebral dysfunction while still reversible. Vasospasm may be minimized with the calcium channel antagonist, nimodipine, which crosses the blood-brain barrier; use of nimodipine has become standard of care in SAH patients for up to 3 weeks after hemorrhage. Hydration, hyperosmolar therapy, hypertensive therapy, and angioplasty of vascular spasm may also be used to reduce risk of infarction. Hydrocephalus may require ventricular shunting.

Rehabilitation and Recovery

A team approach to stroke rehabilitation, starting with a stroke recovery unit with experienced physiatrists and physical therapists, has proven beneficial for the optimum recovery of patients. A specialized stroke unit is particularly helpful in avoiding complications such as infections, contractures, decubiti, and in maximizing independence for patients. Speech and occupational therapists help patients improve their swallowing, communication, and daily living skills.

Constraint-induced therapy is a specific type of physical therapy that involves having a hemiparetic patient wear a large mitt to prevent use of the unaffected limb for several hours daily, forcing the patient to use the affected limb for most tasks. In a randomized trial, constraint-induced therapy with intensive task-directed therapy was associated with functional improvement compared to standard physical therapy (Level B). Further studies are still needed to determine whether the use of constraints or the intensive nature of the therapy itself is responsible for the improvements in function since it is both intensive and expensive.

Depression is a frequent accompaniment of stroke, reflecting both the physical disability and altered brain chemistry. Depression may respond to selective serotonin-reuptake inhibitors (SSRIs) and tricyclic antidepressants. Escitalopram administered prophylactically to stroke patients was effective in preventing the development of depression, though other studies have not confirmed this (Level B). There is also evidence from other trials that SSRI treatment facilitates functional recovery after stroke.

Secondary Stroke Prevention

The optimal secondary prevention strategy for an individual patient depends on the stroke mechanism. For stroke or TIA caused by carotid stenosis of 70% or more of the vessel diameter, carotid endarterectomy (CEA) by a skilled surgeon with an acceptable complication rate (<5%) is preferable to medical therapy in good surgical candidates (Level A). For patients at high risk of surgical complications, including those over age 80, those with cardiac or pulmonary disease, or those with radiation-induced arteriopathy, stenting reduces the risks of cardiac complications (Level B). Trials that tested whether carotid angioplasty and stenting are more effective or safer than carotid endarterectomy in patients at low surgical risk have not demonstrated any benefit over open surgery (Level A). Among patients with symptomatic intracranial stenosis (lesions not amenable to surgery), a recent randomized trial demonstrated that best medical therapy,

including aggressive risk factor control, was associated with a lower recurrence risk (Level B).

Anticoagulation is indicated in patients with definite cardioembolic sources of stroke, such as mechanical valves or atrial fibrillation. In embolic strokes caused by atrial fibrillation, anticoagulation with warfarin was superior to aspirin, with a relative risk reduction of about 68% (Level A). Recommended options for secondary prevention among patients with atrial fibrillation now include warfarin with an INR between 2.0 and 3.0, or use of one of the newer antithrombotic agents, such as dabigatran, rivaroxaban, edoxaban, or apixaban (Level A). For patients who cannot tolerate anticoagulants because of a risk of ICH or bleeding elsewhere, newer treatment modalities, including interventions to exclude the left atrial appendage from the circulation using devices or cinching procedures, show promise in early trials, though they are not yet approved (Level B).

Other causes of cardiogenic emboli require different treatments. Infected prosthetic valves need replacement if emboli persist on antibiotics, or if patients develop heart failure. Emboli from myxomatous tumors of the atria frequently require surgical removal of tumor. The need for anticoagulation among patients with less well-established sources of emboli, such as paradoxical embolism through a patent foramen ovale or aortic arch embolization, is unproven, and current guidelines do not support its use in this setting (Level A). Closure of patent foramen ovale using umbrella-like devices may reduce the risk of recurrent stroke in selected patients (younger patients without other stroke risk factors), though recent trials have not proven this effect; further trials in highly selected patients are ongoing.

All patients with ischemic stroke without a definite indication for anticoagulation, and in whom no contraindication is present, should receive long-term antiplatelet therapy, which reduces the risk of recurrence by 20% to 25% (Level A). Agents currently approved for this purpose include aspirin, dipyridamole, and clopidogrel, a thienopyridine derivative ADP receptor inhibitor. Head-to-head trials have failed to demonstrate a benefit of one of these agents over another; the combination of aspirin and dipyridamole was more effective than either agent alone, but long-term treatment with the combination of aspirin and clopidogrel was no more effective than aspirin alone and increased the risk of significant bleeding. A more recent trial in China suggested that there may be benefit to the combination of aspirin and clopidogrel when used for the short term after stroke or TIA, and a similar study is ongoing in the United States. Aspirin doses as low as 30 mg daily appear effective and have fewer side effects, such as gastrointestinal bleeding, than higher doses. The FDA recommends doses between 50 and 325 mg daily for stroke prevention.

Clinical trials provide evidence for increased use of anti-hypertensive agents in patients with stroke and TIA. There are theoretical concerns about lowering blood pressure in patients with existing cerebrovascular disease due to the possibility that in patients with arterial disease of cerebral vessels and reduced autoregulation, a reduction in blood pressure could worsen perfusion and precipitate clinical events or affect cognition. Randomized trials like PROGRESS provide evidence, however, that blood pressure reduction among patients with cerebrovascular disease reduces risks of recurrent stroke by 28% independently

of a history of hypertension (Level A). Guidelines currently focus on the use of blood pressure agents to achieve recommended target blood pressure levels, rather than on specific agents, which should be individualized depending on a patient's comorbidities.

Trials using HMG-CoA reductase inhibitors, or statins, among cardiac and other vascular disease high-risk patients have demonstrated benefits in stroke risk reduction. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial provides more direct evidence of the benefit of statin therapy in secondary prevention of stroke among patients presenting with stroke or TIA (Level A). SPARCL randomized patients with recent stroke or TIA to atorvastatin 80 mg daily or placebo. Over 5 years, atorvastatin reduced the risk of the primary outcome, recurrent stroke, from 13.1% to 11.2%, an absolute risk reduction of about 2%.

Among those with diabetes, diet and exercise, oral hypoglycemic drugs, and insulin are recommended to obtain glycemic control. While glycemic control reduces risks of microvascular complications, the benefit in reducing macrovascular complications is less certain. In one trial, tight glycemic control of a prospective cohort of newly diagnosed diabetics was not found to significantly reduce stroke risk. Ongoing trials are addressing the use of newer agents in secondary stroke prevention among those with insulin resistance.

Behavioral risk factors are difficult to control, but are important. Smoking is addictive, and cessation may necessitate psychological counseling and medical aids, such as nicotine patches or varenicline. Physical activity should be encouraged, as a sedentary lifestyle is associated with elevations in blood pressure and stroke risk. Alcohol consumption in excess of 2 drinks daily should be discouraged, though there is evidence that moderate alcohol consumption may have protective effects against stroke risk. It should be noted, however, that there is only Level B evidence that control of these risk factors reduces recurrent stroke risk.

PROGNOSIS

The immediate period after an ischemic stroke carries the greatest risk of death, with fatality rates ranging from 8% to 20% in the first 30 days. Age and stroke severity are the most important predictors of prognosis. Case fatality rates are worse for hemorrhagic strokes, ranging from 30% to 80% for intracerebral hemorrhage and 20% to 50% for subarachnoid hemorrhage.

Stroke survivors continue to have a three to fivefold increased risk of death, compared with the age-matched general population. Annual aggregate estimates of death have been 5% for minor stroke and 8% for major stroke. Survival is influenced by age, hypertension, cardiac disease, and diabetes. Patients with lacunar infarcts appear to have a better long-term survival than do those with the other infarct subtypes.

Recurrent stroke is frequent. The immediate period after a stroke carries the greatest risk for early recurrence; rates range from 3% to 10% during the first 30 days. Thirty-day recurrence risks vary by infarct subtypes; the greatest rates are in patients with atherosclerotic infarction and the lowest rates in patients with lacunes. After the early phase, the risk of stroke recurrence continues to threaten the quality of life of a stroke survivor.

Long-term stroke recurrence rates range in different studies from 4% to 14% per year, with aggregate annual estimates of 6% for minor stroke and 9% for major stroke. These rates have been decreasing with the advent of the improved protection strategies outlined above. Recurrent stroke contributes to the burden of dementia and functional decline after stroke. Importantly, cardiac events are also increased in stroke survivors, and pose a major threat of death.

 For a deeper discussion on this topic, please see Chapters 64, "Cardiac Arrhythmias with Supraventricular Origin," and 70, "Atherosclerosis, Thrombosis, and Vascular Biology," in Goldman-Cecil Medicine, 25th Edition.

Traumatic Brain Injury and Spinal Cord Injury

Geoffrey S.F. Ling

Traumatic brain injury (TBI) and traumatic spinal cord injury (TSCI) are leading causes of traumatic death and disability. Over 8 million patients suffer TBI each year; the vast majority (over 80%) are mild TBI or concussion. Approximately 52,000 patients in the U.S. die from severe TBI as a direct consequence. An additional 11,000 patients are severely disabled by TSCI. The vast majority are due to falls, motor vehicle accidents, sports-related occurrences, and assaults. Among the almost 5.5 million TBI and TSCI survivors, most require prolonged rehabilitation.

TYPES OF INJURY

Certain lesions require neurosurgical intervention while others do not. TBI conditions for which emergency neurosurgery are needed are penetrating wounds, intracerebral hemorrhage with mass effect, including subdural and epidural blood, and bony injury, such as displaced fracture and vertebral subluxation. However, focal, hypoxic-anoxic, diffuse axonal and diffuse microvascular injuries typically do not require surgery.

MANAGEMENT

Traumatic Brain Injury (TBI)

Patients with mild or moderate TBI typically recover quickly and fully. It is critical to first remove the TBI victim from play or work to prevent further injury. Diagnosis of mild TBI or concussion begins simply with identifying affected patients. This is often difficult because these patients suffer transient alteration of consciousness with only a minority completely losing consciousness. Most have memory impairment. As a result, patients are typically unaware that they are injured. Thus, it is important that colleagues, coaches, athletic trainers, parents, and other observers have a heightened suspicion when a potential head injury event occurs. If so, then a sideline point-of-injury screening tool should be administered, such as a standardized assessment of concussion (SAC) or sports concussion assessment tool version 3 (SCAT3). SAC is a neuropsychological battery that tests orientation, immediate memory, concentration, and memory recall. An abnormal score is less than 25. If abnormal, the patient is at high risk for having suffered a concussion and thus should be brought to medical attention for further evaluation, diagnosis and treatment.

In the early stage of management, it is important that a neurologist or medical practitioner skilled in managing TBI perform a detailed history, physical, and neurologic examination, especially assessment of cognitive function. In the history, the practitioner should determine the duration of altered sensorium,

amnesia or loss of consciousness a patient may have suffered. The American Academy of Neurology Guidelines uses a grading scale for concussion that is based primarily on the length of these intervals (Table 117-1). Longer periods of abnormal sensorium are associated with higher grades. Higher grades necessitate longer periods of convalescence. Other clinical guides that may be used include the Cantu Grading System and the Colorado Medical Society Guidelines.

The decision to obtain neuroimaging is based on the index of suspicion of intracranial hemorrhage or skull fracture. Both CT and MRI are inadequate in ruling out mild TBI, which is a clinical diagnosis. If a patient has lost consciousness, persistent altered mentation, abnormal GCS score, focal neurologic deficit, or is clinically deteriorating, then neuroimaging should be obtained.

In general, patients with mild TBI do not require major medical intervention; almost all do well after adequate convalescence. It is essential that patients have adequate time for recovery; they should not return to play or work until fully recovered. A second head injury before full recovery may be catastrophic, the second impact syndrome (SIS), which leads to worse clinical outcome, including death.

The patient must be allowed to rest with minimal cognitive burden. There are no specific medications to foster recovery. Treatment is focused on ameliorating symptoms according to published evidence-based guidelines, such as VA/DoD Clinical Practice Guidelines for the Management of Concussion/mild TBI. In general, headache, the most common complaint, can be treated with acetaminophen or a nonsteroidal anti-inflammatory agent. Triptans can be considered if there are features of migraine. Dizziness can be treated with physical therapy. Meclizine should be reserved only for symptoms that are severe enough to impair activities of daily function. Insomnia can be treated with proper sleep hygiene. A sedative can be used acutely and should be

TABLE 117-1 GLASGOW COMA SCORE (GCS)

BEST EYE RESPONSE	BEST VERBAL RESPONSE	BEST MOTOR RESPONSE
1 = No eye opening	1 = No verbal response	1 = No motor response
2 = Eye opening to pain	2 = Incomprehensible sounds	2 = Extension to pain
3 = Eye opening to verbal command	3 = Inappropriate words	3 = Flexion to pain
4 = Eyes open spontaneously	4 = Confused	4 = Withdrawal from pain
	5 = Orientated	5 = Localizing pain
		6 = Obeys commands

GCS, Eye Response + Verbal Response + Motor Response.

limited to non-benzodiazepine agents such as zolpidem. Visual and auditory symptoms should be evaluated by appropriate medical specialists.

The patient is able to return to play or work after at least 24 hours of recovery and when cleared to do so by a neurologist or clinical practitioner experienced in the management of concussion. In many states statutes specify these requirements. In general, the patient is able to return to play when symptoms no longer require treatment. At this point, many practitioners will subject the patient to provocative testing such as performing exertion (e.g., running) followed by cognitive testing. If this does not cause symptoms to recur and the patient performs well cognitively, then he or she is allowed to return to full activity.

For moderate to severe TBI the initial care goals are the “ABCs” of airway, breathing, and circulation. Next is “D” for disability (neurologic). Every patient should undergo a detailed neurologic examination to ascertain the level of neurologic disability. An initial Glasgow Coma Score (GCS) should be assigned to each patient. The GCS (Table 117-2) categorizes patients with TBI and provides a quantifiable measure of impairment.

Patients with severe TBI are those who present with GCS scores of eight or less. To optimize outcome, medical management should adhere to currently accepted clinical guidelines such as the Brain Trauma Foundation “Clinical Guidelines for Severe TBI.” An important early intervention is airway protection, usually by endotracheal intubation. If elevated intracranial pressure (ICP) is suspected, elevate the patient’s head to 30° and keep it midline, ideally with a rigid neck collar (at least until the cervical spine can be evaluated for stability). Mannitol should be given intravenously at a dose of 0.5-1.0 gm/kg. Hyperventilation may also be used with a goal of pCO₂ 34-36 mm Hg. ICP should be kept less than 20 mm Hg with the cerebral perfusion pressure (CPP) greater than 60 mm Hg. A head CT without contrast

should be done as soon as possible to identify lesions that will require surgery and to determine the extent of injury.

If ICP remains poorly controlled, one can consider administering an intravenous bolus of 23% hypertonic saline (50 mL) followed by continuous infusion of 2% or 3% hypertonic saline (75-125 mL/hr) through a central venous catheter. If these interventions are unsuccessful, pharmacological coma or surgical decompression should be considered. Pharmacological coma can be induced with pentobarbital. This is given as a loading dose of 5 mg/kg intravenously, followed by an infusion of 1-3 mg/kg/hr. Alternatively, propofol can be used, which is administered as a loading dose of 2mg/kg intravenously, followed by an infusion up to 200 µg/min. Continuous EEG monitoring is helpful as the limit of drug-induced coma is achieving ICP control or cerebral electrical burst-suppression. Persistently elevated ICP after all these efforts is ominous. Consideration should be given to frontal or temporal lobe decompression and hemicraniectomy.

To meet CPP goals, patients must first be adequately hydrated. The goal of TBI fluid management is to increase the osmolar gradient between systemic vasculature and brain. For this purpose, hyperosmolar intravenous solutions are used, such as normal saline. Other options are hypertonic saline (e.g., 3% sodium solutions). If meeting CPP goals is difficult with intravenous fluids alone, vasoactive pharmacologic agents such as norepinephrine and phenylephrine can be administered. These two agents are preferred because they are considered to have the least effect on cerebral vasomotor tone. Barbiturates and propofol are myocardial depressants, therefore aggressive cardiovascular management will probably be necessary when pharmacological coma is induced.

Agitation can be treated with lorazepam or haloperidol. If inadequate, then infusions of midazolam or propofol may be used. Pain should be controlled: acetaminophen and nonsteroidal anti-inflammatory agents are adequate for mild discomfort; however, for moderate to severe pain, narcotic analgesics such as fentanyl or morphine should be used. A benefit of opioids is that they can be reversed by naloxone to allow reassessment of neurologic status.

Hypoxia, seizures, and fever must be avoided. Maintaining pO₂ at approximately 100 mm Hg is sufficient. Phenytoin is administered for the first 7 days after injury because it will reduce early onset seizures. After 7 days it should be stopped. It can be restarted if seizures recur. Fever should be reduced with antipyretics such as acetaminophen, using a cooling blanket if needed. Other important management considerations include prevention of gastric stress ulcer, deep vein thrombosis (DVT), and decubitus ulcers. Feeding should be instituted as soon as practical to maintain nutrition.

After the initial few hours, efforts should be made to reduce hyperventilation, which is indicated only for initial emergency management. After 12 hours, metabolic compensation negates the ameliorative effects of respiratory alkalosis caused by the hypocapnic state induced by hyperventilation.

Repeated neurologic examination and continuous ICP and CPP measurement are indicated. Generally, the peak period of cerebral edema is from 48 to 96 hours after TBI. Thereafter, the edema resolves spontaneously and clinical improvement should follow.

TABLE 117-2 AMERICAN ACADEMY OF NEUROLOGY CONCUSSION MANAGEMENT

GRADE 1 (MILD)	GRADE 2 (MODERATE)	GRADE 3 (SEVERE)
Remove from duty/work/play	Remove from duty for the rest of the day	Take to emergency department
Examine immediately and at 5-minute intervals	Examine frequently for signs of CNS deterioration	Neurologic evaluation, including appropriate neuroimaging
May return to duty/work/play if clear within 15 minutes	Physician’s neuro exam ASAP (within 24 hours) Return to duty/work/play after 1 full asymptomatic week (after being cleared by physician)	Consider hospital admission
GRADE OF CONCUSSION	RETURN TO PLAY/WORK	
Grade 1 (first)	15 minutes	
Grade 1 (second injury)	1 week	
Grade 2 (first)	1 week	
Grade 2 (second injury)	2 weeks	
Grade 3 (first) (brief LOC)	1 week	
Grade 3 (first) (long LOC)	2 weeks	
Grade 3 (second injury)	1 month	
Grade 3 (third injury)	Consult a neurologist	

A complication of TBI is post-concussive syndrome (PCS). Diagnosis can be made using the Post-Concussion Symptom Scale (PCSS) and Graded Symptom Checklist (GSC). The most common symptoms of PCS are headache, difficulty concentrating, appetite changes, sleep abnormalities, and irritability. PCS has a variable presentation and duration depending on the patient and the severity of TBI. In general, PCS lasts for a few weeks post-injury. However, uncommonly, it can persist beyond a year or more. Treatment is symptomatic. For headache, nonsteroidal anti-inflammatory agents, migraine drugs, and biofeedback can be effective. For cognitive dysfunction, neuropsychological testing may be helpful in determining appropriate intervention, which may include cognitive behavior therapy.

Traumatic Spinal Cord Injury (TSCI)

The emergency management of traumatic injury to the spinal cord has greatly improved with adherence to the American Association of Neurological Surgeons “Guidelines for the Management of Cervical Spine and Spinal Cord Injuries.” Therapy begins with the “ABC” of airway, breathing, and circulation. A secure airway is absolutely vital. For patients suffering from high cervical lesions, spontaneous ventilation will be lost. Lesions below C5 may also impair ventilatory capability. If the airway or ventilatory efforts are compromised, emergency intubation is required. For a patient in whom cervical spine trauma has not been assessed, the preferred method is nasotracheal intubation using fiberoptic guidance. Other approaches are nasotracheal (blind) or orotracheal intubation, provided that cervical spine alignment is maintained by traction.

Maintaining an intravascular volume is essential in TSCI. Hypotension may be due to either neurogenic shock or hypovolemia. For neurogenic shock, vasopressive pharmacologic agents, such as phenylephrine, may be needed. If tachycardia is present, then hypovolemia is the more likely etiology and fluid resuscitation with normal saline is the appropriate initial management.

After addressing the “ABC’s,” a neurologic history and examination should be obtained. An accompanying TBI needs to be considered. Up to 50% of TSCI patients have an associated TBI. Neuroimaging is often indicated, but not all patients need radiographic study. A normal neurologic assessment obviates the need for imaging studies; however, a complaint of burning hands or of pain over the spine, numbness, tingling, or weakness indicates possible spinal cord injury. The time of injury should be recorded as accurately as possible. A detailed neurologic examination is needed to identify the level of the injury, the completeness of any deficits, and to document the degree of neurologic dysfunction at the earliest time possible. The level of the injury is the lowest spinal cord segment with intact motor and sensory function. The prognosis for neurologic improvement is better if the lesion is incomplete than complete. Following the acute injury, serial examinations must be made frequently.

If spinal cord injury is suspected, the patient should be immediately and appropriately immobilized with a rigid collar or back board, or both. Radiologic evaluation should begin with plain x-rays of the bony spine. Abnormalities on x-rays should lead to further neuroimaging. Bony vertebrae should be examined with CT and the spinal cord with MRI. Intervertebral and paravertebral soft tissue are best studied with MRI. A chest x-ray

should also be obtained in order to visualize the lower cervical and thoracic vertebrae. Presence of a pleural effusion in the setting of a possible thoracic spine injury suggests a hemothorax.

If the C-spine x-rays are normal but the patient complains of neck pain, then ligamentous injury may be present. Ligamentous injury is evaluated by flexion-extension C-spine x-rays. However, in the acute period, pain may prevent an adequate study. These patients should be kept in a rigid cervical collar for a few days until the pain and neck muscle spasm resolves. At that time, imaging may be performed. If abnormal, the patient will need surgical evaluation.

The use of methylprednisolone for TSCI is no longer advocated.

Spinal Cord Syndromes

There are three main spinal cord syndromes: Anterior cord, Brown-Sequard, and Central cord. Anterior cord syndrome is associated with deficits referable to bilateral anterior and lateral spinal cord columns. There is loss of touch sensation, pain, temperature, and motor function below the level of the lesion. The posterior column functions of proprioception and vibratory sensation remain intact. In Brown-Sequard syndrome, the deficits are due to injury to a lateral half of the cord. There is functional loss of ipsilateral motor, touch, proprioception and vibration, and contralateral pain and temperature. Central cord results in a “man in a barrel” syndrome: motor paralysis of both upper extremities with sparing of the lower extremities. Weakness is greater proximally than distally. Pain and temperature sensations are generally reduced, but proprioception and vibration are spared.

Spinal Shock

Spinal shock may occur after acute injury causing a temporary loss of spinal reflexes below the level of injury. Neurologic examination will reveal loss of muscle stretch reflexes, bulbocavernosus reflex, and the anal wink. In high cervical injuries, the lower reflexes (bulbocavernosus and anal wink) may be preserved. There may also be the “Schiff-Sherrington” phenomenon, in which reflexes are affected above the level of injury. Additionally, there may be loss of autonomic reflexes leading to neurogenic shock and ileus and urinary retention.

Acute and Subacute Management

In the intensive care unit, the patient will need continued treatment. Once methylprednisolone therapy has completed, there is no need for further steroid use. TSCI patients require close cardiovascular and respiratory monitoring. Other issues are genitourinary, bowel, infectious disease, nutrition, skin, and prophylaxis against ulcers and deep vein thrombosis formation.

Patients suffering from spinal cord injury are at risk for neurogenic shock and dysautonomia with resulting peripheral vasodilation and hypotension. Lesions at T3 or above compromise sympathetic tone with hypotension accompanied by bradycardia: the classic neurogenic shock triad of bradycardia, hypotension, and peripheral vasodilation.

Dysautonomia is treated by ensuring adequate circulating volume. The goal is to fluid resuscitate to a euvolemic state. Blood can be used if the patient is anemic (i.e., hematocrit less than 30%). If blood is not required, then either colloid (e.g., albumin

solutions) or crystalloid (e.g., normal saline) may be used. Central venous pressure (CVP) should be maintained at 4–6 mm Hg. Hypervolemia should be avoided because it will exacerbate peripheral edema. Once an adequate circulating volume has been achieved, vasopressive agents can be used, (e.g., phenylephrine, norepinephrine, or dopamine). The mean arterial pressure (MAP) should be 85 mm Hg or greater. Symptomatic bradycardia can be treated with atropine.

Patients with TSCI are at risk for ventilatory compromise. Patients whose injuries are at C5 or higher typically require mechanical ventilation with an appropriate tidal volume (6–10 mL/kg), FiO₂ and mandatory machine driven rate. The FiO₂ inspired oxygen concentration should give a pO₂ between 80–100 mm Hg. The rate should be set to give a pCO₂ of 40 mm Hg. Positive end-expiratory pressure (PEEP) should also be used to minimize atelectasis. If the patient does not show signs of ventilatory recovery within 2 weeks of intubation, a tracheostomy should be considered. Lesions below C5 may also be associated with inadequate spontaneous ventilation. Mid-cervical lesions may be associated with intact but compromised diaphragm function. If suspected, a “sniff” test under fluoroscopy can be performed to determine if both hemidiaphragms are functioning properly. If not, intubation/tracheostomy with volume-controlled ventilation may be needed. If intact, then pressure support (PS) ventilation sufficient to maintain an appropriate tidal volume with oxygenation and PEEP should be set as described above.

Patients with cervical lesions at C6 and below, including the thoracic cord, do not require mechanical ventilation. However, their ventilatory effort may be inadequate because the thoracic cord innervates intercostal muscles, which are accessory muscles of respiration. Such patients have decreased cough and inability to increase ventilation when needed, leading to atelectasis and inability to clear secretions, which can cause pneumonia. Such patients need assistance with clearing their airway: chest percussion, suctioning, and encouragement in coughing.

Thromboembolic disease is a leading cause of morbidity and mortality in patients with TSCI: up to 80% will develop DVT without prophylaxis. All patients with TSCI should receive both anticoagulation and have mechanical compression devices applied to their legs. Sequential compression devices (SCD) or compression stockings should be placed as soon as possible. When hemostasis is assured, low molecular weight heparin (LMWH) should be initiated. Unfractionated heparin may also be used in conjunction with SCD but LMWH is preferred. An inferior vena cava filter may be placed in those patients in whom anticoagulation therapy is contraindicated, but it should not be the primary means of preventing DVT.

Mid-low thoracic spinal cord injury can lead to ileus. A nasogastric tube should be placed to decompress the stomach. Parenteral nutrition should be started as soon as possible. Enteral feeding should be delayed until gastrointestinal motility returns, usually between 2 to 3 weeks. Pharmacologic agents that promote motility are metoclopramide, erythromycin, and cisapride. Gastric ulcer should be prevented with medication: H₂ receptor antagonists, proton pump inhibitors, antacids, or sucralfate. Pancreatitis and trauma-related bowel perforation occur: loss of abdominal

muscle tone and visceral sensation may mask usual clinical findings of pain, guarding, or rigidity.

Bladder tone may be lost due to spinal shock. A Foley catheter should be placed and maintained for a minimum of 5 to 7 days to drain the bladder and to evaluate circulatory volume and renal status. Once spinal shock resolves, autonomic dysreflexia may occur from bladder distention: skin flushing and hypertension. Clinical examination by palpation and percussion will reveal a distended bladder, which can be treated with intermittent catheterization or bladder training. Phenoxybenzamine may be helpful in this condition.

Nutrition should be given. Until enteral feeding can begin, parenteral nutrition should be used. A caloric level of 80% of the Harris-Benedict prediction should be used for quadriplegic patients. The full Harris-Benedict predicted amount should be used for patients with thoracic spine injuries and below. Skin care is essential to prevent decubitus ulcers. Mechanical kinetic beds, regular log rolling (every 2 hours), and padded orthotics are all useful in minimize this complication.

Orthotics, physical therapy, and occupational therapy (for cervical cord injury) are useful. Therapy should begin as soon as the spine is stabilized with the goal of minimizing contractures and beginning the rehabilitation. Once therapy begins, energy expenditure will increase requiring additional nutrition. If intermittent compression devices need to be removed during therapy, heparin dose may need to be increased.

PROGNOSIS

Traumatic Brain Injury (TBI)

The most useful prognostic indicator following TBI is the neurologic examination at presentation. Clearly, the better the neurologic examination, the higher the likelihood of improved recovery. The initial GCS score is a very reliable prognostic indicator. The lower the initial GCS score, the less likely a patient will have meaningful neurologic or functional recovery.

Traumatic Spinal Cord Injury (TSCI)

For TSCI, the completeness of the injury is the most useful prognosticator. The American Spine Injury Association Impairment Scale grades spinal cord injury on the basis of completeness (Table 117-3). A grade “A” or complete motor and sensory deficit below the lesion is the most ominous prognosis. If such a lesion persists longer than 24 hours, there is little reasonable likelihood of meaningful recovery. On the other hand, partial injuries, even severe, have substantial probability of recovery.

FUTURE

TBI and TSCI are serious neurologic conditions with significant implications on society. Prevention remains the most effective way of reducing the incidences of these diseases. Introduction of practice guidelines have contributed to improved outcome from TBI and TSCI. Sadly, morbidity remains a serious problem. Medical management is largely confined to supportive efforts primarily directed towards minimizing secondary injury, optimizing perfusion and oxygenation, and preventing nonneurologic morbidity. Surgical intervention helps restore structural stability, minimize further injury, and reduce the lesion. However

TABLE 117-3 AMERICAN SPINAL INJURY ASSOCIATION IMPAIRMENT SCALE

GRADE	INJURY TYPE	DEFINITION
A	Complete	No motor or sensory function below the lesion
B	Incomplete	Sensory but no motor function
C	Incomplete	Some motor strength (<3)
D	Incomplete	Motor strength >3
E	None	Sensory & motor normal

neither reverses neuronal death nor fully prevents secondary injury processes. There are ongoing significant medical research efforts to improve our understanding of the pathogenesis of these diseases and find ways to mitigate them. As new pharmacologic, medical, and surgical approaches are introduced, there will be increasing opportunities to restore these patients.

 For a deeper discussion on this topic, please see Chapter 399, "Traumatic Brain Injury and Spinal Cord Injury," in Goldman-Cecil Medicine, 25th Edition.

Epilepsy

Michel J. Berg

DEFINITION/EPIDEMIOLOGY

Epileptic seizures are defined as a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain. Seizures are a common sign of brain dysfunction. A wide variety of symptoms can occur depending on the brain networks involved including involuntary movements, abnormal sensations and behaviors, and impaired consciousness.

Seizures often occur during the course of medical or neurological illnesses in which brain function is temporarily deranged (symptomatic seizures) (Table 118-1). The most common secondary causes of seizures are metabolic derangements (such as hypoglycemia or hyponatremia), intoxications (alcohol, cocaine), acute head trauma, and hypoxic-ischemic conditions (cardiac arrest, syncope, embolic stroke). Symptomatic seizures are usually self-limited and recurrent seizures do not occur after the underlying disorder is corrected. Thus, symptomatic seizures do not constitute epilepsy.

Epilepsy is a chronic disease of the brain characterized by an enduring predisposition to generate epileptic seizures. The diagnosis of epilepsy requires the occurrence of at least one epileptic seizure, but typically is not applied unless there are at least two unprovoked seizures occurring more than 24 hours apart or one unprovoked seizure and a high probability of further seizures

based on additional data such as an epileptiform EEG. The phrase *seizure disorder* is synonymous with the word, epilepsy. Individuals with epilepsy have increased seizure susceptibility (lowered seizure threshold). Genetic factors and prior brain injury (from a multitude of causes) are the major contributors to this susceptibility. The diagnosis of epilepsy encompasses the neurobiological, cognitive, psychological, and social consequences of this condition.

There are many different *epilepsy syndromes* (the epilepsies) with the three major categories being focal epilepsy, idiopathic (genetic) generalized epilepsy, and symptomatic generalized epilepsy (discussed later). Classification of the epilepsy syndrome depends on a number of factors, including the seizure type, etiology, genetic mutations, neuroimaging, and response to therapy.

The care of people with seizures suffers from imprecise terminology usage. The word “epilepsy” is a noun, as in, “a person with epilepsy.” The word “epileptic” is an adjective, as in, “an epileptic seizure.” An individual with epilepsy should not be labeled as an “epileptic.” That is, from the psychosocial perspective, people with epilepsy are more than just an enduring predisposition to seizures and their consequences. Epilepsy is thought of as a disorder, but, to emphasize the impact of the recurrent seizures, epilepsy should be considered a disease. Epileptic seizures, also referred to as electrical seizures, are distinct from nonepileptic (or nonelectrical) seizures, which have a psychological basis and are best referred to as psychogenic nonepileptic attacks (less appropriately termed pseudoseizures; see later). Most seizures in someone with epilepsy occur in an unpredictable fashion. It is this unpredictable timing that results in the major negative impact of epilepsy on quality of life. If functionally impairing seizures occur during waking hours (*diurnal seizures*) then activity restrictions are required, including restriction from driving, operating heavy machinery, climbing heights, and unobserved swimming or bathing (showering with a good drain should be advised). These activity restrictions lead to loss of independence. The psychological impact of having intermittent involuntary loss of body control and the dependency imposed by the activity restrictions are major contributors to the increased incidence of comorbid depression in people with epilepsy (up to 50%).

In many people with epilepsy there are more seizures during sleep due to increased synchronization of neuronal activity. Seizures that occur exclusively in sleep constitute *nocturnal epilepsy*. In women with epilepsy (WWE), seizures sometimes occur more often during the week around menses or at ovulation (*catamenial epilepsy*). Sleep deprivation, alcohol consumption, infectious illnesses, certain medications, and severe emotional stressors can

Acute head trauma, stroke, brain tumor

*The metabolic derangements and drugs listed in Table 118-1 also lower the seizure threshold in people with epilepsy.

further lower the seizure threshold and are associated with more seizures in people with epilepsy (Table 118-1).

Seizures can occur at any time. Ten percent of the population in developed countries has a seizure at some time during their life. In contrast, 0.7% to 1% has current epilepsy (prevalence) and 3% to 4% has epilepsy at some time during their life (lifetime prevalence). In the United States, there are approximately 125,000 new cases of epilepsy diagnosed each year (incidence). The incidence and prevalence are biphasic, with epilepsy being more common in childhood (primarily because of perinatal injury, infections, and genetic factors) and in old age (because of stroke, tumors, and dementia) (Fig. 118-1). In developing countries the frequency of epilepsy is higher because of factors such as increased brain infections with organisms such as cysticercosis.

PATHOLOGY

Prior to the 1990s, the underlying cause was not determined in most people with epilepsy. The advent of MRI and, more recently, genetic analysis has substantially improved our ability to identify the cause of many types of epilepsy. About 70% of adults and 40% of children with new-onset epilepsy have partial (focal) seizures implying a cerebral injury or lesion. The most common lesions are hippocampal sclerosis, neuronal and glial tumors, vascular malformations, neuronal migration disorders (e.g., cortical dysplasia), hamartomas, encephalitis, autoimmunity, cerebral trauma, embolic stroke, and hemorrhage. Hippocampal sclerosis

(sometimes referred to as mesial temporal sclerosis) is particularly common and can occur in isolation or secondary to another epileptogenic lesion (dual pathology). It consists of loss of pyramidal cells and gliosis in several hippocampal subfields. Hippocampal sclerosis is associated with temporal lobe epilepsy and short-term memory dysfunction. Not all patients with cerebral lesions develop epilepsy; how or why a particular lesion becomes epileptogenic is poorly understood.

Hereditary influences have long been associated with epilepsy. During the past several decades, a number of gene mutations have been associated with specific epilepsy syndromes, both focal and generalized. Many of the mutations occur in ion channels, which, not surprisingly, lead to neuronal dysfunction and epilepsy. Two important phenotypic examples of channelopathies are genetic (generalized) epilepsy with febrile seizures plus (GEFS+) and Dravet syndrome (also known as severe myoclonic epilepsy of infancy). GEFS+ is typically associated with a partial loss of function mutation in the voltage-gated sodium channel gene, *SCN1A*, whereas a complete loss of function mutation in the same gene results in Dravet syndrome. Less commonly, mutations in other ion channel genes can lead to the same phenotypic expressions. GEFS+ can begin at any age, although is usually evident in childhood, with various seizure types in different affected family members; some may have febrile seizures after age 6 years (febrile seizures plus), whereas others may have myoclonic, absence, or partial seizures. In contrast, Dravet syndrome typically presents at 6 to 8 months of age with prolonged hemi-clonic seizures associated with an intercurrent fever. Adults with Dravet syndrome are typically mentally retarded with spasticity or ataxia, gait dysfunction, and occasional nocturnal clonic seizures as well as other seizure types. Recognition of Dravet syndrome is important because certain antiepileptic drugs (AEDs) can cause permanent clinical deterioration (e.g., lamotrigine, phenytoin), whereas others are particularly beneficial (e.g., topiramate, levetiracetam, valproate, benzodiazepines).

CHILDREN

ADULTS

FIGURE 118-1 Etiology of epilepsy, according to age, in all newly diagnosed cases in Rochester, Minnesota, 1935–1984. (Modified from Hauser WA, Annegers JF, Kurland LT: Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935–1984, *Epilepsia* 34:453–468, 1993.)

CLINICAL PRESENTATION

Classification and Clinical Manifestations

Seizures are classified by their clinical symptoms and signs. The manifestations of a seizure depend on whether its onset includes most or only a part of the cerebral cortex, on the functions of the involved cortical areas, and on the subsequent pattern of spread within the brain. Seizures are of two broad types: those with onset limited to a specific region of cerebral cortex (*partial or focal seizures*) and those with onset that involves the cerebral cortex diffusely (*generalized seizures*). Seizures are dynamic with an evolving electrical discharge. Thus, highly focal (*simple partial*) seizures can progress into more widespread (*complex partial*) seizures and partial seizures can evolve into secondarily generalized tonic-clonic seizures.

In an individual, seizures are typically stereotyped, although a person can have more than one seizure type and a specific seizure type can have varying intensities. The behaviors that occur during the seizure are termed the *seizure semiology*. The seizure itself is referred to as the *ictus* and the period of time during which the seizure occurs is termed the *ictal phase*. The time after the seizure, until the patient is fully recovered, is the *postictal phase* and the

time between seizures (which can be seconds to years) is the *interictal phase*.

The *epilepsy syndromes* can be divided into three major categories: *focal epilepsy*, *idiopathic (primary) generalized epilepsy*, and *symptomatic generalized epilepsy*. This classification is based on the widely used scheme of the International League against Epilepsy. This scheme is undergoing revision. In the future, the epilepsies may be classified as genetic, structural/metabolic, and unknown cause. The current classification of the epilepsy syndromes closely follows the classification of the seizures. In the following paragraphs, the specific seizure types are described followed by a description of the attendant epilepsy syndromes.

Partial Seizures (Seizure Types)

In *partial seizures* (also known as localization-related or focal seizures) a localized region of the brain has abnormal neurons that intermittently fire hypersynchronously, recruiting the surrounding, otherwise normal neurons, generating a seizure. If the abnormal neuronal firing is confined, there may be no clinical manifestation and the event, which can only be detected with EEG, is termed a *subclinical* or *electrical seizure*.

Simple Partial Seizures

If the electrical discharge involves a clinically functional small area, a *simple partial seizure (SPS)* occurs and manifests as a symptom without impairment of consciousness. The symptom may be a sensation, autonomic function (e.g., nausea or another epigastric sensation), abnormal thought (e.g., fear, *déjà vu*), or involuntary movement. An SPS is commonly called an *aura* and can serve as a warning that a more intense seizure is about to occur. Auras occur in about 60% of patients with focal epilepsy.

During an SPS the patient can interact normally with their environment except for limitations imposed by the seizure itself on specific functions. Thus, SPSs are divided into *SPS without impairment*, which do not interfere with function (e.g., just an internal sensation) and *SPS with impairment*, which can interfere with function (e.g., a jerking limb that would disrupt the ability to drive safely).

The motor signs of a seizure can be *clonic* (rhythmic jerking) or *tonic* (stiffening) movements of a discrete body part. An SPS restricted to the precentral (Rolandic) gyrus that spreads to involve adjacent areas of the primary motor cortex, is expressed as clonic movements that progress in an orderly sequence (*Jacksonian march*) that reflects the motor cortex homunculus topographic organization (e.g., mouth to hand to arm to leg).

Complex Partial Seizures

A *complex partial seizure (CPS)* is a focal-onset seizure with impairment of consciousness. The degree of consciousness impairment ranges from minimal to complete unresponsiveness. The patient's eyes are almost always open during the ictus indicating an awake state (albeit impaired). The eyes may close after the seizure ends and the patient typically experiences some degree of postictal confusion, fatigue, and sometimes headache (with the head pain often ipsilateral to the seizure focus due to the increased metabolic demand). An CPS typically lasts 1 to 3 minutes with a postictal state of a few minutes to hours. The specific signs and symptoms that occur during a partial

TABLE 118-2 LOCALIZATION OF SEIZURES BY SYMPTOMS AND ICTAL MANIFESTATIONS

LOCUS	MANIFESTATION
TEMPORAL LOBE	
Uncus/amygdala	Foul odor
Middle/inferior temporal gyrus	Visual changes: micropsia, macropsia
Parahippocampal-hippocampal area	Déjà vu; jamais vu
Amygdala-septal area	Fear, pleasure, anger, dreamy sensation
Auditory association cortex	Voices, music
Insular, anterior temporal cortex	Lip smacking, drooling, abdominal symptoms, cardiac arrhythmia
FRONTAL LOBE	
Motor cortex	Contralateral clonic movements of face, fingers, hand, foot
Premotor cortex	Contralateral arm extension, hypermotor behaviors
Language areas	Speech arrest, aphasia
Lateral cortex	Contralateral eye deviation
Bifrontal	Absence-like seizure
Parietal lobe cortex	Sensory symptoms
Occipital lobe cortex	Visual hallucinations (often in color), teichopsias, metamorphopsias

seizure characteristically reflect the location of seizure onset (Table 118-2). The location of the focus is important because it can predict the nature of the pathology and directs diagnostic testing. Both medical and surgical treatment is determined, in part, by focus location.

Psychomotor, *temporal lobe*, and *limbic seizures* are terms that have been used in the past to describe a variety of ictal behaviors now classified as CPSs, but they are not synonymous. Not all complex partial seizures arise from the temporal lobe, nor do all involve the limbic system. Similarly, certain temporal lobe and limbic phenomena may not be associated with the alteration in awareness that is required to term it a CPS.

Secondarily Generalized Convulsive Seizures

A focal-onset seizure that spreads throughout the brain results in a *secondarily generalized seizure*. Typically there is a tonic phase that consists of extensor posturing lasting 20 to 60 seconds followed by progressively longer periods of inhibition manifesting as a clonic phase that lasts up to another minute: hence the descriptive name *generalized tonic-clonic (GTC)* seizure. The terms convulsion, GTC, grand-mal, and major-motor seizure are often used interchangeably, although GTC is a specific phenomenological description of the behavior. In some patients, a few clonic jerks precede the tonic-clonic sequence; in others, only a tonic or clonic phase is present.

As a partial seizure transitions into a secondarily generalized convulsion the arm contralateral to the seizure focus may extend first, while the ipsilateral arm is flexed at the elbow. This is termed the *figure-4 sign* and is useful for lateralizing the seizure focus. A loud *tonic-cry* may occur at the onset of a convulsion as air is forcibly expelled through tightly contracted vocal cords. The eyes are open and commonly described to roll upward. During a convulsion, breathing stops and cyanosis may develop. Foaming at the mouth may be present. Oral trauma, especially biting the tongue, is typical. Urinary incontinence is common. Fecal

incontinence is rare. First aid involves turning the patient onto a side as the seizure ends to allow the saliva to drool out the mouth, decreasing the likelihood of aspiration. Witnesses commonly describe a GTC as lasting 5 to 10 minutes or longer; however, the GTC phase rarely lasts longer than 2 minutes. The postictal phase is marked by transient deep stupor, followed in 15 to 30 minutes by a lethargic, confused state, sometimes with automatic behaviors. As recovery progresses, many patients complain of headache, muscle soreness, mental dulling, lack of energy, or mood changes lasting for hours to days. Convulsions result in a number of striking, but transient, physiologic changes, including hypoxemia, lactic acidosis, elevated catecholamine levels, and increased serum concentrations of creatine kinase, prolactin, corticotropin, and cortisol. Complications include oral trauma, vertebral compression fractures, shoulder dislocation, aspiration pneumonia, and, very rarely, sudden death, which may be related to acute pulmonary edema, cardiac arrhythmia, or suffocation. Sudden Unexplained Death in Epilepsy (SUDEP) has garnered increased attention during the past decade, but remains poorly understood.

Partial seizures of all intensities may be followed by a transient neurological abnormality reflecting postictal depression of the epileptogenic cortical area. Thus, focal weakness may follow a partial motor seizure or numbness a sensory seizure. These reversible neurological deficits are referred to as *Todd's paralysis* and last minutes to hours, rarely more than 48 hours. Examination of a patient immediately after a seizure may show transient focal abnormalities that indicate the site or at least the side of seizure origin.

Focal Epilepsy (Epilepsy Syndrome)

Focal (localization-related, partial) *epilepsy* is characterized by recurrent partial seizures. It is divided into two main groups, idiopathic and symptomatic.

Idiopathic Focal Epilepsy

The idiopathic focal epilepsies are thought to be due to subtle genetic developmental anomalies that manifest in childhood and remit during puberty. There are several syndromes including occipital, frontal, and the most common type, *benign epilepsy with central midtemporal spikes* (BECTS), which is also known as *benign Rolandic epilepsy* (BRE). BECTS represents about 15% of all pediatric epilepsies. In BECTS, seizures usually begin between the ages of 3 and 12 years in an otherwise normal child. The seizures consist of brief simple partial hemifacial motor or sensory events. There is typically twitching of one side of the face, speech arrest, drooling, and paresthesias of the face, gums, tongue, or inner cheeks. These signs may be so minor that they escape notice, although the affected child often points to his face and goes to a parent and holds on until it is over; the child then quickly resumes normal activity. Seizures may progress to include hemiclonic movements or hemitonic posturing. Secondarily generalized tonic-clonic seizures occasionally occur, usually during sleep. The parents may report only the convulsions; the focal signature can be missed unless the child is carefully questioned. The EEG reveals distinctive, stereotyped epileptiform discharges over the central and midtemporal regions that are dramatically activated by sleep with a normal underlying background.

Prognosis for BECTS is invariably good, as it is for most of the other benign focal epilepsy syndromes; the seizures disappear and the EEG normalizes by mid to late adolescence. Outcome is not affected by treatment, but AEDs prevent recurrent attacks.

Symptomatic Focal Epilepsy

The symptomatic focal epilepsies are the most common type of epilepsy and are classified based on the cerebral lobe involved during the initial phase of the seizure. Temporal lobe epilepsy is the most frequent, followed by frontal, with rarer cases of parietal and occipital. Although sometimes not identified in life, all cases of symptomatic focal epilepsy have an underlying focal abnormality in the cerebral cortex such as a scar, malformation, growth, or abnormal gene expression. An individual patient with symptomatic focal epilepsy usually has a single focus. However, the focus can involve a large, multilobar circuit. Some patients have multiple foci, each with different seizure manifestations.

Temporal lobe epilepsy (TLE) is the most common epilepsy syndrome of adults, accounting for at least 40% of epilepsy cases. Habitual seizures typically begin in childhood or adolescence although onset in adulthood occurs. There may be a history of childhood febrile seizures. Most patients have complex partial seizures, some of which secondarily generalize. *Medial temporal lobe seizures* involve the hippocampal and amygdalar areas. A rising epigastric sensation or vague cephalic sensation is the most common aura symptom. Less frequently, the classical symptom of a foul smell, *déjà vu*, or other odd thinking occurs. Olfactory auras are referred to as *uncinate seizures* because of their origin in or near the uncus of the medial temporal lobe. In *lateral (neocortical) temporal lobe seizures* language impairment (dominant hemisphere), recurring vocalizations (nondominant hemisphere), eye blinking, or formed visual or auditory hallucinations can occur. As a temporal lobe seizure spreads to involve the dominant temporal lobe or bilateral temporal lobe structures, including the limbic system, the seizure becomes complex. A blank stare is often described by witnesses. Automatic motor behaviors, termed *automatisms*, are common in seizures that involve the limbic system (usually in the temporal lobe). Automatisms include orolimentary signs (e.g., lip-smacking, repetitive swallowing) and repetitive hand movements (manual automatisms).

Frontal lobe epilepsy (FLE) can be difficult to diagnose because the scalp EEG may be normal or not reveal a classic epileptic discharge, even during seizures. Depending on the area involved there are at least four different *premotor* frontal lobe seizure semiological patterns. *Supplementary motor* seizures (superior frontal gyri, posterior aspect) consist of contralateral versive posturing of the head and arms such that a fencing posture is assumed; the contralateral arm is extended, the head is turned strongly to that side, and the ipsilateral arm is flexed and held either up above the head or across the chest. *Lateral frontal* seizures manifest as contralateral head and eye deviation. *Hypermotor* seizures (frontal, poorly localized) can be dramatic and consist of wild asynchronous movements and are often confused with psychogenic nonepileptic attacks; thus, they are sometimes termed *pseudo-pseudoseizures*. Almost all hypermotor seizures last less than 40 seconds and typically occur 1 to 5 times a night during sleep and less often during waking. Obscene verbal expletives are commonly uttered loudly during hypermotor seizures.

Frontal absence seizures are rare and are due to diffuse, bisynchronous frontal epileptic activity. These consist of staring and mimic typical or atypical absence seizures (see later). Seizures arising in the posterior frontal lobe motor cortex (precentral gyrus) are classically clonic with a Jacksonian march.

Parietal and occipital lobe epilepsy involve sensory structures and at least initially, have only subjective symptoms. *Parietal lobe seizures* consist of somatosensory sensations or higher cognitive function disruption. The somatosensory sensations can have a Jacksonian march with sensory symptoms progressing along the sensory homunculus. *Occipital lobe seizures* involve unformed or poorly formed visual hallucinations that are often in color (in contrast to the visual aura of migraine, which is black, gray, and white). Forced eye deviation can occur with occipital seizures. Occipital seizures can have a prolonged discharge lasting tens of minutes that is subclinical or minimally clinical before propagating. Parietal and occipital seizures do not become complex until propagating to the temporal lobes or limbic system. *Reflex seizures* are precipitated by a specific stimulus, such as touch, a musical tune, a particular movement, reading, flashing lights, or certain complex visual images. With the exception of the photosensitive response in juvenile myoclonic epilepsy (see later) which is relatively common, reflex seizures are rare and classified as a type of parietal or occipital lobe epilepsy because these regions mediate sensory functions.

Posttraumatic epilepsy is a type of symptomatic focal epilepsy distinguished by its etiology. The likelihood of developing posttraumatic epilepsy relates directly to the severity of the head injury. The relative risk for developing epilepsy after a penetrating wound to the brain (e.g., bullet or shrapnel) is up to six hundred times that in the general population. Severe closed head injuries result in epilepsy in 20% of patients. Severe closed head injuries are defined by the presence of an intracranial hemorrhage (subdural, epidural, subarachnoid, or cerebral contusion), unconsciousness or amnesia lasting more than 24 hours, or persistent abnormalities on neurological examination, such as hemiparesis

or aphasia. Although the majority of the patients with a severe head injury develop seizures within 1 to 2 years, new-onset epilepsy may appear after 20 years or longer. Mild closed head injuries (uncomplicated brief loss of consciousness, no skull fracture, absence of focal neurological signs, and no contusion or hematoma) may minimally increase the risk of seizures. Posttraumatic epilepsy is always focal or multifocal, although only convulsions may be clinically evident, especially with multifocal injury. Several early seizures within a week of a head injury do not necessarily predict that future epilepsy will be present.

Primary Generalized Seizures (Seizure Types)

Primary generalized seizures begin diffusely and involve both cerebral hemispheres simultaneously from the outset. Primary generalized seizures should be distinguished from partial seizures because in some cases they have similar clinical features, yet respond to different treatments.

Absence seizures (historically termed petit mal) occur mainly in children and are characterized by sudden, momentary lapses in awareness with staring. Sometimes rhythmic blinking occurs with a slight loss of neck tone. Most absence seizures last less than 10 seconds. If the absence lasts longer than 20 seconds, automatisms are usually present, making differentiation from partial seizures based on clinical observation difficult. The EEG has a characteristic pattern of generalized 3 per second spike and slow waves (Fig. 118-2) during an absence seizure. Behavior and awareness return to normal immediately after the seizure ends, although brief confusion may be present if the surroundings changed during the seizure. There is no postictal period and usually no recollection that a seizure occurred.

Myoclonic seizures manifest as rapid, recurrent, brief muscle jerks that can occur unilaterally or bilaterally, synchronously or asynchronously, without loss of consciousness. To be a seizure, the myoclonus must have a corresponding discharge on EEG. Other types of myoclonus, such as benign nocturnal (hypnic) jerks, or subcortical and spinal myoclonus related to lesions,

FIGURE 118-2 Absence (petit mal) epilepsy. The electroencephalogram shows the typical pattern of generalized 3-Hz spike-wave complexes associated with a clinical absence seizure.

which do not have an EEG correlate, are not considered epileptic seizures. The jerks of myoclonic seizures range from small movements of the face or hands to massive bilateral spasms that simultaneously affect the head, limbs, and trunk. Repeated myoclonic seizures may crescendo and evolve into a generalized tonic-clonic seizure. Although myoclonic seizures can occur at any time, clusters shortly after awakening are typical.

Primary generalized tonic-clonic seizures may begin with a few myoclonic jerks or abruptly with a tonic phase lasting 20 to 60 seconds and then a clonic phase of similar duration followed by a postictal state. Although there are usually no focal features, sometimes head turning occurs; this movement does not suggest a specific localization. If the onset is missed, it is often not possible to distinguish a primary generalized convulsion from a secondarily generalized one due to focal epilepsy.

Idiopathic Generalized Epilepsy (Epilepsy Syndrome)

The idiopathic (primary) generalized epilepsies (IGEs) are likely polygenic resulting from a combination of mutations and polymorphisms in genes involved in thalamocortical circuitry. Different members of the same family often have dissimilar phenotypes. However, only rare IGE genes have been identified. A person with IGE has a 10% chance of passing the condition to a child. Most people with IGE have normal intelligence.

Childhood absence epilepsy (CAE; *pyknolepsy*, *petit mal epilepsy*) is the most common type of childhood epilepsy. It begins between 3 to 12 years of age with a peak at 7 years. Children with CAE have frequent absences (often hundreds per day) and are sometimes initially thought to have attention problems or to be daydreamers. Parents tend to report more absences at meal times, but that is due to closer observation; the absences are present throughout the day. One half of children with CAE have occasional GTC seizures. CAE is self-limited and seizures and the EEG abnormalities resolve by young adulthood. The absence seizures of CAE are typically provoked by hyperventilation, a useful procedure in the office setting and during an EEG.

Juvenile myoclonic epilepsy (JME) begins between age 8 and 20 years old. It is characterized by clusters of myoclonic seizures in the morning, starting shortly after awakening. The clusters typically persist for several to 30 minutes. The jerks are predominantly in the arms and last less than one second each. Consciousness is preserved. An affected teenager often fails to mention the morning jerks unless specifically asked. Sometimes there is a history of throwing breakfast utensils or toothbrushes due to the jerks. JME is often diagnosed after a morning GTC seizure. In JME, GTC seizures are particularly common after sleep deprivation or alcohol consumption during the prior night. People with JME are usually photic sensitive. That is, the seizures and EEG discharges are activated by flickering lights between 5 to 20 Hz (*photic-paroxysmal* or *photic-convulsive* response). This is a type of reflex seizure. Some people with JME also have absence seizures. The EEG is similar to that seen in CAE, but the generalized spike and slow wave discharges are slightly faster (3 to 4 Hz) and often have polyspike components. In contrast to CAE, the seizures in JME persist into adulthood and can be lifelong, although they lessen with age.

Less common IGE phenotypes include *juvenile absence epilepsy* (JAE) and *generalized tonic-clonic seizures alone* (GTCA). In JAE the predominant seizure type is absence with onset in the teenage years and, like JME, persists into adulthood. In GTCA the predominant seizure type is a convulsion, sometimes with a predilection for the morning. Less frequent absences or myoclonic seizures can occur in GTCA. Although onset of IGE is typically during childhood or teenage years, rare cases occur with onset in all ages of adulthood and are called *adult absence epilepsy* (AAE).

Symptomatic Generalized Seizures (Seizure Types)

Symptomatic generalized seizures involve rapidly synchronized abnormal brain activity across the corpus callosum or involving midbrain structures occurring in brains with diffuse or multifocal dysfunction usually from early life.

Drop seizures can be either or both tonic and atonic. “Drop” implies that if the patient is upright they fall with no protective reflexes. Patients with drop seizures often suffer head injuries and should wear a helmet except when they are directly attended by a care provider, in a secure chair, or lying down. During a *tonic seizure*, the arms abruptly thrust forward at a 90 degree angle to the body and the entire body stiffens. Classically the fall is backwards. During an *atonic seizure*, tone is abruptly lost in the postural muscles and the patient falls forward.

Atypical absence seizures manifest as staring or mental slowing associated with a slow generalized spike and slow wave discharge (2.5 Hz or less) on the EEG. They may last minutes or even hours. Fluctuating levels of awareness and gradual onset and offset is described with atypical absences.

Symptomatic Generalized Epilepsies (Epilepsy Syndrome)

Symptomatic generalized epilepsies occur in people with multifocal or diffuse brain dysfunction from early in life. There is usually an associated encephalopathy with some degree of developmental delay. In addition to all of the seizure types that occur in focal and idiopathic generalized epilepsy, people with symptomatic generalized epilepsies have tonic and atonic drop seizures and atypical absence seizures.

There are several unrelated types of epilepsy under the Symptomatic Generalized Epilepsy syndrome classification, with the most common being the *Lennox-Gastaut syndrome* (LGS).

The LGS is a common form of symptomatic generalized epilepsy due to diffuse or multifocal brain dysfunction. LGS presents from 2 to 10 years of age. Sixty percent have preexisting encephalopathy and developmental delay and 20% had infantile spasms (see later). LGS is responsible for 5% to 10% of childhood epilepsy. It is characterized by the combination of tonic or atonic seizures, myoclonic seizures, and atypical absences with the characteristic EEG pattern of 2.5 Hz or slower generalized spike and slow waves. During sleep there are bursts of diffuse fast rhythms on the EEG consistent with tonic or atonic seizures often with minimal clinical expression. Tonic-clonic and partial seizures also occur. Almost all people with LGS have developmental delay with associated behavioral disorders. LGS is a chronic condition requiring supervision; many ultimately live in group homes. If drop seizures are present, and the patient is ambulatory, a helmet should be prescribed for protection.

Infantile Spasms are often a precursor of the LGS, although not formally classified as symptomatic generalized epilepsy. By definition, infantile spasms begin during the first year of life. They affect approximately 1 in 5000 children. The epileptic spasms manifest as flexor or extensor tonus, myoclonus, or a mixed pattern. The spasms last 1 to 20 seconds each and occur in clusters for up to 20 minutes. *West Syndrome* is the combination of epileptic spasms, hypsarrhythmia (a chaotic, disorganized epileptiform EEG pattern), and mental retardation. It is common for the term infantile spasms to be used synonymously with West syndrome. Infantile spasms have a poor prognosis with over 90% developing mental retardation and most progressing to symptomatic generalized epilepsy; a small percent of cryptogenic cases recover. There are many causes of infantile spasms including perinatal insults, cerebral malformations, CNS infections, tuberous sclerosis, and inborn errors of metabolism.

Other Seizure Conditions

Febrile seizures affect between 3% and 5% of children younger than the age of 6 years. About 30% of children have more than one episode; the likelihood of recurrence is greater if the first seizure occurs before 1 year of age or there is a family history of febrile seizures. There are a number of genes that, when mutated, predispose to febrile seizures. Although most affected children have no long-term consequences, febrile seizures increase the risk of developing epilepsy later in life. This risk is low for most children (2% to 3%), but is 10% to 15% in those who had prolonged or focal febrile seizures (*complicated febrile seizures*), a family history of nonfebrile seizures, or neurological abnormalities before the first febrile seizure.

DIAGNOSIS

Accurate diagnosis is the cornerstone of epilepsy treatment. The diagnostic evaluation has three objectives: to determine that the events are epileptic seizures, to identify a specific underlying cause, and to establish if the seizures are symptomatic and isolated or if epilepsy is present and, if so, to determine the specific epilepsy syndrome.

History and Examination

The patient's and witnesses' descriptions of the events are central to diagnosis. Extra attention should be given to exploring details of the behavior during the seizure. The setting of the seizure can suggest acute causes such as drug withdrawal, central nervous system infection, trauma, or stroke. Recent-onset seizures in an adult suggest a new intracranial lesion. A remote history of seizures suggests epilepsy. Any focal feature before, during, or after the seizure suggests a structural brain lesion requiring appropriate investigation. The pattern of the seizures and the patient's age are often important clues to the seizure and epilepsy type.

The physical examination is normal in most patients with epilepsy. Examination should seek overt or subtle focal neurological signs: slight unilateral lower facial paresis, clumsy fine finger movements, or mild hyperreflexia. These can be present in focal epilepsy with a contralateral seizure focus. Careful skin examination is indicated to detect features of neurocutaneous syndromes such as a facial port-wine stain involving the upper eyelid

in Sturge-Weber syndrome, hypopigmented macules (ash-leaf spots), shagreen patch, facial angiofibromas in tuberous sclerosis, and café-au-lait spots and axillary freckling in neurofibromatosis. Asymmetry in the size of the hands, feet, or face signifies a long-standing abnormality of the cerebral hemisphere contralateral to the smaller side. Absence seizures can be triggered in untreated children with hyperventilation for 2 to 3 minutes.

Laboratory Tests—EEG

Electroencephalography (EEG) is the most helpful diagnostic test for seizures and epilepsy. EEG findings help establish the diagnosis, classify the seizures correctly, identify the epilepsy syndrome, and make therapeutic decisions. In combination with suitable clinical findings, *epileptiform EEG discharges*, termed *spikes* or *sharp waves*, strongly support a diagnosis of epilepsy. In patients with recurrent seizures, focal epileptiform discharges are consistent with focal epilepsy, whereas generalized epileptiform activity usually indicates a generalized form of epilepsy. However, most EEGs are obtained between seizures, and interictal abnormalities alone cannot prove or disprove a diagnosis of epilepsy. Up to 50% of patients with epilepsy show epileptiform abnormalities on their initial EEG. The chance of capturing epileptiform activity is enhanced by sleep deprivation the night before the test so that the patient sleeps during a portion of the EEG recording. Serial EEGs increase the yield of positive tracings. A small proportion of patients with epilepsy have normal interictal EEGs despite all efforts to record an abnormality.

The interpretation of the interictal EEG is confounded by two factors. Epileptiform discharges occur in about 2% of normal people; many of these may be asymptomatic markers of a genetic trait, especially in children. Also, the interpretation of the EEG is subjective. Normal benign variant waveforms and artifacts can be misinterpreted as epileptiform activity and erroneously considered to be evidence of seizure susceptibility.

Epilepsy can be definitively established by recording a characteristic ictal discharge during a representative clinical attack. This is uncommon during routine EEG recordings, but can be accomplished with *inpatient video-EEG long-term monitoring* performed at many epilepsy centers throughout the world. Inpatient video-EEG monitoring is indicated in people who have ongoing seizures despite being treated with appropriate antiseizure medications. About one third of patients admitted for long-term monitoring are found to not have epilepsy; these patients have psychogenic nonepileptic attacks. In the 25 to 30% of people with focal epilepsy who continue to have disabling seizures despite trials with multiple AEDs, inpatient video-EEG monitoring to define the seizure focus is a critical test for determining candidacy for resective epilepsy surgery.

Laboratory Tests—Neuroimaging

Brain MRI complements EEG findings by identifying structural pathology that is causally related to the development of epilepsy. MRI is the best test to detect epileptogenic cerebral lesions including hippocampal sclerosis, neuronal migration disorders, tumors, focal atrophy, arteriovenous malformations, and cavernous malformations. It is important to obtain a complete imaging study that includes T1-weighted, T2-weighted, and inversion-recovery sequences in coronal and axial planes with and without contrast. Imaging in the coronal plane perpendicular

to the long axis of the hippocampus has improved detection of hippocampal atrophy and hippocampal high T2 signal; findings that correlate with the pathological finding of hippocampal sclerosis and an epileptogenic temporal lobe. Additional sequences that should be routine include T2-weighted gradient-echo (GRE), to detect hemosiderin indicating old hemorrhage associated with vascular malformations or trauma, and diffusion-weighted images (DWI) for cytotoxic edema sometimes present with acute cerebral injury from prolonged seizures.

An MRI should be obtained in all patients suspected of having epilepsy except those with definite benign epilepsy with centrotemporal spikes (BECTS) or definite idiopathic generalized epilepsy (e.g., CAE and JME). CT scan with contrast is an alternate study for those who cannot have MRI, but is not as good at detecting small lesions. Any patient with seizures and abnormal neurological findings or focal slow-wave abnormalities on EEG should have neuroimaging. Repeat neuroimaging should be considered if there is an unexplained change in seizure pattern to evaluate for a new lesion.

Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) use physiologically active, radio-labeled tracers to image the brain's metabolic activity (PET) or blood flow (SPECT). SPECT is most useful when an ictal and interictal study are combined to identify an extratemporal seizure focus. Abnormalities on PET or SPECT can be present when brain structure on MRI is normal.

Other Tests

Routine blood tests rarely offer diagnostic assistance in otherwise healthy patients with epilepsy. Serum electrolytes, liver function tests, and complete blood count are useful with acute new onset seizures and as baseline studies before antiepileptic drug therapy is started. Adolescents and young adults with unexplained seizures should be screened for substance abuse (especially cocaine) with blood or urine studies. Genetic testing should be considered in specific cases with suspected phenotypes, especially if a positive genetic test would alter therapy, such as in SCN1A associated epilepsies (e.g., Dravet syndrome). Lumbar puncture is indicated only if there is a suspicion of meningitis, encephalitis, or a CNS glucose transporter abnormality. Repeated generalized seizures and status epilepticus can increase cerebrospinal fluid protein content slightly and produce a mild pleocytosis for 24 to 48 hours; cerebrospinal fluid pleocytosis should be attributed to seizures only in retrospect after excluding an intracranial inflammatory process. An electrocardiogram (ECG) should be obtained in any young person with a first generalized seizure if there is a family history of arrhythmia, sudden unexplained death, or episodic unconsciousness. An ECG should also be obtained in any patient with a personal history of cardiac arrhythmia or valvular disease.

DIFFERENTIAL DIAGNOSIS

Not every paroxysmal event is a seizure, and misidentification of other conditions leads to ineffective, unnecessary, and potentially harmful treatment. Misdiagnosis accounts for patients who have not responded to antiepileptic drug treatment. The conditions confused with epilepsy depend on the age of the patient and the nature and circumstances of the attacks (Table 118-3).

TABLE 118-3 NONEPILEPTIC EPISODIC DISORDERS THAT MAY RESEMBLE SEIZURES

Movement disorders: subcortical myoclonus, paroxysmal choreoathetosis, episodic ataxias, hyperekplexia (startle disease)
Migraine: confusional, vertebrobasilar, visual auras
Syncope
Behavioral and psychiatric: psychogenic nonepileptic attacks (pseudoseizures), hyperventilation syndrome, panic/anxiety disorder, dissociative states
Cataplexy (usually associated with narcolepsy)
Transient ischemic attack
Alcoholic blackouts
Hypoglycemia

Nonepileptic paroxysmal disorders that are confused with epileptic seizures have sudden, discrete abnormal behaviors, variable responsiveness, changes in muscle tone, and various postures or movements.

Psychogenic nonepileptic attacks (PNEA), such as pseudoseizures and psychogenic nonelectrical seizures, frequently cause intractable “epilepsy” in adults. PNEA are due to the unconscious mind converting emotional conflicts or stressors into a physical state, mimicking a seizure. Some patients with psychogenic seizures also have epilepsy. Definitive diagnosis requires video-EEG documentation, although a history of atypical and nonstereotyped attacks, emotional or psychological precipitants, psychiatric illness, lack of response to antiepileptic drugs, and repeatedly normal interictal EEGs suggest psychogenic attacks. About 80% of patients with PNEA have been the victims of physical or sexual abuse. PNEA are more common in females.

Panic attacks (anxiety attacks) with hyperventilation can superficially resemble partial seizures with affective, autonomic, or special sensory symptoms. Hyperventilation typically causes perioral and finger tingling. Prolonged hyperventilation results in muscle twitching or spasms (tetany); affected patients may faint.

Syncope (see Chapter 9) refers to the symptom complex that occurs when there is a transient global reduction in cerebral perfusion associated with cardiovascular dysfunction. Loss of consciousness lasts only a few seconds, uncommonly a minute or more, and recovery is usually rapid. If the cerebral ischemia is sufficiently severe, the syncopal episode may include tonic posturing of the trunk or clonic jerks of the arms and legs and incontinence (*convulsive syncope*).

Some forms of *migraine* can be mistaken for seizures, especially if the headache is atypical or mild. The visual aura, present in some migraineurs, is typically black, gray, and white; a colored aura almost always indicates an epileptic seizure. Basilar artery migraine, usually in children and young adults, can include lethargy, mood changes, confusion, disorientation, vertigo, bilateral visual disturbances, and loss of consciousness.

TREATMENT

If the cause of symptomatic seizures is corrected, AEDs are usually not necessary. Adults with a single, unprovoked seizure and normal clinical and laboratory findings frequently do not have subsequent seizures; AEDs are usually not indicated if only one seizure has occurred. However, patients with focal neurological findings on clinical, radiological, or EEG examinations are more likely to have repeated seizures. In individual

patients, social considerations may dictate treatment after a single seizure.

Medication Therapy

If seizures are recurrent, the goal of treatment is complete seizure freedom. In the United States, as of 2013, there were 25 AEDs in standard use to treat epilepsy with several other medications sometimes used as adjuncts. There is no perfect AED; all have potential toxic side effects and idiosyncratic reactions. For over one half of people with epilepsy the appropriate AED for their type of seizures can be completely effective and well tolerated. However, for about one quarter of people with epilepsy, no AED or combination of AEDs is completely effective. Once the seizure type and epilepsy syndrome is determined, an initial and, if needed, subsequent AED, should be chosen based on both its anticipated efficacy and toxicity profile. All AEDs can cause sedation, cognitive dysfunction, and incoordination in some patients, especially at high levels. Various rare, sometimes life threatening, reactions can occur with all of the AEDs. Commonly encountered situations are:

Idiopathic generalized epilepsy (CAE, JME, others)

- In all idiopathic generalized epilepsies, valproate or lamotrigine are the first line agents and result in complete seizure control in 85% to 90% of patients.
 - Valproate tends to cause weight gain and has been associated with the development of polycystic ovary syndrome, particularly in adolescent females. It results in hair loss in about 5%. It has an increased risk of teratogenicity.
 - Lamotrigine has a small but significant risk of a severe rash (e.g., toxic epidermal necrolysis, Stevens Johnson syndrome) for about the first 2 months after starting. A slow dose escalation substantially lowers this risk. Lamotrigine's metabolism is substantially inhibited by valproate, so in combination, lower doses of lamotrigine are required. Occasionally lamotrigine worsens myoclonus, but it is effective in most cases of JME.
- Second line options include clobazam, topiramate, levetiracetam, and zonisamide.
- In childhood absence epilepsy with exclusively absence seizures, ethosuximide should be the first choice. If any convulsions have occurred, valproate or lamotrigine should be used.
- If there is a history of more than 5 minutes of crescendo absences or myoclonus (often described as a "foggy" state) culminating in a convulsion, then oral benzodiazepines (lorazepam or diazepam) can abort the cluster and prevent a convulsion.
- Absences and myoclonus can be exacerbated by carbamazepine, oxcarbazepine, and GABAergic compounds including gabapentin, pregabalin, and tiagabine. These AEDs should be avoided in idiopathic generalized epilepsy.

Focal Epilepsy

- Almost all of the AEDs (except ethosuximide) can be effective in focal epilepsy. The choice of the first AED should be guided by side effect concerns and pharmacokinetics.
- Phenytoin is the most commonly used AED in focal epilepsy in developed countries. It is typically loaded in the emergency room after the initial seizures and subsequently continued.

However, phenytoin has substantial short- and long-term toxicity and its levels are difficult to regulate due to saturation kinetics and multiple drug interactions. Its toxicities include hirsutism, coarsening of features, and gingival hyperplasia, especially in children and adolescents. Long-term toxicities include osteomalacia, peripheral neuropathy, and cerebellar degeneration with permanent incoordination. Peak level toxicities include nystagmus, gait instability, ataxia and, if the level rises above 50, acute cerebellar degeneration and cardiac arrhythmias.

- Carbamazepine, oxcarbazepine, topiramate, levetiracetam, lamotrigine, and zonisamide are currently used as first line therapy for partial seizures. Carbamazepine and oxcarbazepine can cause hyponatremia. Topiramate can lead to weight loss (often desired), but also has undesirable cognitive side effects and predisposes to renal stones. Levetiracetam can cause severe mood changes and marked sedation, but is usually well tolerated. Lamotrigine needs to be titrated slowly due to the rash risk. Zonisamide, which also predisposes to renal stones, has a long half-life (48 to 72 hours) so is a good option for intermittently noncompliant patients.
- Patients of Asian ancestry should be tested for the HLA-B*1502 allele and patients of Northern European ancestry tested for the HLA-A*3101 allele prior to initiating treatment with carbamazepine, oxcarbazepine, and eslicarbazepine. Patients with these alleles are at increased risk of Stevens Johnson syndrome and toxic epidermal necrolysis when exposed to these drugs.
- Adjunctive treatment for partial seizures includes clobazam, valproate, pregabalin, lacosamide, gabapentin, perampanel, and primidone. The proportion of gabapentin absorbed decreases with increasing dose, which limits its effectiveness. For most, pregabalin is a better choice. Primidone is rapidly converted to phenobarbital by some people, limiting its use.
- Phenobarbital is the most widely used AED in the world due to its low cost. However, it causes sedation and cognitive impairment, and it should be avoided except in difficult to control epilepsy. The exception is neonatal seizures where it is the most commonly accepted AED.

Symptomatic generalized epilepsy (LGS, others)

- All AEDs have a role in the treatment of symptomatic generalized epilepsy, but seizure freedom is rarely achieved. At a minimum, control of the more severe seizures, including drop seizures and convulsions should be the target of therapy. Polytherapy is usually required.
- Valproate is commonly the initial medication instituted.
- Added efficacy can occur with clobazam, lamotrigine, topiramate, levetiracetam, rufinamide, and zonisamide.
- Felbamate may be effective, but its use should be limited to epileptologists due to the significant risk of fatal aplastic anemia and liver failure.
- The vagus nerve stimulator (see later) has a specific role in reducing the severity of seizures in this condition.
- Dravet syndrome and possibly the related syndrome of GEFS+ respond best to topiramate, levetiracetam, and benzodiazepines. Some drugs, including lamotrigine and phenytoin, worsen Dravet syndrome.

Dosing of AEDs must be done with care. Only a few of the AEDs are safe to load or start at a full therapeutic dose. Most should be started with a gradual dose escalation. Management guidelines are: (1) The type of seizures and epilepsy should be defined and the preferred medication should be given in usual doses and then increased until seizure control is complete or side effects occur (Table 118-4); (2) If seizures persist at toxic levels, or if major side effects occur, another agent should be tried; (3) Do not stop one agent until another has been added. Otherwise, status epilepticus may occur; (4) If seizures persist after two agents have been given to toxic levels, consider referral to a specialized epilepsy center for complex combination therapy and video-EEG long-term monitoring; (5) Toxic levels of some AEDs (e.g., phenytoin and carbamazepine) can cause seizures; (6) Extended release and longer acting AEDs are preferred for most patients; (7) Patients should be counseled to adhere to the medication regimen. Pill boxes should be encouraged. Medication noncompliance is a leading cause of poor seizure control.

Epilepsy Surgery

In most patients, epilepsy is controlled with medication. When seizures cannot be controlled by adequate trials of two appropriate single agents or by the combination of two agents, the epilepsy is termed *medically intractable* (or *refractory*), a situation encountered in approximately 25% of patients with symptomatic focal epilepsy. Such patients are at risk for the consequences of seizures: inability to drive; stigmatization by schools, employers, and families; and threats to personal educational and occupational goals. In appropriately selected cases, epilepsy surgery can abolish seizures with restoration of normal neurological function. The accurate localization of a small, safely resectable seizure focus requires intensive investigation at a specialized center.

Dietary Therapy

The *ketogenic diet* is a very high fat diet with restricted carbohydrates and protein carefully designed to cause a ketotic state mimicking starvation, but supplying adequate nutrition. It is mainly used in developmentally delayed children with severe symptomatic generalized epilepsy. The ketogenic diet can be

effective in this most refractory form of epilepsy, resulting in seizure-freedom in 15% to 20%. However, the diet is hard to maintain and requires a dedicated, cooperative caregiver and a specially trained dietician.

The *modified Atkins diet* (MAD) and *low glycemic-index diet* are scaled-down versions of the ketogenic diet with mainly carbohydrate restriction. These diets are more palatable than the ketogenic diet and can be tolerated by adults. The slight ketosis achieved sometimes results in a dramatic seizure reduction in any form of epilepsy.

Neurostimulators

The *vagus nerve stimulator* is an implanted device similar in appearance to a cardiac pacemaker. The stimulating electrode is placed on the left vagus nerve in the neck and programmed to stimulate the nerve for 30 seconds every 3 to 5 minutes. Swiping a magnet over the device gives an extra stimulation that can sometimes abort a seizure. In up to two thirds of patients, partial seizures are reduced by 50% or more and seizure intensity decreases.

Another strategy in medically refractory focal epilepsy is the *responsive neurostimulator*. Chronically implanted electrodes at the seizure foci are used to rapidly detect seizure onset and abort the seizure within a few seconds by delivering an electrical stimulation directly to the seizure focus. *Deep brain stimulation* to the bilateral anterior nuclei of the thalami may also improve seizure control.

Status Epilepticus

Status epilepticus can occur with partial or generalized epilepsy and is defined as prolonged or rapidly recurring seizures without full intervening recovery. *Acute repetitive seizures* are defined as a cluster of seizures over minutes to hours with intervening recovery.

Convulsive status epilepticus (Grand mal, major-motor) is a medical emergency. Continuous generalized epileptic activity can damage the brain permanently. The most frequent cause is abrupt withdrawal of AEDs (e.g., noncompliance) in a person with known epilepsy. Other precipitants include withdrawal of alcohol or drugs in a habitual user, cerebral infection, trauma, hemorrhage, and brain tumor.

TABLE 118-4 FREQUENTLY PRESCRIBED ANTIPILEPTIC DRUGS

NONPROPRIETARY AED NAME	ADULT TOTAL DOSE PER DAY	DOSE FREQUENCY (IN HOURS)	"THERAPEUTIC" CONCENTRATIONS
Carbamazepine	800-1600 mg	6-8 (12 for sustained release)	6-12 µg/mL
Ethosuximide	750-1500 mg	8-12	40-100 µg/mL
Gabapentin	900-3600 mg	6-8	Uncertain
Lacosamide	200-600 mg	12	Uncertain
Lamotrigine*	100-800 mg	12	2-15 µg/mL
Levetiracetam	500-3000 mg	12	15-45 µg/mL
Clobazam	20-60 mg	12	Uncertain
Oxcarbazepine	600-2400 mg	8-12	15-45 µg/mL
Phenobarbital	60-240 mg	24	15-40 µg/mL
Phenytoin	200-600 mg	24	10-20 µg/mL
Pregabalin	100-600 mg	8-12	Uncertain
Topiramate	50-600 mg	12	2-20 µg/mL
Valproate	500-6000 mg	8 (12-24 for sustained release)	50-120 µg/mL
Zonisamide	100-600 mg	24	Uncertain

*Slow initial dose titration mandatory for lamotrigine and often indicated for other agents.

Complex partial status epilepticus manifests as a sustained state of confusion often associated with motor and autonomic automatisms. Some attacks produce bizarre behavior or stupor. Patients may resist assistance due to their abnormal state, which can last for hours or even days. The EEG usually shows nearly continuous discharging activity predominating in one or both temporal regions.

Absence status epilepticus (petit mal status) resembles complex partial status and consists of a confused state with some automatic behaviors. The EEG is characteristic with continuous runs of generalized 3 to 4 Hz spike and slow wave activity. The condition occurs in children or young adults with known absence epilepsy. Rarely, absence status occurs as the first manifestation of epilepsy in adults with no history of seizures. *Atypical absence status* with fluctuating confusion lasting for hours or longer occurs in patients with symptomatic generalized epilepsy (e.g., Lennox-Gastaut syndrome) and is accompanied by a generalized spike and slow wave pattern of 2.5 Hz or slower on the EEG.

Partial motor status, also known as *epilepsy partialis continua*, ranges from highly focal, clonic movements of the face or hand to jerks that involve most of the limb or half the body. The clonus frequency can vary from one every three seconds to three per second. It is relatively uncommon. Its causes include stroke, trauma, neoplasms, encephalitis, and hyperglycemia; sometimes the cause never becomes clear. *Epilepsy partialis continua* often resist all efforts at treatment and neurosurgical removal of the causative lesion is sometimes required.

Physicians infrequently witness seizures; most of the time they learn about the semiology during the history. Merely observing a patient in the midst of a seizure does not indicate that the patient should be treated for status epilepticus. However, once status epilepticus is diagnosed, treatment is urgent. The longer status epilepticus lasts, the more difficult it is to terminate and the more likely it is to cause brain damage. Aggressive therapy is mandatory for convulsive status epilepticus (Table 118-5). If initial therapy is not rapidly effective, anesthetic agents requiring intubation and ventilation should be used within an hour of onset. Complex partial status can also result in permanent neuronal injury and should similarly be treated aggressively, although therapeutic decisions are often made to try to stop complex partial status with agents that do not cause respiratory depression to avoid intubation. Absence status is unlikely to result in permanent sequelae and usually responds promptly to benzodiazepine treatment. Investigation of the cause of the status epilepticus should be undertaken during the treatment and continued after the seizures stop. Severe hyperglycemia can produce refractory partial motor and complex partial status; seizures stop once hyperglycemia is corrected.

Postanoxic status myoclonus is accompanied by generalized polyspike epileptiform discharges on the EEG but is usually unresponsive to treatment for status epilepticus. It typically indicates an irreversible condition with a poor prognosis.

GENETIC COUNSELING AND PREGNANCY

Heredity

Patients with epilepsy should be advised about the hereditary risks to their offspring, although in most people with epilepsy it does not influence their decision about having children. The

TABLE 118-5 TREATMENT OF CONVULSIVE STATUS EPILEPTICUS

TIME (MIN)	STEPS
0-5 (ABCs)	Give O ₂ ; ensure adequate ventilation Monitor: vital signs, ECG, oximetry Establish intravenous access; obtain blood samples for glucose level, complete blood cell count, electrolytes, Ca, Mg, toxins, and AED levels
6-9 (glucose) (benzodiazepine)	Give glucose if blood glucose level is low or unavailable. In adults give 100 mg thiamine as well. Intravenously administer 1-2 mg of lorazepam or midazolam or 5-10 mg of diazepam as initial therapy. Alternatively use rectal diazepam gel 0.2 mg/kg.
10-20	If the initial dose of benzodiazepine is not effective, then continue to intravenously administer either lorazepam 1-2 mg every 5 minutes up to a maximum of 0.1 mg/kg or diazepam 5-10 mg every 5 minutes up to a maximum of 30 mg in patients over 12 years old. If diazepam or midazolam is used and the status epilepticus stops, phenytoin (or another AED) should be administered promptly to prevent recurrence of seizures as diazepam and midazolam's duration of action against seizures can be less than 30 minutes.
21-40 (phenytoin)	If status epilepticus persists, administer 20 mg/kg of fosphenytoin* intravenously no faster than 3 mg/kg/min up to 150 mg/min in adults. (Alternatively use phenytoin at maximum 1mg/kg/min up to 50 mg/min in adults in a proximal IV.) Monitor carefully for hypotension, arrhythmia, local extravasation.
>40 (phenobarbital) (intubate)	If the seizures do not stop after fosphenytoin/phenytoin, give 20 mg/kg of phenobarbital intravenously at maximum 100 mg/min. When phenobarbital is given after a benzodiazepine, ventilatory assistance is usually required.
(general anesthesia)	If status epilepticus persists, give general anesthesia (e.g., propofol, midazolam, or lorazepam drip) to induce a burst suppression pattern (EEG monitoring, if available, should be instituted). Vasopressors or supplemental IV fluids are often necessary.
(alternatives)	Alternative/additional treatments include IV valproate (30 mg/kg) load, levetiracetam, and lacosamide.

ABCs, Airway, breathing, and circulation; AED, antiepileptic drug.

*Always dosed in phenytoin-equivalents (PE).

idiopathic epilepsies have complex inheritance with about 10% of children of an affected parent developing seizures. There are over 200 Mendelian-inherited syndromes with epilepsy, all rare.

Teratogenicity

Children of mothers taking antiseizure medications have a birth defect rate of 6% to 9%, which is two to three times that of the general population. Convulsions, however, pose a substantial risk to the mother and fetus. Thus, AEDs should not be stopped during pregnancy. Two AEDs, valproate and carbamazepine, have been incriminated in neural tube closure defects. Since the neural tube closes by 28 days of fetal development, this defect develops before the mother is aware she is pregnant. Phenytoin, phenobarbital, and primidone have been associated with a spectrum of neurodevelopmental abnormalities. All five of these older AEDs are classified as pregnancy category D by the FDA and should be avoided if possible. Large registries suggest that the newer AEDs have less teratogenicity, but the data are

incomplete. Use of two or more AEDs (polytherapy) increases the teratogenic risk. Pregnancies in women with epilepsy should be planned. During the year prior to conception, an attempt should be made to minimize the teratogenic potential of the AEDs by changing to a newer AED, to monotherapy from polytherapy, or tapering off the AEDs, if there are reasons to believe that seizures will not recur (see later). The lowest effective dose of the AEDs should be used, but this must be balanced with the risk of a breakthrough seizure. Folic acid deficiency is a well-established factor in neural tube closure defects in the general population. There is little evidence that additional folic acid in a well-nourished woman with epilepsy decreases the AED effects on neural tube closure. However, it is common practice to place women with epilepsy of childbearing age on supplemental folic acid (1 mg) as prophylaxis against a neural tube closure defect. Once pregnancy is planned or recognized, the dose of folic acid is commonly increased to 4 mg per day.

Management during and after Pregnancy

Women with epilepsy have a 1.5- to 3-fold increased rate of complications of pregnancy, including bleeding, toxemia, abruptio placentae, and premature labor. They should be managed as high risk pregnancies. High-quality (focused or type 2) ultrasound, maternal serum alpha-fetoprotein level (elevated in neural tube closure defects), and amniocentesis for chromosomal analysis are used to identify fetal malformations.

During pregnancy AED concentrations decrease due to increased hepatic and renal clearance and increased plasma volume. The free fraction of highly protein-bound AEDs (e.g., phenytoin and valproate) typically increases due to decreased albumin concentration and increased competition for binding sites by sex steroids. Thus, it is essential to monitor drug levels (free levels for highly protein-bound AEDs) prior to conception and at regular intervals throughout pregnancy. Hepatic induction of glucuronidation can dramatically reduce lamotrigine levels, sometimes requiring doubling or tripling of the lamotrigine dose to maintain prepregnancy levels. Lamotrigine levels should be measured at least every month throughout pregnancy. Similarly, oxcarbazepine levels fall by about one third beginning in the first trimester and, thus, the dose should be increased and the level checked at least each trimester.

Emesis, a common problem during early pregnancy, can result in missed and partial doses of AEDs. The expectant mother should have specific instructions to retake a full or partial dose of her AEDs if vomiting occurs after medications are taken. After the child is born, the dose of AEDs should be tapered to the pre-pregnancy amount within days to weeks. The AED levels can be checked 1 to 2 weeks after completing the taper to confirm they are at the patient's baseline. In general, breastfeeding is not contraindicated in women taking antiepileptic drugs.

During the postpartum period the mother with epilepsy may be at increased risk of seizures, especially if her seizures are activated by lack of sleep. To decrease this risk, a support person should perform at least one of the nighttime feedings. Patients whose seizure semiology would put the infant at risk (e.g., dropping or excessively clutching the baby) require childcare modification or supervision.

PSYCHOSOCIAL CONCERNS

Ongoing epileptic seizures often have major emotional consequences for the patient and family. Comorbid depression is present in up to 50% of patients with refractory epilepsy and 20% of patients with controlled epilepsy. Anxiety disorders are also common. Both are often unrecognized and untreated. In people with epilepsy, quality of life impairment is better correlated with depression than seizure frequency. The unpredictable nature of seizures and the necessary activity restrictions cause dependence, decreased self-worth, embarrassment, underemployment, and helplessness. Reduced libido and hyposexuality are common in patients with epilepsy and are often unrecognized.

Family dynamics are often disrupted by the presence of epilepsy. Both families and patients often fear seizures (seizure phobia). Family members may think their loved one is dying when they have a convulsion, especially for the first time. Patients with epilepsy are helped most by complete seizure control, but reassurance and optimistic social guidance can aid immeasurably. Once seizure control is achieved, affected persons should be encouraged to live a near normal life, using common sense as a guide. Although activity restrictions may eventually be lifted, patients with past epilepsy (with the exception of CAE and benign epilepsy with centro-temporal spikes, which completely remit) should be advised to avoid head contact sports, high alpine climbing, scuba diving, and professions requiring work at heights, large amounts of driving, or weapon use.

All states grant automobile driver's licenses to patients with epilepsy provided that no seizures have occurred for specified periods (typically six months to one year). Life and health insurance policies can generally be obtained. Epilepsy foundations and local social service organizations can assist patients with case coordination, including social and vocational considerations.

PROGNOSIS

Sixty to 70% of people with epilepsy achieve a 5-year remission of seizures within 10 years of diagnosis. About half of these patients are eventually seizure-free without AEDs. Factors favoring remission include an idiopathic form of epilepsy, a normal neurological examination, and onset in early to middle childhood (excluding neonatal seizures). Approximately thirty percent of patients continue to have seizures and never achieve a permanent remission with medications. In the United States, the prevalence of intractable epilepsy is 1 to 2 per 1000 population. Such patients should be evaluated at an epilepsy center. Injuries due to seizures are common. Advising patients not to cook, or to use back burners or microwave ovens, can prevent some serious burns. A helmet is advisable for those with drop seizures.

Sudden unexplained death in epilepsy (SUDEP) occurs in 1 per 1000 patients per year taking all forms of epilepsy together. In the most refractory epilepsies, the SUDEP rate is greater than 1 per 200 patients per year. SUDEP may be due to excessive autonomic nervous system sympathetic tone during an unwitnessed seizure with resultant cardiac arrhythmia or pulmonary edema. Suffocation can occur after an unwitnessed convulsion if the patient ends up face down in a pillow. Accidental deaths related to seizures (e.g., motor vehicle collisions) further increase the death rate.

Aspiration with convulsions is common, but can be prevented by turning the head to one side as the convulsion ends.

DISCONTINUING ANTIEPILEPTIC DRUGS

Many patients with epilepsy become seizure-free on medication for an extended period of time. Some patients can discontinue antiepileptic drugs without a relapse. Successful drug withdrawal is most likely if initial seizure control was readily achieved using monotherapy, there were relatively few seizures before remission, and the EEG and neurological examination are normal just before the AEDs are tapered off. A seizure-free interval of at least 2 years is important to reduce the likelihood of relapse; some advocate that seizure-freedom should be present for at least 5 years unless the epilepsy syndrome is known to remit (e.g., CAE or BECTS). Conversely, risk of relapse is high if seizure control was difficult to establish and required polytherapy, if there were frequent convulsions before control was achieved, a focal abnormality is present on neurological examination, or if the EEG demonstrates focal disturbances of background activity or epileptiform activity at the time AED withdrawal is considered.

 For a deeper discussion of this topic, please see Chapter 403, "The Epilepsies," in Goldman-Cecil Medicine, 25th Edition.

Central Nervous System Tumors

Bryan J. Bonder and Lisa R. Rogers

DEFINITION/EPIDEMIOLOGY

Central nervous system (CNS) tumors are of two types, primary or metastatic. Primary tumors arise from a variety of cell types within the parenchyma of the brain or spinal cord or the meninges adjacent to the brain or spinal cord. Metastatic tumors result from spread of systemic cancer to the brain, spinal cord, or meninges. This chapter considers both primary and metastatic brain tumors.

The incidence of primary malignant and nonmalignant brain tumors in the United States is 14.8/100,000. Approximately 20,500 individuals were diagnosed with primary malignant brain tumors in 2007 in the United States. High-grade gliomas and meningiomas are the most common types of adult primary brain tumors. The incidence of primary brain tumors is low in young adults but increases with advancing age and reaches a plateau between the ages of 65 and 79 years. There is a recent rise in the incidence of primary brain tumors among elderly patients, but part of this increase is due to improved detection methods. Meningiomas are the most common benign intracranial tumor and account for up to one third of benign brain tumors. The incidence of primary CNS lymphoma (PCNSL) is increasing in all age groups, accounted for only in part by CNS lymphoma associated with the acquired immunodeficiency syndrome (AIDS). Population-based studies suggest an incidence rate of 10/100,000 population with brain metastasis, but brain metastatic tumors are more common than primary CNS tumors. Because incidence rates are based on tumor registries and many patients with brain metastasis do not undergo surgery, they are underrepresented in these statistics.

Primary brain tumors are the second most common cancers in children. Medulloblastomas are the most common malignant pediatric brain tumor. In the United States, between 350 and 500 new cases of pediatric and adult medulloblastomas are diagnosed each year, and the majority of these are pediatric.

The cause of most CNS tumors is unknown. Aside from exposure to ionizing radiation, no environmental agents are known to be causative. Hereditary syndromes that are associated with an increased risk of CNS tumors include neurofibromatosis 1 and 2, tuberous sclerosis, von Hippel-Lindau disease, Li-Fraumeni syndrome, and Turcot's syndrome, but account for less than 1% of primary CNS tumors. Although the chromosomal abnormalities associated with many of these syndromes is known, the specific mechanisms leading to CNS neoplasia have not been defined.

PATHOLOGY

The World Health Organization classification defines brain tumors based on the cell of origin and includes a grading system, which is of use in predicting the biological behavior of the tumor. Most adult primary brain tumors are of neuroepithelial origin and result from neoplastic transformation of astrocytes, oligodendrocytes, or ependymocytes. Astrocytomas are the most common primary brain tumor in adults. Meningiomas derive from arachnoidal cap cells in the meningeal covering of the brain. Common locations of meningioma are the cerebral convexity, falx and parasagittal area, olfactory groove, sphenoid wing, and posterior fossa. They are comprised of heterogeneous histopathology patterns and careful neuropathological assessment is needed for accurate grading.

PCNSL is a rare form of non-Hodgkin lymphoma, typically of B cell origin. It presents within the white matter of the cerebral hemispheres, often in a periventricular location, and is often multiple, especially in AIDS patients. Brain metastasis develops when tumor cells gain access to the systemic circulation and embolize to the brain. Metastases occur most commonly from solid tumors arising in the breast, lung, colon, and skin (melanoma). Lung cancer, both non-small and small cell type, is the most common tumor overall to metastasize to the brain and constitutes up to 50% of cases of brain metastasis. In women, breast cancer is the most common source of brain metastasis. Malignant melanoma is a much less common systemic cancer but carries a high risk of brain metastasis; up to 50% of stage IV melanoma patients develop brain metastasis. Colon and renal cell carcinoma are also common underlying tumors. Other solid tumors are less frequent. Medulloblastomas are of primitive neuro-ectodermal origin and are highly cellular. Homer Wright rosettes can be found in up to 40% of cases. Medulloblastomas are grade IV tumors as they are invasive and rapidly growing, with a tendency to disseminate through the CSF.

CLINICAL PRESENTATION

Symptoms and signs caused by brain tumors typically result from compression or invasion of adjacent neural tissue by the tumor or from vasogenic edema resulting from disruption of the blood-brain barrier caused by vessel compression or invasion from tumor or from "leaky" blood vessels present within tumors. Neoangiogenesis associated with tumor growth typically results in embryonic vessels that lack a normal blood-brain barrier. Because of the uncompromising rigidity of the cranial vault, both histologically benign and malignant tumors may cause symptoms

even when they are small. Symptoms caused by low-grade primary brain tumors tend to be slowly progressive whereas those in mid-grade and high-grade histology are acute or subacute (over weeks to months). The exception is the clinical presentation of a low-grade glioma with seizure. Metastatic tumors often present in a subacute fashion but may present acutely when hemorrhage into the tumor occurs. Hemorrhage into metastatic brain tumors is most common with renal cell, melanoma, lung, and choriocarcinomas.

The clinical symptoms and signs depend on the location of tumor. In most pediatric patients with brain tumor, tumors arise in the posterior fossa and result in diplopia, ataxia, dysphagia, or nausea/vomiting. Most of adult brain tumors arise in the cerebral hemispheres and present with symptoms and signs related or supratentorial structure involved: unilateral limb weakness, aphasia, and memory loss are common. Tumors in either location may present with generalized symptoms arising from increased intracranial pressure or meningeal irritation. Headache occurs in up to two thirds of patients as a presenting sign. There are no characteristics unique to this headache, but useful clinical clues include a new or different headache pattern, a progressively worsening headache, and one that occurs at night or on awakening. The pain may localize to the side of the tumor in patients with supratentorial tumors, whereas patients with infratentorial tumors frequently describe pain in the retro-orbital, retroauricular, or occipital region. Other generalized symptoms include changes in mood or personality, a decrease in appetite, and nausea. Projectile vomiting, common in children with posterior fossa tumors, is rare in adults. Meningiomas generally grow slowly; they may also be found incidentally during the evaluation of unrelated neurologic symptoms. Seizures are a frequent presenting sign of low-grade gliomas. Seizures may develop over the course of the illness in a high percentage of other patients with glioma, often in association with tumor progression.

DIAGNOSIS/DIFFERENTIAL

All patients suspected of having a brain tumor should undergo a contrast-enhanced magnetic resonance imaging (MRI) brain scan. If MRI is not available or is contraindicated because of a pacemaker or other condition, brain computed tomography (CT) should be obtained. Brain MRI is preferred because it is more useful in imaging the temporal and posterior fossae and it is more sensitive in detecting the extent of parenchymal involvement by tumor of any type. In addition, advanced sequences such as diffusion, perfusion, and spectroscopy add to the diagnostic accuracy of imaging. Vasogenic edema resulting from leakage of intravascular fluid through a disrupted blood-brain barrier can accompany any type of brain tumor and is easily visible on MRI.

High-grade gliomas typically appear as irregularly shaped contrast-enhancing masses surrounded by edema. Central necrosis is characteristic of glioblastoma (Fig. 119-1). Anaplastic gliomas appear similar, except for less frequent tumor necrosis. Although there are exceptions, most low-grade gliomas do not enhance after intravenous contrast injection (Fig. 119-2). Meningiomas typically demonstrate smooth and homogeneous enhancement originating from the extra-axial space and may also compress adjacent brain. PCNSLs typically present as multiple contrast-enhancing lesions within the white matter but in rare

FIGURE 119-1 Contrast-enhanced T1-weighted MRI demonstrates irregular contrast enhancement with central necrosis in the left temporal lobe. There is adjacent vasogenic edema and mass effect on midline structures.

FIGURE 119-2 Coronal T-weighted MRI following contrast injection in a low-grade astrocytoma shows low attenuation and no contrast enhancement, typical of a low-grade glioma.

instances do not show contrast enhancement. Brain metastases are often located at the grey-white junction of the brain and demonstrate homogeneous enhancement or peripheral enhancement surrounding a necrotic center. When single, a brain metastasis cannot be accurately distinguished from other neoplasm or non-neoplastic entities. Medulloblastomas are usually large by the time they are identified and demonstrate homogeneous enhancement within or superior to the floor of the fourth

FIGURE 119-3 Contrast-enhanced T1-weighted MRI shows a large enhancing tumor in the midline of the cerebellum with compression of the fourth ventricle.

ventricle location (Fig. 119-3). They are often accompanied by hydrocephalus. The desmoplastic variant of medulloblastomas can be located lateral to the fourth ventricle.

The differential diagnosis of contrast-enhancing lesions includes brain abscess, but infection is a consideration only in rare clinical situations. Diffusion-weighted magnetic resonance images can be useful in distinguishing tumor from infection. Low-grade gliomas can be misdiagnosed as cerebral infarction, especially on brain CT. Periventricular enhancement in PCNSL can sometimes be confused with active multiple sclerosis lesions or with brain metastasis. Dural pathologies such as sarcoidosis, meningeal infection, or dural metastasis can mimic a meningioma. Posterior fossa ependymomas in children can mimic medulloblastomas.

Biopsy or resection is the preferred method to establish the histology and grade of primary brain tumors. Exceptions include PCNSL in which malignant cells are identified in the CSF or by vitreous biopsy to establish the diagnosis, and brainstem gliomas in which the MRI appearance is characteristic and biopsy is considered dangerous.

TREATMENT

Maximal surgical resection is the goal for patients with benign and malignant primary brain tumors with the exception of PCNSL in which clinical deterioration can result from resection, and biopsy alone is recommended for diagnosis. Surgical resection provides tissue for analysis and often relieves neurological symptoms; maximal surgical resection improves outcome. Surgical resection is also indicated in patients with a single brain metastasis and who have limited systemic disease with a prognosis of at least 3 months. Small patient series also indicate that resection of up to three brain metastases can be beneficial in extending overall survival and improving quality of life. More than three metastases are typically treated with radiation therapy without surgery.

Standard therapy for newly diagnosed glioblastoma is maximal resection and external beam radiation of 60Gy over 6 weeks in combination with daily temozolomide followed by temozolomide for 6 months. In a prospective randomized trial of newly diagnosed glioblastoma patients, the median survival with radiation and temozolomide was 14.6 months versus 12.1 months with radiation alone. In addition, the 2-year survival rate was superior with the combined regimen (26.5%) versus radiation alone (10.4%). O-6-methylguanine DNA methyltransferase (MGMT) is a DNA repair gene that reduces the efficacy of temozolomide and other DNA-damaging treatments for cancer. Methylation of the MGMT promoter in tumor tissue silences this gene and results in improved survival in glioblastoma. Determination of the promoter status of MGMT is often obtained as a part of clinical research trials but is rarely used in clinical practice.

The introduction of “targeted agents” that are designed to deactivate oncogenic pathways is a major advance in cancer treatment, including glioblastoma. Bevacizumab, a monoclonal antibody to vascular endothelial growth factor, is associated with a high response rate (6 month progression-free survival of 46%) in recurrent glioblastoma, although the effect on overall survival is not significant. Molecular markers in glioblastoma that are predictive and prognostic of outcome have not yet been identified. There is some evidence that tissues harboring IDH1 mutations are correlated with a superior outcome compared with wild type IDH1. The discovery of molecular “drivers” may lead to identification of targets for therapy.

Anaplastic gliomas are treated by maximal surgical resection, followed by external beam radiation. Despite the overall better prognosis for anaplastic gliomas, chemotherapy is frequently recommended but of uncertain benefit. One anaplastic glioma exquisitely sensitive to chemotherapy is the AO with codeletions of 1p and 19q. Small clinical trials have evaluated the benefit of chemotherapy alone in these patients. Deferring radiation until the time of tumor progression may reduce the CNS toxicity associated with brain radiation.

The long-term progression-free survival and overall survival of low-grade glioma patients is better than those with glioblastoma or anaplastic glioma, but malignant transformation occurs in up to 50% of such patients and close monitoring is required. Patients with low-grade gliomas should be treated initially with surgical resection. Postsurgical management of low-grade gliomas remains controversial, specifically whether radiation should be administered at diagnosis or delayed until the time of progression. The only prospective clinical trial to compare early versus delayed radiation therapy demonstrated that early radiation does not improve survival but does delay the time to tumor progression. In general, radiation therapy is deferred for patients younger than 40 years of age who have undergone complete resection. An ongoing cooperative group trial seeks to determine if temozolomide chemotherapy added to radiation offers a survival advantage over radiation alone.

Maximal surgical resection is important in patients with meningioma to reduce the risk of relapse. When complete removal is not possible, radiation therapy should be considered, depending upon the location of the tumor and regardless of grade. Radiation therapy is recommended regardless of the

extent of resection for malignant meningioma. Chemotherapy for this disease has been disappointing.

Symptoms and imaging abnormalities associated with PCNSL often improve with the administration of corticosteroids because of the cytotoxic effects of steroids on lymphoma cells. However, administration of steroids before brain biopsy reduces the yield of tissue biopsy. Surgical biopsy, but not resection, is the recommended method for diagnosis. The treatment for this tumor is currently evolving as new treatments emerge. Methotrexate chemotherapy is the most effective treatment. Combining high-dose methotrexate with standard-dose brain radiation carries a risk of neurotoxicity, especially in elderly patients, but reduced-dose whole brain radiation following methotrexate chemotherapy is currently under study.

Standard therapy for patients with a single brain metastasis is complete resection if the tumor is in a noneloquent part of the brain and if the extent of systemic disease predicts a survival of at least 4 to 6 months. In addition, some patients with limited systemic cancer show a survival benefit with resection of up to three metastatic tumors. Resection is typically followed by whole brain radiation or stereotactic surgery to the tumor margin. If the patient does not receive whole brain radiation, close observation with periodic MRI scans is indicated to assess for recurrence at the original site or at other sites in the brain. For patients presenting with more than three metastases, whole brain radiation as indicated. A meta-analysis of the addition of stereotactic radiosurgery and whole brain radiation did not identify a survival benefit when compared with whole brain radiation therapy alone, except for patients with a single brain metastasis (6.5 versus 4.9 months). A variety of systemic chemotherapies show therapeutic efficacy in newly diagnosed and recurrent brain metastasis, depending upon the sensitivity of the brain metastasis to the agent, rather than to delivery of the drug to the lesion.

The extent of resection is prognostic in medulloblastomas. Staging evaluations for the extent of disease include postoperative MRI of the brain and spine and lumbar CSF sampling. Prospective randomized trials and single-arm trials suggest that adjuvant chemotherapy administered during and after craniospinal radiation improves the progression-free survival and overall survival in both average and poor risk groups. The therapy for children younger than 3 years of age excludes craniospinal radiation therapy because of the long-term deleterious effects and includes surgery and chemotherapy alone. Distinct subgroups of medulloblastomas have been identified, and profiling of these subgroups reveals distinct genomic events, several of which represent actionable targets for therapy.

Vasogenic edema associated with parenchymal and meningeal tumor causes neurological symptoms and signs, and it can be life-threatening. Treatment with corticosteroids often reduces edema and improves neurologic function. Dexamethasone is the preferred steroid because of its long half-life. Patients with symptoms related to vasogenic edema often improve within 48 hours of dexamethasone administration. Doses used for treatment of tumor-related edema are typically 4-24 mg/day given in divided doses (2 to 4 times daily). Because steroids can be associated with a variety of adverse effects, the lowest dose and duration of administration should be sought. In patients with severe neurologic signs related to brain edema, an intravenous bolus of 10 to

20 mg dexamethasone should be considered. If the neurologic signs are life-threatening, including signs of brain herniation, mannitol and dexamethasone should be administered and urgent neurosurgical consultation obtained. Seizures should be aggressively managed with antiepileptic drugs. Nonenzyme inducing antiepileptic drugs are generally favored because of a better safety profile than enzyme-inducing drugs and because of the lack of interaction with other medications prescribed to treat the tumor, including steroids and chemotherapy. Prophylactic antiepileptic drugs are generally not recommended for patients with a primary or metastatic brain tumor when there is no history of seizure.

PROGNOSIS

The histology of high-grade glioma, performance status, and age are important predictors of prognosis. Glioblastoma has the worst prognosis, with a median survival of just over 1 year even with aggressive therapy. Good prognosis patients can live more than 2 years. Data from the nationwide Surveillance, Epidemiology, and End Results registry identified an overall median survival of 15 months and 42 months for patients with anaplastic astrocytomas and anaplastic oligodendrogliomas, respectively. This analysis did not include the status of 1p19q chromosomal loss, and the more favorable survival of patients with codeletions was not demonstrated. Low-grade gliomas have a median survival of approximately 5 years, but there is individual variation depending on age, size of tumor, and extent of resection.

Recurrence rates in meningioma depend upon grade and vary from greater than 25% in grade 1 to greater than 90% in grade 3. Risk factors for recurrence include incomplete resection, tumor grade, young age, specific subtypes, brain infiltration, and high proliferative rate.

Five-year survival rates in meningioma are approximately 69% overall but vary significantly with tumor grade. Survival in PCNSL ranges from 1 to several years, depending on patient age and treatment modality. Performance status, age, status of the extracranial tumor, and number of brain metastases are factors that predict prognosis in patients with brain metastasis. The median survival ranges from 3 to 6 months in patients with multiple metastases treated with whole brain radiation therapy. Patients with a single metastasis with limited extracranial disease who undergo surgical resection and whole brain radiation therapy have significantly improved survival (40 weeks) as compared with those who undergo whole brain radiation therapy alone (15 weeks). Importantly, the improved survival is accompanied by a longer period of functional independence. The 5-year progression-free survival in medulloblastomas is 70% to 85%. However, more than one third of patients experience recurrence, and there is no standard therapy at the time of recurrence. Median survival after recurrence is usually less than 1 year. For children less than 3 years of age at diagnosis, 5-year progression-free survival ranges between 30% and 70%, depending on the extent of dissemination at diagnosis.

Demyelinating and Inflammatory Disorders

Anne Haney Cross

INTRODUCTION

In demyelinating CNS disorders, previously normal myelin is lost due to an acquired, typically inflammatory disease. The prototypic CNS demyelinating disorder is multiple sclerosis (MS). Other disorders of this type include neuromyelitis optica (NMO), acute disseminated encephalomyelitis (ADEM), acute transverse myelitis (TM), and optic neuritis (ON).

MULTIPLE SCLEROSIS

Definition/Epidemiology

According to the National Multiple Sclerosis Society, MS affects over 2 million people worldwide. It is a presumed autoimmune disorder, although the exact etiology is still not fully understood. MS begins as a relapsing remitting disease in greater than 80% of patients and ultimately becomes progressive in greater than 50% of untreated patients. Patients with progressive MS accumulate neurologic disability, with or without discrete relapses. MS is more common in females, with the current female to male ratio in North America and in Europe estimated at 2-4:1. An exception is primary progressive MS (see [Clinical Presentation](#)), where the female to male ratio is 1:1.

MS is most common in persons of northern European ancestry. Recent genome-wide association studies indicate that many genes affect the risk of MS, although most confer only a small risk of disease (odds ratios less than 1.5). Alleles within the HLA-DR region (DRB1*15:01 > DRB1*13:03 > DRB1*03:01) are the most well-established and confer the greatest risk with odds ratios between 1.5 and 4 for most populations of northern European ancestry.

Environmental factors can also confer risk for MS. Modifiable factors include low vitamin D blood level, high body mass index during adolescence/young adulthood, and smoking cigarettes. Seropositivity to the Epstein Barr virus increases the risk of MS; a symptomatic case of infectious mononucleosis confers greater risk than seropositivity alone. Though relatively high at 1/1000 to 1/500, the incidence of MS appears relatively stable in North America, the United Kingdom, and Europe. Incidence of MS may be increasing in several regions where MS was not previously prevalent, such as Iran, Turkey, Sicily, and South Africa. These reports of increasing incidence may reflect a real increase or just improved recognition and diagnosis.

Pathology

Classically, MS causes demyelinating CNS white matter lesions with relative sparing of axons. The most common pathology of active lesions in white matter is perivascular mononuclear cell infiltration (monocyte/macrophages, lymphocytes), with a variable presence of antibody and activated complement. Acutely active white matter lesions display blood-brain barrier breakdown, which is manifest on MRI by gadolinium enhancement. Despite its categorization as a “white matter disease,” gray matter is frequently damaged in MS. Gray matter lesions have been under-recognized because they are difficult to see by MRI, and are often not appreciated pathologically without special stains. Such gray matter lesions may occur in the white matter tracts within deep gray structures such as the thalamus or be within gray matter itself, such as in the cerebral cortex. Cortical gray matter lesions can be subpial, extend into cortex from underlying white matter (leukocortical), or be wholly within the cortex. Cortical lesions are characterized by activated microglia and relatively fewer infiltrating lymphocytes and macrophages when compared with white matter MS lesions. Ectopic lymphoid tissue containing B cells, a finding associated with chronic inflammation, has also been observed in meninges of progressive MS subjects.

Clinical Presentation

MS may manifest with a variety of symptoms and signs. Common presentations include: optic neuritis, diplopia (often caused by internuclear ophthalmoplegia due to a propensity of MS to affect the medial longitudinal fasciculus), TM, brainstem syndromes, sensory disturbances, and weakness. Less frequent presentations include seizures, cognitive problems, bladder control problems, and pain. Clinically isolated syndrome (CIS) refers to a single attack that is likely due to CNS demyelination. CIS may be acute or subacute in onset, and may involve a single or more than one CNS region. CIS presentations may look identical to MS attacks, but a formal diagnosis of MS cannot be made until the occurrence of separation of lesions in time. Ultimately, most CIS patients do develop MS. In one study, over 85% of CIS patients with even one silent abnormality on brain or spinal cord magnetic resonance imaging (MRI) eventually developed clinically definite MS. On the other hand, only about 20% of those without any other MRI abnormalities developed clinically definite MS.

Three main clinical subtypes of MS are defined based on clinical course: relapsing remitting, secondary progressive, and primary progressive. Relapsing remitting MS is characterized by clinical stability between individual attacks from which the patient may or may not fully recover. Secondary progressive MS patients have gradual neurologic deterioration and may also have superimposed attacks. Secondary progressive MS develops following an initial relapsing-remitting course in a substantial proportion of relapsing remitting patients, although this proportion may be declining with the advent of disease-modifying therapies. About 10% of MS patients have primary progressive MS, which is characterized by gradual downhill progression from onset without any clinical attacks. It has been proposed to discontinue the uncommon fourth clinical designation, progressive relapsing MS, in favor of *primary progressive MS with activity*.

Diagnosis

The diagnosis of MS requires dissemination of CNS disease in time and in space. No other disease should provide a better explanation. MRI, spinal fluid analyses, evoked potentials (EPs) and ocular coherence tomography (OCT) are tools that may aid in the diagnosis. The McDonald criteria (Table 120-1) allow new MRI lesions to be used to define disease in time after an initial first attack (clinically isolated syndrome). These criteria have made diagnosis easier, without losing significant specificity.

MRI

Classic features seen on brain and spinal cord MRI greatly aid in the certainty of diagnosis. MS lesions are characterized by increased intensity on T2-weighted (T2w) and T2-FLAIR (fluid attenuated inversion recovery) images (Fig. 120-1A). Lesions are usually ovoid, and often localize to the periventricular or subcortical regions, the corpus callosum, the brainstem, and the cervical spinal cord. Periventricular lesions are typically at right angles to the lateral ventricles and bear the moniker “Dawson’s fingers.” On sagittal images, lesions in the corpus callosum are usually flame-shaped (Fig 120-1C). On T1w images, MS lesions may be isointense or hypointense. T1w hypointensity in a chronic inactive lesion denotes underlying tissue damage, including axonal loss (Fig. 120-1D). Enhancement of lesions following administration of gadolinium containing contrast agents indicates blood-brain barrier breakdown, and that a lesion is active (Fig. 120-1B). Enhancing lesions are also often T1w hypointense, but the hypointensity resolves more than 50% of the time. A ring pattern of enhancement is common. Most enhancing MS lesions display no edema or mass effect, but occasional “tumefactive” MS lesions have significant edema on MRI and may require biopsy for diagnosis.

Spinal Fluid Analysis

Evidence of increased intrathecal immunoglobulin synthesis is present in more than 90% of MS patients. Elevated concentrations of CSF IgG and IgM, CSF-restricted oligoclonal bands of immunoglobulin (Fig. 120-2), and a high intrathecal IgG synthesis rate are seen. The IgG index, which is derived from the ratio of CSF to serum IgG and takes BBB integrity into account, is elevated. A mild lymphocytic pleocytosis is frequently seen in CSF during MS relapses.

TABLE 120-1 THE 2010 REVISED MCDONALD CRITERIA

CLINICAL PRESENTATION	LESIONS	ADDITIONAL DATA NEEDED FOR MS DIAGNOSIS*
≥2 attacks	Objective clinical evidence of ≥2 lesions or objective clinical evidence of 1 lesion and reasonable historical evidence of a prior attack	None
≥2 attacks	Objective clinical evidence of 1 lesion	DIS demonstrated by >1 T2w lesion in at least 2 of 4 MS-typical regions of CNS, or 2nd clinical attack at alternate site in CNS
1 attack	Objective clinical evidence of ≥2 lesions	DIT demonstrated by simultaneous presence of asymptomatic gad+ lesion and non-enhancing lesions or a new T2w and/or gad+ lesion on follow-up MRI after a baseline scan, or 2nd clinical attack
1 attack	Objective clinical evidence of 1 lesion (CIS)	For DIS, ≥1 T2w lesion in at least 2 of 4 MS-typical regions of CNS; For DIT, as above; or await a 2nd clinical attack implicating different CNS region
Gradual neurologic progression suggestive of MS (PPMS)	1 year or more of disease progression plus 2 of 3 of following criteria: evidence for DIS in the brain based on ≥1 T2w lesions characteristic of MS, evidence of DIS in the spinal cord ≥2 T2w cord lesions positive CSF (elevated IgG index or oligoclonal bands not present in serum)	

(Modified from Polman CH, Reingold SC, Banwell B, et al: Diagnostic criteria for multiple sclerosis: 2010 revisions to the McDonald criteria, *Ann Neurol* 69(2): 292–302, 2011, Table 4.)

DIS, Dissemination in space; DIT, dissemination in time.

*These criteria were developed using CIS presentations and are therefore most applicable in patients who present with a typical CIS suggestive of CNS inflammatory demyelinating disease. Alternative diagnoses that might better explain the disorder must be considered and reasonably excluded.

Evoked Potentials

Evoked potentials (EPs) detected by surface electrode recording have in the past been useful in detecting subclinical demyelination in the brainstem (auditory EPs), spinal cord (somatosensory EPs), and optic nerves (visual EPs). The advent of high resolution MRI has made these tests less useful.

Optical Coherence Tomography

Optical coherence tomography (OCT) is a safe and rapid means to image the retina and detect evidence of prior optic neuritis. OCT uses safe infrared light to provide images of the retinal layers, including the retinal nerve fiber layer (RNFL) which contains axons that form the optic nerve. The RNFL is thinner than normal in those with remote optic neuritis. Also, RNFL thickness correlates with neurodegenerative aspects of MS, such as brain atrophy.

Differential Diagnosis

The diagnosis of MS requires the exclusion of diseases that might better explain the clinical scenario. The differential diagnosis of MS is broad (Table 120-2). Some diseases that can mimic MS

FIGURE 120-1 **A**, Axial fluid-attenuated inversion recovery (FLAIR) image of the brain from a patient with MS revealing classical periventricular and deep white matter high-signal intensity lesions. **B**, Axial T1-weighted image following gadolinium contrast administration in the same patient as **A**. Enhancing lesions after gadolinium contrast administration, indicating loss of integrity of the blood-brain barrier that is seen with active MS lesions. One enhancing lesion in the right parietal region is ring enhancing. **C**, Sagittal FLAIR image of the brain of an MS patient demonstrating classical flame-shaped pericallosal lesions radiating outward from the ventricle. **D**, Axial T1-weighted image showing areas of T1 low signal intensity (“black holes”).

FIGURE 120-2 Isoelectric focusing gel of cerebrospinal fluid (CSF) and serum of a patient with multiple sclerosis. The CSF (*upper lane*) shows oligoclonal bands cathodal to the pH 8.0, which are not seen in the serum (*lower lane*).

have relapses and others display progressive courses. “Red flags” that are atypical for MS, such as non-CNS symptoms (arthritis, rash, pulmonary, or GI symptoms), bilateral hearing loss, peripheral neuropathy, or atypical time of onset (early childhood or after age 50) should lead the clinician to question the diagnosis of MS.

For a deeper discussion of these topics, please see Chapter 411, “Multiple Sclerosis and Demyelinating Conditions of the Central Nervous System,” in Goldman-Cecil Medicine, 25th Edition.

Treatment

MS treatment can be divided into three categories: treatment of symptoms (e.g. spasticity, fatigue, or depression), treatment of acute relapses, and disease-modifying therapies. This discussion will be largely limited to the latter two categories. [Table 120-3](#) lists some major symptoms and their therapies in MS.

TABLE 120-2 DIFFERENTIAL DIAGNOSIS OF DEMYELINATING DISEASES

DISEASE CATEGORY*	EXAMPLES OF DISORDERS†
Immune-mediated /autoimmune	Multiple sclerosis, neuromyelitis optica (NMO), acute demyelinating encephalomyelitis (ADEM), idiopathic optic neuritis, CRION, idiopathic transverse myelitis, Behçet's disease
Infectious	Progressive multifocal leukoencephalopathy (PML), HTLV-I, HIV, CNS abscess, Lyme disease, Whipple disease, neurosyphilis
Metabolic	Vitamin B12, vitamin E or copper deficiency, central pontine and extrapontine myelinolysis
Neurodegenerative	spinocerebellar ataxias, spine disease (e.g. compressive cervical spondylopathy)
Rheumatologic	Sarcoidosis, systemic lupus erythematosus, antiphospholipid antibody syndrome, Sjögren syndrome
Genetic Disorders	Adrenomyeloleukodystrophy/adrenomyeloneuropathy, hereditary spastic paraparesis, CADASIL, Leber's optic neuropathy, Perlzeus-Merzbacher, Wilson's disease
Neoplastic/Paraneoplastic	CNS Lymphoma, meningeal carcinomatosis, paraneoplastic CRMP-5 IgG, anti-Amphiphysin-1 Abs
Vascular	CNS vasculitis (e.g., giant cell arteritis, primary CNS vasculitis, etc.), spinal dural fistula, Susac syndrome
Iatrogenic	TNF inhibitors, CNS irradiation

*Several of the disorders listed could be placed in more than one category.

†This list is not comprehensive.

TABLE 120-3 SELECTED MS SYMPTOMS AND THEIR MANAGEMENT

SYMPTOM/SIGN	TREATMENT(S)
Stiffness/cramps/spasms/spasticity	baclofen, tizanidine (evidence level A)
Fatigue	Amantadine, modafanil, armodafinil, amphetamines
Depression	Selective serotonin reuptake inhibitors, cognitive behavior therapy
Pain/paresthesias/trigeminal neuralgia	gabapentin, carbamazepine, oxcarbazepine, pregabalin, amitriptyline
Gait impairment	Fampridine SR (Evidence level A)
Nystagmus, with visual impairment	Gabapentin
Dizziness/Vertigo	Meclizine, dimenhydrinate, benzodiazepines
Urinary urgency/incontinence/neurogenic bladder	Oxybutynin, tolterodine, other anticholinergics, BOTOX injection
Impotence/erectile dysfunction	Sildenafil, tadalafil, testosterone supplementation if low
Tonic spasms	Phenytoin, carbamazepine

Relapses that alter function or cause pain are typically treated with corticosteroids. Severe relapses are usually managed with intravenous methylprednisolone at 500-1000 mg daily for 3 to 5 doses, followed by a short oral corticosteroid taper (usually prednisone). Oral corticosteroid tapering courses may be used for mild relapses. Blood pressure, serum electrolytes and glucose, and patient mood should be monitored during corticosteroid therapy. Based on the multi-center Optic Neuritis Treatment Trial (ONTT), this regimen will lead to more rapid recovery from the attack, but is unlikely to alter the degree of eventual recovery (evidence level A).

For severe relapses that do not respond to high-dose IV corticosteroids, a small randomized study showed that plasma exchange can be effective. Plasma exchange was followed by rapid functional improvement in over 40%, with early initiation of plasma exchange treatment the single factor most associated with significant improvement (level A). Subjects in this trial likely included patients with neuromyelitis optica (NMO) and acute disseminated encephalomyelitis (ADEM), in addition to MS.

Relapsing remitting MS (RRMS) is one of only a handful of chronic neurologic disorders with effective disease modifying therapies. The beta-interferons (BIFNs) and glatiramer acetate (GA) are FDA-approved for relapsing remitting MS (level A).

The BIFNs and GA all reduced annualized relapse rate by about 30% in early pivotal studies. Most have also been shown to delay progression to definite MS in patients with clinically isolated syndrome who are at high risk for developing MS.

As of 2015, twelve different DMTs with seven different mechanisms of action are available for MS (Table 120-4). The approved agents have distinct and variable risk profiles. As there are currently no biomarkers that direct the choice of disease modifying therapies for an individual patient, selection of the disease modifying therapy for an individual is based on disease course and severity, patient comorbidities, and individual preferences.

Five BIFNs are approved for use in relapsing remitting MS and clinically isolated syndrome in the United States. They differ in dosage, side effects, and incidence of neutralizing antibody induction. Three BIFNs are identical to endogenous human BIFN-1a (poly ethyleneglycol has been covalently attached to one of the three for longer duration of effect); the other two are BIFN-1b, which differs by one amino acid. BIFNs are immunomodulators, though their exact mechanism of action in MS is not fully established. BIFN therapy is associated with increased circulating soluble VCAM-1, which could produce an effect similar to that of the monoclonal antibody natalizumab. Patients taking BIFNs require monitoring of hepatic transaminases and CBC; elevation of transaminases is uncommon, but may require dose adjustment or discontinuation. Common side effects include a "flu-like" feeling for several hours after a dose, which is usually improved by nonsteroidal anti-inflammatory medications or acetaminophen. BIFNs are given by injection and, as with any injectable drug, skin infection can occur. BIFNs are rated Pregnancy Category C; the BIFNs should be discontinued before conception.

Glatiramer acetate is given as a daily 20 mg subcutaneous injection, or 40 mg SQ three times per week. The drug is a random polymer of four amino acids that are abundant within myelin basic protein, a major protein in CNS myelin. It is considered immunomodulatory not immunosuppressive, although its mechanism of action is not fully understood. Glatiramer acetate has no known drug interactions, and laboratory monitoring is not needed. Side effects include injection site reactions and an uncommon transient tachycardia reaction that occurs soon after an injection. Lipatrophy at injection sites may develop with prolonged use. Glatiramer acetate is pregnancy category B, and is

TABLE 120-4 DISEASE MODIFYING MEDICATIONS FOR MS

DRUG (BRAND NAME), DOSING	APPROVED	MS INDICATION	MECHANISM OF ACTION
Interferon beta 1b (Betaseron, Extavia), 250ug SQ qod	1993, 2009	RRMS, CIS	Inhibits “pro-inflammatory” cytokines, such as interferon (IFN)-gamma, tumor necrosis factor alpha, and lymphotoxin. Increases IL-10.
Interferon beta 1a (Avonex) 30ug IM weekly	1996	RRMS, CIS	
Interferon beta 1a (Rebif) 22 or 44ug SQ 3x /wk.	2002	RRMS	
Interferon beta 1a (Plegridy) 125ug SQ every 14 days	2014	Relapsing forms of MS	Adhesion molecule and class II MHC induction reduced. Alters T cell cytokine profile toward that of Th2 immunomodulatory cells.
Glatiramer acetate (Copaxone) 20mg SQ daily, or 40mg SQ 3x/wk	1996 2014	RRMS, CIS	
Mitoxantrone (Novantrone) 12mg/m ² IV q 3 months	2000	Worsening RRMS, relapsing SPMS PRMS	Anthracenedione chemotherapeutic agent
Natalizumab (Tysabri) 300mg IV q 4 weeks	2004/2006	Relapsing MS*	Monoclonal antibody targeting the alpha-4-integrins, part of the VLA-4 adhesion molecule.
Fingolimod (Gilenya) 0.5mg po daily	2010	Relapsing MS, approved for treatment naïve patients	Down-modulates sphingosine-1-phosphate receptors, lymphocytes unable to migrate out of lymphoid tissue. May have direct effects in CNS
Teriflunomide (Aubagio) 7mg or 14mg po daily	2012	Relapsing MS, approved for treatment naïve patient	Inhibits dihydroorotate dehydrogenase, thus inhibiting proliferation of activated lymphocytes
Dimethyl fumarate (Tecfidera) 240mg po BID	2013	Relapsing MS, approved for treatment naïve patients	Activates nuclear factor erythroid 2-related factor 2 (Nrf2) pathway which enhances response to oxidative stress
Alemtuzumab (Lemtrada) IV infusion, SQ in development	2014	Relapsing forms of MS	Monoclonal antibody that lyses cells expressing CD52

considered the safest MS disease modifying therapy to use in women who may become pregnant.

Mitoxantrone is an anthracenedione chemotherapeutic agent that is FDA approved for secondary progressive MS, progressive relapsing MS, or worsening relapsing-remitting MS. It is administered by IV infusion every 3 months and has a lifetime dose limit due to dose-related cardiotoxicity. In a prospective randomized 2-year study enrolling worsening relapsing-remitting or secondary progressive MS patients, those that received mitoxantrone had longer time to first treated relapse and improved level of disability compared with those randomized to placebo (level A). Beneficial effects were still measurable 12 months after treatment discontinuation. In addition to dose-limiting cardiotoxicity, mitoxantrone is associated with leukemia in approximately 1% of MS patients. Because of these risks and with the advent of more targeted medications, mitoxantrone is not commonly used in the United States.

Natalizumab is a humanized monoclonal antibody targeting the α -4-integrins, part of the VLA-4 adhesion-related heterodimer. The dose is 300 mg given intravenously every 4 weeks. A 2-year phase 3 trial of natalizumab showed 68% reduction in annualized relapse rate, 42% reduction in sustained disability, and over 90% reduction in gadolinium-enhancing lesions compared with placebo (level A). Natalizumab was temporarily removed from the market in 2005 due to an association with progressive multifocal leukoencephalopathy, a severe viral disorder caused by the JC virus. Because of its association with progressive multifocal leukoencephalopathy, this drug is generally recommended in cases of an inadequate response or intolerance of an alternate MS therapy. Patients receiving it must take part in a risk-mitigation program and can only be infused at certified infusion centers. Natalizumab is pregnancy category C.

Fingolimod was the first oral disease modifying therapy to be approved for relapse rate reduction in MS. This once daily 0.5 mg capsule reduces annualized relapse rate by about 50% and disability progression by about 25% versus placebo (level A). Fingolimod has several risks, including macular edema, pulmonary dysfunction, bradycardia, and herpetic infections.

It is contraindicated in some settings, such as recent myocardial infarction or uncontrolled heart failure, and with certain medications (such as class IA and class III anti-arrhythmic drugs). Medical monitoring for potential bradycardia for at least 6 hours is necessary for the first dose. Fingolimod is pregnancy category C.

Teriflunomide is a once daily oral tablet of 7 mg/day or 14 mg/day. Two phase 3 studies in relapsing patients with relapsing forms of MS found that the 14 mg/day dose significantly reduced annualized relapse rate by over 30% and disability progression by around 30% (level A). The 7 mg dose had a lesser beneficial effect. Thus, the 14 mg daily dose is favored by many clinicians. Teriflunomide can cause hepatotoxicity, and it is contraindicated in pregnancy (pregnancy category X). If necessary, teriflunomide can be rapidly eliminated from the body using cholestyramine, otherwise it persists for long periods. Teriflunomide is closely related to the drug leflunomide, approved for rheumatoid arthritis in 1998.

Dimethyl fumarate is a capsule taken orally twice daily. In phase 3 trials, it reduced MS relapse rates by 44 to 53% and also improved MRI outcomes (level A). The white blood cell count may drop and should be monitored. As of late 2014, one fatal case of PML in a person taking the medication and with persistent low lymphocyte counts has occurred. Adverse effects include flushing, gastrointestinal side effects, and rash. Dimethyl fumarate is pregnancy category C.

Alemtuzumab is a monoclonal antibody targeting cells expressing CD52, which includes T and B lymphocytes, monocytes, and other mononuclear white blood cells. In the CARE-MS I and II studies in RRMS patients, alemtuzumab was compared not to placebo, but instead to 44 μ g BIFN-1a given subcutaneously three times per week. Patients treated with alemtuzumab had lower annualized relapse rate (by 49% and 53.8%) and disability progression (by 28% and 42%). Alemtuzumab leads to a profound drop in the white blood cell count, which may last for months or even years. In trials, secondary autoimmune diseases developed in a sizeable proportion of alemtuzumab-treated subjects, with autoimmune thyroid disease being most common.

Prognosis

MS is highly variable. It is occasionally “benign” in which case the disease has little impact on quality of life. It can also be severe with considerable disability or early death. Most patients fall in between these extremes. Poor prognostic indicators at onset of MS include primary progressive course, male gender, frequent attacks, prominent motor or cerebellar findings, and high initial MRI lesion burden. Expected lifespan of people with MS is reduced overall by 7 to 14 years. Suicide rate is 1.7 to 7.5 times that of the general population. Albeit controversial, the use of disease modifying therapies (BIFNs and GA) likely improves not only relapse rate but long-term disability and even mortality. In one non-randomized study, early initiation of disease modifying therapies within a year of symptom onset was associated with better long-term outcomes.

NEUROMYELITIS OPTICA (DEVIC'S DISEASE)

Definition/Epidemiology

Neuromyelitis optica (NMO), also called Devic's Disease, is an inflammatory CNS disorder causing both demyelination and necrosis. NMO can be monophasic, but is more often characterized by attacks of optic neuritis and longitudinally extensive TM that are not necessarily concurrent. NMO was once believed to be a subtype of MS, but now is known to be a different disorder associated in most cases with autoantibodies to the aquaporin 4 (AQP4) water channels, which are strongly expressed by astrocytes. Histopathological changes in NMO are mostly in the spinal cord and optic nerve; the brain is less involved. AQP4 is expressed outside of the CNS in the kidney, stomach, and other tissues, but curiously no pathology has been recognized in the non-CNS organs expressing AQP4.

NMO is much less common than MS, with estimates by the Guthy-Jackson Charitable Foundation of 4,000 patients in the

United States, and a half million worldwide. It is even more female-preponderant than MS, with female to male ratio estimated from 4 : 1 to 8 : 1. Children and adults both develop NMO. Unlike MS, NMO is *not* associated with HLA-DRB1*15:01, and it affects those of Asian, African, and Hispanic ancestry disproportionately.

Clinical Presentation

NMO presents clinically as an acute attack of optic neuritis and/or TM; it often takes a relapsing course. Gradually progressive NMO has not been described (helping to distinguish it from progressive MS). Other autoimmune diseases often occur together with NMO including Sjögren's syndrome, systemic lupus erythematosus, Hashimoto's disease, and myasthenia gravis.

Diagnosis/Differential

In 2004, researchers first reported the presence of a serum IgG autoantibody to cerebral vessels in NMO; this was later found to target aquaporin 4. NMO-IgG/ AQP4-IgG is highly specific (>90%) and relatively sensitive (~75%) for NMO. Fulfilling two out of three of the following criteria is reported to be 99% sensitive and 90% specific for NMO in the setting of optic neuritis and TM: (1) longitudinally extensive spinal cord lesion, which is greater than or equal to 3 segments in length (Figure 120-3); (2) NMO-IgG positivity; and (3) brain MRI not typical or diagnostic for MS. NMO-IgG seropositive patients with isolated optic neuritis or longitudinally extensive TM are currently described as having “NMO spectrum disorder.”

For a deeper discussion of these topics, please see Chapter 411, “Multiple Sclerosis and Demyelinating Conditions of the Central Nervous System,” in Goldman-Cecil Medicine, 25th Edition.

FIGURE 120-3 **A**, Sagittal T2w image of the upper spinal cord in a 37-year-old female with NMO. She developed quadriplegia over several days, and was AQP4-IgG seropositive. Two years later she had right eye optic neuritis, which left her with visual acuity of only 20/200. The spinal cord lesion (arrows) had mild mass effect and was contiguous over 6 vertebral segments. **B**, Sagittal T2w image of the upper spinal cord in a 24-year-old male with MS shows a lesion (arrow) in the posterior cord at C2. This patient had moderate vibration loss in the legs but was otherwise asymptomatic.

Pathology

NMO lesions affect both white and gray matter and are located mainly in the spinal cord and optic nerves. In the brain, they are most common in the hypothalamus and around the fourth ventricle. NMO lesions center on blood vessels, where IgG, IgM, and complement activation products are seen. The vessels are abnormally thickened and hyalinized. Active NMO lesions show infiltration by mononuclear cells (lymphocytes, monocytes), neutrophils, and eosinophils. Older lesions display demyelination, axon loss, and death of oligodendroglia and neurons. In vitro and animal studies indicate that AQP4-IgG itself is pathogenic, causing complement- and antibody-mediated damage.

Treatment

Acute relapses are treated with high-dose corticosteroids. If these are not effective, plasma exchange is usually tried.

Because NMO is a rare disease, large multi-center randomized, controlled trials of disease modifying therapies are lacking. Several short case series have pointed toward possible efficacy of azathioprine plus prednisone, rituximab, and mycophenolate mofetil for prevention of future attacks (level C). Eculizumab, a monoclonal antibody that inhibits the complement cascade, was used in a small open-label trial in AQP4-IgG positive NMO patients. Over one year, 85% had no relapses and no patient progressed in disability (level B). Of note, beta-interferons are not effective for NMO and may actually increase the rate of attacks.

Prognosis

The necrotic nature of NMO results in worse outcomes than MS. Seropositive NMO patients tend to have more frequent and severe relapses than AQP4-IgG negative patients. Death can be a consequence and is often due to respiratory failure. The death rate in a retrospective study covering 1950-1997 was over 30%. Less than 10% mortality was reported in a more recent retrospective study of Caucasian NMO patients.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) is an acute, inflammatory, presumed immune-mediated disorder of the CNS that is encountered primarily in children but may occur in adults. An antecedent viral infection, or occasionally a vaccination, is common. ADEM presents with multifocal neurologic symptoms and signs. These can include encephalopathy, which may manifest as reduced level of consciousness (even coma), or as behavioral changes (e.g. confusion or irritability). Fever is common. Seizures, optic neuritis, and spinal cord involvement can all occur. Males and females are about equally affected. ADEM is usually monophasic, although relapsing ADEM has been described. On MRI, both white and gray matter CNS regions are affected. Gray matter involvement can include the basal ganglia, a region not typically affected in MS. The periventricular white matter region is often spared, unlike MS. When present, enhancement with gadolinium occurs in all lesions simultaneously. CSF often shows pleocytosis and an elevated protein, but no infection. Findings typical of MS, such as oligoclonal bands, are not usual. No randomized prospective treatment trials for acute disseminated encephalomyelitis are reported. Intravenous methylprednisolone followed by a prednisone taper is typically administered,

and the response is usually good (level D). Over 80% of cases recover well. As ADEM is only rarely recurrent, long-term immunomodulatory/immunosuppressive therapy is not indicated. A rare hemorrhagic form of ADEM (Weston Hurst syndrome) is more severe and can lead to death or severe disability.

ACUTE TRANSVERSE MYELITIS

Transverse myelitis (TM) is an inflammatory spinal cord syndrome presenting with abrupt or subacute onset of motor and/or sensory loss below a specific spinal level. Control of bladder and bowel is often affected, as is autonomic function below the level. Back pain and paresthesias may be prominent. Many cases of acute TM are idiopathic, but treatable causes must be ruled out. An urgent MRI with and without gadolinium should be obtained to look for compressive etiologies needing immediate treatment. After a compressive etiology has been ruled out, a lumbar puncture to assess CSF for cell count, glucose, and protein, and cultures and PCRs for infectious causes should be done. The usual tests for MS should be performed, and CSF should be analyzed for evidence of neoplastic etiology. Serum AQP4-IgG, paraneoplastic panels and chest CT should be considered. CSF may also be tested for NMO-IgG, angiotensin converting enzyme, and paraneoplastic antibodies when no etiology is forthcoming.

Acute TM can be the presenting episode for MS (where the TM is generally incomplete and asymmetric) or NMO (where the TM affects ≥ 3 spinal cord segments). Acute TM can also be caused by spinal cord infarction due to occlusion of the anterior spinal artery. Infections by viruses can cause acute or subacute TM. The most common viruses associated with acute TM are varicella zoster, herpes virus type 2, and cytomegalovirus. The retroviruses HTLV-I and HIV can each cause a myelopathy that is usually subacute. West Nile virus can cause a myelopathy that resembles poliomyelitis, with flaccid paralysis due to infection and death of anterior horn cells. Subacute TM may be caused by vitamin B12 or copper deficiency, or infiltrating or compressive syndromes such as tumors or abscesses. Nitrous oxide anesthesia can precipitate an acute onset myelopathy in the case of borderline vitamin B12 deficiency. Rheumatologic disorders such as Sjögren's disease, systemic lupus erythematosus, and Behçet's disease can all cause TM. Paraneoplastic syndromes associated with anti-CRMP-5 and anti-amphiphysin can cause a tract-specific myelopathy. The history and physical examination should be performed with these disorders in mind.

Treatment is determined by the most likely etiology. Idiopathic TM is treated much like TM in MS or NMO, with intravenous methylprednisolone at 500 mg to 1000 mg/day, usually followed by a short oral prednisone taper (evidence level D). When response to intravenous methylprednisolone is suboptimal, plasma exchange should be considered.

IDIOPATHIC ACUTE OPTIC NEURITIS

Inflammatory demyelinating optic neuritis can occur as part of MS or NMO, or as an idiopathic entity. Classically, optic neuritis presents over hours with loss of vision together with pain exacerbated by eye movement. Vision loss may range from subclinical to frank blindness. Color vision and contrast sensitivity are disproportionately affected. On examination, a relative afferent

pupillary defect is seen in unilateral optic neuritis. Acute demyelinating optic neuritis is often retrobulbar without papillitis. On MRI, the optic nerve can be swollen and enhance after gadolinium contrast. After recovery from the acute episode, the optic disk may appear pale, and the relative afferent pupillary defect may persist. Transient worsening of vision when the body temperature rises due to exercise or fever (Uhthoff's phenomenon) may occur following recovery. The differential diagnosis includes other causes of acute monocular or binocular vision loss, such as Leber's hereditary optic neuropathy, giant cell arteritis, and acute non-arteritic anterior ischemic optic neuropathy.

The Optic Neuritis Treatment Trial studied patients with acute optic neuritis (either idiopathic or due to MS) who were randomized to one of three treatments, intravenous methylprednisolone versus oral prednisone taper versus oral placebo. Visual acuity initially recovered faster in the intravenous methylprednisolone group, but by 6 months later there was no difference among the three groups (level A). Recovery of vision was good. Patients from this trial were examined 10 years later and acuity in the affected eyes was 20/20 or better in 74% and less than 20/200 in only 3%. However, recurrence of optic neuritis was common, and had occurred in either eye in 35% of the patients. Recurrences were more frequent in those who had MS than those with idiopathic optic neuritis ($P < .001$).

CHRONIC RELAPSING INFLAMMATORY OPTIC NEUROPATHY

First described in 2003, chronic relapsing inflammatory optic neuropathy (CRION) is an inflammatory optic neuropathy characterized by acute relapses, but often with more severe visual loss than idiopathic optic neuritis or optic neuritis associated with MS. Patients with CRION can have onset at any age and the entity has been described worldwide. Prevalence rates and epidemiology are still unclear. As in other types of optic neuritis, eye pain at onset is frequent. Return of pain can herald a relapse. Uveitis is present in a small percentage of cases. Five diagnostic

criteria for CRION have been suggested: (1) optic neuritis with at least one relapse, (2) objective visual loss, (3) AQP4-IgG seronegative, (4) contrast enhancement on MRI of acutely inflamed optic nerve, and (5) response to immunosuppressive treatment and relapse on withdrawal. Other diseases that might present similarly, such as sarcoidosis and giant cell arteritis, should be ruled out. Treatment for acute CRION is similar to that for other causes of optic neuritis, using intravenous methylprednisolone followed by oral corticosteroids. Relapses are common upon corticosteroid discontinuation. Successful long-term treatment with "steroid sparing" agents such as methotrexate, azathioprine, or mycophenolate mofetil has been reported. The underlying pathology is not yet known, but the disease appears inflammatory based on clinical presentation, imaging, and specific medication response. Eventual visual outcomes are often poor. One report indicated that visual acuity was less than 20/200 in one third of CRION patients.

Neuromuscular Diseases: Disorders of the Motor Neuron and Plexus and Peripheral Nerve Disease

Carlayne E. Jackson

INTRODUCTION

Neuromuscular diseases are classified into four groups, according to which portion of the motor unit is involved (Table 121-1). Motor neuron and peripheral nerve diseases are considered in this chapter; myopathies are considered in Chapter 122, and neuromuscular junction diseases are considered in Chapter 123. The symptoms and signs of the neuromuscular diseases are at times indistinguishable. However, some useful general rules apply to assist with localization based on the distribution of weakness, presence or absence of sensory symp-

toms, reflex abnormalities, and specific associated clinical features (Table 121-2).

Electromyography and Nerve Conduction Studies

Electromyography (EMG) and nerve conduction studies can also be useful diagnostic tools in localizing the lesion in a patient with a suspected neuromuscular disease. The measurement of electrical activity arising from muscle fibers is performed by inserting a needle electrode percutaneously into a muscle. Normal muscle is electrically silent at rest. Spontaneous activity during complete relaxation occurs in myotonic disorders, in inflammatory myopathies, and in denervated muscles. Spontaneous activity of a single muscle fiber is called a *fibrillation*, and such activity of part of or an entire motor unit is called a *fasciculation*. In myotonia, repeated muscle depolarization and contraction occur despite voluntary relaxation. Abnormalities in motor unit potentials occur during the course of denervation; with the development of reinnervation, the remaining motor units increase in amplitude and become longer in duration and polyphasic (E-Fig. 121-1). Conversely, in muscle diseases such as the muscular dystrophies and other diseases that destroy scattered fibers within a motor unit, the motor unit action potentials are of lower amplitude and shorter duration and are polyphasic. A reduced recruitment (interference) pattern from maximum voluntary effort occurs in denervation. Conversely, in patients with primary muscle disease, submaximal voluntary effort produces a full recruitment pattern despite marked weakness.

Nerve conduction is studied by stimulating a peripheral nerve (e.g., the ulnar) with surface electrodes placed over the nerve. The resulting action potential is recorded by electrodes placed over the nerve more proximally in the case of large sensory nerve fibers and over the muscle distally in the case of motor nerve fibers in a mixed motor sensory nerve. For sensory nerves, the sensory nerve action potential (SNAP) is quantitated, and for motor nerves, the compound muscle action potential (CMAP) is quantitated.

TABLE 121-1 CLASSIFICATION OF NEUROMUSCULAR DISEASES

SITE OF INVOLVEMENT	TYPICAL EXAMPLES
ANTERIOR HORN CELL	
Without upper motor neuron involvement	Spinal muscular atrophy Progressive muscular atrophy Bulbospinal muscular atrophy Poliomyelitis West Nile virus
With upper motor neuron involvement	Amyotrophic lateral sclerosis Primary lateral sclerosis
PERIPHERAL NERVE	
Mononeuropathy	Carpal tunnel syndrome Ulnar palsy Meralgia paresthetica
Multiple mononeuropathies	Mononeuritis multiplex (e.g., polyarteritis nodosa), leprosy, sarcoidosis, amyloidosis
Polyneuropathies	Diabetic neuropathy Charcot-Marie-Tooth disease Guillain-Barré syndrome
NEUROMUSCULAR JUNCTION	
	Myasthenia gravis Lambert-Eaton syndrome
MUSCLE	
	Duchenne muscular dystrophy Dermatomyositis

E-FIGURE 121-1 Motor unit potentials. The shaded muscle fibers are functional members of the motor unit; the axon, which enters from the upper left, branches terminally to innervate the appropriate muscle fibers. The motor unit action potential produced by each motor unit is seen at the upper right; its duration is measured between the two small vertical lines. The normal-appearing but unshaded fibers belong to other motor units. **A**, The normal situation, with five muscle fibers in the active unit. **B**, In this myopathic unit, only two fibers remain active; the other three (shrunken and unshaded) have been destroyed by a muscle disease. **C**, Four fibers that belonged to other motor units and had been denervated have now been reinnervated by terminal axon sprouting from the healthy motor unit. Both the motor unit and its action potential are now larger than normal. Note that only under these abnormal circumstances do fibers in the same unit lie next to one another. (From Griggs RC, Bradley WG: Approach to the patient with neuromuscular disease. In Isselbacher KJ, Braunwald E, Wilson JD, et al, editors: Harrison's textbook of internal medicine, ed 13, New York, 1994, McGraw-Hill, p 2364.)

TABLE 121-2 CLINICAL FEATURES OF THE NEUROMUSCULAR DISEASES

CLINICAL FEATURE	ANTERIOR HORN CELL	PERIPHERAL NERVE	NEUROMUSCULAR JUNCTION	MUSCLE
DISTRIBUTION OF WEAKNESS	Asymmetrical limb or bulbar	Symmetrical, usually distal	Extraocular, bulbar, proximal limb	Symmetrical, proximal limb
ATROPHY	Marked and early	Mild, distal	None (or very late)	Slight early; marked later
SENSORY INVOLVEMENT	None	Dysesthesias, loss of sensation	None	None
REFLEXES	Variable (depending on degree of upper motor neuron involvement)	Decreased out of proportion to weakness	Normal in myasthenia gravis, depressed in Lambert-Eaton syndrome	Decreased in proportion to weakness
CHARACTERISTIC FEATURES	Fasciculations, cramps	Combined sensory and motor abnormalities	Fatigability	Usually painless

DISEASES OF THE MOTOR NEURON (ANTERIOR HORN CELL)

Amyotrophic Lateral Sclerosis

Definition and Epidemiology

The most common *acquired* motor neuron disease, amyotrophic lateral sclerosis (ALS), is a progressive, typically fatal disorder. The incidence is approximately 2 per 100,000 population, and there is a slight male predominance. The peak age of onset is in the sixth decade, although the disease can occur at any time throughout adulthood. Epidemiologic studies have incriminated risk factors for ALS including exposure to insecticides, smoking, participation in varsity athletics, and military service in the Gulf War. The cause of ALS is largely unknown, with 95% of cases considered “sporadic,” and 5% related to an autosomal dominant disease (familial ALS [FALS]). FALS is an adult-onset disease that is clinically and pathologically indistinguishable from sporadic ALS. FALS is caused by mutations in many genes, including the C9orf72, SOD1, TARDBP, FUS, ANG, ALS2, SETX, and VAPB genes. Mutations in C9orf72 can also cause sporadic ALS.

(E-Table 121-1).

Pathology

ALS results from degeneration of the cortical motor neurons originating in layer five of the motor cortex and descending via the pyramidal tract (resulting in upper motor neuron signs and symptoms) and from degeneration of the anterior horn cells in the spinal cord and their brainstem homologues innervating bulbar muscles (resulting in lower motor neuron signs and symptoms) (Table 121-3).

Clinical Presentation

Clinical symptoms relating to the upper motor neuron degeneration include loss of dexterity, slowed movements, muscle weakness, stiffness, and emotional lability. Signs on neurologic examination that confirm an upper motor neuron lesion include pathologic hyperreflexia, spasticity, and extensor plantar responses (Babinski’s sign). Lower motor neuron signs and symptoms caused by anterior horn cell degeneration include weakness, muscle atrophy, fasciculation, and cramps. Fasciculations in the absence of associated muscle atrophy or weakness are usually benign and may be aggravated by sleep deprivation, stress, and excessive caffeine ingestion. Muscle weakness in patients with ALS usually begins distally and asymmetrically and may manifest as a monoparesis, hemiparesis, paraparesis,

TABLE 121-3 SYMPTOMS AND SIGNS ASSOCIATED WITH AMYOTROPHIC LATERAL SCLEROSIS

SYMPTOMS	SIGNS
UPPER MOTOR NEURON DEGENERATION	
Loss of dexterity	Pathologic hyperreflexia
Slowed movements	Babinski’s sign
Weakness	Hoffman’s sign
Stiffness	Jaw jerk
Pseudobulbar affect	Spasticity
LOWER MOTOR NEURON DEGENERATION	
Weakness	Muscle atrophy
Fasciculations	Fibrillation potentials on electromyography
Cramps	Neurogenic atrophy on muscle biopsy

or quadriparesis. It may also be limited initially to the bulbar region, resulting in difficulty with swallowing, speech, and movements of the face and tongue. For unclear reasons, ocular motility is spared until the very late stages of the illness. Bowel and bladder function and sensation remain spared throughout the course of the disease. Degeneration of the corticobulbar projections innervating the brainstem can lead to pseudobulbar affect causing difficulty controlling laughter and/or tearfulness. Up to 50% of patients with ALS may also have a component of frontotemporal dementia characterized by executive dysfunction, poor insight, personality changes (disinhibition, impulsivity, and apathy), abnormal eating habits, poor hygiene, and language dysfunction.

Diagnosis and Differential Diagnosis

The diagnosis of ALS remains one of “exclusion,” in which other potential causes must be ruled out through a variety of neuroimaging, laboratory, and electrodiagnostic investigations (E-Table 121-2). For example, compression of the cervical spinal cord or cervicomedullary junction from tumors or cervical spondylosis can produce weakness, atrophy, and fasciculations in the upper extremities and spasticity in the lower extremities, closely resembling ALS.

Treatment

Specialized multidisciplinary clinic referral should be considered for patients with ALS to optimize health care delivery (Level B) and prolong survival (Level B). The only current U.S. Food and Drug Administration (FDA)–approved therapy for ALS is riluzole 50 mg twice per day, which in clinical trials prolonged

E-TABLE 121-1 HEREDITARY MOTOR NEURON DISEASES

	LOCUS	GENE
AUTOSOMAL DOMINANT		
ALS 1	21q	Superoxide dismutase
ALS 4	9q34	Senataxin
ALS 6	16p11	FUS
ALS 8	20q	Vesicle-associated protein B
ALS 9	14q11	Angiogenin

E-TABLE 121-2 DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC EVALUATION FOR PATIENTS WITH SUSPECTED MOTOR NEURON DISEASE

DIFFERENTIAL DIAGNOSIS	DIAGNOSTIC EVALUATION
TOXINS—LEAD, MERCURY	24-hr urine collection for heavy metals
METABOLIC DISORDERS	
Hypoglycemia	Serum chemistry
Hyperparathyroidism	Parathyroid hormone level, calcium
Hyperthyroidism	Thyroid function studies
PARANEOPLASTIC DISORDER	MRI scan, anti-Hu antibody
IMMUNOLOGIC MECHANISM	Complete blood count, sedimentation rate, anti-nuclear antibody, rheumatoid factor, serum protein electrophoresis, anti-GM1 antibodies
VITAMIN/MINERAL DEFICIENCIES	Copper, vitamin B12, folate levels
BACTERIAL/VIRAL INFECTION	HIV, HTLV-1, Lyme titers, CSF exam/culture
STRUCTURAL LESION	
Cervical spondylosis	MRI of brain and cervical spine
Chiari malformation or syrinx	
Spinal cord arteriovenous malformation	
Parasagittal or foramen magnum tumor	

TABLE 121-4 SYMPTOM MANAGEMENT FOR MOTOR NEURON DISEASES

RESPIRATORY INSUFFICIENCY	SPASTICITY
Noninvasive positive pressure ventilation	Baclofen 10-20 mg qid
Cough-assist devices	Dantrium 25-100 mg qid
DYSARTHRIA	PSEUDOBULBAR AFFECT
Augmentative speech device	Serotonin reuptake inhibitors
DYSPHAGIA	Amitriptyline 25-75 mg qhs
Percutaneous endoscopic gastrostomy placement	Dextromethorphan/Quinidine 20/10 mg bid
Suction machine	WEAKNESS
SIALORRHEA	Ankle foot orthosis
Amitriptyline 25-75 mg qhs	Wheelchair
Glycopyrrolate 1-2 mg q8h	Elevated toilet seat
Botulinum toxin	

survival by 2 to 3 months (Level A). The mechanism of this effect is not known with certainty; however, riluzole may reduce excitotoxicity by diminishing presynaptic glutamate release. Initiation of noninvasive positive pressure ventilation (NPPV) on a spontaneous timed mode has also been shown to prolong survival up to 20 months, slow the rate of forced vital capacity (FVC) decline (Level B), and improve quality of life (Level C). NPPV should be initiated when the forced vital capacity (FVC) is less than 50%, the maximal inspiratory pressure is less than 60 cm, or when patients report symptoms that suggest nocturnal hypoventilation (e.g., daytime fatigue, frequent arousals, supine dyspnea, morning headaches). A cough-assist device can be used to assist with clearing upper airway secretions and has been shown to minimize the risk of pneumonia in clinical trials (Level C). A percutaneous gastrostomy (PEG) tube should be considered for prolonging survival and stabilizing body weight (Level B) in patients with impaired oral food intake. Symptomatic therapy for spasticity, pseudobulbar affect, muscle cramping, and sialorrhea is also essential in maintaining patient dignity and quality of life (Table 121-4). Augmentative speech devices can assist patients with communication and computer access.

Prognosis

Mean survival from onset of symptoms is 2 to 5 years, with 10% of patients surviving beyond 10 years. The majority of deaths are related to respiratory muscle failure and aspiration pneumonia.

Other Acquired Motor Neuron Diseases

Other motor neuron diseases involve only particular subsets of motor neurons (Table 121-5). Progressive muscular atrophy (PMA) is a pure lower motor neuron disease that accounts for 8% to 10% of patients with motor neuron disease. Weakness is typically distal and asymmetrical, and bulbar involvement is rare. Patients with PMA generally have a better prognosis than those with ALS, with a survival of 3 to 14 years. Primary lateral sclerosis (PLS) is a pure upper motor neuron syndrome in which patients demonstrate either a slowly progressive spastic paralysis or dysarthria. This is a rare disorder, accounting for 2% of all motor neuron cases. Survival is generally years to decades.

TABLE 121-5 CLINICAL SPECTRUM OF MOTOR NEURON DISEASES*

UPPER AND LOWER MOTOR NEURON INVOLVEMENT	LOWER MOTOR NEURON INVOLVEMENT
Sporadic amyotrophic lateral sclerosis	Motor neuronopathy related to malignancy or paraproteinemia
<i>Familial amyotrophic lateral sclerosis</i>	Poliomyelitis
UPPER MOTOR NEURON INVOLVEMENT	West Nile virus
Primary lateral sclerosis	Postpolio syndrome
<i>Familial spastic paraparesis</i>	<i>Hexosaminidase deficiency</i>
	Progressive muscular atrophy
	<i>Spinal muscular atrophy</i>
	Type I: Infantile onset (Werdnig-Hoffmann disease)
	Type II: Late infantile onset
	Type III: Juvenile onset (Kugelberg-Welander disease)

*Italicized disorders are hereditary.

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is a hereditary form of motor neuron disease in which only the lower motor neuron is affected. The SMAs may begin in utero, in infancy, in childhood, or in adult life and represent the first class of neurologic disorders in which a developmental defect in neuronal apoptosis most likely produces the disease. Two genes are involved in SMA types 1 to 3: the neuronal apoptosis inhibitor protein (NAIP) and survival motor neuron (SMN) genes.

Bulbospinal muscular atrophy (BSMA) or Kennedy's disease is an X-linked recessive disorder in which the mean age at onset is 30 years; the range is from 15 to 60 years. BSMA is a trinucleotide repeat disorder with a CAG expansion encoding for a polyglutamine tract in the first exon of the androgen receptor gene, on chromosome Xq11-12. The mechanism by which disruption of the androgen receptor gene alters the function of bulbar and spinal motor neurons is not known. An inverse correlation exists between the number of CAG repeats and the age of onset of the disease. Affected individuals exhibit chin fasciculations, midline furrowing and atrophy of the tongue, and proximal weakness. Dysphagia and dysarthria are common, and up to 90% of patients demonstrate gynecomastia and infertility. Two findings distinguishing this disorder from ALS are the absence of upper motor neuron signs and in some patients the presence of a subtle sensory neuropathy.

DISORDERS OF THE BRACHIAL AND LUMBOSACRAL PLEXUS

The roots within the cervical, lumbar, and sacral regions organize into the cervical, lumbar, and sacral plexuses before giving rise to individual peripheral nerves. Diseases of these plexuses (plexopathies) tend to be *focal* in symptoms and signs, whereas many diseases of the peripheral nerves and muscles are *generalized*.

Brachial Plexopathy

The brachial plexus is constituted by mixed nerve roots from C5 to T1 that fuse into upper, middle, and lower trunks above the level of the clavicle and redistribute into lateral, posterior, and medial cords below that landmark (E-Fig. 121-2). Symptoms include weakness, pain, and sensory loss in the shoulders or arms.

E-FIGURE 121-2 The brachial plexus is comprised of mixed nerve roots from C5 to T1 that fuse into upper, middle, and lower trunks above the level of the clavicle and redistribute into lateral, posterior, and medial cords. (From Morton D, Peterson KD, Albertine KH: Gray's dissection guide for human anatomy, ed 2, Philadelphia, 2006, Churchill Livingstone.)

Upper trunk lesions may be due to trauma and idiopathic brachial plexitis (see later discussion). Lower trunk lesions may result from malignant tumor invasion, thoracic outlet syndrome, or as a complication of sternotomy. If the entire plexus is involved, radiation injury, trauma, and late metastatic disease are the most common causes.

Acute Autoimmune Brachial Neuritis

Acute autoimmune brachial neuritis is characterized by the abrupt onset of severe pain, usually over the lateral shoulder, but at times extending into the neck or entire arm. The acute pain generally subsides after a few days to a week; by this time, weakness of the proximal arm becomes apparent. The serratus anterior, deltoid, and supraspinatus are the most commonly affected muscles, but other muscles of the shoulder girdle may also be affected. In rare cases, most of the patient's arm and even the ipsilateral diaphragm are involved. Sensory loss is usually slight and generally involves the axillary nerve distribution. Weakness lasts weeks to months and be accompanied by severe atrophy of the shoulder girdle. No therapy has been shown to alter or shorten the clinical course, although steroids and analgesics may reduce pain. Most patients recover within several months to 3 years. The disorder frequently follows an upper respiratory infection or an immunization, but in many instances no antecedent illness occurs. It is bilateral in one third of cases but is always asymmetrical; it may recur in 5% of patients. Recurrent brachial plexopathies that are painless may be related to an autosomal dominant disorder, hereditary neuropathy with liability to pressure palsies (HNPP), caused by a deletion, or point mutation of PMP-22 protein (chromosome 17p).

Lumbosacral Plexopathy

The lumbosacral plexus is formed from the ventral rami of spinal nerves T12 to S4. These divide within the plexus into ventral and dorsal branches that form the femoral, sciatic, and obturator nerves. The plexus is located within the substance of the psoas major muscle. Clinical features include proximal pain and weakness in anterior thigh muscles (femoral) or posterior thigh muscles and the buttocks. Bowel and bladder dysfunction may also occur. Diabetes, malignant invasion, radiation therapy, infection (herpes zoster), psoas abscess, trauma, and retroperitoneal hemorrhage are common causes. An autoimmune form is much less frequent than brachial neuritis.

DISORDERS OF THE PERIPHERAL NERVES

Definition and Epidemiology

Peripheral neuropathy refers to a large group of disorders that can produce focal (mononeuropathy or multiple mononeuropathies) or generalized nerve dysfunction (polyneuropathies) (Table 121-6). Peripheral neuropathies are prevalent neurologic conditions, affecting 2% to 8% of adults, with the incidence increasing with age. They range in severity from mild sensory abnormalities, found in up to 70% of patients with long-standing diabetes, to fulminant, life-threatening paralytic disorders such as Guillain-Barré syndrome (GBS).

Mononeuropathies are disorders in which only a single peripheral nerve is affected. The most common cause is nerve

TABLE 121-6 CLASSIFICATION AND CAUSES OF PERIPHERAL NEUROPATHY

TYPE OF NEUROPATHY	EXAMPLES
MONONEUROPATHIES	
Compressive	Carpal tunnel syndrome, ulnar palsy
Hereditary	Hereditary neuropathy with predisposition to pressure palsies
Inflammatory	Bell's palsy
Multiple mononeuropathies	Vasculitis (mononeuritis multiplex), diabetes, leprosy, sarcoidosis, amyloidosis
POLYNEUROPATHIES	
Hereditary	Charcot-Marie-Tooth disease
Endocrine	Diabetes, hypothyroidism
Metabolic	Uremia, liver failure
Infections	Leprosy, diphtheria, human immunodeficiency virus, Lyme disease
Immune mediated	Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy
Toxic	Lead, arsenic, alcohol, drug induced
Paraneoplastic	Lung cancer

entrapment such as median nerve compression resulting in carpal tunnel syndrome or peroneal nerve injury causing footdrop (Table 121-7). When more than one peripheral nerve is involved, the term *mononeuropathy multiplex* or *multiple mononeuropathies* is often used. Multiple mononeuropathies are most commonly seen in diabetes mellitus and vasculitis but also occur in leprosy, vasculitis, sarcoidosis, hereditary neuropathy with predisposition to pressure palsies, and amyloidosis.

Polyneuropathies are a group of disorders affecting the motor, sensory, and autonomic nerves. These disorders may predominantly affect the nerve axon (axonal neuropathies), myelin sheath (demyelinating neuropathies), or the small- to medium-sized blood vessels supplying the nerves (vasculitic neuropathies). The clinical features of the polyneuropathies reflect the pathology of the underlying process.

Pathology

In the symmetrical *axonal* polyneuropathies, the underlying pathology is usually a slowly evolving type of axonal degeneration that involves the ends of long nerve fibers first and preferentially. With time, the degenerative process involves more proximal regions of long fibers, and shorter fibers are affected. This pattern of distal axonal degeneration or *dying back* of nerve fibers results from a wide variety of metabolic, toxic, and endocrinologic causes.

In the *demyelinating* polyneuropathies, the underlying pathology involves the myelin sheath.

Demyelination of a peripheral nerve at even a single site can block conduction, resulting in a functional deficit identical to that seen after axonal degeneration. In contrast to repair by regeneration, however, repair by remyelination can be rapid. Autoimmune attack on the myelin sheath occurs in the inflammatory demyelinating neuropathies (GBS and chronic inflammatory demyelinating polyneuropathy [CIDP]) and some neuropathies associated with paraproteinemias (see later discussion). Inherited disorders of myelin such as Charcot-Marie-Tooth (CMT) disease comprise the other major category of demyelinating neuropathies. Other causes include toxic, mechanical, and

TABLE 121-7 COMMON MONONEUROPATHIES

	PRECIPITATING FACTORS	MOTOR SIGNS AND SYMPTOMS	SENSORY SIGNS AND SYMPTOMS	TREATMENT
MEDIAN NERVE				
Entrapment at the wrist (carpal tunnel syndrome)	Repetitive wrist flexion or sleep	Weakness in thenar muscle; inability to make a circle with the thumb and index fingers	Numbness, tingling, and/or pain in thumb, index finger, middle finger, and medial half of ring finger. Tinel and Phalen signs	Neutral wrist splint, carpal tunnel injections or surgery
ULNAR NERVE				
Entrapment at the elbow	External compression in condylar groove, fracture of humerus	Weakness or atrophy of the interossei and thumb adductor	Sensory loss in the little finger and contiguous half of the ring finger	Elbow pads; ulnar nerve transposition or decompression of cubital tunnel
RADIAL NERVE				
Entrapment at the spiral groove	Prolonged sleeping on arm after drinking excessive amounts of alcohol: "Saturday night palsy"	Wrist drop with sparing of elbow extension; weakness of finger and thumb extensors	Sensory loss on dorsum of hand	Spontaneous recovery; wrist splint
FEMORAL NERVE				
	Abdominal hysterectomy, hematoma, prolonged lithotomy position, diabetes	Weakness and atrophy of quadriceps	Sensory loss in anterior thigh and medial calf	Physical therapy
LATERAL FEMORAL CUTANEOUS NERVE				
Meralgia paresthetica	Obesity, pregnancy, diabetes, constrictive belts	None	Sensory loss, pain, or tingling over anterolateral thigh	Weight loss; spontaneous recovery
PERONEAL NERVE				
Entrapment at the fibular head	Habitual leg crossing, knee casts, prolonged squatting, profound weight loss	Weakness of ankle dorsiflexors or evertors and toe extensors	Sensory loss in anterolateral leg and dorsum of foot	Ankle-foot orthosis; remove source of compression
SCIATIC NERVE				
	Injection injury, fracture or dislocation of hip	Weakness of hamstrings, ankle plantar flexors or dorsiflexors	Sensory loss in buttock, lateral calf and foot	Ankle-foot orthosis; physical therapy
TIBIAL NERVE				
Entrapment in tarsal tunnel	External compression from tight shoes, trauma, tenosynovitis	None	Sensory loss and tingling in sole of foot	Tarsal tunnel injection, eliminate source of compression, medial arch support

physical injuries to nerves. Although these examples have nearly pure demyelination, many neuropathies have both axonal degeneration and demyelination. This mixed pathologic abnormality reflects the mutual interdependency of the axons and the myelin-forming Schwann cells. Vasculitic neuropathies occur as a result of disease of the small- or medium-sized blood vessels that leads to ischemia and infarction of isolated peripheral nerves. The term *mononeuritis multiplex* is also used to describe this clinical situation, in which there is multifocal involvement of individual nerves.

Clinical Presentation

The clinical picture of an *axonal* polyneuropathy includes early loss of muscle stretch reflexes at the ankle and weakness that initially involves the intrinsic muscles of the feet, the extensors of the toes, and the dorsiflexors at the ankle. The motor signs are usually mild in contrast to the sensory abnormalities, which may include numbness, tingling, and burning sensations (dysesthesias). The sensory symptoms usually begin symmetrically in the toes and feet and then ascend proximally to the legs in a "stocking" distribution. When the sensory abnormalities reach the level of the knees, the symptoms begin in the hands, in a "glove"

distribution. Truncal and abdominal dysesthesias may develop once the sensory abnormalities ascend to the level of the elbows.

The prominent clinical feature of an acquired *demyelinating* polyneuropathy is weakness that affects not only the distal muscles, but also the proximal and facial muscles. Unlike in an axonal neuropathy, sensory loss is rarely the presenting symptom. Patients generally have diffuse hyporeflexia or areflexia.

Vasculitic neuropathies typically present with acute or subacute asymmetrical, predominantly distal weakness and sensory loss associated with severe pain.

Diagnosis and Differential Diagnosis

Neuropathic disorders can be broadly divided into those that are acquired and those that are hereditary (Table 121-8). Acquired disorders are the more common and have many causes: metabolic or endocrine disorders (diabetes mellitus, renal failure, porphyria); immune-mediated disorders (GBS, CIDP, multifocal motor neuropathy, antimyelin-associated glycoprotein neuropathy); infectious causes (human immunodeficiency virus [HIV], Lyme disease, cytomegalovirus [CMV], syphilis, leprosy, diphtheria); medications (HIV drugs, chemotherapies); environmental toxins (heavy metals); or paraneoplastic processes. Diabetes

TABLE 121-8 HEREDITARY NEUROPATHIC DISORDERS

	INHERITANCE PATTERN	GENETIC DEFECT	CLINICAL FEATURES
Hereditary sensorimotor neuropathies	AR, AD, or X-linked	See E-Table 121-4	Pes cavus, distal atrophy and weakness, hammer toes
Familial amyloid polyneuropathy	AD	Transthyretin Gelsolin	Pain, autonomic dysfunction
Fabry disease	X-linked	Apolipoprotein AI α -Galactosidase	Cardiac ischemia, renal disease, stroke, cutaneous angiokeratomas
Tangier disease	AR	Apolipoprotein A	Low HDL levels, orange tonsils
Refsum disease	AR	Phytanic acid oxidase	Retinitis pigmentosa, cardiomyopathy, deafness, ichthyosis

AD, Autosomal dominant; AR, autosomal recessive; HDL, high-density lipoprotein.

mellitus and alcoholism are the most common causes of polyneuropathy in developed countries. As many as one third of acquired neuropathies are cryptogenic in which the etiology can never be identified. Causes of mononeuritis multiplex include systemic vasculitis (rheumatoid arthritis, systemic lupus erythematosus, Wegener's granulomatosis, Churg-Strauss syndrome, polyarteritis nodosa) and primary peripheral system vasculitis (25% of cases).

Because of the many causes, it is important to approach the patient with neuropathy systematically, beginning with the patient's history and physical examination. It is essential to determine which nerves are involved (motor, sensory, or autonomic) and in what specific combination ([Table 121-9](#)). Small-fiber neuropathies often manifest with unpleasant or abnormal sensations such as a burning pain, electric shock-like sensations, cramping, tingling, pins and needles, or prickly feelings such as the limb "feeling asleep." Large-fiber neuropathies can manifest as numbness, tingling, or as gait ataxia. Symptoms suggesting motor nerve involvement include muscle weakness that typically involves the distal foot muscles. Autonomic nerve involvement is suggested by symptoms of orthostatic hypotension, impotence, cardiac arrhythmia, or bladder dysfunction.

The distribution of muscle weakness is important. In axonal neuropathies, the weakness predominantly involves the distal lower extremity muscles, and in demyelinating neuropathies the weakness can involve both proximal and distal muscles as well as facial muscles. Most neuropathies result in *symmetrical* weakness. If asymmetry is present, motor neuron disease, radiculopathy, plexopathy, compressive mononeuropathies, or mononeuritis multiplex should be considered. The intensity and distribution of painful dysesthesias can be informative. Although many axonal neuropathies are associated with a burning sensation in the feet, pain as the chief complaint suggests specific causes of neuropathy ([Table 121-10](#)). A neuropathy that manifests with acute, asymmetrical weakness, and severe pain suggests vasculitis.

In patients with severe, asymmetrical proprioceptive deficits, with sparing of motor function, the site of the lesion is usually the sensory neuron. This specific syndrome has a relatively limited differential diagnosis, including paraneoplastic process, Sjögren's syndrome, cisplatin toxicity, vitamin B₆ toxicity, and HIV infection.

Most neuropathies are relatively insidious in onset, particularly those associated with metabolic or endocrine disorders. Acute neuropathies may be caused by a vasculitic process, toxin exposure, porphyria, or GBS. GBS is commonly preceded by

TABLE 121-9 DIFFERENTIAL DIAGNOSIS OF NEUROPATHIC DISORDERS BASED ON SYMPTOMS

MOTOR SYMPTOMS ONLY	SENSORY SYMPTOMS ONLY	AUTONOMIC SYMPTOMS
Porphyria	Cryptogenic sensory polyneuropathy	Amyloid neuropathy

a viral illness, immunization, or a surgical procedure. The neurologic history must thoroughly explore potential toxic exposures such as prior medications and alcohol use ([E-Table 121-3](#)).

Because many neuropathies are hereditary, it is essential to obtain a detailed family history, specifically inquiring about a history of gait instability, use of adaptive equipment, or skeletal deformities of the feet. Hereditary neuropathies may be autosomal recessive, autosomal dominant, or X-linked. In some situations it may be helpful to actually examine family members because the severity of disease may vary considerably from one generation to the next. The most common hereditary neuropathy is CMT disease (see later discussion).

A complete neurologic examination should always be performed in a patient complaining of numbness. If the patient shows evidence of upper motor neuron involvement in addition to the sensory loss, vitamin B₁₂ or copper deficiency should be considered, even in the absence of apparent anemia. An elevated

E-TABLE 121-3 ETIOLOGY OF NEUROPATHIC DISORDERS: TOXIC AGENTS

AXONAL		DEMYELINATING		
SENSORY	SENSORY & MOTOR	MOTOR		MIXED

methylmalonic acid or homocystine level can also help confirm this diagnosis in patients with borderline B₁₂ levels. The presence of weakness and upper motor neuron signs without associated sensory loss suggests ALS.

If the neuropathy is associated with mental status abnormalities, then pyridoxine intoxication or deficiencies of thiamine, niacin (“dementia, diarrhea, dermatitis”), and vitamin B₁₂ should be considered in the differential diagnosis. Lyme disease (see [Chapter 90](#)) may result in both peripheral nervous system symptoms (facial nerve palsies, paresthesias, weakness) and central nervous system symptoms (dementia, headache). Acquired immunodeficiency syndrome (AIDS) can also affect both the central and the peripheral nervous systems. GBS and CIDP usually occur at the time of HIV seroconversion, whereas sensory neuropathy, mononeuritis multiplex, and CMV polyradiculopathy generally occur in the context of low CD4 counts in the terminal stages of the disease.

Once a preliminary differential diagnosis is developed based on the history and neurologic examination findings, laboratory studies can confirm the diagnosis. Laboratory tests to identify potentially treatable causes of neuropathy are included in [Table 121-11](#). Additional studies can be ordered based on the suspected diagnosis. An impaired glucose tolerance test is found in more than half of patients with cryptogenic sensory peripheral neuropathy and is more sensitive than tests of fasting glucose or hemoglobin A_{1c} (HbA_{1c}). In a patient with acute, asymmetrical weakness and sensory loss, screening for an inflammatory process (ESR, ANA, RA, SS-A, SS-B) is appropriate. In addition, genetic testing is now available for most patients with CMT disease. If a monoclonal protein is identified on serum protein electrophoresis, a skeletal survey, urine immunofixation electrophoresis, and bone marrow biopsy should be ordered to rule out an underlying lymphoproliferative disorder. If the patient has a monoclonal protein associated with autonomic dysfunction, congestive heart failure, or renal insufficiency, a biopsy (rectal, abdominal fat, or sural nerve) should be considered for diagnosis of amyloidosis. CIDP can be associated with a monoclonal gammopathy, and in this situation patients should be treated with immunosuppressive therapy. Monoclonal gammopathies observed in patients with an axonal peripheral neuropathy are frequently benign (monoclonal

gammopathy of unknown significance) and do not necessarily warrant therapy.

A lumbar puncture is indicated only if an acquired demyelinating neuropathy such as GBS or CIDP is being considered. In these cases one expects to find “albuminocytologic dissociation” with an elevation in cerebrospinal fluid (CSF) protein and a relatively normal white blood cell (WBC) count. If the CSF WBC count is greater than 50/mm³, Lyme disease, HIV-associated disease, or a paraneoplastic process must be considered.

Electrodiagnostic studies consisting of nerve conduction testing and EMG can be a helpful extension of the physical examination. These studies are useful in defining whether the neuropathic process is caused by a primarily axonal or demyelinating process. In general, axonal degeneration decreases the amplitude of the compound muscle action potential out of proportion to the degree of reduction in peripheral nerve conduction velocity, whereas demyelination produces prominent reduction in conduction velocities. Nerve conduction testing can help determine, in the case of a demyelinating neuropathy, whether the process has an acquired or hereditary cause. A uniform slowing of nerve conduction usually suggests a hereditary cause. Electrodiagnostic studies can identify subclinical neuropathy (in patients receiving potentially neurotoxic medications) and can quantitate the extent of axon loss. Finally, these studies can localize the lesion in the case of radiculopathies, plexopathies, and multiple mononeuropathies.

Sensory nerve biopsies should be obtained for diagnosis of a vasculitic neuropathy because treatment involves potentially toxic medications. Performing a muscle biopsy in addition to the nerve biopsy may improve the diagnostic yield and should be considered because the inflammation is random and focal and easily missed. Nerve biopsies are not indicated in “cryptogenic” neuropathies, diabetic neuropathy, or motor neuron disease. If nerve conduction studies are normal, skin biopsies allow quantification of the number of epidermal nerve fibers. A length-dependent decrease in the number of these fibers can help confirm a small fiber neuropathy.

Treatment

Despite a very thorough history, examination, and laboratory studies, the cause of as many as one third of neuropathies remain unknown. In this situation, the focus of management is pain control. Patients with neuropathy frequently report a burning, searing, and aching sensation in their feet and hands that interferes with sleep. Neuropathic pain is difficult to treat but may respond to various medications having different mechanisms of action ([Table 121-12](#)). It is important to “start low and taper slow” and to treat for a minimum of 4 weeks before concluding that an agent is ineffective. In patients with a vasculitic neuropathy, therapy with corticosteroids in addition to a cytotoxic agent can stabilize and in some cases improve the neuropathy.

Prognosis

Peripheral neuropathies caused by axonal degeneration are generally progressive unless the underlying cause can be identified and treated. Recovery from axonal degeneration requires nerve regeneration, a process that often requires 2 to 3 years. Prognosis

TABLE 121-11 PERIPHERAL NEUROPATHY LABORATORY STUDIES

STANDARD TESTS	TESTS INDICATED IN SELECTED CASES
B ₁₂	Anti-Hu antibody
Complete blood count	ESR, ANA, RF, SS-A, SS-B
Glucose tolerance test	Genetic studies for Charcot-Marie-Tooth
Rapid plasmin reagin	Human immunodeficiency virus
SMA20	Lyme antibody
Serum protein electrophoresis and immunofixation electrophoresis	Phytanic acid
Thyroid function tests	24-hr urine for heavy metals
Nerve conduction studies or electromyogram	Quantitative sensory testing
	Lumbar puncture
	Nerve biopsy
	Skin biopsy
	Tilt table testing

TABLE 121-12 SYMPTOMATIC TREATMENT FOR NEUROPATHIC PAIN

TRICYCLIC ANTIDEPRESSANTS

Nortriptyline 10-150 mg qhs (Level U)	Duloxetine 60-120 mg qd (Level B)	
Imipramine 10-150 mg qhs (Level U)	Pregabalin 150-600 mg qd (Level A)	
Desipramine 10-150 mg qhs (Level U)	Sodium valproate 250-500 mg BID (Level B)	
Venlafaxine 75-225 mg qd (Level B)		
ANTICONVULSANTS		
Gabapentin 300-1200 mg tid (Level B)		
Carbamazepine 100-200 mg tid (Level U)		
	ALTERNATIVE TREATMENTS	
	Tramadol 50-100 mg qid (Level B)	
	Lidoderm patches (Level C)	
	Capsaicin cream (Level B)	
	Transcutaneous nerve stimulation	
	Acupuncture	

of demyelinating and vasculitic neuropathies is extremely variable, depending on the cause.

COMMON MONONEUROPATHIES

Common mononeuropathies are explored in [Table 121-7](#).

Carpal Tunnel Syndrome

Carpal tunnel syndrome results from compression of the median nerve at the wrist as it passes beneath the flexor retinaculum. Precipitating factors include activities that require repetitive wrist movements, such as mechanical work, gardening, house painting, and typing. Predisposing causes include pregnancy, diabetes, acromegaly, rheumatoid arthritis, chronic renal failure, thyroid disorders, and primary amyloidosis.

Symptoms usually begin in the dominant hand but commonly involve both hands over time. Patients typically report numbness, tingling, and burning sensations in the palm and in the fingers supplied by the median nerve: the thumb, index finger, middle finger, and medial one half of the ring finger. Some patients report that all fingers become numb. Pain and paresthesias are most prominent at night and often interrupt sleep. The pain is prominent at the wrist but may radiate to the forearm and occasionally to the shoulder. Shaking the hand relieves both pain and paresthesias. Percussion of the median nerve at the wrist provokes paresthesias in a median nerve distribution in 60% of patients (Tinel sign), and flexion of the wrist for 30 to 60 seconds provokes pain or paresthesias in 75% of cases (Phalen sign).

The diagnosis is based on clinical symptoms and signs. Electrodiagnostic studies may demonstrate prolongation of the sensory or motor latencies across the wrist in up to 85% of patients. In more severe cases, EMG may demonstrate evidence of denervation in the abductor pollicis brevis.

Treatment initially includes avoidance of repetitive wrist activities and the use of a neutral wrist splint. If these conservative measures fail, injections of lidocaine and methylprednisolone can be given into the carpal tunnel or surgical treatment by section of the transverse carpal ligament can effectively decompress the nerve. Indicators that have been shown to predict failure with conservative management include age greater than 50 years, disease duration greater than 10 months, constant paresthesias, and a positive Phalen sign in less than 10 seconds.

Ulnar Palsy

The ulnar nerve may become entrapped at the elbow because of external compression in the condylar groove. Injury may also occur years after a malunited supracondylar fracture of the humerus with bony overgrowth. Contrary to the findings in carpal tunnel syndrome, muscle weakness and atrophy characteristically predominate over sensory symptoms and signs. Patients notice atrophy of the first dorsal interosseous muscle and difficulty performing fine manipulations of the fingers. Numbness of the little finger, the contiguous one half of the ring finger, and the ulnar border of the hand may be present. Ulnar nerve compression can be confirmed with electrodiagnostic studies demonstrating slowed motor conduction velocity across the elbow. Treatment includes the use of elbow pads to avoid compression or surgical procedures including transposition of the ulnar nerve or decompression of the cubital tunnel.

Peroneal Neuropathy

The peroneal nerve can become compressed as it wraps around the fibular head and passes into the fibular tunnel between the peroneus longus muscle and the fibula. Compression may occur as a result of habitual leg crossing, prolonged bedrest, knee casts, prolonged squatting, anesthesia, or profound weight loss. The nerve can also be compressed as a result of Baker cysts, fibular fractures, blunt trauma, tumors, or hematomas at the knee. Symptoms include “footdrop” with selective weakness of the ankle dorsiflexors and evertors as well as the toe extensors. Reflexes remain normal, and sensory loss generally involves the anterolateral leg and dorsum of the foot. Electrodiagnostic studies demonstrate slowing of the peroneal conduction velocity across the fibular head and may demonstrate denervation if axonal injury is present. Compressive injuries usually resolve spontaneously within weeks to months. Magnetic resonance imaging (MRI) and surgical exploration should be considered if symptoms are progressive.

SPECIFIC ACQUIRED POLYNEUROPATHIES

Guillain-Barré Syndrome: Acute Inflammatory Demyelinating Polyneuropathy

Since the advent of polio vaccination, Guillain-Barré (GBS) has become the most frequent cause of acute flaccid paralysis throughout the world. GBS is an immune-mediated disorder that follows an identifiable infectious disorder in approximately 60% of patients. The best-documented antecedents include infection with *Campylobacter jejuni*, infectious mononucleosis, CMV, herpesvirus, and mycoplasma. *C. jejuni* is often associated with more severe axonal cases.

The initial symptoms of GBS often consist of tingling and pins-and-needles sensations in the feet and may be associated with dull low back pain. By the time of presentation, which occurs hours to 1 to 2 days after the first symptoms, weakness has usually developed. The weakness is usually most prominent in the legs, but the arms or cranial musculature may be involved first. Muscle stretch reflexes are lost early, even in regions where strength is retained. Cutaneous sensory deficits (loss of pain and

temperature) are relatively mild; however, large fiber function (vibration and proprioception) is more severely impaired. Other clinical features include pain (20%), paresthesias (50%), autonomic symptoms (20%), facial weakness (50%), ophthalmoparesis (9%), bulbar weakness, and respiratory failure (25%). Symptoms associated with GBS typically evolve over a 2- to 4-week period, with approximately 90% of patients showing no evidence of progression beyond 4 weeks. For this reason, patients who are seen within several weeks from onset continue to require hospitalization for close observation. Respiratory muscle strength should be monitored with bedside measurements of the forced vital capacity. Intubation should be initiated when the forced vital capacity falls below 15 mL/kg.

Treatment may include either intravenous gammaglobulin (0.4 g/kg/day for 5 days) or plasmapheresis (the exchange of the patient's plasma for albumin) (200 mL/kg over 7 to 10 days). Clinical studies have confirmed equal efficacy between these two therapies, with no additional benefit conferred with combination therapy. Corticosteroids are not effective in GBS. Indications for therapy include inability to ambulate independently, impaired respiratory function, or rapidly progressive weakness.

Clinical features predicting a poor prognosis or prolonged recovery time include rapidly progressive weakness, need for mechanical ventilation, and low-amplitude compound muscle action potentials. The mortality rate remains 5% to 10%, usually because of respiratory complications, cardiac arrhythmia, or pulmonary embolism. With appropriate supportive care and rehabilitation, 80% to 90% of patients recover with little or no disability.

Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy (CIDP) has been considered the “chronic form” of GBS, because by definition the symptoms must progress for at least 8 weeks. The clinical features include proximal and distal weakness, areflexia, and distal sensory loss. Autonomic dysfunction, respiratory insufficiency, and cranial nerve involvement can occur but are much less common than in GBS. Treatment for CIDP includes the use of oral immunosuppressive agents such as prednisone, cyclosporine, mycophenolate mofetil, and azathioprine. Intravenous immune globulin and plasmapheresis are also indicated for severe or refractory cases.

Diabetic Neuropathy

Diabetes mellitus is the most frequent cause of peripheral neuropathy worldwide. The diabetic neuropathies take many clinical forms, including symmetrical polyneuropathies and a wide variety of individual plexus or nerve disorders.

Diabetes mellitus often causes a slowly progressive, distal, symmetrical sensorimotor polyneuropathy (DSPN). DSPN is uncommon at the time of diagnosis of diabetes, but its prevalence increases with duration of diabetes with a lifetime prevalence of 55% for type 1 and 45% for type 2. The precise pathogenesis is not defined, but, similar to the ocular and renal complications, diabetic neuropathy can be reduced in incidence and in severity by maintaining blood glucose levels close to normal.

Initial symptoms may consist of numbness, tingling, burning, or prickling sensations affecting the feet and toes. Mild distal weakness and gait instability may subsequently develop. The sensory symptoms can then slowly progress to involve a “stocking-glove pattern.” The small-fiber dysfunction often produces spontaneous neuropathic pain in which unpleasant sensations can be evoked by normally innocuous stimuli, such as the bed sheets on the toes at night. Continuous burning or throbbing pain may occur, and prolonged walking is often distressing. In severe cases, patients may develop foot ulcers in insensitive areas that necessitate amputation. Autonomic dysfunction is also frequently associated with DSPN including impotence, nocturnal diarrhea, sweating abnormalities, orthostatic hypotension, and gastroparesis.

Other less common neuropathies associated with diabetes include cranial neuropathies (the sixth, third, and rarely fourth nerves), mononeuropathies, mononeuropathy multiplex, radiculopathies, and plexopathies. Diabetic amyotrophy (also known as *diabetic lumbosacral polyradiculopathy*) is a distinctive disorder characterized by severe thigh pain followed by proximal greater than distal lower extremity weakness that progresses over a period of months. The onset is invariably unilateral, but the condition may progress to involve both lower extremities. Physical therapy and effective pain management are essential; treatment with immune modulators is controversial.

Toxic-Induced Neuropathies

Toxic-induced neuropathies constitute a large number of disorders caused by alcohol, drugs, heavy metals, and environmental substances (E-Table 121-3). The majority of toxic neuropathies manifest as a distal sensorimotor axonal neuropathy that chronically progresses over time unless the offending agent is eliminated. Clinical evaluation should focus on the temporal relationship between exposure and the onset of sensory or motor symptoms as well as symptoms of systemic toxicity.

Critical Illness Polyneuropathy

Critical illness polyneuropathy (CIP) is a common cause of failure to wean from a ventilator in a patient with associated sepsis and multi-organ failure. Clinical features include generalized or distal flaccid paralysis, especially involving the lower extremities, depressed or absent reflexes, and distal sensory loss with relative sparing of cranial nerve function. The diagnosis can be confirmed with nerve conduction studies showing evidence of a severe, generalized axonal neuropathy. CSF protein should be normal and, in addition to conduction studies, distinguishes CIP from GBS.

SPECIFIC HEREDITARY POLYNEUROPATHIES

Charcot-Marie-Tooth Disease

The eponym Charcot-Marie-Tooth (CMT) identifies a group of heritable disorders of peripheral nerves that share clinical features but differ in their pathologic mechanisms and the specific genetic abnormalities (E-Table 121-4). CMT is the most common heritable neuromuscular disorder, with an incidence of 17 to 40 cases per 100,000.

E-TABLE 121-4 CHARCOT-MARIE-TOOTH DISEASE

DISORDER	LOCUS/PROTEIN	INHERITANCE	USUAL ONSET	SPECIFIC CLINICAL FEATURES
CMT1: DEMYELINATING				
CMT1A	17p11.2 Peripheral myelin protein 22 (PMP22)	AD	1st decade	Distal weakness
CMT1B	1q22 Myelin protein zero (P0)	AD	1st decade	Distal weakness More severe
CMT1C	16p13.1-p12.3 LITAF	AD	2nd decade	Distal weakness
CMT1D	10q21.1-q22.1 Early growth response protein 2 (EGR2)	AD	2nd decade	Distal weakness Ptosis
CMT1F	8p21 NF-68	AD	1 to 40 years	Distal weakness Ataxia
CMTX	Xq13.1 Connexin 32	X-linked	2nd decade	Distal weakness Hearing loss Encephalopathy
HNPP	17p11.2 Peripheral myelin protein 22 (PMP22)	AD	3rd decade	Focal episodic weakness
Dejerine-Sottas (HSMN3)	8q23,17p11,10q21 Early growth response protein 2 (EGR2) Peripheral myelin protein 22 (PMP22)	AD	2 yrs	Severe weakness
CMT2: DOMINANT; AXONAL				
CMT2A	1p36.2 Kinesin-like protein (KIF1B)	AD	10 years	Distal weakness
CMT2A2	1p36 Mitofusin 2 (MFN2)	AD	10 years	Distal weakness Hearing loss
CMT2B	3q21 RAB7	AD	2nd decade	Distal weakness Sensory loss Acromutilation
CMT2C	12q23-24 TRPV4	AD	1st decade	Vocal cord and distal weakness
CMT2D	7p15 Glycyl-tRNA (GARS)	AD	16 to 30 years	Distal weakness arms > legs
CMT2E	8p21 Synthetase Neurofilament triplet L protein (NEFL Sequencing)	AD	1 to 40 years	Distal weakness
CMT2F	7q11-21 HSPB1	AD	2nd decade	Difficulty walking
CMT2G	12q12	AD	15 to 25 years	Distal weakness
CMT2K	8q21 GDAP1	AD	Infant	Distal weakness Vocal cord
CMT2L	12q24 HSPB8	AD	15 to 33 years	Distal weakness
CMT2M	19p13 DNM2	AD	0 to 50 years	Distal weakness, legs > arms, ophthalmoparesis
CMT2N	16q22 AARS	AD	6 to 54 years	Distal leg weakness Asymmetric
CMT4: RECESSIVE; DEMYELINATING				
CMT4A	8q13-q21.1 Ganglioside-induced differentiation protein-1 (GDAP1)	AR	Childhood	Distal weakness Vocal cord
CMT4B1	11q22 Myotubularin-related protein 2 (MTMR2)	AR	2 to 4 yrs	Distal and proximal weakness
CMT4B2	11p15 Set binding factor 2 (SBF2)	AR	1st 2 decades	Distal weakness Sensory loss Glaucoma
CMT4C	5q32 SH3TC2	AR	5 to 15 yrs	Delayed walking
CMT4D	8q24.3 NDRG1 protein	AR	1 to 10 yrs	Gait disorder Hearing loss
CMT4E	10q21.1-q22.1 Early growth response protein 2 (EGR2)	AR	Birth	Infant hypotonia Arthrogryposis Respiratory failure
CMT4F	19q13.1-q13.2 Periaxin (PRX)	AR	1 to 3 yrs	Motor delay Sensory loss
CMT4H	12p11.21 FGD4	AR	10 to 24 mo	Walking delay Scoliosis
CMT4J	6q21 FIG4	AR	Congenital to adult	Asymmetric proximal and distal weakness
CMT3 (Dejerine-Sottas)	P0, PMP-22, EGR2, Periaxin	AR	2 years	Severe weakness

CMT disease usually manifests during the first to second decades with symptoms related to insidious footdrop: frequent tripping and inability to jump well or run as fast as other children. Over time, distal upper extremity weakness develops, resulting in difficulty with buttoning, handling keys, and opening jars. Examination reveals distal weakness and wasting of the intrinsic muscles of the feet, the peroneal muscles, the anterior tibial muscles, and the calves (inverted champagne bottle legs). A variable degree of impaired large-fiber sensory function is reflected in reduced vibratory sensation at the toes. Muscle stretch reflexes are lost, first at the ankles. Typically, a foot deformity exists, with high arches (pes cavus) and hammer toes, reflecting long-standing muscle imbalance in the feet. Most patients with CMT disease have nearly normal occupational and daily activities, and they have a normal life span. Although no specific treatment has been developed, the foot drop can be treated by appropriate bracing of the ankle with ankle-foot orthoses. Genetic counseling and education of affected patients and their families are important, both for reassurance and to preclude unnecessary diagnostic evaluation of affected members in future generations.

Demyelinating forms of CMT are classified as CMT1 and axonal forms as CMT2. CMT is usually transmitted as an autosomal dominant trait; however, X-linked dominant transmission is responsible for approximately 10% of cases. Rare autosomal recessive forms are designated CMT4, and these patients tend to have an earlier onset and more severe phenotype. CMT1A is the most common form and accounts for 90% of CMT1 and 50% of all CMT cases. CMT1A is associated with the 17p11.2-p12 duplication in the *PMP22* gene expressed by Schwann cells. A deletion or a point mutation of the *PMP22* gene produces a different phenotype: HNPP, which is characterized by recurrent episodes of focal entrapment with attacks of weakness and numbness in the peroneal, ulnar, radial, and median nerves (in descending order of frequency) or in a brachial plexus distribution.

FAMILIAL AMYLOID NEUROPATHIES

Amyloid neuropathy is an autosomal dominant disorder caused by extracellular deposition of the fibrillary protein amyloid in peripheral nerve and sensory and autonomic ganglia, as well as around blood vessels in nerves and other tissues. The age of onset varies from 18 to 83 years. In all forms of amyloidosis, the initial

and major abnormalities affect the small sensory and autonomic fibers. Involvement of small fibers responsible for pain and temperature sensibilities leads to loss of the ability to perceive mechanical and thermal injuries and to an increased risk of tissue damage. As a result, painless injuries present a major hazard of this disorder; in advanced stages, they can lead to chronic infections or osteomyelitis of the feet or hands and the necessity for amputation. Amyloid deposition in the heart can lead to cardiomyopathy. Mutations in transthyretin, apolipoprotein A1, or gelsolin are responsible. Early recognition is essential, as liver transplantation has been shown to halt disease progression.

Muscle Diseases

Jeffrey M. Statland and Robert C. Griggs

INTRODUCTION

Skeletal muscle fibers are the effector cells of the nervous system, turn thoughts into actions, and are the means by which we interact with our environment. Myopathies are primary diseases of the muscle and can be both inherited and acquired (Table 122-1). Myopathies can result in weakness and muscle wasting, myalgias, cramps, muscle breakdown, or contractures. Inherited disorders affect muscle proteins involved in transmission of signals from the neuromuscular junction, proteins involved in energy production or metabolism, or structural proteins that anchor and transmit force from the contractile apparatus to the extracellular matrix. Acquired myopathies are caused by external factors and can be due to metabolic derangements, toxic exposures or drugs, infections, or autoimmune dysfunction causing inflammation in the muscle. Acquired myopathies often improve with treatments geared towards eliminating or ameliorating the precipitating factors. To date, there have not been specific treatments for most inherited disorders of muscle, but as our understanding of the molecular pathological mechanisms of these disorders advances, new disease-directed therapies are entering clinical trials.

ORGANIZATION AND STRUCTURE OF MUSCLE

Each muscle is enclosed in a connective tissue sheath made up of collagen and extracellular matrix proteins called the epimyseum, which merges at either end to form the tendons, which attach muscle to bone. The epimyseum divides internally into the perimysium, which separates the muscle into individual bundles of muscle fibers called fascicles. The endomyseum surrounds and provides support for the individual fibers. Each muscle fiber is a single multi-nucleated syncytial cell and can be as long as 10 cm. On cross section, muscle fibers appear polygonal in shape and in adults range from 40 to 80 micrometers in diameter. Medium size arterioles and veins run in the perimysium, with capillaries between the individual muscle fibers. On hematoxylin and eosin stains, cytoplasm appears pink and the nuclei blue, with a thin rim of white, the epimyseum, between fibers (Fig. 122-1A). Each

individual muscle fiber has multiple nuclei, which are found beneath the sarcolemma membrane on the periphery of the cell. The amount of connective tissue between fibers, the position and number of myonuclei, and the amount and distribution of mitochondria can all be indicators of disease.

The plasma membrane around the muscle fiber is called the sarcolemma, and inside there are a large number of myofibrils made of thick (myosin) and thin (actin) filaments, which make up 70% to 80% of the volume of the cell, and when activated, create force. Electrochemical signals carry the signal from the nerve, through the neuromuscular junction, into the muscle fiber along the sarcolemma and t-tubule system. Muscle ion channels line this network and carry electrochemical signals. Mitochondria and enzymes involved in glycolysis and fatty acid metabolism provide energy for muscle. A network of proteins, the dystrophin-glycoprotein complex (DGC), anchors the myofibrils to the subsarcolemma cytoskeleton and connects to the extracellular matrix (Fig. 122-2). Many inherited myopathies are due to mutations in these ion channels, metabolic enzymes, or structural anchoring proteins.

ASSESSMENT

The work-up of a patient with a suspected myopathy is a staged process and involves a history and physical examination, followed by laboratory studies, electrodiagnostic testing, muscle biopsy, and genetic testing (Table 122-2). The family history is important because muscle disease can run in the family and may not have been previously diagnosed. Questions about whether family members require assistive devices to walk or wheelchairs, and concerning common extra muscular manifestation of muscular dystrophies can be useful. The genetic myopathies can be inherited in an autosomal dominant or recessive fashion, be X-linked, show maternal inheritance, or be sporadic (Table 122-3).

The most common symptom of a patient with muscle disease is a loss of function caused by weakness (see Table 122-2). Other common symptoms, like fatigue or myalgias (muscle pain), are less specific than muscle weakness. Muscle cramping is most often benign, and can be secondary to neuropathic changes. Muscle contractures are sustained contractions that are distinguished from cramping on electrodiagnostic testing, where contractures are electrically silent. Tendon contractures, on the other hand, are a fixed shortening of the tendon, and associated with long-standing disuse.

EXAMINATION

The physical examination uses a standard modified Medical Research Council scale of motor strength to determine the

TABLE 122-1 OVERVIEW OF MYOPATHIES

HEREDITARY MYOPATHIES	ACQUIRED MYOPATHIES
Muscular dystrophies	Inflammatory myopathies
Congenital myopathies	Endocrine myopathies
Metabolic/Mitochondrial myopathies	Systemic illness/infectious myopathies
Channelopathies	Toxic/Drug-induced myopathies

FIGURE 122-1 Muscle biopsies hematoxylin and eosin staining. **A**, Normal adult muscle medium power. Notice polygonal muscle fibers arranged in fascicles with blue staining nuclei on the periphery. A small arteriole is visible (*white arrow*). **B**, Duchenne muscular dystrophy low power. Note the variability in fiber size with rounding of fibers, increase in connective tissue, and fatty deposition. **C**, Centronuclear congenital myopathy. Notice variability in fiber size, large rounded fibers, and characteristic central nuclei in most fibers (*white arrow*). **D**, Dermatomyositis on low power. Notice the prominent perifascicular atrophy of fibers, with inflammatory infiltrates (*white arrow*).

FIGURE 122-2 The dystrophin-glycoprotein complex. Muscle structural proteins connect the contractile apparatus to the internal cytoskeleton and the extracellular matrix. Mutations in proteins from the extracellular matrix to the anchoring proteins, which connect the extracellular matrix to the internal cytoskeleton to proteins, which attach the internal cytoskeleton to the contractile apparatus are all involved in the inherited muscular dystrophies and myopathies.

TABLE 122-2 WORK UP FOR A PATIENT WITH SUSPECTED MYOPATHY

FEATURE	DESCRIPTION
HISTORY	
Age of onset	Congenital, childhood, adult
Chronic, progressive, or episodic	Dystrophies are usually progressive; congenital static; metabolic/channelopathies episodic
Triggers	Exercise, foods, temperatures
FAMILY HISTORY	
Dominant, recessive, or no family history	
WEAKNESS ON EXAM	
Proximal	Difficulty lifting objects, climbing stairs, getting up from chair, scapular winging, waddling gait, Gower's sign
Distal	Difficulty making a tight fist, fastening buttons, opening jars, wrist drop, foot drop
Facial	Difficulty squeezing the eyes shut, transverse smile, inability to pucker or blow out cheeks, inability to whistle
Oculopharyngeal	Ptosis, restricted extra ocular movements, coughing after drinking, and difficulty swallowing
Cardiac	Cardiac conduction defects, cardiomyopathy
Respiratory	Using accessory muscles, difficulty lying flat
LABORATORY	
CK	Dystrophies/inflammatory myopathy increased >10x normal; congenital 3-5x normal; metabolic >10x normal during attacks
Thyroid / Parathyroid	High TSH, low T4, low PTH, Ca ²⁺
ELECTRODIAGNOSTIC STUDIES	
Irritated muscle shows fibrillations and positive sharp waves; myopathic motor units are brief, low amplitude, and polyphasic; myotonia spontaneous waxing and waning motor unit amplitude and frequency	
MUSCLE BIOPSY	
Changes in muscle fiber shape and composition of fiber types, amount of connective tissue, presence of inflammatory cells, necrotic muscle fibers, regenerating fibers, number or morphology of mitochondria, or abnormal deposits of fat or glycogen	
GENETIC TESTING	
Confirmatory for inherited myopathies	

TABLE 122-3 INHERITANCE PATTERN IN GENETIC MYOPATHIES

X-LINKED	
Duchenne/Becker muscular dystrophy	Oculopharyngeal muscular dystrophy
Emory-Dreifuss muscular dystrophy	Channelopathies
	Central core myopathy
AUTOSOMAL DOMINANT	
Myotonic dystrophy types 1 and 2	AUTOSOMAL RECESSIVE
Facioscapulohumeral muscular dystrophy	Limb-girdle muscular dystrophy (2A-2S)

pattern and degree of involvement of various muscles (Table 122-4). But just as important as isolated strength testing are functional motor tasks, particularly in children. Patients may have difficulty climbing stairs, rising from a low chair or toilet, getting up from the floor, trouble lifting objects over their heads and washing or brushing their hair, or difficulty opening jar tops and fastening buttons. Muscles should be inspected for atrophy or hypertrophy and range of motion around the joints for evidence of tendon contractures. Ten broad patterns of muscle

TABLE 122-4 MODIFIED MEDICAL RESEARCH COUNCIL MOTOR STRENGTH TESTING SCALE

GRADE	DEGREE OF STRENGTH
5	Normal strength through entire range of motion and against resistance
5-	Equivocal, barely detectable weakness
4+	Able to move against gravity and resistance, but examiner can break
4	Able to move against gravity and some resistance
4-	Able to resist gravity but only minimal resistance
3+	Able to overcome gravity and transient resistance, but then quickly gives out
3	Able to overcome gravity but no resistance
3-	Able to resist gravity but not through full range of motion
2	Able to move through range of motion with gravity eliminated
1	Trace muscle contraction
0	No contraction

weakness occur in myopathies (Table 122-5). Most myopathies have the proximal, limb-girdle pattern. There are other, highly distinctive, patterns. Weakness that is asymmetric and includes the face, proximal arms and shoulders, and distal lower extremities is characteristic of facioscapulohumeral muscular dystrophy. Weakness that starts in the distal finger flexors (patients cannot curl fingers when making a fist) and proximal lower extremities (the quadriceps) is virtually pathognomonic for sporadic inclusion body myositis. A patient in middle age who presents with ptosis and difficulty swallowing is highly characteristic for oculopharyngeal muscular dystrophy. In all cases these patterns need to be distinguished from other diseases of the nervous system causing similar patterns of weakness (see Chapters 121 and 123.).

DIAGNOSTIC TESTING

The most useful initial laboratory study is the serum creatine kinase (CK), which is commonly elevated in both inherited and acquired myopathies. Despite the obvious localizing value of elevated muscle enzymes it is important to remember not all elevations in serum CK are due to myopathy (Table 122-6).

Electrodiagnostic testing can help distinguish between neurogenic and myopathic causes for weakness. In muscle disease nerve conduction studies are normal. Changes on electromyography characteristic for muscle disease include: chronic changes characterized by small, brief duration, polyphasic motor units; and more acute changes (irritable myopathic changes), which include fibrillations or positive sharp waves.

Muscle biopsies can be an important diagnostic test in patients whose family history and physical examination does not suggest a particular myopathic diagnosis. Characteristic morphological changes are hallmarks of the congenital myopathies (e.g., central core disease, or centronuclear myopathy), inflammatory myopathies (dermatomyositis and polymyositis), and metabolic myopathies (glycogen storage disorders), but most myopathies result in nonspecific muscle changes including rounding of muscle fibers, variation in fiber size, and increased number of internal nuclei.

In patients for whom the family history is suggestive of an inherited myopathy or in which the diagnosis is important to help guide surveillance or treatment, genetic testing is confirmatory.

TABLE 122-5 CHARACTERISTIC PATTERNS OF MUSCLE WEAKNESS AND ASSOCIATED MYOPATHIES

PATTERN	WEAKNESS	DISEASES
Proximal limb-girdle	Symmetrical, pelvic and shoulder girdle muscles. Distal muscles to lesser extent. \pm Neck flexor/ extensor.	Nonspecific: Duchenne muscular dystrophy; limb-girdle muscular dystrophy; inflammatory myopathies; certain autoimmune neuropathies
Distal	Symmetrical, distal upper or lower extremity. Proximal muscles to lesser degree.	Nonspecific: Miyoshi myopathy (calves); Welander myopathy (wrist and finger extensors); Nonaka and Markesbery/Udd myopathy (tibialis anterior); rule out neuropathy
Proximal arm/distal leg	Scapuloperoneal distribution: periscapular muscles (proximal arm) and anterior compartment distal leg (tibialis anterior). Scapular winging. Can be asymmetrical.	When face involved highly suggestive of facioscapulohumeral muscular dystrophy; with elbow contractures Emery-Dreifuss dystrophy; scapuloperoneal dystrophies; certain limb-girdle dystrophies; congenital myopathies
Distal arm/proximal leg	Distal forearm muscles (distal finger flexors) and proximal leg (quadriceps). Other muscles variable. Often asymmetrical.	Highly suggestive of sporadic inclusion body myositis; also consider myotonic dystrophy
Ptosis \pm ophthalmoparesis	Ocular weakness at presentation. Restriction of eye movements often without diplopia. Occasionally followed by pharyngeal weakness. Variable extremity weakness	Ocular and pharyngeal weakness highly suggestive of oculopharyngeal muscular dystrophy; ptosis and ophthalmoplegia without pharyngeal involvement mitochondrial myopathies
Neck extensor weakness	Neck extensors, “dropped head syndrome.” Variable neck flexor. \pm extremity weakness.	In isolation consider isolated neck extensor myopathy; rule out amyotrophic lateral sclerosis and myasthenia gravis
Bulbar weakness	Tongue and pharyngeal weakness	Certain myopathies (e.g., oculopharyngeal muscular dystrophy); significant overlap with neuromuscular junction and motor neuron disease
Episodic pain, weakness, and myoglobinuria	May be triggered by exercise or metabolic stress	Metabolic myopathies; may also occur in deconditioning
Episodic weakness delayed or unrelated to exercise	May be triggered by food, stress, rest after exercise	Characteristic of periodic paralyses
Stiffness and decreased ability to relax	May be episodic, triggered by cold	Characteristic of myotonic disorders; but may be seen in other myopathies; acquired conditions (e.g. stiff person syndrome)

	IDIOPATHIC

INHERITED MYOPATHIES

Muscular Dystrophies

The muscular dystrophies are inherited myopathies characterized by progressive weakness and mutations in genes coding for structural and other muscle proteins. Typically the muscular dystrophies are divided into the dystrophinopathies, the myotonic dystrophies, facioscapulohumeral muscular dystrophy, Emery-Dreifuss muscular dystrophy, and the limb-girdle dystrophies (Tables 122-7, 122-8, and E-Table 122-1). The limb-girdle muscular dystrophies (LGMD) are a diverse group of diseases due to mutations in more than 20 genes. The LBMDs are inherited in either autosomal dominant or recessive fashion, and present anywhere from childhood to later in life, having as the name implies, a limb-girdle pattern of weakness (E-Table 122-1). Another group of patients who have dystrophic changes in the muscle from birth, often with accompanying changes in the brain on

MRI, include congenital muscular dystrophies (see Table 122-8; not discussed in text). The traditional distinction between dystrophies and other inherited myopathies is becoming blurred as our genetic understanding advances because mutations for different diseases are often allelic.

Dystrophinopathies

Definition and Epidemiology

Dystrophinopathies are X-linked recessive disorders resulting from mutations of the large dystrophin gene located at Xp21. The incidence of Duchenne muscular dystrophy is 1 in 5300 male births; one third of the cases result from a new mutation. Becker muscular dystrophy is a milder form of dystrophinopathy and is less common than the Duchenne form, with an incidence of 5 per 100,000.

Pathology

Dystrophin is a large subsarcolemmal cytoskeletal protein that, along with the other components of the dystrophin-glycoprotein complex, provides support to the muscle membrane during contraction. Muscle biopsies are typically not required for diagnosis but show variability in fiber size; active and chronic changes, including necrotic and regenerating fibers; and, later in the disease, increased connective tissue and deposition of fat (Fig. 122-1B).

Clinical Presentation

Mutations in dystrophin result in a spectrum of disorders reflecting variations in the amount of functional dystrophin still expressed—from Duchenne muscular dystrophy and Becker’s on the severe end, to isolated quadriceps weakness and isolated cardiomyopathy in the middle, and to cramps and myalgias with

E-TABLE 122-1 LIMB-GIRDLE MUSCULAR DYSTROPHIES—ABBREVIATED LIST

INHERITANCE	NOMENCLATURE	MUTATION	AGE	CK	PHENOTYPES	SURVEILLANCE
Autosomal dominant*	1A	5q31; MYOT (myotilin)	18-40	Normal to 15x	limb-girdle pattern; tight Achilles tendons; dysarthria	Respiratory involvement; trouble swallowing
	1B	1q21; LMNA (lamin A/C)	Variable; birth to adulthood	Normal to mildly elevated	Limb-girdle pattern; contractures	Significant cardiac involvement
	1C	3p25 CAV3 (caveolin 3)	5-adulthood	3x-40x	Limb-girdle pattern; rippling muscle disease; elevated CK and cramping; distal myopathy (hand/foot)	Cardiac involvement
	1D	2q35; DES (desmin)	Teens to adulthood	2x-4x	Limb-girdle pattern	Cardiac involvement
	1E	7q36 DNAJB6 (30s-60s	Normal to 5x	Limb-girdle pattern; lower > upper	Trouble swallowing
Autosomal recessive†	2A	15q15 CAPN3(Calpain-3)	2-40s	Normal to 80x	Limb-girdle pattern; scapular winging; paraspinal involvement/scoliosis	
	2B	2p13 DYSF (dysferlin)	Teens to 20s	10x to 72x	Limb-girdle pattern; Miyoshi distal myopathy (calf wasting); tibialis anterior	Respiratory late
	2C-2F	13q12 (γ - sarcoglycan); 17q12 (α - sarcoglycan); 4q12 (β -sarcoglycan); 5q33 (δ - sarcoglycan)	3-15	>10x	Limb-girdle pattern; mild to severe phenotype; contractures/scoliosis; calf pseudo-hypertrophy	Respiratory and cardiac involvement; orthopedics
	2G	17q12 TCAP (telethonin)	9-15	3x-30x	Limb-girdle pattern; distal tibialis anterior	
	2I	19q13 FKRP (fukutin related protein)	Birth to 20s	10x to 30x	Limb-girdle pattern; upper > lower	Respiratory involvement

*Other autosomal dominant mutations: 1F 7q32 TNPO3; 1G 4q21; 1H 3p23.

†Other recessive mutations: 2H 9q33 TRIM32; 2J 2q24 Titin; 2L 11p14 ANOS.

TABLE 122-7 PREVALENT MUSCULAR DYSTROPHIES

DISEASE	INHERITANCE	MUTATIONS	AGE OF ONSET	PHENOTYPES	TREATMENT
Dystrophinopathies	X-linked recessive	Xp21; ~75% deletion or duplication; remaining sequence variant	Duchenne diagnosis by age 4; Becker variable	Limb-girdle pattern. Duchenne: severe progressive and life limiting. Becker progressive but not as severe, more variable. Calf pseudo-hypertrophy; isolated quadriceps weakness; isolated cardiomyopathy	Prednisone (or deflazacort) for Duchenne; ACE β -blocker for afterload reduction in cardiomyopathy; yearly to biannual surveillance for respiratory, cardiac and orthopedic problems
Myotonic dystrophy type 1	Autosomal dominant	19q13; CTG expansion > 50 repeats	Classic 20-30s; congenital at birth	Limb-girdle, can have distal weakness. Classic: myotonia and muscle wasting, temporal wasting, frontal balding; cataracts; cardiac conduction deficits; and diabetes. Congenital: severe and progressive, respiratory deficits, intellectual disability, and death ~45 years if survive neonatal period	Mexiletine for symptomatic myotonia; Yearly surveillance for cataracts, cardiac conduction deficits, and respiratory involvement.
Myotonic dystrophy type 2	Autosomal dominant	3q13; CCGT expansion > 75 repeats	30s	Limb-girdle pattern; multi-system involvement cataracts, cardiac conduction deficits; diabetes	Mexiletine for symptomatic myotonia; Yearly surveillance for ocular, cardiac, and respiratory involvement
Facioscapulohumeral muscular dystrophy	Autosomal dominant	4q35; ~95% between 1-10 D4Z4 repeats; ~5% decreased methylation <20% D4Z4 region	20s	Scapuloperoneal pattern with facial involvement; can have marked asymmetry; significant axial involvement	Supportive; screening dilated eye exam; hearing studies as indicated clinically; respiratory studies once wheelchair bound
Emery-Dreifuss muscular dystrophy	X-linked recessive; autosomal dominant or recessive	~70% Xq28 Emerin or FHL1 mutation; 1q21 lamin A/C, both dominant and recessive mutations reported	Joint contractures childhood; progressive weakness 20s-30s	Scapuloperoneal pattern; joint contractures, particularly at elbows, significant cardiac involvement	Yearly surveillance for cardiac and respiratory involvement; orthopedic evaluation for symptomatic contractures
Oculopharyngeal muscular dystrophy	Autosomal dominant and recessive	14q11 PABPN1 (Polyadenylate-binding protein) GCG repeats 7-13	40s (range 20s-60s)	Typically ptosis 2-3 years before dysphagia; limb-girdle pattern weakness	Swallow study; consider blepharoplasty for ptosis, consider cricopharyngeal myotomy for severe swallowing difficulty

TABLE 122-8 CONGENITAL MUSCULAR DYSTROPHIES

NAME / AKA	GENE	INHERITANCE	PHENOTYPE	CNS INVOLVEMENT
Merosin-deficient	6q22; laminin alpha-2	Autosomal recessive	Hypotonia; contractures; scoliosis or rigid spine; respiratory involvement; external ophthalmoplegia	MRI diffuse white matter changes; 20-30% seizures
Bethlam myopathy / Ullrich muscular dystrophy	21q22; 2q37; COL6 (collagen 6 spectrum disorders)	Autosomal dominant or recessive	Hypotonia; contractures; distal joint laxity; keloid; respiratory involvement	
Dystroglycanopathy	9q34 (POMT1); 14q24 (POMT2); 9q31 (fukutin); 19q13 (FKRP); 22q12 (LARGE); 1q32 (POMGnT1); 7p21 (ISPD)	Autosomal recessive	Spectrum of disorders but characteristic intellectual, eye, and brain involvement; motor early death, to acquiring ambulation	Walker Warburg Syndrome: severe eye involvement, cobblestone lissencephaly, hypoplastic cerebellum and brainstem. Muscle eye Brain Syndrome: common eye involvement, pachygyri/polymicrogyri, hypoplastic cerebellum and brainstem. Fukuyama: mild eye involvement, cortex mild changes, hypoplastic cerebellum but normal brainstem
SEPN1 related myopathy	1q36 (SEPN1)	Autosomal recessive	Cervicoaxial weakness, rigid spine syndrome, early nocturnal hypoventilation, medial thigh wasting	
LMNA related	1q22 (lamin A/C)	Autosomal dominant and recessive	Cervicoaxial weakness, dropped head, rigid spine syndrome, respiratory and cardiac involvement	

elevated serum CK on the mild end. Duchenne muscular dystrophy manifests as early as age 2 to 3 years with delays in motor milestones and difficulty running. Patients can have marked pseudo-hypertrophy of the calf muscles. And when asked to get up from the floor, boys use a Gower's maneuver (use hands to push up). The average age of diagnosis is around 4 years of age. The proximal muscles are the most severely affected, and the course is relentlessly progressive. Patients begin to fall frequently by age 5 to 6, have difficulty climbing stairs by age 8 years, and are usually confined to a wheelchair in their early teens. The smooth muscle of the gastrointestinal tract is involved and may cause intestinal pseudo-obstruction. The average IQ of boys with Duchenne muscular dystrophy is low, reflecting central nervous system involvement.

Diagnosis and Differential Diagnosis

Diagnosis is based on clinical history, physical examination, serum CK, and is confirmed by genetic testing. The majority of patients have deletions or duplications in the dystrophin gene. In the remaining patients, mutations can be small insertions or deletions, point mutations, or splicing errors. Other differential considerations are congenital myopathies and muscular dystrophies, and limb-girdle muscular dystrophies.

Treatment

Duchenne muscular dystrophy is a combination of surveillance for respiratory, orthopedic, and cardiac involvement, and the use of prednisone. Prednisone and deflazacort (a synthetic derivative of prednisolone available in other countries) improve strength and motor function in boys with Duchenne muscular dystrophy. Cardiac evaluation should begin at the time of diagnosis and, if cardiac involvement is found, afterload reduction is recommended (ACE inhibitor, β -blocker). Respiratory function should be monitored beginning prior to wheelchair use or when the forced vital capacity drops below 80%. Regular orthopedic screening for scoliosis and bone health is recommended. New investigational strategies for treatment include gene therapy, exon skipping strategies, and readthrough of premature stop mutations, all of which are designed to make the cell produce some form of dystrophin. There are no guidelines for the treatment of Becker muscular dystrophy and clinical presentation is highly variable, but monitoring for cardiac and respiratory involvement is warranted. Some female carriers of dystrophin mutations may become symptomatic later in life, and may have severe cardiomyopathy.

Prognosis

Patients with Duchenne muscular dystrophy die of respiratory complications in their 20s unless they are provided with respiratory support. Congestive heart failure and arrhythmias can occur late in the disease. The disease course for other dystrophinopathies is highly variable.

Myotonic Dystrophy

Definition and Epidemiology

Myotonic dystrophies are autosomal dominant diseases characterized by muscle wasting and myotonia. There are two types and

both are due to expanded DNA repeats: type 1 (DM-1) due to CTG expansion on chromosome 19; and type 2 (DM-2) to CCGT expansion on chromosome 3. DM-1 is the most prevalent adult muscular dystrophy, with an incidence of 13.5 per 100,000 live births.

Pathology

In both myotonic dystrophy types 1 and 2, accumulation of aberrant RNA in the nucleus binds regulatory proteins and causes aberrant splicing of a variety of proteins. Both disorders are multisystem diseases, affecting skeletal, cardiac, smooth muscle, and other organs, including the eyes, the endocrine system, and the brain. Muscle biopsies are not required for diagnosis but characteristic findings include rows of internal nuclei (boxcar appearance), ring fibers, type 1 fiber predominance, and later, fibrosis and fatty infiltration.

Clinical Presentation

DM-1 can present at any age, with the usual onset of symptoms in the late second or third decade. However, some affected individuals may remain symptom-free their entire lives. A severe form of DM-1 with onset in infancy is known as congenital myotonic dystrophy. The severity of DM-1 generally worsens from one generation to the next (anticipation). Typical patients exhibit facial weakness with temporalis muscle wasting, frontal balding, ptosis, and neck flexor weakness. Extremity weakness usually begins distally and progresses slowly to affect the proximal limb-girdle muscles. Percussion myotonia can be elicited on examination in most patients, especially in the thenar and wrist extensor muscles. DM-2 is typically milder but can present in an identical fashion to DM-1; however, some patients can only have a mild proximal limb-girdle pattern of weakness. Associated manifestations in the myotonic dystrophies include cataracts, testicular atrophy and impotence, intellectual impairment, and hypersomnia associated with both central and obstructive sleep apnea.

Diagnosis and Differential Diagnosis

The diagnosis is based on clinical examination, demonstration of myotonia on electromyography, and is confirmed by genetic testing. Myotonic dystrophy needs to be distinguished from other adult onset muscular dystrophies and non-dystrophic myotonic disorders.

Treatment

Yearly surveillance for cardiac and respiratory involvement is recommended. Mexiletine, a type IB anti-arrhythmic medication, can be used for symptomatic myotonia. There is currently no treatment to halt disease progression but many therapies targeting the interaction between RNA accumulations and regulatory proteins, or RNA accumulations themselves, are under investigation.

Prognosis

Respiratory muscle weakness may be severe, with impairment of ventilatory drive. Chronic hypoxia can lead to cor pulmonale. Cardiac conduction defects are common and can produce sudden death. Pacemakers may be necessary.

Facioscapulohumeral Muscular Dystrophy

Definition and Epidemiology

The majority of patients with facioscapulohumeral muscular dystrophy (FSHD) have disease inherited in an autosomal dominant fashion due to a deletion of a large repetitive element on chromosome 4 (FSHD-1). An additional 5% of patients (FSHD-2) will have disease with digenic inheritance, which occurs through a deletion-independent pathway. The prevalence of FSHD is 1 : 15,000.

Pathology

Both forms of FSHD lead to changes in methylation on chromosome 4 leading to the de-repression of the gene, *DUX4*, which is typically silenced in adult muscle; it is believed to cause disease in a toxic gain-of-function fashion. Muscle biopsy is typically not required for the diagnosis, but shows nonspecific myopathic changes. Up to 30% of biopsies can show inflammatory infiltrates.

Clinical Presentation

Patients typically present in their late teens or early twenties with weakness in a characteristic pattern, often with dramatic side-to-side asymmetry: typically first in the face, shoulders, and arms, later involving the trunk and distal lower extremities. Patients are unable to squeeze their eyes shut, have a transverse smile, scapular winging, loss of proximal muscle mass with often preserved forearm muscles, and a positive Beevor's sign (movement of the umbilicus up or down when asked to tense the abdominal muscles). Extramuscular manifestations of FSHD are rare: retinal vascular changes, which can occasionally lead to symptomatic retinal vasculopathy termed Coat's syndrome, high frequency hearing loss, and often asymptomatic atrial arrhythmias.

Diagnosis and Differential Diagnosis

Diagnosis is based on clinical examination, family history, and is confirmed by genetic testing. The differential diagnosis includes other myopathies or neuropathies with a scapuloperoneal pattern of weakness.

Treatment

There is no treatment for the weakness of FSHD. A dilated eye examination is indicated at the time of diagnosis, and surveillance for respiratory involvement for patients with pelvic girdle weakness or who are confined to wheelchair.

Prognosis

FSHD is not life limiting, but approximately 20% over the age of 50 will require a wheelchair.

CONGENITAL MYOPATHIES

Congenital myopathies are defined by their appearance on biopsy (see E-Table 122-2; Fig. 122-1C), and have a large number of genetic mutations associated with them. They are usually present at birth with hypotonia and subsequent delayed motor development. If the child survives the perinatal period, most congenital myopathies are relatively nonprogressive and may not be diagnosed until the second or third decade. Clinical findings

common in the congenital myopathies are reduced muscle bulk, slender body build, a long and narrow face, skeletal abnormalities (high-arched palate, pectus excavatum, kyphoscoliosis, dislocated hips, and pes cavus), and absent or reduced muscle stretch reflexes.

METABOLIC MYOPATHIES

Metabolic myopathies are muscle diseases due to mutations in enzymes responsible for energy production including glycogen, lipid, and mitochondrial metabolism (see E-Table 122-3). Classically, these disorders present in older children or adults with episodes of exercise intolerance, muscle cramping, or pain associated with myoglobinuria. Newborn and infants present with severe multisystem disorders that are often fatal.

Glucose and Glycogen Metabolism Disorders

Definition and Epidemiology

Glucose, and its storage form glycogen, is essential for the short-term, predominantly anaerobic energy requirements of muscle (see E-Table 122-3). Disorders of glucose and glycogen metabolism (called glycogenesis) have two distinct syndromes: static symptoms of fixed weakness without exercise intolerance or myoglobinuria, and dynamic symptoms of exercise intolerance, pain, cramps, and myoglobinuria. Acid maltase deficiency (Pompe disease) is an example of the first and is notable for enzyme replacement therapy, which is life extending for the childhood variant. McArdle's disease is an example of the second. These are rare disorders with incidence rates for the individual disorders of around 1 : 100,000. The incidence varies between region and ethnic group. For example, acid maltase deficiency has an incidence as high as 1 : 14,000 in African Americans. The prevalence of McArdle's disease is approximately 1 : 100,000.

Pathology

All are due to mutations in enzymes responsible for glucose or glycogen metabolism. Muscle biopsies usually show subsarcolemmal accumulation of glycogen.

Clinical Presentation

Acid maltase disease typically has a severe infantile form with respiratory and cardiac involvement and a slowly progressive adult myopathy, which can affect the diaphragm, so surveillance for respiratory involvement is important. However, McArdle's disease presents with severe episodes of muscle cramping and contractures associated with exercise and a fixed myopathy later in life. Many patients note a "second wind" phenomenon after a period of brief rest so that they can continue the exercise at the previous level of activity.

Diagnosis and Differential Diagnosis

Diagnosis is made by characteristic appearance on muscle biopsy with subsequent study of the enzyme activity or by searching for specific genetic mutations. The differential diagnosis includes other glycogen storage disorders, disorders of lipid metabolism, or mitochondrial disorders.

E-TABLE 122-2 CONGENITAL MYOPATHIES

PATHOLOGICAL FINDING	ASSOCIATED GENES	PHENOTYPE	SURVEILLANCE
Central cores, multicore	19q13 RYR1 (ryanodine receptor); 1q36 SEPN1; 14q11 MYH7	limb-girdle pattern weakness; scoliosis; respiratory involvement; malignant hyperthermia susceptibility	Caution with anesthesia
Nemaline rod	Sarcomeric thin filament genes: 1q42 ACTA1; 1q21 TPM3; 9p13 TPM2; 2q23 NEB; 19q13 TNNT1; 14q13 CFN2; 3p22 KCHL40	Limb-girdle pattern, Hypotonia, absent tendon reflexes, facial weakness, neck flexors	Respiratory involvement; independent ambulation by 18 months predictive of survival
Centronuclear	Myotubular: Xq28 XMTM1; 19p13 DNM2; 12q21 MYF6; 2q14 BIN1; 19q13 RYR1; 2q31 TTN	Limb-girdle pattern; hypotonia; respiratory involvement; cardiac rarely	Respiratory involvement
Fiber type disproportion (type 1)	See nemaline rod; plus Xq13, 1p36 SEPN1;	Limb-girdle pattern, scoliosis, hypotonia, respiratory involvement	Respiratory involvement
Reducing body	Xq26 FHL1	Limb-girdle pattern, scoliosis, hypotonia, respiratory involvement	Respiratory involvement; cardiac late
Sarcotubular Myofibrillar	9q31 TRIM32 Desmin-storage: 2q35 Desmin; 11q22 alpha beta crystalline; 5q31 myotilin; 10q23 ZASP; 2q32 filamin C; 10q25 BAG3	Limb-girdle pattern, scapular winging Limb-girdle pattern, cardiomyopathy	Cardiac involvement

E-TABLE 122-3 SELECTED METABOLIC MYOPATHIES

CLASS	NAME	ENZYME/GENE	PHENOTYPE	TESTING
GLYCOGEN STORAGE				
Type II	Pompe's disease	Acid maltase / <i>GAA</i> , 17q21	Infantile: hypotonia, cardiomegaly, hepatomegaly, fatal in 1 st year without treatment. Adult: limb-girdle weakness, respiratory failure	Muscle biopsy with non-rimmed vacuoles, and PAS positive material. Decreased enzyme activity in muscle, lymphocytes, or fibroblasts
Type III	Cori-Forbes disease	Debrancher / <i>AGL</i> , 1p21	Infantile: hypotonia. Adult: Limb-girdle pattern with distal weakness, respiratory involvement	Muscle biopsy PAS positive glycogen deposits. Decreased enzyme activity in fibroblasts or lymphocytes
Type IV	Andersen disease	Branching / <i>GBE1</i> , 3p12	Infantile: hypotonia. Adult: limb-girdle pattern, ± distal	PAS-positive, diastase-resistant filamentous polysaccharides (polyglucosan bodies); decreased enzyme activity in skin fibroblasts, muscle or liver.
Type V	McArdle's disease	Myophosphorylase / <i>PYGM</i> , 11q13	Infantile: profound weakness. Adult: Exercise intolerance, cramps, fatigue, limb-girdle pattern, second wind phenomenon	Electrically silent muscle contractures; Subsarcolemmal glycogen deposits; Decreased enzyme activity from muscle;
Type VII	Tauri's disease	Phosphofructokinase / <i>PFKM</i> , 12q13	Childhood: cramps, fatigue, exercise intolerance	Accumulation of free glycogen in muscle; hemolytic anemia; enzyme deficiency in muscle, erythrocytes
LIPID METABOLISM				
	Carnitine palmitoyltransferase II deficiency	CPT II, 1p32	Neonatal/infantile: severe, fatal. Adult: exercise or illness related, cramping, myoglobinuria, usually no fixed weakness	Low total serum carnitine; increased acylcarnitine fraction; reduced enzyme activity in skeletal muscle
	Very long chain acylcoenzyme A dehydrogenase deficiency	ACADVL, 17p13	Childhood: nonketotic hypoglycemia can have severe form with cardiomyopathy. Adult: rare, exercise/fasting induced myalgias or myoglobinuria.	Reduced VLCAD activity in fibroblasts; increased lipid staining in muscle
	Long chain acylcoenzyme A dehydrogenase deficiency	ACADL, 2q34	Infancy: failure to thrive, nonketotic hypoglycemia, cardiomegaly, encephalopathy. Adult: myopathy with cramps and myoglobinuria	Reduced total and free carnitine levels; increased long chain acylcarnitine esters; reduced enzyme activity in fibroblasts
	Medium chain acylcoenzyme A dehydrogenase deficiency	ACADM, 1p31	Infancy: failure to thrive, nonketotic hypoglycemia, cardiomegaly, encephalopathy. Adult: mild myopathy later in life.	Reduced total and free carnitine; decreased enzyme activity in lymphocytes, fibroblasts, and liver; excess lipid in muscle
MITOCHONDRIAL				
	Myoclonic Epilepsy associated with Ragged Red Fibers (MERRF)	Mitochondrial mutations, ~80% m.8344 A>G;	Onset usually childhood, epilepsy, myoclonus, ataxia, dementia, short stature, optic atrophy, wolf Parkinson white syndrome	Muscle biopsy ragged red fibers; elevated lactic acid; mitochondrial sequencing;
	Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS)	Mitochondrial mutations, ~80% m. 3243 A>G	Childhood onset, normal psychomotor development, then episodes of encephalopathy, migraine, seizures, stroke like symptoms, anorexia and vomiting, short stature, deafness, myopathy with exercise intolerance	Muscle biopsy ragged red fibers; elevated lactic acid; mitochondrial sequencing;
	Mitochondrial neurogastrointestinal encephalopathy (MNGIE)	Genomic mutations, <i>TYMP</i> , 22q13	Onset childhood/teenage, visceral neuropathy (gastroparesis, obstipation, diarrhea), ptosis, external ophthalmoplegia, sensory > motor neuropathy, hearing loss, myopathy	Muscle biopsy ragged red fibers; elevated lactic acid; mitochondrial sequencing
	Kearns-Sayre Syndrome	Single large mitochondrial deletion (~80%); also individual mutations	Onset less than 20 years; external ophthalmoplegia; pigmentary degeneration of retina; heart block; myopathy	Muscle biopsy ragged red fibers; elevated lactic acid; mitochondrial sequencing
	Leigh Syndrome	Many genes nuclear (complex I-IV); <i>SURF-1</i> , 9q34; mitochondrial	Typical: Onset 1st year; hypotonia; episodic vomiting, ataxia; encephalopathy; hearing loss; visual loss; death often within 2 years of onset. Mitochondrial: variable age of onset; less severe;	Muscle normal histology but COX negative; elevated lactate (CSF >blood); MRI high T2 in lentiform and caudate nuclei
	Progressive External Ophthalmoplegia (PEO)	Nuclear: <i>POLG</i> 15q25; <i>ANT1</i> 4q35; <i>Twinkle</i> 10q23; <i>POLG2</i> 17q. Mitochondrial: deletions or depletion	Onset variable typically >20 years; ptosis; ophthalmoparesis often without double vision; plus syndromes have myopathy and variable organ involvement.	Muscle biopsy ragged red fibers; genetic testing or mitochondrial sequencing;

GAA, Acid α-glucosidase; GBE1, glycogen branching enzyme 1.

Treatment

The only glycogen storage disorder with a therapy approved by the U.S. Federal Drug Administration is enzyme replacement for infantile or adult-onset acid maltase deficiency. Treatment for the other glycogen storage disorders is supportive.

Prognosis

Severe infantile forms of most these disorders can often involve multiple organs and be fatal. A less severe adult myopathic phenotype is also common.

DISORDERS OF FATTY ACID METABOLISM

Disorders of lipid metabolism differ from glucose and glycogen disorders in that the metabolic derangement is in the enzymatic breakdown of fatty acids (see [E-Table 122-3](#)). Many present in childhood with episodes of encephalopathy precipitated by fasting with hypoketotic hypoglycemia. Serum fatty acid profiles often show reduced carnitine and increased longer chain fractions, depending on whether the mutation is in very long chain, long chain, or medium chain fatty acid metabolism. Adults typically show exercise intolerance and myoglobinuria and may have developed a mild limb-girdle pattern myopathy. The most prevalent disorder of fatty acid metabolism is carnitine palmitoyltransferase II deficiency. This disease ranges from a lethal neonatal form to an adult form with muscle pain and recurrent myoglobinuria, often precipitated by intense exercise, febrile illness, or fasting. The diagnosis is usually made by detection of reduced carnitine palmitoyltransferase enzyme activity in skeletal muscle.

Mitochondrial Myopathies

Definition and Epidemiology

Mitochondrial myopathies can present at any age, with varying degrees of severity or weakness, affect multiple organ systems, and have any pattern of inheritance (see [E-Table 122-3](#)). Mutations affect enzymes necessary for normal mitochondrial function, and can be mitochondrial or nuclear. The overall prevalence for mitochondrial disorders is thought to be approximately 1:8500; however, the prevalence of individual mitochondrial syndromes is much lower and ranges from just a handful of cases, to 1 to 6 per 100,000.

Pathology

Mutations can occur in both mitochondrial DNA (in which case inheritance is maternal) and nuclear DNA (autosomal dominant, recessive, or x-linked). Mitochondrial disorders produce biochemical defects proximal to the respiratory chain (involving substrate transport and usage) or within the respiratory chain. On muscle biopsy, muscle fibers contain abnormal mitochondria. Pathologically these fibers have a “ragged red” appearance on biopsy stains (trichrome) and may fail to react for cytochrome c oxidase.

Clinical Presentation

Despite the diversity, there are certain patterns that are characteristic for mitochondrial disorders, including slowly progressive myopathy and myalgias, which worsen with exertion or illness,

and ptosis and/or ophthalmoplegia. [E-Table 122-3](#) lists common clinical mitochondrial syndromes. 

Diagnosis and Differential Diagnosis

The diagnosis is based on clinical history, serum lactate levels, which are often elevated at rest, and characteristic findings on muscle biopsy. Diagnosis is confirmed by mitochondrial or nuclear genetic testing.

Treatment

Treatment is largely supportive, and includes identification of other multisystem involvement, including diabetes, cardiac and ophthalmological involvement, and hearing loss. Many agents have been tried in mitochondrial diseases, including coenzyme Q10, creatine, and carnitine; however, a meta-analysis showed no clear evidence for benefit for any treatment. Aerobic exercise may reduce fatigue and improve muscle function, although there are no large trials of efficacy.

Prognosis

The severity and prognosis depends partially on the load of abnormal mitochondrial DNA as well as the degree of multisystem involvement. Certain clinical syndromes with more predictable prognosis have been described (see [E-Table 122-3](#)).

MUSCLE CHANNELOPATHIES

The muscle channelopathies are a spectrum of disorders due to mutations in muscle ion channels commonly divided into the nondystrophic myotonias and periodic paralyses. Most are inherited in an autosomal dominant fashion, with episodic symptoms, often triggered by temperature or certain foods.

Nondystrophic Myotonias

Definition and Epidemiology

Nondystrophic myotonias are due to mutations in muscle chloride (CLCN1 on chromosome 7) or sodium (SCN4A on chromosome 17) channels resulting in hyperexcitable muscle and myotonia. The overall worldwide prevalence for nondystrophic myotonias is 1:100,000.

Pathology

Mutations in chloride channels cause a loss of function. Loss of hyperpolarizing chloride conductance cannot counteract a buildup of potassium in the t-tubule system during repetitive contractions, which results in a depolarized sarcolemma. Sodium mutations, on the other hand, cause anomalous depolarizing sodium currents due to alterations in fast or slow channel inactivation, or hyperpolarizing shifts in channel activation curves.

Clinical presentation

The nondystrophic myotonias have myotonia in common; on examination this can be seen as delayed muscle relaxation after contraction. Patients have trouble opening their eyes or fist when instructed to squeeze them shut. On percussion of the thenar eminence or wrist extensors there is a catch then delay in the relaxation phase. Electromyography shows a characteristic waxing and waning motor unit amplitude and frequency that

when amplified sounds like a dive bomber or motorcycle revving. Symptoms usually start in the first decade, and patients can have a characteristic muscular build. Chloride channel mutations can be both dominantly and recessively inherited and have a characteristic warmup of myotonia with repetition. Sodium channel myotonias typically have more myotonia on eye closure and can demonstrate a paradoxical worsening of myotonia with activity (paramyotonia).

Diagnosis and Differential Diagnosis

Diagnosis is based on family history, myotonia on clinical examination, and electrodiagnostic testing. It is confirmed by genetic testing. The differential diagnosis includes myotonic dystrophy and secondary causes of myotonia (other myopathies and drugs associated with myotonia—e.g., statins, fibric acid derivatives, and colchicine).

Treatment

Treatment for nondystrophic myotonias consists of non-mutation-specific sodium channel blockade: mexiletine, a class IB antiarrhythmic, is the first line therapy but phenytoin, procainamide, and flecainide have also been used. Certain sodium channel myotonias respond to the carbonic anhydrase inhibitor acetazolamide.

Periodic Paralysis

Definition and Epidemiology

The periodic paralysis are disorders due to mutations in the calcium (CACN1A5 on chromosome 1), sodium (SCN4A on chromosome 17), and potassium channels (KCNJ2 on chromosome 17) that result in depolarized but inexcitable sarcolemma and episodes of paralysis. Overall prevalence for the primary periodic paralysis is greater than 1 : 100,000 and varies between conditions from 1 : 100,000 to 1 : 1,000,000.

Pathology

Hyperkalemic periodic paralysis is due to sodium mutations that lead to persistent inward sodium current causing both myotonia and paralysis depending on the relationship of depolarization to the sodium channel inactivation potential. Hypokalemic periodic paralysis is due to an anomalous gating pore current that, in low potassium conditions, produces a depolarizing current larger than hyperpolarizing potassium currents. Andersen Tawil syndrome is due to loss of function in a potassium inward rectifier.

Clinical Presentation

Common to all is attacks of flaccid tetraplegia, often brought on by rest after exercise, or in the mornings, and is associated with changes in extracellular potassium. Hyperkalemic periodic paralysis is due to mutations in sodium channels and is associated with either high or normal extracellular potassium. Triggers include potassium-rich foods. In hypokalemic periodic paralysis attacks are associated with low extracellular potassium, and are triggered by carbohydrates, stress, alcohol, or rest after exercise. Andersen-Tawil syndrome is due to mutations in a potassium inward rectifier and is characterized by the clinical triad of attacks of flaccid paralysis, dysmorphic features (wide-set eyes, narrow mandible,

low-set ears, bent fifth finger, and common origin for the second and third toes), and polymorphic ventricular tachyarrhythmias.

Diagnosis and Differential Diagnosis

Diagnosis is based in family history and clinical history, supported by electrodiagnostic testing and confirmed by genetic testing.

Treatment

In all of the periodic paralysis disorders mild exercise at onset of weakness can abort attacks of paralysis. Treatment for acute attacks consists of carbohydrates (hyperkalemic periodic paralysis) or potassium supplementation (hypokalemic periodic paralysis). Prophylactic treatment for all the periodic paralysis consists of carbonic anhydrase inhibitor acetazolamide.

ACQUIRED MYOPATHIES

Unlike the inherited myopathies, the acquired myopathies are typically secondary to another process: toxic, inflammatory, or infectious. Pathological changes can be distinctive and are not due to mutations in muscle-related proteins. Clinically, symptoms appear acutely or subacutely. Treatment often includes eliminating the precipitating factor.

Inflammatory Myopathies

The idiopathic inflammatory myopathies can be divided into dermatomyositis/polymyositis and sporadic inclusion body myositis (Table 122-9).

Dermatomyositis/Polymyositis

Definition and Epidemiology

Dermatomyositis/Polymyositis (DM/PM) are acquired idiopathic diseases of muscle characterized by inflammation and variable symmetrical proximal muscle weakness, associated with elevated serum creatine kinase and irritable features on electromyography. The overall annual incidence is approximately 1 in 100,000.

Pathology

Dermatomyositis shows a characteristic pattern on muscle biopsy of perifascicular atrophy with perivascular inflammatory infiltrates and positive pericapillary membrane attack complex staining (Fig. 122-1D). In contrast, polymyositis shows endomyseal inflammatory infiltrates with invasion of non-necrotic fibers, without other pathological changes.

Clinical Presentation

Dermatomyositis has a bimodal age of onset with peaks in childhood and adulthood, with an acute to insidiously progressive onset of painless symmetrical proximal muscle weakness with characteristic skin changes, which include heliotrope rash, shawl sign (maculopapular violaceous rash in v-shape around neck), Gottron's nodules (erythematous papular rash on the extensor surfaces of the hands or fingers), and mechanic's hands (dry, cracked skin on the dorsal or ventral hands). In contrast, Polymyositis is largely a diagnosis of exclusion, occurring in adults and not associated with skin changes. Myalgias are more common in polymyositis. In both DM/PM can be associated with respiratory

TABLE 122-9 IDIOPATHIC INFLAMMATORY MYOPATHIES

MYOPATHY	SEX	TYPICAL AGE AT ONSET	PATTERN OF WEAKNESS	CREATINE KINASE	MUSCLE BIOPSY	RESPONSE TO IMMUNOSUPPRESSIVE THERAPY
Dermatomyositis	Women > men	Childhood and adult	Proximal > distal	Increased (up to 50× normal)	Perifascicular atrophy, inflammation, complement deposition on capillaries	Yes
Polymyositis	Women > men	Adult	Proximal > distal	Increased (up to 50× normal)	Endomyseal inflammation; invasion of non-necrotic fibers	Yes
Sporadic Inclusion Body Myositis	Men > women	Elderly (>50 yr)	Proximal and distal; predilection for finger and wrist flexors, knee extensors	Increased (<10× normal)	Endomyseal inflammation, rimmed vacuoles; electron microscopy: 15- to 18-nm tubulofilaments	No

involvement, difficulty swallowing, or cardiomyopathy. Both DM/PM can be associated with underlying malignancy (dermatomyositis more frequently than polymyositis), so screening for malignancy is recommended especially in patients over age 40.

Diagnosis and Differential Diagnosis

Diagnosis is based on clinical history and examination findings in conjunction with irritable changes on electromyography (e.g., fibrillation potentials and positive sharp waves) and characteristic muscle biopsy. Both can be associated with autoantibodies (e.g., ANA). The most useful is the anti-Jo-1 antibody, which can be seen more frequently in patients with pulmonary involvement.

Treatment

For both DM/PM the first line of treatment is prednisone. Steroid-sparing immunosuppressive therapies (e.g., methotrexate, azathioprine) are often added for those patients requiring long-term therapy in order to reduce the required dose of prednisone or to replace prednisone completely. In patients who do not respond to conventional therapy, intravenous immunoglobulin or rituximab may be effective.

Prognosis

Most patients respond to immunosuppressive therapies.

Sporadic Inclusion Body Myositis

Definition and Epidemiology

Sporadic inclusion body myositis (s-IBM) is an idiopathic, slowly progressive muscle condition in older adults (occurring in more men than women), associated with inflammation and characteristic pathological changes on muscle biopsy. It is the most common inflammatory muscle disease in patients over 50, affecting 3.5 per 100,000.

Pathology

Muscle biopsies resemble polymyositis with endomyseal inflammatory infiltrates and invasion of non-necrotic fibers. Distinctive for IBM are vacuoles rimmed by mitochondria and electron microscopy, which shows 15 to 18 nm tubulofilamentous inclusions.

Clinical Presentation

S-IBM is a slowly progressive, often asymmetric weakness occurring usually after 50 years of age initially in a distinctive pattern,

including distal forearm muscles (distal finger flexors) and quadriceps wasting and weakness. This can progress to involve almost any muscle and can affect swallowing in up to 70% of patients.

Diagnosis and Differential Diagnosis

Diagnosis is based on clinical history and examination and characteristic muscle pathology. The main differential diagnosis is other idiopathic inflammatory myopathies or late-onset inherited myopathies, including a hereditary form of IBM.

Treatment

Unlike the other inflammatory myopathies, IBM does not respond to immunosuppression. Treatment is supportive.

Prognosis

Most patients with s-IBM progress to need a wheelchair over 10 to 15 years. Swallowing difficulty can be life threatening.

Infectious Myositis

An acute viral myositis can occur in the setting of an influenza viral upper respiratory tract infection. In addition to typical influenza-associated myalgias, affected patients develop muscle pain, proximal weakness, and elevated CK levels. The disorder is self-limited, but when severe it is often associated with myoglobinuria and occasionally with renal failure. A similar syndrome can complicate infections with other viruses.

An inflammatory myopathy can occur in the setting of human immunodeficiency virus infection, either in early or in later acquired immunodeficiency syndrome. The clinical presentation resembles polymyositis. The patient's condition may improve with corticosteroid therapy. The disorder must be distinguished from the toxic myopathy caused by zidovudine, which responds to dose reduction. Although rarely seen, tuberculosis can present with muscle abscess (pyomyositis) either in the setting of pulmonary or disseminated disease or in isolation.

Myopathies Caused by Endocrine and Systemic Disorders

Thyroid studies should be obtained in any adult coming in with a new complaint of muscle weakness. Patients with hyperthyroidism often have some degree of proximal weakness but this is rarely the presenting manifestation of thyrotoxicosis. Hypothyroid myopathy is associated with proximal weakness and

myalgias, muscle enlargement, slow relaxation of the reflexes, and marked (up to 100-fold) increase of the serum CK level.

Excess corticosteroids can result from endogenous Cushing's syndrome or can be caused by exogenous glucocorticoid administration. Iatrogenic corticosteroid myopathy (or atrophy) is the most common endocrine-related myopathy. However, muscle weakness is rarely the presenting manifestation of Cushing's syndrome and, in virtually all instances of corticosteroid myopathy, other factors contributing to weakness are also present. Therapy consists of reducing the corticosteroid dose to the lowest possible level. Exercise and adequate nutrition prevent and may improve weakness.

Toxic Myopathies

Many drugs have been associated with muscle damage, proximal weakness, elevated CK levels, myopathic EMG readings, and abnormalities on muscle biopsy. Symptoms generally improve after stopping the medication. Some drugs can produce acute, rapidly progressive muscle destruction and myoglobinuria, particularly the hypocholesterolemic drugs, including the statins and fibric acid derivatives. In some patients statin use has been associated with a subsequent autoimmune necrotizing myopathy associated with antibodies to HMG-CoA.

Critical illness myopathy (CIM), also termed, acute quadriplegic myopathy, develops in a patient in the intensive care setting and is often discovered when a patient is unable to be weaned off a ventilator. The cause of the diffuse weakness is the prolonged daily use of either high-dose intravenous glucocorticoids or non-depolarizing neuromuscular blocking agents, often both. Patients

often have had sepsis and multi-organ failure. The diagnosis of critical illness myopathy can be confirmed by muscle biopsy, which shows the loss of myosin-thick filaments on electron microscopic examination. Treatment is supportive after discontinuation of the offending agents.

Neuromuscular Junction Disease

Emma Ciafaloni

Neuromuscular junction diseases are caused by abnormal neuromuscular transmission of the action potential from the nerve terminal to the muscle, and they can be autoimmune (myasthenia gravis, Lambert Eaton Syndrome), hereditary (congenital myasthenic syndromes), or toxic (botulism, organophosphate intoxication).

MYASTHENIA GRAVIS

Definition/Epidemiology/Pathology

Myasthenia gravis (MG) is a rare autoimmune disease caused by antibodies against the postsynaptic acetylcholine receptors (AChR Ab) in the neuromuscular junction. All ages are affected but incidence is higher in women younger than 40, and in men older than 50. Prevalence is approximately 20 in 100,000. Transient neonatal MG occurs in about 12% of newborns of myasthenic mothers and is caused by transplacental passive transfer of antibodies from the mother to the fetus. Thymoma is found in 10% of patients with MG and thymic hyperplasia is present in 65%.

Clinical Presentation

MG is characterized by fluctuating, fatigable weakness either isolated to the ocular muscles (ocular MG), or involving ocular as well as limb, bulbar, and respiratory muscles (generalized MG). The majority of patients present first with ocular symptoms (blurred vision, double vision, droopy eyelids), but about 15% of cases present with bulbar symptoms first (dysarthria, dysphagia, shortness of breath), or limb weakness. Ptosis is usually asymmetric. Myasthenia crisis is a true neurological emergency that occurs in 15% to 20% of patients and consists of severe dysphagia or respiratory failure requiring ventilator support and/or tube feeding in an ICU setting.

Diagnosis and Differential Diagnosis

The diagnosis of MG is based on a combination of clinical history, physical examination, and confirmatory tests. The ice pack test is a simple and relatively sensitive test to differentiate ptosis caused by MG from other causes of ptosis. In this test an ice pack is applied to the ptotic eye for 2 minutes and an improvement of 2 mm or more in ptosis supports MG.

Edrophonium chloride (Tensilon) is a short-acting acetylcholinesterase inhibitor administered IV to demonstrate symptom improvement in patients with MG. A positive Tensilon test is defined as an unequivocal improvement in strength in an affected muscle after 2 to 5 minutes from administration of 2 mg incremental doses up to 10 mg. Atropine should be available

during a tensilon test because bradycardia and hypotension are possible side effects. Edrophonium testing can be positive in other disorders.

Electrodiagnostic testing with 3 Hz repetitive nerve stimulation (RNS) demonstrates a compound muscle action potential (CMAP) decrement more than 10% in about 50% to 75% of patients with generalized MG, but is abnormal in less than 50% of patients with purely ocular symptoms. Single fiber electromyography (SFEMG) is the most sensitive test in the diagnosis of MG and reveals increased jitter and blocking in 99% of patients with generalized MG, and in 97% of those with purely ocular MG when a weak muscle is tested. SFEMG is usually available only in specialized EMG laboratories.

Serum antibody testing for AChR Ab (binding antibody) is positive in about 80% of patients with generalized MG, and 50% of patients with purely ocular symptoms. Anti MuSK antibody is detected in a portion of seronegative patients, usually men.

Chest CT should be performed to rule out thymoma. Thyroid function should be evaluated because thyroid disease is commonly associated with MG. Electrodiagnostic and serum antibody testing help with differentiating MG from motor neuron disease, Lambert-Eaton myasthenic syndrome (LEMS), and Guillain-Barre syndrome (GBS).

Treatment

Pyridostigmine 30 to 60 mg every 4 hours improves symptoms in most patients with MG; it is used alone to treat purely ocular and generalized cases with only minimal or mild weakness, or in combination with immunosuppressant drugs in patients with more severe manifestations. Prednisone is effective in improving muscle weakness in a short period of time, but long-term use is associated with side effects. Azathioprine and mycophenolate mofetil are used for long-term treatment and as steroids-sparing agents. Plasmapheresis and IVIG are used for cases with severe bulbar or generalized weakness, respiratory crisis, and in refractory patients who do not respond to oral immunomodulating medications. Thymoma resection is indicated in all patients with MG and thymoma. Thymectomy is also recommended as an option in patients with nonthymomatous autoimmune MG to increase the probability of remission or improvement. Thymectomy is usually not recommended in patients over age 60. Some medications may exacerbate the symptoms of MG or precipitate the initial signs and symptoms of the disease (Table 123-1).

Prognosis

Most patients with MG who are optimally treated experience improvement or remission of their symptoms. About 10% of

TABLE 123-1 DRUGS TO BE AVOIDED OR USED WITH CAUTION IN MYASTHENIA GRAVIS**DRUGS TO BE AVOIDED**

- D-penicillamine and α -interferon should not be used in myasthenic patients because they can cause Myasthenia Gravis (MG)
- Botulinum toxin treatment should be avoided as it blocks NMT

DRUGS TO USE ONLY WITH CAUTION AND MONITOR FOR EXACERBATION OF MG SYMPTOMS

- Selected antibiotics, particularly aminoglycosides, telithromycin (Ketek) and ciprofloxacin (many other antibiotics have been reported to increase weakness in occasional patients with MG)
- Magnesium, magnesium salts contained in some laxatives and antacids
- Neuromuscular blocking agents such as succinylcholine and vecuronium should only be used by an anesthesiologist familiar with MG
- Quinine, quinidine or procainamide
- Beta-blockers (propranolol; timolol maleate eyedrops)
- Calcium channel blockers
- Iodinated contrast agents

patients with MG experience refractory symptoms despite optimal treatment. Mortality is currently less than 5%.

LAMBERT-EATON MYASTHENIC SYNDROME (LEMS)

Definition/Epidemiology/Pathology

Lambert-Eaton myasthenic syndrome (LEMS) is an acquired, presynaptic neuromuscular transmission disorder caused by antibodies against the P/Q type voltage-gated calcium channel (VGCC). P/Q VGCC antibodies cause reduced Ca^+ influx into the presynaptic nerve terminal resulting in decreased acetylcholine release and neuromuscular transmission failure. LEMS is associated with cancer, usually small cell lung carcinoma, in 60% of cases. LEMS may predate tumor detection by up to 3 years. LEMS is very rare and more common in men (3:1).

Clinical Presentation

LEMS should be suspected whenever the triad of muscle weakness, dry mouth, and decreased or absent reflexes is present. Patients have fluctuating weakness and fatigability of proximal limb and trunk muscles, with the lower limbs more severely affected than the upper ones. Difficulty walking is a common symptom. Dysphagia, dysarthria, and ocular symptoms (ptosis, blurred vision, and diplopia) are less common than in MG. Tendon reflexes are hypoactive or absent and may increase following short exercise of the muscle. Autonomic manifestations (dry mouth, impotence, decreased sweating, orthostatic hypotension, and slow pupillary reflexes) occur in 75% of patients.

Diagnosis and Differential Diagnosis

Serum antibodies against P/Q VGCCs are found in nearly all cases of paraneoplastic LEMS, and in about 90% of non-paraneoplastic cases. Electrodiagnostic testing can help confirm the diagnosis by demonstrating reduced CMAP amplitudes in distal hand muscles; CMAP facilitation of at least 100% after 10" maximal voluntary contraction or high frequency RNS (posttetanic facilitation); and CMAP decrement greater than 10% with low frequency RNS. Patients diagnosed with LEMS

should be screened and monitored with chest CT for lung cancer, especially if they are smokers and over age 50. LEMS and MG can be differentiated with electrodiagnostic and antibody testing.

Treatment

Symptomatic treatment with 3,4-DAP 5 to 10 mg every 3 to 4 hours and up to a maximum daily dose of 80 to 100 mg is most effective in improving muscle strength in patients with LEMS. Side effects at doses up to 60 mg per day are rare. Acral and perioral paresthesias occur within minutes from a dose and resolve in about 15 minutes. It is contraindicated in patients with seizures. 3,4-DAP is not currently FDA approved in the United States, but it can be obtained in specialized neuromuscular centers. Pyridostigmine 60 mg every 4 hours is also used to improve symptoms. In patients in whom symptoms are not adequately controlled with 3,4-DAP and pyridostigmine, immunomodulation with prednisone, azathioprine, or mycophenolate mofetil is used. Severe weakness is treated with plasmapheresis or IVIG. The underlying cancer should be treated.

Prognosis

In paraneoplastic LEMS the prognosis is determined by the underlying cancer. The presence of LEMS in patients with small cell lung cancer (SCLC) is associated with longer survival from the malignancy. Non-paraneoplastic LEMS, when optimally treated, has an excellent prognosis and normal life expectancy, although patients may continue to experience various degrees of muscle weakness.

BOTULISM

Definition/Epidemiology/Pathology

Botulism is a rare, potentially lethal, paralytic illness caused by the neurotoxin produced by the anaerobic, spore-forming bacterium *Clostridium botulinum*. Botulinum toxin blocks voluntary and autonomic cholinergic neuromuscular junctions by binding irreversibly to the presynaptic nerve endings where it inhibits the release of acetylcholine. Human forms of the disease include foodborne botulism most commonly caused by home-canned food, wound botulism with most cases occurring among "black tar" heroin users, and infant botulism occurring usually in the second month of life due to intestinal colonization. Outbreaks of foodborne botulism occur in prison inmates due to ingestion of pruno, an alcoholic drink made illicitly in prison. About 145 botulism cases are reported each year in the United States; approximately 15% are foodborne, 65% are infant, and 20% are wound botulism.

Clinical Presentation

The disease is characterized by symmetric descending flaccid paralysis starting with blurred or double vision, ptosis, dysphagia, dry mouth, dysarthria, and muscle weakness. Symptoms usually start 18 to 36 hours after ingesting contaminated food.

Botulism should be suspected in any infant with poor feeding and sucking, constipation, dilated pupils, weak cry, poor tone, and respiratory distress. Sensory examination and mental status are normal.

Diagnosis and Differential Diagnosis

All suspected cases of botulism need to be reported to public health authorities immediately. Local health department and CDC laboratories can confirm the diagnosis by detecting the toxin in serum, stool, or gastric or wound aspirate specimens. Electrodiagnostic testing can also confirm the diagnosis by demonstrating persistent post-tetanic facilitation of CMAP of at least 20%, a decremental response greater than 10% with slow RNS, and increased jitter and blocking on SFEMG. Electrodiagnostic tests are also helpful in differentiating botulism from Guillain-Barré syndrome and myasthenia gravis.

Treatment

Prompt intensive care support with mechanical ventilation and parenteral feeding as needed are crucial in reducing mortality. Timely administration of equine antitoxin within the first 24 hours may arrest the progression of paralysis and decrease the duration of illness. The antitoxin is provided by the CDC through the local health departments. Children less than 12 months old should not be fed honey because it can contain *Clostridium botulinum*.

Prognosis

The proportion of patients with botulism who die has fallen from 50% to between 3% and 5% in the past 50 years. Recovery of muscle strength may take several months. Mortality in untreated botulism is 60%.

ORGANOPHOSPHATE POISONING

Organophosphorus compounds (OPs) are used as pesticides and developed for chemical warfare. Exposure to even small amounts of an OP can be fatal and death is usually caused by

respiratory failure. OPs cause inhibition of acetylcholinesterase (AChE) accumulation of acetylcholine at the cholinergic receptor sites, producing continuous stimulation of cholinergic fibers throughout the nervous system. A combination of an antimuscarinic agent (e.g., atropine), AChE reactivator, such as one of the pyridinium oximes (i.e., pralidoxime, trimepridoxime, obidoxime, and HI-6), and diazepam are used for the treatment of OP poisoning in humans.

 For a deeper discussion on this topic, please see Chapter 422, "Disorders of Neuromuscular Transmission," in Goldman-Cecil Medicine, 25th Edition.

Geriatrics

124 The Aging Patient

Mitchell T. Heflin and Harvey Jay Cohen

The Aging Patient

Mitchell T. Heflin and Harvey Jay Cohen

INTRODUCTION

Over the last century, the number of Americans over the age of 65 years increased from 3 million to nearly 45 million in 2013, accounting for 13% of the population. During the same period the population over age 85 grew rapidly, expanding from 100,000 in 1900 to nearly 6 million in 2013. By 2030, the number of adults over age 65 will likely reach 72 million, or just over 20% of the total population. Ten million of those people will be over age 85 (Fig. 124-1). A report from the National Institute on Aging and the U.S. State Department points out that this phenomenon is not isolated to the United States. Around the globe, the percentage of the population over 65 years of age will increase by 25% to 50% over the next 25 years and by 140% in developing nations.

The aging of the world's population compels virtually all health care providers to gain competency in geriatrics, the clinical science of assessment, prevention, and treatment of illness in older adults. A basic grasp of geriatrics requires understanding at epidemiologic, biologic, and clinical levels. The provider must appreciate the impact of aging on presentation of and

predisposition to certain conditions, identification of goals of care, and selection of treatment strategies. Moreover, care of older adults demands a multifaceted approach, accounting for individual, family, and community resources for caregiving. Finally, the practice of geriatrics requires an appreciation for systems of care that include interprofessional teams working in a variety of settings ranging from home to hospital to long-term care. This chapter will provide an introduction to geriatrics and the essentials of caring for older adults.

EPIDEMIOLOGY OF AGING

Most experts believe that the rapid growth of the population of older adults reflects the many health care successes of the twentieth century. Fries, in his landmark paper, attributes the extension of the human lifespan to “the elimination of premature death, particularly neonatal mortality.” Improvements in other aspects of public health, including adequate nutrition and housing, safe drinking water, immunizations, and antibiotics, have led to lower rates of mortality throughout childhood and early adulthood, affording an opportunity for more people to

Population Age 65 and Over and Age 85 and Over, Selected Years 1900–2010 and Projected 2010–2050

Reference population: These data refer to the resident population.

FIGURE 124-2 Percent surviving by age. Deaths tracked by state registries, 1900 to 1902, and by national registry, 1949 to 1951 and 1999 to 2001. (From Arias E, Curtin LR, Wei R, et al: U.S. decennial life tables for 1999-2001, United States life tables, Natl Vital Stat Rep 57:1-10, 2008.)

survive to late life. Examination of survival curves across the twentieth century demonstrates a marked change in the shape of the overall graph from nearly linear in 1900 to rectangular in the 1990s, with much of the mortality compressed into late life (Fig. 124-2). Although the life expectancy at birth over the same period has risen dramatically from 47 years to nearly 77 years with up to 10% of the birth cohort surviving to age 95, the maximum lifespan defined as the age of the oldest surviving humans has remained remarkably stable.

THE BIOLOGY OF AGING

The relatively static nature of the maximum lifespan reflects the human body's limits at the cellular, tissue, and organ level in dealing with the stresses of aging. Across cell types and organ systems, certain consistent age-related alterations in function exist. Variability in tissue and organ function decreases, as evidenced by less fluctuation in heart rate or hormone secretion. Organ systems also exhibit predictable declines in function over time. These changes are most evident at times of stress, and ultimately these systems are slower to react and recover. The overall result is an impaired ability to deal with any demands beyond a narrow range outside the normal. This progressive restriction in the capacity to maintain homeostasis can be depicted as a steady tapering in the reserve available in multiple organ systems as time progresses (Fig. 124-3). In this situation an individual may function within the normal range in the absence of crisis, but stress such as acute illness may exceed his or her capacity to restore function and recover health. The result at best may be a decline in health and ability, and at worst, death.

THEORIES OF AGING

Scientific research provides a number of plausible theories of aging, which can be grouped into two major categories. *Error or*

FIGURE 124-3 Classic schematic representation of decreased homeostatic reserve. (From Fries J, Crapo LM: *Vitality and aging: implications of the rectangular curve*, San Francisco, 1981, WH Freeman.)

damage theories propose that aging occurs because of persistent threats from damaging agents and an ever-declining ability to respond to or repair this damage. *Program theories* postulate that genetic and developmental factors most significantly determine the biologic life course and the maximal age of the organism. In actuality, biologic aging may reflect a complex combination of many types of events.

The free radical theory of aging proposes that oxidative metabolism results in an excess of highly reactive byproducts, called *oxygen free radicals*, which damage proteins, DNA, and lipids. Molecular injury eventually leads to cell dysfunction and ultimately to tissue and organ disrepair. A second theory asserts that the accumulation of glucose-related molecules on proteins contributes to their dysfunction and degradation. These “glycosylated” molecules become more abundant over time and lead to impaired function at the tissue and organ level. Theory proponents point to the many chronic problems that routinely arise in patients with diabetes mellitus as proof of the significance of this phenomenon.

A different line of reasoning asserts that human lifespan and aging result from genetic-based timing mechanisms. Older theories suggest that evolutionary pressures are biased for traits that promote health and reproduction in early adulthood, possibly at the expense of health and function in late life. Furthermore, little selective pressure exists against negative traits that emerge in late life, leaving humans prone to the ill effects of aging. Geneticists have identified, among species of fruit flies and certain nematodes, specific genes that result in a significant prolongation in the organism's lifespan. Work is ongoing to discover similar genetic sequences among mammalian models.

Study of the enzyme telomerase has also generated much interest among theorists on aging. In a process called apoptosis, cells undergo programmed death to be replaced by younger cells. These divisions and replacements are limited by the number of generations intrinsic to a specific cell line (the Hayflick phenomenon). As telomeres located on the ends of chromosomes are depleted, cell aging and demise eventually occur. The enzyme telomerase prevents telomere shortening and may increase a cell's number of allotted replications and thereby extend the lifespan

of the organism. Of course, this advantage must be weighed against the price of “immortality,” namely the increased risk of malignancy.

Caloric restriction (CR), or the purposeful reduction of food intake, is the only intervention that has been shown to reproducibly extend maximal lifespan in certain laboratory animal models. In rats, lifespan increases an average of 20 months with a 40% reduction in calories. Rhesus monkeys enrolled in a trial of caloric restriction appear to have improvements in metabolic markers and a lower disease burden than controls after 15 years but have had no definitive extension in lifespan. The mechanism is not well understood but may be metabolically mediated. In observational studies in humans, those with lower average body temperature, lower insulin levels, and higher dehydroepiandrosterone sulfate (DHEAS) levels (all changes found in calorically restricted monkeys) appeared to survive longer. Current research is focused on reproducing this phenomenon in human subjects and discovering chemical agents that mimic or mediate these metabolic effects, including resveratrol and sirtuins.

To understand the changes in the individual's ability to cope with physiologic stress with age, one must also examine the changes at the level of the organ system. Table 124-1 provides an overview of these changes by system. As will be evident, although normal aging is not itself a diagnosis, it is, indeed, fertile ground for disease and disability.

TABLE 124-1 CHANGES IN PHYSIOLOGIC FUNCTION WITH AGE

ORGAN SYSTEM	AGE-RELATED DECLINE IN FUNCTION
Special senses	Presbyopia Lens opacification Decreased hearing Decreased taste, smell
Cardiovascular	Impaired intrinsic contractile function Increased ventricular stiffness and impaired filling Decreased conductivity Increased systolic blood pressure Impaired baroreceptor function
Respiratory	Decreased lung elasticity Decreased maximal breathing capacity Decreased mucus clearance Decreased arterial PO ₂
Gastrointestinal	Decreased esophageal and colonic motility
Renal	Decreased glomerular filtration rate
Immune	Decreased cell-mediated immunity Decreased T-cell number Increased T-suppressor cells Decreased T-helper cells Loss of memory cells Decline in antibody titers to known antigens Increased autoimmunity
Endocrine	Decreased hormonal responses to stimulation Impaired glucose tolerance Decreased androgens and estrogens Impaired norepinephrine responses
Autonomic nervous	Impaired response to fluid deprivation Decline in baroreceptor reflex Increased susceptibility to hypothermia
Peripheral nervous	Decreased vibratory sense Decreased proprioception
Central nervous	Slowed speed of processing and reaction time Decreased verbal fluency Increased difficulty learning new information
Musculoskeletal	Decreased muscle mass

PO₂, Partial pressure of oxygen.

THE FRAILTY PHENOTYPE

Biologic changes of aging portend the increased vulnerability of humans to illness and functional decline in late life—a state commonly referred to as “frailty.” Recent research has established a definition of frailty that moves beyond traditional components of chronologic age, comorbidity, and disability to identify a unique clinical entity with independent predictive capacity. Two prevailing models of frailty have emerged—one focused more exclusively on a set of physiologic changes occurring in a cyclical pattern and the other that includes measures of both physiologic markers as well as disease burden. The “cycle of frailty” ties together the individual system-specific changes and identifies key events or clinical presentations that create a specific phenotype, including weight loss, weakness, poor endurance, slowness, and inactivity (Fig. 124-4).

Frailty, defined as three or more of these conditions, independently predicts falls, declines in mobility, loss of ability to perform activities of daily living (ADLs), hospitalization, and death. This definition seems to provide a defined link between aging-related disease and disability and, perhaps, a target for interventions to prevent the onset of functional decline. Many believe, however, that this model remains difficult to recognize or measure in the clinical setting. The other definition conceives of frailty as a result of accumulation of problems (or deficits) that ultimately exceeds an individual's ability to maintain function and health. This count of deficits generates an index predictive of disability and death. To some degree both models capture different aspects of complex and heterogeneous phenomenon of vulnerability to declines in health and function with aging.

CLINICAL CARE OF OLDER ADULTS

Caring for older adults requires a strong foundation in the basics of internal medicine integrated with an appreciation for the complexity and heterogeneity of the impact of aging on health and well-being. The clinician must possess strong diagnostic skills, given that older adults may have atypical presentations or multiple comorbid conditions and functional decline. In addition, the clinician must monitor for a number of nonspecific conditions, such as problems with mobility, mood, or mentation that affect self-care capacity and safety. Treatment strategies present unique challenges as well, often requiring a balance of pharmacologic and nonpharmacologic interventions with careful consideration of the individual's goals for care. This section presents the core components of the comprehensive assessment of the older patient.

COMORBID CONDITIONS, FUNCTION, AND LIFE EXPECTANCY

With advancing age and declines in reserve, older adults experience high rates of chronic illness and related functional decline. Eighty percent of those over age 65 years have at least one chronic illness, and 50% have two or more comorbid conditions. Some of these conditions contribute directly to increased rates of mortality, including the leading causes of death among older adults—heart disease, cancer, stroke, lung disease, and Alzheimer's disease. Many common diseases, however, primarily threaten

For clinicians, navigating the myriad options for management of multiple chronic conditions requires individualized assessment of risks, benefits, and specific goals of various therapies. Estimates of life expectancy, integrating the impact of age, comorbid illness, and function, have been generated to assist in medical decision making. These estimates assist providers in predicting median survival and thus can help in estimating the potential life remaining in which one might benefit from a given procedure or therapy (Fig. 124-5). For example, the options offered to a frail 85-year-old man with less than 3 years left to live may be quite different from those presented to his healthy counterpart of the same age with a median life expectancy of 5 to 7 years. In addition, any decision should take into account the individual patient's goals and preferences. A variety of prognostic tools exist to assist clinicians with estimating survival in different populations and care circumstances. These tools can be accessed online in an interactive fashion for clinicians at <http://eprognosis.ucsf.edu/>.

PRESENTATION OF DISEASE IN THE OLDER ADULT

Competent care of the frail older adult starts with recognition of disease, even in the absence of typical signs and symptoms. Presentation of disease among older adults may differ dramatically

from that expected in younger patients; manifestations of distress may be subtle or nonspecific, and improvement is less obvious and slower. These phenomena occur for a number of reasons. As noted previously, older adults experience high rates of comorbid illness, which may confound the clinician's ability to diagnose a problem accurately. For example, a patient with heart disease and chronic obstructive pulmonary disease who visits the office because of dyspnea may be experiencing a flare of his or her pulmonary disease or an atypical presentation of ischemic heart disease or both. Reporting of symptoms may also be affected by psychosocial factors, including limited access to the health care system, cognitive problems, or minimization of symptoms as "normal aging." Likewise, health care providers may minimize complaints by older adults with complex medical illness or frail health.

The alert clinician may anticipate "geriatric" presentations for certain conditions (Table 124-2). Hyperthyroidism can manifest with apathy, malaise, depression, and fatigue, while lacking classic symptoms of tremor, tachycardia, or sweating. It can also manifest with heart failure and is highly prevalent among older adults with new-onset atrial fibrillation. Likewise, older patients with hypothyroidism may atypically demonstrate

FIGURE 124-5 Upper, middle, and lower quartiles of life expectancy for women and men at selected ages. (From Walter LC, Covinsky KE: Cancer screening in elderly patients: a framework for individualized decision making, JAMA 285:2750–2756, 2001.)

TABLE 124-2 PRESENTATIONS OF DISEASE IN OLDER ADULTS*

DIAGNOSIS	POTENTIAL PRESENTING SYMPTOMS AND SIGNS
Myocardial infarction	Altered mental status Fatigue Fever
Infection	Functional decline Altered mental status Functional decline Hypothermia
Hyperthyroidism	Altered mental status Anorexia Atrial fibrillation Chest pain Constipation Fatigue Weight gain
Depression	Cognitive impairment Failure to thrive Functional decline
Electrolyte disturbance	Altered mental status Falls
Malignancy	Fatigue Personality changes Altered mental status Fever
Pulmonary embolus	Pathologic fracture Altered mental status Fatigue Fever Syncope
Vitamin deficiency	Altered mental status Ataxia Dementia Fatigue
Fecal impaction	Altered mental status Chest pain Diarrhea
Aortic stenosis	Urinary incontinence Altered mental status Fatigue

*This table represents only a limited list of select disease processes and presentations; it is not meant to serve as an exhaustive reference for use during patient care activities.

failure to thrive, weight loss, cognitive decline, or depression. In the presence of infection, older adults may not reliably mount fever or experience localized symptoms. Studies have demonstrated that lowering the threshold definition of fever can improve the diagnostic utility of body temperature as a sign of bacterial infection. Although chest pain remains the most common and important symptom of ischemic heart disease, dyspnea in the absence of chest pain is a commonly reported symptom, particularly in older adults and those with multiple comorbidities.

In truth, any medical illness may manifest nonspecifically among older adults, particularly those in frail health. Nonspecific symptoms related to an underlying illness include changes in mentation, difficulty with balance and falls, new urinary incontinence (UI), and a general change in functional ability. These presentations are often referred to as the “geriatric syndromes” and are detailed later. A lack of understanding of how disease presentation differs among older adults can lead to delays in diagnosis and treatment and result in worse outcomes. Research indicates that altered presentation predicts not only suboptimal care, but future functional decline and increased mortality.

MEDICATIONS

Medication-related problems are very common in older adults. In the United States, outpatients over age 65 take, on average, three to five medications. Although medications may be indicated for specific medical conditions, use of multiple medications increases the risk for drug-drug interactions and associated adverse drug events. Altered pharmacokinetics and pharmacodynamics contribute to adverse drug events, which are a common cause of hospitalization and morbidity in older persons. Common changes in pharmacokinetics include changes in body composition, with increased fat stores and decreased body water. Fat-soluble medications, such as benzodiazepines, have a prolonged duration of effect because of this phenomenon. Age-related declines in glomerular filtration rates result in decreased clearance of many medications, including such drugs as atenolol, digoxin, and lithium. Accurate calculations of creatinine clearance will inform drug choice and dosing and improve prescribing safety. Pharmacodynamic changes include decreased sensitivity to certain commonly prescribed drugs, such as β -blockers, and increased sensitivity to other agents, such as narcotics and warfarin.

Given the risks of medication use in older adults, health care providers and systems must employ strategies to improve both the effectiveness and safety of prescribing. Evidence-based recommendations include the following:

- Maintain an up-to-date medication list, including over-the-counter medications and herbal supplements.
- Comprehensively review medications at least once annually (if not at every visit) and, in particular, at the time of transitions between care settings (e.g., after hospitalization). A clear indication for each medication, and documentation of response to therapy (particularly for chronic conditions) should be included.
- Assess for duplication and drug-drug or drug-disease interactions. Using a drug information database will help with this process.
- Assess adherence and affordability and inquire about the patient’s system for administering medications (e.g., a pillbox).
- Assess for specific classes of medications commonly associated with adverse events: warfarin, analgesics (particularly narcotics and nonsteroidal anti-inflammatory drugs [NSAIDs]), antihypertensives (particularly angiotensin-converting enzyme [ACE] inhibitors and diuretics), insulin and hypoglycemic agents, and psychotropics.
- Be suspicious that new symptoms arise from adverse effects of current drugs, not new disease.
- Minimize or avoid use of anticholinergic medications, which present specific risks.

In addition to following these general principles, prescribing providers also benefit from consulting lists of potentially inappropriate medications. The Beers List of Potentially Inappropriate Medications (PIMs) provides an evidence-based guide to drugs that should be avoided if possible or used with caution in older adults. A clear and rational approach to prescribing and ongoing management of medications that accounts for indication, interactions, and adherence may reduce the risk of common adverse events.

COGNITION

Dementia

The prevalence of dementia increases with age, with estimates ranging from 20% to 50% after age 85. The most common forms of dementia include Alzheimer's disease, Lewy body dementia, and vascular dementia. The latter is commonly present in combination with Alzheimer's disease in a condition termed *mixed etiology dementia*. Dementia is characterized by impairment in one or more cognitive domains severe enough to disrupt function or occupation. Mild cognitive impairment (MCI) is present when an individual has discernible cognitive limitations without apparent functional impact. Patients with MCI develop dementia at a rate of approximately 15% per year. Dementia is associated with a higher risk of falls, functional impairment, institutionalization, and death. Caregivers of demented individuals also face increased rates of stress and health problems. Clinicians diagnose dementia through symptom and functional history (often including the input of caregivers), cognitive assessment, and physical examination. A number of instruments, including the MOCA (see [Chapter 108](#)), clock-drawing test, and the Mini-Cog, are validated screening tools. The time-tested Mini Mental State Examination (MMSE) offers an assessment of multiple cognitive domains but does not provide adequate measure of executive function and is prone to lack of sensitivity in individuals with high premorbid intelligence and lack of specificity in those with low levels of education. Validated assessments of executive function include the clock-drawing test, verbal fluency test, and the Trail B test. Instruments also exist for collecting data regarding patient function from a relative or caregiver. In patients suspected of having dementia, personal safety with respect to firearms, driving, and the home environment should be assessed. A careful medication review and physical examination, including vital signs, complete neurologic assessment, including gait and balance, are, of course, essential in dementia to reveal findings that point to a specific cause (see [Chapter 116](#)).

Delirium

The differential diagnosis for cognitive problems other than dementia is broad, and includes delirium, mood disturbance, and drug effects. The differentiation of dementia and delirium may present the most significant challenge, particularly in hospitalized elders ([Table 124-3](#)). Delirium is characterized by its acuity and alteration in global cognitive function, whereas dementia is chronic and affects specific cognitive domains. Differentiation often hinges on history, which may be lacking at presentation. Delirium affects more than 2 million hospitalized persons each year. Its incidence is variably estimated at 25% to 60% among patients in acute care settings and results in extra hospital days and related expenditures. Delirium is also associated with prolonged hospital stay, increased costs, increased readmission rates to the hospital (12% to 65% at 6 months), higher in-hospital and 1-year mortality, and incident dementia. The Confusion Assessment Method (CAM) offers a validated tool to diagnose delirium. Per the CAM, delirium is likely present if the patient has both an acute onset of confusion with fluctuating course and inattention, and either disorganized thinking or altered level of consciousness. Key risk factors for delirium include older age,

TABLE 124-3 FEATURES OF DELIRIUM VERSUS DEMENTIA

FEATURE	DELIRIUM	DEMENTIA
Onset	Acute	Insidious
Course	Fluctuating, lucid at times	Generally stable
Duration	Hours to weeks	Months to years
Alertness	Abnormally low or high	Usually normal
Perception	Illusions and hallucinations common	Usually normal
Memory	Immediate and recent impaired	Recent and remote impaired
Thought	Disorganized	Impoverished
Speech	Incoherent, slow, or rapid	Word-finding difficulty
Physical illness or medication causative	Frequently	Usually absent

cognitive impairment, comorbid illness, and impairments in vision and hearing. Precipitating factors related to acute illness include hypoxia, electrolyte abnormalities, dehydration, and malnutrition as well as medications and alcohol withdrawal. Although treatment of delirium is difficult and revolves around the underlying medical issues, controlled trials have demonstrated that a multi-modal intervention is effective in reducing rates of delirium in high-risk patients. There is evidence that the use of restraints in combative or confused older adults leads to increased morbidity and mortality. Nonpharmacologic management strategies include reorientation and preservation of sleep patterns, family or caregiver presence at the bedside, and early mobilization. The use of pharmacologic agents, specifically neuroleptics, should be reserved for patients in whom nonpharmacologic strategies do not help and the patient presents a risk of harm to self or others.

MOOD

Older adults commonly experience depressive symptoms, with prevalence estimates as high as 15% to 19% among those over age 75, although in community-dwelling elders, major depressive disorder is actually less common than in younger adults. The presence of comorbid illness and grief often confound the presentation of depression. As a result, it can remain undetected despite its significant adverse impact on quality of life, morbidity, and mortality. Suicide rates are almost twice as high among older persons when compared with the general population, with the rate highest for white men over 85 years of age. Among older adults, depression can manifest atypically with cognitive, functional, or sleep problems, as well as complaints of fatigue or low energy. Several instruments have been developed and validated for screening for depression in elders. Asking two simple questions about mood and anhedonia (“Over the past 2 weeks have you felt down, depressed, or hopeless?” and “Over the past 2 weeks have you felt little interest or pleasure in doing things?”) may be as effective as using longer instruments. Longer screening questionnaires, such as the Geriatric Depression Screen (GDS) or Patient Health Questionnaire (PHQ-9), are also useful tools in the ambulatory setting. Any positive screening test result should trigger a full diagnostic interview. When screening for depression in elders, it is particularly important to have systems in place to provide feedback of screening results, a readily

accessible means of making an accurate diagnosis, and a mechanism for providing treatment and careful follow-up. Recent trials indicate that the addition of counseling to pharmacologic therapy confers additional benefit for older, frail patients with depression. Anxiety is more common than depression among older adults and may similarly result in physical and cognitive symptoms, insomnia, agitation, psychosis, and isolation. Clinicians should consider a diagnosis of generalized anxiety, panic, or agoraphobia in older adult patients with any of these symptoms.

MOBILITY

Problems with mobility are common among older persons. Among those over age 65, 20% of men and 32% of women report difficulty with one or more of five specific physical activities (stooping or kneeling, reaching overhead, writing, lifting 10 pounds, or walking two to three blocks). Among these, respondents cite problems with walking most commonly. Difficulties with balance and gait present significant risks for older adults. Approximately 30% of community-dwelling elders fall each year. The annual incidence of falls approaches 50% in patients over 80 years of age. Five percent of falls in older adults result in fracture or hospitalization. Risk factors for falls include a history of falls, fear of falling, decreased vision, cognitive impairment, medications (particularly anticholinergic, psychotropic, and cardiovascular medications), diseases causing problems with strength and coordination, and environmental factors. Effective interventions for people with a history of falls or who are at risk for falling involve addressing multiple contributing factors. Providers should regularly inquire about recent falls or a fear of falling in older patients. For patients who report falling, the assessment should include review of circumstances of the fall(s), measure of orthostatic vital signs, visual acuity testing, cognitive evaluation, and gait and balance assessment. A brief physical examination maneuver called the “timed get up and go” has the patient arise from a sitting position, walk 10 feet, turn, and return to the chair to sit. A time of more than 12 seconds to complete the process, or observation of postural instability or gait impairment, suggests an increased risk of falling. Gait speed, an additional measure of mobility, predicts changes in ability and health status in older adults. Gait speed is measured over a 10-meter span with the patient walking at a comfortable pace. A speed of less than 1.0 m/sec is associated with increased mortality; 0.8 m/sec predicts difficulty navigating outside the home, and a speed of less than 0.6 m/sec predicts a high risk of falls and functional decline. For those found to be at risk for falls, providers should also review all medications for possible causative agents and inquire about home safety. High-risk patients should be evaluated for assistive devices and a supervised exercise program (Table 124-4).

VISION AND HEARING

Problems with vision and hearing are very common among older adults and frequently complicate the management of comorbid conditions and accelerate functional decline. Significant vision loss occurs in 16% to 18% of adults over age 65. Common causes include glaucoma, cataracts, age-related macular degeneration, and retinopathy from hypertension and diabetes. Decreased visual acuity increases fall risk and has been associated with all-cause mortality. Such problems may be detectable with regular

testing via bedside tools such as the Snellen or Jaeger eye chart. Given the implications of vision loss for function and safety, a general ophthalmologic examination every 1 to 2 years is recommended for all older adults. Furthermore, ophthalmologic centers have recognized the multifaceted challenges faced by older adults with vision impairment and have developed specialized low vision clinics offering evaluation by optometrists, occupational therapists, and social workers with a focus on improving quality of life and maintaining independence.

Hearing loss is the third most common ailment in older adults (behind hypertension and arthritis), affecting an estimated 40% to 66% of those over age 75. It is associated with depression, social isolation, poor self-esteem, cognitive decline and functional disability. Pure tone audiometry is the reference standard for screening for hearing loss, but a simple whispered voice test is also highly sensitive and specific. Ideally all older adults would undergo annual hearing screen by questionnaire and handheld audiometry. Unfortunately, the lack of reimbursement for hearings aids under most insurance plans, including Medicare, presents a major barrier for many older adults.

CONTINENCE

UI affects up to 30% of community-dwelling older adults and at least half of those residing in skilled nursing facilities. It occurs more frequently in women, but this gender disparity narrows as the rate of UI in men increases after age 85. The impact of UI on health ranges from increased risk of skin irritation, pressure wounds, and falls, to social isolation, functional decline, and depression. For caregivers of older adults, UI complicates physical care and can contribute to decisions for placement in skilled nursing facilities. Common comorbid conditions include diabetes mellitus, heart failure, arthritis, and dementia.

A systematic approach to the investigation of UI can often reveal a cause and potential solution. It is important to first determine if the incontinence is acute or chronic in nature. Acute causes of incontinence are often attributable to specific medical problems, including infection, metabolic disturbance, or medication effects. The mnemonic DIAPERS recalls the various potential acute causes of UI (*D*, delirium; *I*, infection; *A*, atrophic vaginitis; *P*, pharmaceuticals; *E*, excess urine output from congestive heart failure [CHF] or hyperglycemia; *R*, restricted mobility; and *S*, stool impaction). If the UI is chronic, then further history can characterize the nature of the symptoms from among four types. Urge incontinence from detrusor overactivity is the most common type. Patients with this problem will complain of urinary frequency, nocturia, and a sudden onset of urge to void. Stress incontinence occurs with incompetence of pelvic musculature or urethral sphincter, and is characterized by small amounts of leakage with laughing, sneezing, coughing, or even standing. Overflow incontinence results from urinary retention, often related to prostatic hyperplasia in men or bladder atony in patients with diabetes or spinal cord injury. Patients often have constant dribbling or leakage without a true sense of needing to void. Finally, functional incontinence results from comorbid conditions that limit a patient's ability to act on or interpret the need to void, mobility problems such as arthritis, and weakness or cognitive problems. Table 124-5 describes the various types of incontinence and suggested approaches. Of course, older adults

TABLE 124-4 RECOMMENDED COMPONENTS OF CLINICAL ASSESSMENT AND MANAGEMENT FOR OLDER PERSONS LIVING IN THE COMMUNITY WHO ARE AT RISK FOR FALLING

ASSESSMENT AND RISK FACTOR	MANAGEMENT
Circumstances of previous falls*	Change in environment and activity to reduce the likelihood of recurrent falls
Medication use <ul style="list-style-type: none"> High-risk medications (e.g., benzodiazepines, other sleep medications, neuroleptics, antidepressants, anticonvulsives, or Class IA antiarrhythmics—including Quinidien, Procainamide, and Disopyramide)** Four or more medications† 	Review and reduction of medications
Vision* <ul style="list-style-type: none"> Acuity <20/60 Decreased depth perception Decreased contrast sensitivity Cataracts 	Ample lighting without glare; avoidance of multifocal glasses while walking; referral to an ophthalmologist
Postural blood pressure (after ≥5 min in a supine position, immediately after standing, and 2 min after standing)* <ul style="list-style-type: none"> ≥20 mm Hg (or ≥20%) drop in systolic pressure, with or without symptoms, either immediately or after 2 min of standing 	Diagnosis and treatment of underlying cause, if possible; review and reduction of medications; modification of salt restriction; adequate hydration; compensatory strategies (e.g., elevating head of bed, rising slowly, or performing dorsiflexion exercises); pressure stockings; pharmacologic therapy if the above strategies fail
Balance and gait†† <ul style="list-style-type: none"> Patient's report or observation of unsteadiness Impairment on brief assessment (e.g., the "get up and go" test or performance-oriented assessment of mobility) 	Diagnosis and treatment of underlying cause, if possible; reduction of medications that impair balance; environmental interventions; referral to physical therapist for assistive devices and for gait, balance, and strength training
Targeted neurologic examinations <ul style="list-style-type: none"> Impaired proprioception* Impaired cognition* Decreased muscle strength†† 	Diagnosis and treatment of underlying cause, if possible; increase in proprioceptive input (with an assistive device or appropriate footwear that encases the foot and has a low heel and thin sole); reduction of medications that impair cognition; awareness on the part of caregivers of cognitive deficits; reduction of environmental risk factors; referral to physical therapist for gait, balance, and strength training
Targeted musculoskeletal examinations of legs (joints and range of motion) and examination of feet*	Diagnosis and treatment of underlying cause, if possible; referral to physical therapist for strength, range-of-motion, and gait and balance training, and for assistive devices; use of appropriate footwear; referral to podiatrist
Targeted cardiovascular examination† <ul style="list-style-type: none"> Syncope Arrhythmia (if there is known cardiac disease, abnormal electrocardiogram, and syncope) 	Referral to cardiologist; carotid-sinus massage (in case of syncope)
Home-hazard evaluations after hospital discharge††	Removal of loose rugs and use of nightlights, nonslip bathmats, and stair rails; other interventions as necessary

From Tinetti ME: Clinical practice. Preventing falls in elderly persons, *N Engl J Med* 348(1):42–49, 2003.

*Recommendation of this assessment is based on observations that the finding is associated with an increased risk of falling.

†Recommendation of this assessment is based on one or more randomized controlled trials of a single intervention.

††Recommendation of this assessment is based on one or more randomized controlled trials of a multifactorial intervention strategy that included this component.

TABLE 124-5 CAUSES, TYPES, AND TREATMENT OF URINARY INCONTINENCE

TYPE	DEFINITION	CAUSE	TREATMENT
Stress	Leakage associated with increased intra-abdominal pressure (coughing, sneezing)	Hypermobility of the bladder base, frequently caused by lax perineal muscles	Pelvic muscle exercise, timed voiding, α -adrenergic drugs, estrogens, surgery
Urge	Leakage associated with a precipitous urge to void	Detrusor hyperactivity (outflow obstruction, bladder tumor, detrusor instability), idiopathic (poor bladder), compliance (radiation cystitis), hypersensitive bladder	Bladder training, pelvic muscle exercise, bladder-relaxant drugs (anticholinergics, oxybutynin, tolterodine, imipramine)
Overflow	Leakage from a mechanically distended bladder	Outflow obstruction, enlarged prostate, stricture, prolapsed cystocele, acontractile bladder (idiopathic, neurologic [spinal cord injury, stroke, diabetes])	Surgical correction of obstruction, intermittent catheter drainage
Functional	Inability or unwillingness to void	Cognitive impairment, physical impairment, environmental barriers (physical restraints, inaccessible toilets), psychological problems (depression, anger, hostility)	Prompted voiding, garment and padding, external collection devices

with multiple comorbid conditions often have incontinence that results from a combination of chronic and/or acute causes.

Continence problems are frequently treatable but are often not raised by patients as a concern. A targeted history and physical examination can often identify the cause of UI and lead to appropriate intervention. Asking about and documenting the presence or absence of UI should be done biannually, as well as determining whether the UI, if present, is bothersome to the patient or caregiver. In addition to a history of acute and chronic causes, a

targeted physical examination should include an assessment for fluid overload, genital and rectal examination, and neurologic evaluation. Urine and blood tests are indicated to evaluate for infection, metabolic causes, and renal dysfunction. In addition, for patients suspected of having urinary retention, catheterization or ultrasound can help define the postvoid residual and determine any need for catheter placement and further urologic evaluation. Many institutions now offer more specialized evaluation and care through incontinence clinics, which offer a

multidisciplinary approach to management, addressing both pharmacologic and nonpharmacologic options. Effective nonpharmacologic options include scheduled toileting, bladder training, and biofeedback. Use of these strategies may avoid the use of medications with frequent adverse effects, such as anticholinergic medications for detrusor overactivity.

NUTRITION

Older adults experience high rates of malnutrition related to multiple causes, including medical illness, dental problems, or access issues related to limited mobility, cost, or cognitive problems. Approximately 15% of older outpatients and half of hospitalized elders are malnourished, and have associated increases in morbidity and mortality. The utility of general laboratory testing is limited, but a combination of serial weight measurements and inquiries about changing appetite can reveal nutritional problems in the older adults. Vulnerable elders with an involuntary weight loss of 10% or more in 1 year or less should undergo further evaluation for undernutrition, including assessment of medical or medication-related causes, dental status, problems with acquiring or preparing food, appetite and intake, swallowing ability, and previous directions for dietary restrictions.

SOCIAL AND LEGAL ISSUES

The social history for older persons includes assessment of resources for direct caregiving and financial support available. These issues become particularly important for frail older adults, given their physical and economic vulnerability.

Caregiving

The clinician should always inquire about who is providing care for the older patient, including both personal care with ADLs and help with IADLs, such as transportation, medications, food preparation, finances, and housekeeping. This list should include both formal caregivers, such as home health professionals or hired aides, and informal caregivers, such as family members, neighbors, or friends. The majority of elder care provided in the United States is delivered by informal caregivers. Over 34 million people in the United States provide informal care for older adults and, of these, 8.9 million are caring for persons suffering from dementia. The majority of informal caregivers are women and elderly themselves, with an average age of 63 years. The stress of providing daily care can have serious deleterious effects on the caregiver's health. Studies have demonstrated adverse effects on blood pressure and immune function, and increased rates of cardiovascular disease and death. In addition, caregivers have alarmingly high rates of psychological illness, with symptoms of depression reported in up to 50%. This problem is particularly prevalent in those providing care for patients with dementia. The presence of mental illness further raises the risk of verbal or physical abuse or neglect of the patient. The clinician must recognize caregiver problems early and consider referral to a social worker, patient resource manager, or, when available, a geriatric assessment team. Key risk factors for stress include a frail family caregiver; a patient with cognitive impairment, emotional disturbance, substance abuse, sleep disruption, or behavioral problems; low income or financial strain; and acute illness or hospitalization. Providers should recognize signs and symptoms of physical

or mental strain, and regularly inquire about caregiver burden with an offer to talk apart from the patient if need be.

A number of resources exist to support caregivers and provide strategies for problem solving and self-care. Community-based programs provide assistance with meals, transportation, and respite care options through volunteer organizations or subsidized programs. Counseling on both the physical and emotional aspects of care has been demonstrated to reduce health risks to the caregiver and delay institutionalization, including in-home or institutional respite stays to provide caregivers with precious time off. Studies consistently demonstrate that such services are underused by caregivers.

Mistreatment

Older adults are particularly vulnerable to mistreatment due to poor health, functional dependence, and social isolation. Mistreatment is defined as either elder abuse (harm caused by others) or self-neglect. Self-neglect is thought to be the most common form of mistreatment, but true rates are difficult to estimate. Risk factors include cognitive impairment and recent functional decline. Elder abuse has been reported in 3% to 8% of the older adult population in the United States, although this is likely an underestimate due to underreporting by patients and lack of recognition by health care providers. Abuse assumes many forms including psychological, financial, physical, sexual abuse, and neglect. Studies have demonstrated that neglect and abuse are associated with higher rates of nursing home placement and mortality among older adults. Signs of physical abuse include contusions, burns, bite marks, genital or rectal trauma, pressure ulcers, or unexplained weight loss. Other forms of abuse may be more difficult to discern on examination, but can be improved with direct questions such as "Has anybody hurt you?"; "Are you afraid of anybody?"; or "Is anyone taking or using your money without your permission?" Any suspicion of abuse or neglect should be reported to Adult Protective Services. Of note, 44 states and the District of Columbia have laws mandating reporting of suspected elder abuse.

Finances

The older adult population in the United States varies widely in measures of wealth. Although the overall rate of poverty among adults over age 65 has declined over the last 50 years, 10% of older adults still live at or below the poverty line, and the percentage is higher among African Americans (24%) and Hispanics (21%). Providers should screen for financial problems because these issues have direct implications for health status and well-being. Older adults with limited means are more prone likely to have problems affording medications, meals, and basic amenities. Referrals to community resource networks can help identify options for help with basic needs, including housing options and congregate meals. Information on agencies and services in specific locales can be identified at www.eldercare.org.

Advance Directives

Advance directives come in a number of different forms and serve a variety of purposes. Ideally these documents articulate a person's preferences for care in the event of serious illness or incapacitation. Often they will describe limits on care and

circumstances in which life sustaining or restoring measures may be withheld or even withdrawn. Traditionally, advance directives have included a living will and health care power of attorney. The living will often addresses situations in which the patient has a terminal illness, persistent vegetative state, or progressive neurologic condition and can include explicit directions for care management including withdrawal or withholding of specific measures, including artificial nutrition and hydration. Living wills are ideally paired with a companion document, the health care power of attorney, which designates the person's preferred decision maker, or proxy, in the event of an incapacitating illness. For patients who have not created a health care power of attorney, typically the spouse or other first-degree relative is the default decision maker. If no proxy is designated and no next of kin is available, guardianship may be obtained. Guardianship is a legal proceeding whereby the court appoints a surrogate decision maker. The physician's responsibility includes determination of a person's capacity for independent decision making in the event of altered sensorium or progressive cognitive impairment. This involves an assessment of his or her ability to understand the situation, ask questions, weigh options and render an opinion and, in certain situations, may require a full geriatric or neuropsychological assessment. Traditional advance directives, particularly the living will, have been criticized as having limited utility in conveying specific preferences. Recently, more detailed forms have emerged to record very specific preferences and limits for measures such as hydration, nutrition, hospitalization, and resuscitation. Examples include the Medical Orders for Scope of Treatment (MOST) and Physician's Orders for Life Sustaining Treatment (POLST) forms. Of course, effective completion and application of any of these forms should include a goals of care conversation conducted with the primary care provider ideally involving family caregivers. In addition, as preferences change over time depending on health status, health care providers should encourage older adults to revisit and renew their advance directives on an annual basis.

● HIGH-RISK CIRCUMSTANCES

The Hospitalized Patient

Millions of older adults are hospitalized in the United States each year for a variety of acute illnesses and elective procedures. Fortunately, in the United States, Medicare Part A covers much of the cost associated with acute care, including hospitalization and follow-up rehabilitation. While in the hospital, however, older adults are vulnerable to myriad complications related to both their compromised health state and problems inherent to the acute care environment itself. As noted previously, delirium afflicts hospitalized elders at a very high rate and increases risk of prolonged hospital stays, nursing home admission, and death. Hospitalized older adults also experience the effects of immobilization, with loss of muscle strength and deconditioning. Acutely, these factors increase the risk of falls and impair function and ability to provide self-care. In addition, poor oral intake may result in malnutrition, and illness-related fluid losses cause dehydration. As a result, hypotension and protein-calorie malnutrition are common problems. Immobility and malnutrition both predispose the acutely ill patient to the development of pressure

wounds, which can develop in under 2 hours. All these problems worsen in the presence of delirium or depressed mood. Environmental factors also contribute to problems, including tethers such as catheters and intravenous lines (which increase risk of falls), noisy wards, and frequent tests and procedures that further disrupt diurnal rhythms and sleep. Up to one third of hospitalized older adults experience a decline in their ability to perform ADLs in the course of their hospitalization. Patients who experience declines in function during hospitalization have higher rates of rehospitalization, prolonged institutionalization, and mortality after discharge, and many (41%) never return to their preadmission level of function. To combat these problems, some hospitals have created specialized inpatient geriatric care units, often termed *acute care for elders (ACE) units*. These units incorporate adaptations in the physical environment and specially trained staff to provide safe, patient-centered care designed to maximize restoration of function and prevent common complications of hospitalization. In randomized trials, ACE units and their consultative counterpart, the Mobile ACE (or MACE), have reduced lengths of stay, improved care transitions, and lowered readmissions. Likewise, geriatric evaluation and management (GEM) units (described later) offer specialized, team-based post-acute care with an emphasis on rehabilitation and return to prior level of function.

Care Transitions

As noted previously, older adults experience high rates of complications during acute illness and require prolonged periods of time to recover. For this reason, management in the post-acute period represents a critical and complex time in their care. Specifically, older adults with acute illness often find themselves transferred among different care settings and providers. Nearly one quarter of hospitalized older adults are discharged to skilled nursing facilities, and another 12% are discharged with home health care. Of those discharged to skilled facilities, about one fifth will return to the hospital within 30 days. Transitions in care represent high-risk episodes, and evidence shows that patients and caregivers frequently experience miscommunication, medication errors, and missed essential laboratory tests or appointments during this period. Recent trials have demonstrated a reduction in rehospitalization through a structured discharge and transition plan that includes medication reconciliation before and after discharge, careful planning for laboratory and appointment follow-up, communication with patients and caregivers about expectations and preferences, and specific coaching for patients and caregivers in symptom management and care. More information on care management in transitions is available at www.caretransitions.org.

● SYSTEMS OF CARE

Ambulatory and Home Care

The majority of care for older adults occurs in the outpatient setting. Much of the cost of this care, including visit fees, laboratory tests, x-ray studies, and vaccinations, is covered under Medicare Part B, for which patients pay a monthly premium. Outpatient visits may occur with the physician, physician assistant, nurse practitioner, or clinical nurse specialists, depending on the nature

of the problem and the structure of the setting. Other key members of the care team include social workers, pharmacists, psychologists, and physical and occupational therapists. Most assessments discussed in this chapter can be performed in outpatient settings, including functional assessments, cognitive and mood screening, gait and balance assessment, medication review, eye and ear examinations, and continence evaluations. Interview of a caregiver can augment the information collected. Care in this setting can be complicated, though, by problems with transportation and ineffective or inefficient communication among multiple providers, particularly for patients with multiple specialists.

Over the last several years, home care has reemerged as an effective means of providing health care for older adults. As with the outpatient setting, Medicare Part B will reimburse providers in part for services rendered in the home. In addition, if a rehabilitative or skilled service is needed, Medicare Part A provides coverage. Patients receiving services in the home must be “homebound,” implying that they are significantly functionally impaired and travel with assistance out of the home infrequently and usually only for medical purposes. Services rendered in the home include a full range of evaluations by teams of providers from a variety of health professions depending on needs. Social workers often lead these visits and perform case management, assessing financial and other resource needs. Nurses, clinical nurse specialists, and/or nurse practitioners provide skilled services when necessary, including health education, symptom monitoring, or wound care. Physical and occupational therapy can assess mobility and home safety and greatly enhance function and independence. Furthermore, examination of a person’s home environment can reveal much about his or her safety and nutrition, and can facilitate education or intervention in these areas. Physicians may serve as medical directors of such programs, but may also perform visits themselves to learn more about a given patient’s health status. If significant concerns exist about a patient’s safety, particularly in the setting of cognitive impairment, a home visit may provide information about the need for more urgent interventions, including referrals to Adult Protective Services. Research has demonstrated that coordinated home care programs can improve management of chronic disease, including dementia, diabetes mellitus, and congestive heart failure, as well as to reduce rehospitalization in patients with congestive heart failure.

Long-Term Care

The phrase *long-term care* describes the array of services available to provide care for patients with disability from chronic and acute conditions. This definition includes the services offered in the outpatient and home settings described previously. Most associate the term, however, with the system of nursing facilities providing personal and medical care for disabled adults of all ages. Skilled nursing facilities provide long-term care for those with permanent disabilities from chronic illness or short rehabilitative stays after acute illness (e.g., stroke) or procedures (e.g., joint replacement). The scope of services may also include end-of-life care in conjunction with a hospice care team. Facility staff includes licensed nurses who give 24-hour supervision, with much of the personal care provided by certified nursing assistants. Each facility also has a medical director overseeing various

aspects of medical care. An attending physician, who may or may not be the medical director, performs patient visits every 30 to 60 days. Most SNFs also employ physical, occupational, and speech therapists for rehabilitation care, dietitians, social workers, and recreational therapists. Patients with moderate or severe dementia constitute approximately 60% of patients living in skilled nursing facilities. Although Medicare Part A provides payment for rehabilitative stays of 100 days or less (with a copayment for days 21 to 100), it does not finance long-term stays. Such patients pay out of pocket, through long-term care insurance, or through Medicaid, a joint federal and state assistance program. Medicaid constitutes 47% of all payment sources for skilled nursing facility care.

For patients with less complex care needs, assisted living facilities or domiciliary care homes provide an alternative arrangement for long-term care. Although these facilities vary dramatically in their size and structure, most provide nonskilled care for patients who need some assistance with activities of daily living. Licensed nurses may be present during some specified periods of time, and other professions may visit the facility intermittently to provide services such as physical therapy. Facilities do not have medical directors, and patients normally continue to see a primary care provider in the outpatient setting. Unlicensed staff, including nursing aides, provides most of the personal care and assistance. Medicaid provides some reimbursement for this type of care, but the majority of residents pay out of pocket or through other assistance programs, such as Social Security. For those with adequate means, a living option has emerged that combines independent living, assisted living and skilled care in one location. Continuing care retirement communities allow residents to live within the same community while moving through or between levels of care. They offer residents convenient central resources, such as recreational and dining facilities, transportation, and onsite health care.

PACE

In the 1970s, a group providing care for older Chinese adults in San Francisco developed a model of long-term care centered in the community. Proponents of this model, entitled the Program of All-inclusive Care for the Elderly (PACE), believed that the community (rather than the institution) provided a better location to meet the chronic care needs of older adults. From its start as a community-based effort in California, the PACE model has grown with the support of private foundations and Medicare demonstration projects; now PACE is a benefit for elders who qualify for both Medicare and Medicaid. Reimbursement is at 95% of the cost of nursing home care in the area where the patient lives. Participants must be over 55 and certified by the state to be eligible for nursing home care. The PACE program then uses combined Medicare and Medicaid funds otherwise slated to pay for the individual’s long-term care to provide care in the community; much of it coordinated through senior centers offering an array of resources and services, including the following*:

- Adult day care, offering nursing; physical, occupational, and recreational therapies; meals; nutritional counseling; social work; and personal care

*Information from the National PACE Association website at www.npaonline.org.

- Medical care provided by a PACE physician familiar with the history, needs, and preferences of each participant
- Home health care and personal care
- All necessary prescription drugs
- Social services
- Medical specialists such as audiology, dentistry, optometry, podiatry, and speech therapy
- Respite care

When necessary, PACE participants are admitted to the hospital or nursing home. These services are provided under the auspices of the PACE program as part of the care package, and the program bears full financial risk. The benefits of care for older adults, particularly those of limited means, appear to be substantial.

Geriatric Care

In caring for frail older adults with complex care needs, consultation with a geriatrician or geriatrics-focused team can often provide highly useful information. The geriatrician can assist in the assessment and management of the specific conditions or situations described earlier. He or she can help with difficult decisions regarding treatment options in the context of multiple comorbidities and limited life expectancy, and offer advice on appropriate level or setting of care for an older adult. Geriatricians complete a minimum of 1 year of fellowship after residency training in internal medicine or family practice. After training they are eligible for board certification and qualified to work in a number of different settings, including the hospital, long-term care, home care, and outpatient clinics. Comprehensive assessment by a geriatrician or geriatrics team includes components detailed previously, including evaluation of the patient's medical condition, function, and social support. Normally the consultant will work with an interdisciplinary team that may include a nurse case manager, physician's assistant, social worker, physical or occupation therapist, pharmacist, psychologist and others. The outcome of the geriatric assessment is a comprehensive plan for safely restoring the patient to optimal function with mutually agreeable and realistic goals of care.

In the setting of acute illness, geriatricians also provide important services. As described earlier, acute-care-for-elders units can improve patient care and prevent iatrogenic complications. Similarly, once patients are medically stable, transfer to a specialized geriatrics care unit, often termed a geriatric evaluation and management unit, may be possible, to provide a comprehensive medical assessment and plan for transition of care. Early consultation with a geriatrician and an interdisciplinary team in the acute care setting can help in the management of complex medical illness and with communication with patients and caregivers about post-hospitalization options. Subsequent to hospitalization, locating facilities or services that offer comprehensive care by a geriatrician and interdisciplinary team would be ideal, including a coordinated approach that uses specific strategies to manage transitions of care.

For a deeper discussion on this topic, please see Section IV, "Aging and Geriatric Medicine," in Goldman-Cecil Medicine, 25th Edition.

Palliative Care

Robert G. Holloway and Timothy E. Quill

INTRODUCTION

Palliative care is both a philosophy of care and an area of specialization within several medical fields. The primary goal of palliative care is to minimize suffering and to support the best possible quality of life for patients and their families. Patients with serious and debilitating illness need and deserve excellent symptom control, assistance with difficult medical decisions, effective communication and collaboration among their providers, addressing of psychosocial problems, and an empathetic presence that fosters hope and healing relationships. Palliative care affirms life by supporting the patient's goals for the future in light of a full understanding of their medical condition, potentially including their hopes for cure, life-prolongation, relief from suffering, as well as preparation for death when time is short. This process includes exploring what would be left undone if treatment does not go as hoped, who should make medical decisions for the patient if decision-making capacity is lost, and what, if any, limits might be set on aggressive therapy.

Palliative care provides an organized, highly structured system for delivering care by an interdisciplinary team, including physicians, nurses, social workers, chaplains, counselors, as well as other health care professionals. Palliative care should be integrated within various health care settings including the hospital, emergency department, nursing home, home care, assisted living facilities, and outpatient settings. Palliative care remains very unevenly available, so many patients and families needlessly suffer having either no, limited, or delayed access to appropriate palliative care. Basic palliative care should be part of the tool kit for all physicians who care for seriously ill patients, and specialty palliative care should be available for the more challenging symptom management and complex and often conflictual medical decision making.

The integration of palliative care into the experiences of patients and families is designed to meet several objectives. First, to ensure that pain and symptom control, psychosocial distress, spiritual issues, and practical needs are addressed throughout the continuum of care. Second, to make certain that patients and families obtain the information they need in an ongoing and comprehensible manner to understand their prognosis and treatment options. This process incorporates their values and preferences and is sensitive to changes in the patient's condition over time. Third, palliative care seeks to provide seamless care coordination across settings with high-quality communication among providers. Finally, for those patients who are not going to recover, palliative care prepares patients and families, to the extent possible, for the dying process and for death, including options for

hospice care and opportunities for personal growth and bereavement support.

COMMON ILLNESS TRAJECTORIES AND PALLIATIVE CARE

There are four distinct trajectories of functional decline before dying (E-Fig. 125-1). These trajectories have major implications for palliative care and health care delivery. Patients and families likely have different physical, psychological, social, and spiritual needs depending on the trajectory of their illness before they die. Being aware of these trajectories can help providers deliver appropriate care that integrates both disease-directed and palliative treatments.

Trajectory 1: Short Period of Evident Decline before Death

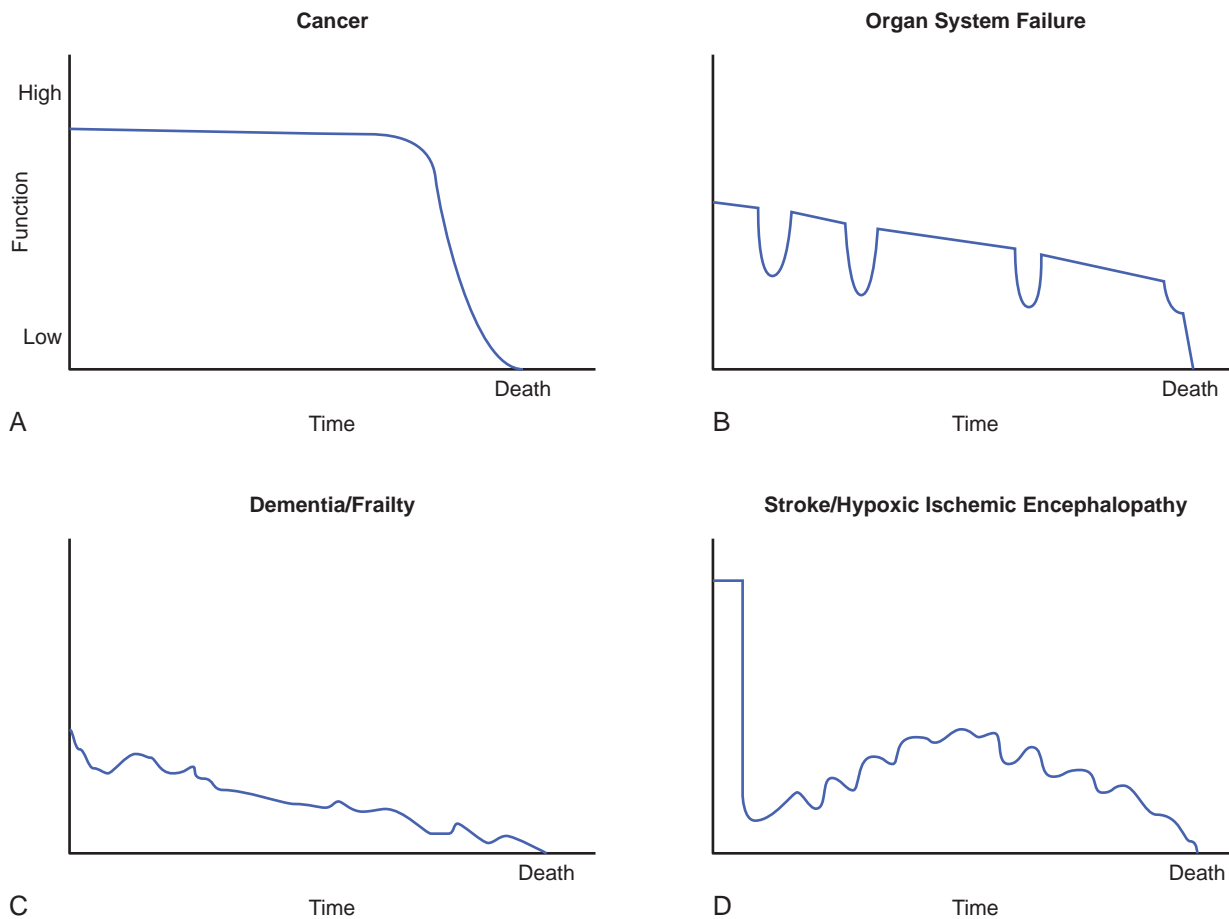

Cancer typifies this trajectory. Function is preserved until rather late, followed by a predictable and precipitous decline over weeks to months. The onset of decline usually suggests metastatic tumor. A more predictable decline in function can assist in anticipating care needs, transitioning away from curative treatments toward a more exclusive emphasis on palliation, and eventually into hospice care. Not all malignancies follow this trajectory (e.g., prostate, breast) and some non-malignant conditions may follow this course.

Trajectory 2: Chronic Illness with Exacerbations and Sudden Dying

Congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), end-stage liver disease, and AIDS typify this trajectory. These organ system diseases represent chronic illnesses with occasional, acute exacerbations (e.g., physiological stress that overwhelms the body's reserves), often requiring hospital admission. Patients can have a return of function after an exacerbation, but often not to the level of their baseline. They also may die suddenly during an exacerbation, but it is difficult to predict in advance. Prognosticating is very challenging in this trajectory. When patients choose to forego or stop aggressive life support, planning for aggressive symptom relief during a future exacerbation is essential.

Trajectory 3: Prolonged Dwindling

Dementia and frailty typify this trajectory. These patients have a prolonged course of physical and cognitive decline and become increasingly frail. Additional diagnoses include other neurodegenerative conditions (e.g., Parkinson's disease, amyotrophic lateral sclerosis) and patients with multiple moderate to severe

E-FIGURE 125-1 In patients with cancer, function typically remains high until the very late stages of disease (**A**); this is the model of illness for which hospice care was developed. Patients with chronic organ system failure such as heart failure or obstructive lung disease are often ill for prolonged periods, with frequent exacerbations followed by recovery of function (**B**). Patients with dementia also follow a chronic course, with dwindling reserve over time (**C**). Sudden neurological injury (stroke, hypoxic ischemic injury, traumatic brain injury) often results in a sudden decrement of well-being and function associated with a high mortality (**D**). Recovery is prolonged and slow with frequent setback and accumulating disability over time. (Modified from Murray SA, Kendall M, Boyd K, et al: Illness trajectories and palliative care, *BMJ* 330:1007–1011, 2005.)

comorbidities (e.g., arthritis, visual impairment, past mild strokes, diabetes with neuropathy). Gradual decline in function, weight loss, fatigue, and low levels of activity are core features. Caregiver burden is usually immense. Prognosticating survival is difficult and complications, such as pneumonia and fractures, may be terminal events. The benefits and burdens of artificial nutrition and hydration must be balanced in the late stages.

Trajectory 4: Sudden, Severe Neurological Injury

Sudden impairment trajectories are those that stem from sudden neurological injury that can lead to profound cognitive and functional impairment. These include stroke, hypoxic ischemic encephalopathy, and traumatic brain injury. The vast majority of deaths occur either early after the event when treatments are withheld or withdrawn, or in the chronic stage in survivors who have accumulating debility (these events represent the leading cause of adult disability). At the extremes of impairment are persistent vegetative states, minimally conscious states, and locked-in syndrome. But there is a vast spectrum of severe impairments short of these extremes that raise questions about how to manage potentially severe debility with little or uncertain chances of improvement. This trajectory requires a health care system responsive to negotiating goals of treatment with patients and surrogates who may consider these future health states to be “worse than death.”

COMMUNICATION SKILLS AND NEGOTIATING GOALS OF TREATMENT

Excellent communication skills are central to palliative care: communication with patients, family, other physicians, nurses, and other members of the health care team. The overarching aim is to assist the patient and family in establishing the goals of current and future treatment in a process of shared decision making. When negotiating goals of treatment in palliative care, the focus is often to assist with the following decisions: to help decide types and aggressiveness of disease-directed therapies; to ensure optimum palliation of symptoms; to assist in hospice determinations; to discuss initiating, withholding or withdrawing therapies; to facilitate advance care planning; and to initiate surrogate decision-making if the patient lacks capacity. These discussions occur at various time points in the course of advancing illness when new and important information is learned and needs to be communicated to the patient and family. The need to renegotiate goals should also be anticipated when triggers of advancing disease suggest limited life expectancy or excessive suffering. These discussions are almost always variants of “bad news” discussions.

The overall approach to communication and negotiating goals of care in each of these scenarios is similar (Table 125-1). This includes running an effective family meeting with or without the patient present. Initial elements include establishing the proper setting, identifying key stakeholders, and “doing your homework” (i.e., discussing potential plans with all relevant subspecialties who may have communicated with the patient and families). When the meeting begins, find out what the patient and family understand about the medical condition and ask about what added information they want. Keeping an open mind and trying

to hold back on a fixed agenda (e.g., to “get the DNR” or to “stop futile care”) helps clinicians allow patients and families sufficient time to “tell their stories” and provides the context within which effective decision making can occur. In general, the more patients and families speak in the early parts of such meetings, the better.

The provider then needs to share prognostic information and discuss the benefits and burdens of the available treatment options. Alerting the patient or family of impending bad news (e.g., “I am afraid I have some difficult news to share with you”) is a useful initial communication strategy. The amount of information should be paced with frequent pauses to allow time for emotional responses. Comprehension should be frequently checked, and questions should be encouraged using an “ask-tell-ask” strategy. The skilled clinician can flexibly assess, probe, and pace the content and depth of the discussion in an emotionally responsive (acknowledge, explore, empathize, and legitimize) and culturally competent manner. This includes the ability to understand and respect diverse religious practices and differing preferences about degree of truth telling. When appropriate, the clinician should make recommendations based on scientific knowledge as well as awareness of a patient’s values and preferences, and be prepared to help resolve conflicts among patient, family members, and providers. Finally, providers need to develop strategies to preserve and potentially reframe hope, including ways to “hope for the best” and simultaneously “prepare for the worst.” Commitments to minimize suffering and to not abandon the patient and family are essential. At the end of the discussions, the provider should summarize key aspects of what was reviewed and establish a follow-up plan for future communications and treatments.

Estimating and Communicating Prognosis

A core component of information shared in the palliative care setting is prognosis. Understanding prognosis is central to making decisions (e.g., treatment, comfort measures, hospice). Prognosis is a prediction of possible future outcomes of a disease (e.g.,

TABLE 125-1 GENERAL STRATEGY FOR COMMUNICATING AND NEGOTIATING GOALS OF CARE IN COMMON PALLIATIVE CARE SETTINGS

Step 1	Prepare and establish setting Do not have a rigid preset agenda
Step 2	Ask patient and family what they know and understand Provide sufficient time for patients and families to “tell their story” Active listening skills
Step 3	Find out how much patient and family want to know Acknowledge and explore emotions
Step 4	Give information in small amounts, and frequently check understanding Discuss prognosis and benefits and burdens of treatment options Be mindful of overly optimistic and pessimistic predictions Be prepared to make recommendations
Step 5	Respond to emotions and empathetic response Convey honesty and reframe hope Use “I wish” statements
Step 6	Summarize, establish and implement plan, follow-up Possible time-limited trial

survival, symptoms, function, quality of life, family and financial impact) with or without treatment. Most patients and families want to know prognosis. Since there are some patients and families that may not want to know prognosis or want it communicated in a particular way, it is essential to begin by finding out what the patient and family knows and wants to know.

Inaccurate predictions may lead to poor decision making. Indeed, physicians tend to overestimate survival in patients with advanced cancer by about 30%, and the bias is more pronounced the longer the physician-patient relationship. Overly optimistic predictions can lead to overuse of ineffective or unwanted disease-directed treatment, delay in hospice referrals, false expectations, unnecessary tests and procedures, and poor symptom control. Therefore, accurately estimating and communicating prognosis is central to optimal decision making in advanced illness and at the end of life.

In advanced illnesses, common factors found to be predictive of short-term survival (i.e., less than 6 months) include performance status, anorexia-cachexia syndrome, delirium, and dyspnea. In addition to a physician's subjective predictions of survival, there exist models to assist with prognostic estimates, including generic models for particular populations (e.g., hospice enrollees) as well as disease-specific models (e.g., cancers, heart failure, liver disease, stroke, AIDS, spinal cord compression). Hospice eligibility criteria also differ for specific diseases. While not uniformly reliable, they can be useful in formulating estimates where prognosis might be 6 months or less if the disease is allowed to run its natural course (a prognostic criterion).

For an individual patient, however, prognostic uncertainty remains the rule. Therefore, it is important to integrate both evidence and experience-based medicine, and present the information in formats tailored to the particular patient (verbal descriptions, numeric, frequencies, or graphics). Prognostic estimates should be bounded with ranges to convey realistic uncertainty, being sure to allow for exceptions in both directions. For example, *“in my experience, patients with your condition live on average a few weeks to a few months. It could be longer, but it could also be shorter.”* For survival-predominate prognoses (e.g., *“How long do I have?”*), be mindful of overly optimistic prognoses, remembering to think of and convey the lower bound (e.g., *“some may live longer, but others may, unfortunately, live shorter”*). For outcome-predominant prognoses (e.g., *“What will life be like?”*), be mindful of overly pessimistic predictions, remembering the power of adaptation and engendering hope by helping patients and families find new meaning.

● SUFFERING AND SYMPTOM MANAGEMENT

Palliative care aims to relieve suffering, which is defined as severe distress related to events that threaten the stability of personhood or interconnectedness of the physical, psychological, spiritual and social aspects of self. Beginning with simple, open-ended screening questions, such as *“In what ways are you suffering most?”* and following with more domain-related screening questions (e.g., physical, psychological, spiritual, social) may allow for more probing and multidimensional inquiries to better understand the various sources of and contributions to an individual's suffering.

One of the first steps in the care of any seriously ill patient is to control pain and other forms of physical suffering. There are

striking similarities between the burden of symptoms experienced in patients dying of cancer and non-cancer conditions. Although the profile of symptoms may differ, each disease carries with it troubling symptoms that can potentially be addressed and managed.

Physical Symptoms

Pain

Uncontrolled pain dominates all other experiences, and most pain can be relieved using basic pain management strategies. This includes a detailed history and physical examination, categorizing the likely type or types (i.e., somatic, visceral, neuropathic) and severity (rated on a 0-10 scale) of pain, knowledge about proper opioid dosing strategies, and judicious use of consultations and invasive interventions (e.g., nerve blocks, epidural analgesia). The overarching three-tiered approach is to use nonopioids (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs) for mild pain, weak opioids (e.g., hydrocodone or codeine) for mild-to-moderate pain, and strong opioids (e.g., morphine, hydromorphone, fentanyl, methadone) for moderate to severe pain.

Risk factors for potential opioid abuse or misuse should be screened for even in the presence of clearly defined terminal illness, including any lifetime personal or family history of opioid, alcohol, or other substance abuse. If risk factors are present (about 20% of the population), special precautions should be taken to minimize the risk of abuse, including clearly defined and adhered to prescribing contracts and strict limits and expectations about renewals and dose alteration processes. One single prescriber should be responsible for all opioid prescriptions and renewals, and one pharmacy should be used. If clinicians are inexperienced with such prescribing, formal consultation with specialists in palliative care and/or addiction medicine should be considered.

Most seriously ill patients with chronic moderate to severe pain should be initially started on around-the-clock dosing using a short-acting opioid. [Table 125-2](#) shows the equianalgesic dosing, usual starting doses, half-life, and duration for the commonly available opioid agents. Once the total daily dosing has been determined (sum of all scheduled and “as needed” doses), the patient may be switched to a long-acting opioid to cover the baseline requirements. As needed opioids for breakthrough pain should be approximately 10% of the total daily dose every 1 to 2 hours orally or every 30 to 60 minutes subcutaneously or intravenously. If a patient is requiring more than 4 to 6 breakthrough doses per day, he should be in contact with the prescribing clinician for re-evaluation of dosing. Continuous intravenous or subcutaneous infusions of opioids may be needed for rapid control of severe pain. Methadone is useful in palliative care because of its excellent oral bioavailability, lack of active metabolites in renal impairment, low cost, flexible route of administration (PO, IV, SC), and possible effect on both neuropathic and somatic pain. However, it does have a dose-dependent, progressively long half-life and arrhythmogenic potential.

Constipation occurs with all opioids, and it should be anticipated and treated. Other predictable but less common side effects include nausea, myoclonus, urinary retention, pruritis, and delirium. Some of these side effects are time-limited with

PATIENTS**
(◆ ½ dose for elderly, or severe renal
or liver disease)

initiation (e.g., nausea), while others can be managed by dose reduction or opioid rotation (e.g., myoclonus, delirium). Major respiratory depression is extremely rare if the opioid is dosed appropriately and proportionate to the severity of symptoms. In the absence of a prior personal or family history of drug and alcohol abuse, addiction is rare in the presence of serious illness, but physical dependence (i.e., withdrawal symptoms upon abrupt cessation) and tolerance (i.e., decrease in drug effect over time) should be expected. Naloxone should be rarely used unless a clear overdose is suspected, or if life-threatening complications occur. Special caution about opioid prescribing is needed in the elderly and debilitated patients, and recommended starting doses should be reduced by approximately 50%. There are additional opioid selection recommendations for patients with renal insufficiency (avoid morphine and codeine; use hydromorphone and oxycodone with caution; methadone and fentanyl (optimal) and hepatic insufficiency (cautiously use fentanyl, hydromorphone, oxycodone, or methadone; avoid or decrease dose of morphine).

Non-pain

There are numerous non-pain physical symptoms that can dominate and overwhelm the clinical picture in any given patient. These include dyspnea, nausea and vomiting, constipation, anorexia-cachexia, fatigue, bleeding, agitation, apathy, myoclonus, pruritis, and specific functional deficits. Each symptom requires a structured approach to the history and physical examination with a full exploration of the potential etiologies and treatment options; informed by the prognosis and preferences of the patient and family. (For practical information geared to basic palliative management of pain and other symptoms, see Quill TE, Holloway RG, Shah MS, et al: *Primer of Palliative Care*, ed 5, Illinois, 2010, American Academy of Hospice and Palliative Medicine.)

Psychological Distress

Depression, anxiety, and delirium are all common in the palliative care setting. They are frequently under-recognized and under-treated. Appropriate diagnosis and treatment can improve quality of life.

Nearly all patients in palliative care and their families experience sadness, preparatory grief, and transient anxiety as illness advances. Grief or normal sadness is often experienced in waves with retained capacity for pleasure. Depression is more enduring, persistent and intense, and may be associated with hopelessness, helplessness, worthlessness, and guilt. Two screening questions assessing depressed mood and anhedonia include: “*Are you depressed?*” and “*Do you have much interest and pleasure in doing things?*” One should be cautious about overusing somatic symptoms to diagnose depression (e.g., fatigue, anorexia, sleep disturbance) because they frequently overlap with physiological changes associated with advanced disease. For depression and anxiety, consider and rule out contributions from physical symptoms (e.g., uncontrolled pain), medical causes (e.g., hypothyroidism, hyperthyroidism), and medications. Effective pharmacological and non-pharmacological treatments exist for both depression and anxiety, though treatment selection depends on symptom intensity, patient prognosis, and treatment benefits

and burdens. Other members of the interdisciplinary team (social worker, chaplain, and psychologist) often play a critical role in assessment and ongoing management.

Delirium, an acquired and fluctuating disorder of consciousness and cognition, occurs commonly in the palliative care setting. The level of psychomotor activity can vary from hyperactive (“agitated” delirium) to hypoactive (“quiet” delirium). Nearly 80% of the delirium in the palliative care setting is the hypoactive variant. As a result, it is often under-diagnosed or misdiagnosed as depression and fatigue. The most common causes of delirium in palliative care include medications (e.g., opioids), metabolic disorders due to progressive organ failure, and infection. Meticulous attention to the history from collateral sources (e.g., nurses, caregiver) and a detailed medication history are essential for an accurate diagnosis. While delirium may reverse if an obvious cause is identified and removed, frequently it represents an important marker of progressive illness so cognitive improvements may be transient and incomplete. In addition to etiology-specific treatment (e.g., change or stop medications, treat infection, oxygen, hydration, biphosphonates), environmental interventions are recommended for all patients (e.g., quiet reassurance, gentle re-orientation, optimize sensory input, minimize night disruptions). Pharmacological management should be used sparingly and cautiously, and may include antipsychotic medications, benzodiazepines, and psychostimulants (for the hypoactive variant).

Spiritual and Existential Pain

Spiritual and existential distress is prevalent in patients and families with serious illness, especially at the end of life. Spirituality is about one’s relationship with and responses to transcendent questions that confront one as a human being (e.g., search for meaning and purpose in life). Religion is a set of texts, practices, and beliefs about the transcendence shared by a community. Spirituality is broader than religion. The spiritual issues of seriously ill and dying patients often center on questions of meaning, value, and relationships. Dying patients want to be assured of their value in the face of actual or perceived threats to their intactness as a human being (e.g., physical and cognitive declines, altered appearances). Spirituality can help people find hope in despair and help restore purpose.

One of the goals of palliative care is to relieve spiritual and existential distress. Patients and families often welcome such discussions. Examples of open-ended questions to facilitate this dialogue include: “*Are you at peace with all of this?*” and “*Is faith (religion, spirituality) important to you?*” Acknowledgement and empathetic listening are the most important responses for most clinicians, as opposed to trying to provide “correct answers.”

Other strategies for fostering hope and meaning include developing caring relationships, setting attainable goals, involving the patient in the decision-making process, affirming the patient’s worth, using lighthearted humor (when appropriate), and reminiscing with life review. It is important, however, to know one’s professional boundaries and refer to chaplains or clergy from the patient’s faith traditions if questions move beyond the realm of general exploration (e.g., “*It sounds like it would be good to explore this with someone with more experience than I have. Would it be okay for me to send our chaplain in to discuss this with you?*”).

The Role and Use Of Diagnostic Tests and Invasive Procedures

Several questions should be considered in determining the appropriateness of aggressive medical or palliative interventions near the end of life: What is the goal or expected outcome of the proposed intervention? What is the probable efficacy of the intervention? What is the patient's baseline level of function and life expectancy? What are the potential side effects and burdens of the intervention? What are the patient's and family's wishes, values, and preferences?

The range of medical and palliative options available is huge, so the challenge is to determine what makes sense to enhance the well-being of this patient at this particular stage of illness. Palliative interventions range from pure symptom management and support to invasive options, such as chemotherapy, radiotherapy, surgical/endoscopic interventions, stenting procedures, thoracentesis, paracentesis, pericardiocentesis, home inotropic therapy, non-invasive ventilation, antibiotics, or transfusions. The challenge is to individualize discussions, so that patients can take full advantage of treatments that will help them meet their goals without having their experience dominated by near futile invasive interventions.

The Role of Hospice

Hospice care is a specialized form of palliative care aimed at those patients and families in the terminal stages of illness. In 2011, 1.65 million patients were served by hospice programs in the United States. Median length of stay on hospice is less than 3 weeks. In order to qualify for the Medicare Hospice Benefit, two physicians must sign a statement certifying that the patient's prognosis for survival, if the disease runs its natural course, is likely to be 6 months or less. Hospice criteria exist to assist in making these determinations for common medical conditions. Hospice care can be delivered in hospitals, patient's homes, nursing homes, or dedicated "hospice houses." The Medicare Hospice Benefit covers most costs related to terminal care without a deductible, which includes palliative medications, nursing oversight, supplies, and bereavement care. Hospice also covers up to 4 hours of custodial caregiver services per day; however, family and/or friends must provide the remaining care if the patient is to stay at home. Hospice it does not cover custodial caregiver services if the patient is admitted to a nursing facility.

Cancer continues to be the most common diagnosis for patients dying in hospice programs. However, the prevalence of non-cancer diagnoses is increasing and now represents more than 50% of all hospice admissions. Discussing hospice with patients and families can be challenging. First, it is often initially viewed as a "bad news" discussion given that patients and families need to confront the fact that disease-directed treatment is no longer effective and that prognosis is likely to be 6 months or less. Second, given the reimbursement restrictions, patients may also need to forgo particular types of treatment that are important to them (e.g., acute hospital or ICU-level care, dialysis, chemotherapy, milrinone for heart failure).

Request for Hastened Death and Last Resort Options

The prevalence of suicidal ideation and suicide attempts is higher in patients with advanced life-limiting illness compared to those without serious disease. In Oregon where physician-assisted suicide is legally permitted (subject to safeguards), the prevalence of a patient's wanting to explore a health care professional's willingness to help hasten death is about 1/50, whereas only about 1/500 die using physician-assisted suicide. The motivation behind such initial explorations may relate to relentless physical suffering, disfigurement, hopelessness, loss of dignity, fear of being a burden, or a "cry for help." Most enduring requests from patients with progressive medical illnesses, however, arise not from inadequate symptom control, but from a patient's belief about dignity, meaning, and control over the circumstances of death. Although some providers might be uncomfortable with exploring such requests, they need to be approached systematically with a diligent search to understand the root causes before responding.

A careful evaluation includes a precise clarification and exploration as to exactly what the patient is asking and why. Is the request based on transient thoughts about ending life (common) or a serious appeal for assistance (relatively rare)? Does the request occur in the context of intense physical suffering, psychological despair, an existential crisis, or a combination of factors? Does the patient have full decision-making capacity? Is the request proportionate to the level of suffering? Evaluating such requests can be emotionally fatiguing and conflicting, and clinicians need self-awareness in distinguishing their emotions from the patient's, including tending to one's own support by sharing the burden of such requests with trusted colleagues.

Responding to such a request should first include intensification of a search for potentially reversible contributions to suffering. This will often include treating physical and psychological symptoms, aggressive attempts to foster hope, consulting psychiatrists or spiritual counselors, and creative brainstorming with trusted colleagues and team members. Some requests for hastened death persist, despite optimal palliative care. In such circumstances, the clinician should seek out a second opinion and confront the possibilities. These possibilities include withdrawal of life-sustaining interventions, palliative sedation, voluntary cessation of oral intake, and assisted suicide (illegal in the United States except for the states of Oregon, Washington, Vermont, and Montana). While it is important to support the patient, the clinician must balance integrity and non-abandonment. This may include drawing specific boundaries of what the clinician can and cannot do, while still searching in earnest for a mutually acceptable solution.

COMMON ETHICAL CHALLENGES IN PALLIATIVE CARE

Inadequate Treatment of Pain and the Myth that Pain Medication Hastens Death

Evidence abounds that pain is under-treated in many medical settings, including those patients who are severely and even terminally ill (especially women, the elderly, minorities and those

who are cognitively impaired). Some under-treatment stems from fears about addiction as well as concerns about the possibility of hastening death. When patients with prior addiction problems are excluded, the incidence of new addictive behavior when opioids are used to treat pain in those with a well-defined, serious illness is rare. Similarly, there is very little data to suggest that properly prescribed opioids hasten death. In fact, current evidence supports the idea that opioids may prolong life in these patients and enhance quality of life in those with advanced illness and major pain or dyspnea.

Addiction and diversion exist in medically ill populations. Alcoholism and substance abuse exist in medically ill populations as they do in all other parts of society. When patients with such risk factors develop painful, potentially life-limiting medical conditions, they deserve adequate pain treatment, but with extreme caution because of the risk of reactivating or aggravating abuse behavior, including diversion of prescription drugs for recreational purposes. Prescribing contracts that specify one single medical prescriber, set amounts around the clock and as needed limits, face-to-face encounters for all renewals, and dose adjustments only after direct conversation with the prescriber, are all essential parts of the plan. Consultations with experts in palliative care and/or substance abuse should be requested if there is any difficulty adhering to the contract.

When Patients and Families Want Near Futile Treatment

The patient autonomy movement in medicine has led to patients and families taking an active role in their own medical decision making. This is generally a positive development except in two circumstances: 1) when physicians stop taking an active role using their expertise to guide patients in their decision making, thereby abdicating their professional responsibility of advocating for the best possible treatment based on the patient's medical condition and personal values, and 2) when patients or their families want and even demand near futile treatment toward the end of their lives despite physician's advice that treatment has much more burden than benefit. Physicians might try to respond to patients who want "everything" by suggesting that they want to try everything that is "more likely to help than harm," but avoid any treatment that is most likely to "do more harm than good." However, some patients and families will accept no limits on treatment no matter what the burden and the improbability of success. Of course, truly futile treatment should not be offered or provided upon request, but absolute futility has been difficult to define in many cases.

Feeding Tube Questions When Patients Stop Eating and Drinking

Many patients gradually stop eating and drinking as a natural part of the dying process, but this can be very hard for patients and families to accept in light of fears about "starving to death" and in view of seemingly simple technologies that can potentially combat and even reverse the problem. In fact, with few exceptions, feeding tubes have not been shown to prolong life in most advanced illnesses such as metastatic cancer or advanced Alzheimer disease. It is important to know about the exceptions (e.g. esophageal and oropharyngeal cancers, amyotrophic lateral

sclerosis, acute stroke), but also to have an open discussion about the naturalness of diminished eating and drinking as many illnesses progress. If there is uncertainty about whether a particular patient might benefit from a feeding tube, and patient and family are clear about wanting to give it a try, the clinician can frame the decision as a "time-limited trial" to see how the patient tolerates tube feeding psychologically as well as physiologically in a specified timeframe. A nasogastric tube has a built-in time limit of about a month before a PEG tube needs to be inserted as a potential framework for such a trial. Explaining to patients and families about the positive aspects of natural feeding, even in small amounts, of real food (smell, taste, and enjoyment) may help focus the decision on important quality of life issues (that may otherwise be ignored), rather than more technical, physiological issues.

LAST HOURS AND DAYS OF LIVING

An integral aspect of palliative care is preparing and guiding the patient and caregivers through the dying process. When prognosis is measured in hours to days there are typical signs and symptoms that usually occur. Patients become weak and fatigued and gradually lose mobility. There is also a gradual and predictable decrease in food and fluid intake. Most patients do not experience hunger and thirst, and the associated mouth dryness that occurs is easily palliated with small sips or sponges of cold water. Caregivers will frequently ask about intravenous hydration. In rare instances, intravenous or subcutaneous fluids may temporarily improve mental status and energy in the final days of life. Most of the time, however, the benefits are difficult to discern and the excessive fluids may contribute to end-of-life physiologic conditions (edema, ascites, effusions, and pulmonary secretions) that do not improve longevity and may worsen comfort.

As patients become weaker, there is a predictable decrease in the level of consciousness with increasing periods of somnolence eventually giving way to a comatose state. Education about this process should include associated changes in respiratory patterns and to anticipate progressive periods of apnea, interspersed with episodes of hyperpnea and deep breathing (Cheyne-Stokes respirations). During this process caregivers often feel they are on "a roller-coaster ride" and gentle guidance on what to expect can allay concerns. As consciousness wanes, swallowing slows and the cough reflex weakens. As a result, saliva pools in the oropharynx and can result in noisy respiration ("death rattle"), which can usually be palliated to some degree with transdermal scopolamine, glycopyrrolate (PO, IV, SC) or sublingual atropine ophthalmic drops. Families should be reminded that these symptoms are a natural part of the dying process, and that persistent shortness of breath is relatively uncommon, but can be treated with opiates and benzodiazepines, if needed.

As death approaches, reduced perfusion causes cooling and cyanosis of the extremities and a decrease and darkening of the urine. Most deaths are relatively peaceful, but a few can be preceded by periods of intense agitation and restlessness (hyperactive terminal delirium). Antipsychotic medications and conventional doses of benzodiazepines can usually treat terminal delirium. Prior to and when death occurs, families should be encouraged to carry out cultural or religious rituals that are important to them. Providers should express condolences, be

available for questions and responsive to intense emotional reactions that sometimes occur. A short condolence card or letter is almost always appreciated. If possible, efforts should be made to follow-up with family members and caregivers deemed at risk for complicated bereavement and grief.

PROSPECTUS FOR THE FUTURE

Palliative care became an officially recognized subspecialty within the United States in 2006. Physicians from 10 specialties can be board certified in hospice and palliative medicine including: family medicine, internal medicine, emergency medicine, pediatrics, physical medicine and rehabilitation, anesthesiology, psychiatry, neurology, radiology, and surgery. As patients live longer with chronic illness, there will be an increasing need to fully integrate palliative care providers and programs within hospitals, nursing homes, and the outpatient setting; and to ensure that all primary care providers and non-palliative specialists develop the skill sets needed to provide basic palliative care.

There is a compelling need for research to better define the optimal timing, setting, and delivery of palliative care to improve the quality of life and lessen the suffering of patients and families with advanced illness.

ALCOHOL ABUSE

Alcohol abuse is a major public health problem. In 2010, an estimated 2,735,511 deaths worldwide were attributable to alcohol use. About 58.3 million people in the United States (nearly one quarter of persons aged 12 years or older) participate in binge drinking, and almost 16 million (6.2% of the population aged 12 or older) report heavy drinking, defined as binge drinking on at least 5 days in the past month. Alcohol use is the third leading preventable cause of death in the United States (exceeded only by cigarette smoking and obesity) and claims over 80,000 lives annually. In 2011, an estimated 11% of persons aged 12 years or older drove under the influence of alcohol at least once. Alcohol use contributes to roughly 31% of all fatalities caused by motor vehicle accidents, or approximately 10,000 vehicular deaths annually, and is a major contributor to risky sexual behavior, domestic violence, homicide, and suicide. For the year 2006, the estimated economic cost of excessive drinking in the United States was \$223.5 billion: 72% from lost productivity, 11% from healthcare costs, 9% from criminal justice costs, and 7.5% from other effects.

DEFINITION AND EPIDEMIOLOGY

The American Psychiatric Association has specific criteria for the diagnosis of *alcohol use disorder*; these 11 criteria are described in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, and are listed in [Table 126-1](#). Alcohol use disorder is further characterized as mild, moderate, or severe, based on the number of criteria the individual meets; 2 to 3 criteria indicate a mild disorder, 4 to 5 criteria a moderate disorder, and 6 or more a severe disorder. The so-called *binge drinker* is defined as one who typically consumes five or more drinks on a single occasion.

Among individuals aged 12 or older, whites are more likely to report current alcohol use than other racial groups ([Fig. 126-1](#)), and men are more likely than women to be drinkers (57% versus 47%, respectively). The average age at first alcohol use is 17 years; 65% of college students currently use alcohol ([Fig. 126-2](#)); and more than half of all college students admit to heavy episodic drinking. Although the prevalence of ethanol use is highest in individuals younger than 30 years of age, survey data suggest that about two thirds of persons over age 30 consume it.

PHARMACOLOGIC AND METABOLIC FACTORS

After oral ingestion, alcohol is absorbed predominantly in the small intestine, and its rate of intestinal absorption is accelerated by the simultaneous ingestion of carbohydrates and carbonated

beverages. Prolonged retention of alcohol in the stomach, as occurs when food is consumed before drinking, delays alcohol absorption because absorption in the stomach is considerably slower than in the duodenum. Once in the blood, alcohol equilibrates rapidly across all membranes, including the blood-brain barrier, thereby accounting for the prompt onset of its euphoric effects. Maximal blood alcohol concentrations are reached 45 to 75 minutes after alcohol is ingested.

The liver metabolizes approximately 90% of ethanol to acetaldehyde via the alcohol dehydrogenase pathway; subsequently, acetaldehyde is converted by aldehyde dehydrogenase to acetate, which enters the Krebs cycle. At low or moderate serum concentrations of ethanol, the alcohol dehydrogenase pathway functions almost exclusively in metabolizing ethanol. At high concentrations, the microsomal ethanol oxidizing system (CYP2E1) contributes to metabolism. Less than 10% of ethanol is excreted unchanged through the skin, kidneys, and lungs. Elimination of alcohol from the body is affected by obesity, food intake, previous exposure to alcohol, and variability among individuals in the efficiency of the alcohol and aldehyde dehydrogenase systems.

TABLE 126-1 CRITERIA FOR THE DIAGNOSIS OF ALCOHOL USE DISORDER

TWO OR MORE OF THE FOLLOWING IN THE PREVIOUS 12 MONTHS

- Recurrent alcohol use resulting in a **failure to fulfill major** obligations at work, school, or home
- Recurrent alcohol use in situations in which it is physically **hazardous**
- Continued alcohol use despite having persistent or **recurrent social or interpersonal problems** caused or exacerbated by the effects of alcohol
- Tolerance**, as defined by:
 - need for markedly increased amounts of alcohol to achieve intoxication or desired effect; and/or
 - markedly diminished effect with continued use of the same amount of alcohol
- Withdrawal**, as manifested by:
 - characteristic alcohol withdrawal syndrome; and/or
 - alcohol is taken to relieve or avoid withdrawal symptoms
- Alcohol is often taken in **larger amounts** or over a longer period than was intended
- Persistent desire or **unsuccessful efforts to diminish** or to control alcohol use
- A great deal of **time** is spent in activities necessary to obtain, use, or recover from the effects of alcohol
- Important social, occupational, or recreational **activities are relinquished or reduced** because of alcohol use
- Alcohol use is **continued despite knowledge** of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol use
- Craving** or a strong desire or urge to use a specific type of alcohol

Modified from the American Psychiatric Association: *Diagnostic and statistical manual of mental disorders*, ed 5, Washington, D.C., 2013, American Psychiatric Press.

FIGURE 126-1 Current, binge, and heavy alcohol use among persons aged 12 or older, by race and ethnicity, according to the National Survey on Drug Use and Health (2011). Binge drinking is defined as having five or more drinks on a single occasion. Heavy alcohol use is defined as having had five or more drinks on the same occasion on each of five or more days in the previous 30 days. (From Substance Abuse and Mental Health Services Administration: Results from the 2011 National Survey on Drug Use and Health: Summary of National Findings, NSDUH Series H-44, HHS Publication No. [SMA] 12-4713, Rockville, Md., 2012, Substance Abuse and Mental Health Services Administration.)

FIGURE 126-2 Current, binge, and heavy alcohol use among persons aged 12 or older, by age, according to the National Survey on Drug Use and Health (2007). Binge drinking is defined as having five or more drinks on a single occasion. Heavy alcohol use is defined as having had five or more drinks on the same occasion on each of five or more days in the previous 30 days. (From Substance Abuse and Mental Health Services Administration: Results from the 2011 National Survey on Drug Use and Health: Summary of National Findings, NSDUH Series H-44, HHS Publication No. [SMA] 12-4713, Rockville, Md., 2012, Substance Abuse and Mental Health Services Administration.)

These enzymatic variations also influence a person's risk of developing an alcohol use disorder. The mechanism is thought to involve elevated acetaldehyde levels resulting from a more rapid conversion of ethanol (in cases of alcohol dehydrogenase variants with higher enzymatic activity) or slower elimination of acetaldehyde oxidation (in cases of aldehyde dehydrogenase variants with reduced enzymatic activity). Acetaldehyde causes facial flushing, nausea, and tachycardia, which make individuals reduce their intake of alcohol.

MECHANISMS OF ALCOHOL-INDUCED ORGAN DAMAGE

The major organs that are susceptible to damage by alcohol are the liver, pancreas, heart, brain, and bone (Table 126-2). Several alcohol-related medical disorders are caused by various nutritional deficiencies; ethanol is deficient in proteins, minerals, and vitamins. Therefore, the initial management of the alcoholic patient must attend to suggested dietary deficiencies (e.g., thiamine) and electrolyte deficiencies, including potassium, magnesium, calcium, and zinc.

Alcohol-related liver disease is the leading preventable cause of hepatic failure in the industrialized world. Genetic factors are thought to play a role in susceptibility to this disorder, since alcoholic liver disease is more prevalent in whites than in other ethnic groups (despite a similar magnitude of ethanol consumption). The histopathologic features of alcoholic liver disease

TABLE 126-2 MEDICAL COMPLICATIONS OF ALCOHOL ABUSE

NEUROLOGIC	ELECTROLYTE OR NUTRITIONAL
Encephalopathy (Wernicke, with oculomotor dysfunction; gait ataxia)	Thiamine deficiency
Marchifava-Bignami disease (demyelination of corpus callosum)	Niacin deficiency
Central pontine myelinosis	Folate deficiency
Cognitive dysfunction	Vitamin B12 deficiency
Amnesia (i.e., Korsakoff syndrome)	Vitamin D deficiency
Dementia	Zinc deficiency
Cerebellar degeneration	Hypokalemia
Peripheral neuropathy	Hypomagnesaemia
Seizures	Hypocalcaemia
HEMATOLOGIC	ENDOCRINE
Anemia (often with macrocytosis)	Diabetes mellitus
Leukopenia	Gynecomastia
Thrombocytopenia	MUSCULOSKELETAL
GASTROINTESTINAL	Myopathy
Esophagitis	Osteoporosis
Esophageal varices	Testicular atrophy
Gastritis	Amenorrhea
Gastrointestinal bleeding	Infertility
Pancreatitis	MISCELLANEOUS
Hepatitis	Spontaneous abortion
Cirrhosis	Fetal alcohol syndrome
Splenomegaly	Increased risk of cancer (breast, oropharyngeal, esophageal, hepatocellular, colorectal)
CARDIOVASCULAR	Accidents, trauma, violence, suicide
Hypertension	
Cardiomyopathy	
Stroke	
Arrhythmias (especially atrial fibrillation)	

include fatty infiltration, hepatitis, fibrosis, and end-stage cirrhosis.

CLINICAL PRESENTATION

Acute Alcohol Intoxication

Mild ethanol intoxication produces slurred speech, ataxia, irregular eye movements, and poor coordination. Signs of CNS depression and associated cerebellar or vestibular dysfunction include dysarthria, ataxia, and nystagmus. Although blood alcohol concentrations are not precisely correlated with the degree of intoxication and the clinical effect of ethanol widely varies among individuals, stupor and coma usually develop at blood concentrations approaching 400 mg/dL. Blood levels of 500 mg/dL often are fatal; however, it is important to understand that death may occur even when the blood alcohol concentration is as low as 300 mg/dL.

Withdrawal Syndrome (Convulsions)

Alcohol withdrawal occurs in three stages. The signs of minor withdrawal usually appear 6 to 12 hours after the discontinuation of ethanol and are caused by central adrenergic hyperexcitability; they consist of anxiety, tremors, sweating, tachycardia, diarrhea, and insomnia. Additional evidence of autonomic nervous system hyperactivity often appears within 12 to 24 hours and includes increased startle response, nightmares, and visual hallucinations. Alcohol withdrawal seizures (so-called *rum fits*) are generalized clonic-tonic convulsions that occur 12 to 48 hours after the discontinuation of ethanol and are estimated to occur in 2% to 5% of alcoholics.

Delirium Tremens

Delirium tremens (DTs) is characterized by delirium (a confused state with varying levels of consciousness), hallucinations, disorientation, agitation, tremor (caused by marked autonomic nervous system over activity), tachycardia, hypertension, fever, and diaphoresis. It occurs in approximately 5% of alcoholics, most often in chronic heavy abusers with underlying neurologic damage. If unrecognized and untreated, the in-hospital mortality rate of DTs approaches 25%; with early recognition and treatment the mortality is only 5%.

TREATMENT

Intervention strategies in alcohol abusers are designed to modify the individual's attitudes, knowledge, and skills to prevent alcohol misuse. In the outpatient setting, increased frequency of contact between the primary care physician and the patient increases the likelihood of detection, intervention, and prevention of heavy alcohol consumption. All scheduled office visits should include alcohol screening, assessment, and brief attempts at intervention (one or more discussions lasting 10 to 15 minutes), if indicated, as studies show that this approach decreases alcohol intake and its consequences. Behavioral or pharmacologic treatment should be considered because two thirds of treated patients have a reduction in the amount of consumption (by more than 50%) as well as the consequences of consumption (e.g., alcohol-related injury or job loss). A year after treatment, one third of patients are either abstinent or drink moderately without consequences.

Screening and Intervention Strategies

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) provides several web-based guidelines for alcohol screening during the routine health examination (www.niaaa.nih.gov). A four-step plan exists with which physicians can (1) screen patients for alcohol use, (2) assess for the presence of alcohol-related problems, (3) provide advice concerning appropriate action, and (4) monitor the patient's progress. For the current drinker, the physician should inquire about the number of drinks consumed per day, number of days per week on which ethanol is consumed, and total number of drinks consumed per month. Alcohol consumption that exceeds 14 drinks per week or three drinks per day should trigger an in-depth assessment of alcohol-related problems. The physician should ascertain if the individual is at risk for alcohol-related problems, has an existing problem, or may be alcohol-dependent. Difficulties with work-related, interpersonal, or family relationships and/or evidence of high-risk behavior despite self-reported low-risk consumption indicate that the individual is at risk for alcohol use disorder.

The CAGE questionnaire (each of the letters in the acronym refers to one of the questions) (Table 126-3) is a useful screening tool for identifying alcohol-dependent individuals. A positive response to two or more of the four questions is indicative of a potential alcohol problem and should prompt questions regarding the quantity and frequency of consumption. The Alcohol Use Disorders Identification Test (AUDIT) (Table 126-4) is the most widely validated instrument for use in primary care settings. Utilizing 10 items and taking two to three minutes to complete, it is better suited to settings where visit times are longer or when it can be completed and scored before a clinician visit. On physical examination, evidence of alcoholic liver disease may be exhibited as jaundice, hepatomegaly, palmar erythema, male gynecomastia, spider angiomas, and ascites. The serum γ -glutamyltransferase concentration typically is elevated in individuals who drink excessively.

Low-Risk Drinking

A standard drink contains 12 g of alcohol, an amount similar to that found in one 12-oz bottle of beer or wine cooler, one 5-oz glass of wine, or 1.5 oz. of distilled (e.g., 80 proof) spirits. In men older than age 64 years and in women older than 21 years, the limit for moderate drinking is one drink per day. For younger men, moderate drinking is defined as no more than two drinks per day. For the same amount of ingested ethanol, women and older adult men achieve a higher blood concentration of ethanol than younger men owing to their smaller volume of body water. A reasonable blood alcohol level should not exceed 50 mg/dL.

A blood-alcohol level as low as 80 mg/dL may exceed the legal definition for driving under the influence (DUI) or driving while

TABLE 126-3 CAGE: AN ALCOHOLISM SCREENING TEST

1. Have you ever felt you should *cut down* on your drinking?
2. Have people *annoyed* you by criticizing your drinking?
3. Have you felt *guilty* about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (i.e., as an *eye-opener*)?

TABLE 126-4 COMMONLY ABUSED DRUGS

SUBSTANCE: CATEGORY AND NAME	EXAMPLES OF COMMERCIAL AND STREET NAMES	HOW ADMINISTERED*	INTOXICATION EFFECTS AND POTENTIAL HEALTH CONSEQUENCES
CANNABINOIDS			Euphoria, slowed thinking and reaction time, drowsiness, inattention, confusion, impaired balance and coordination, enhanced perception, cough, frequent respiratory infections, impaired memory and learning, increased heart rate, anxiety, panic attacks, tolerance, addiction
Hashish	Boom, gangster, hash, hash oil, hemp	Smoked, swallowed	
Marijuana	Blunt, dope, ganja, grass, herb, joint, bud, Mary Jane, pot, reefer, green trees, smoke, sinsemilla, skunk, weed	Smoked, swallowed	
K2/Synthetic Marijuana	Spice, K2, fake weed, Yucatan fire, skunk, moon rocks,	Smoked, swallowed	Vomiting, agitation, hallucinations, hypertension, myocardial infarction, death, withdrawal and addiction symptoms.
SEDATIVE-HYPNOTICS (CNS DEPRESSANTS)			Reduced pain and anxiety, feeling of well-being, lowered inhibitions, labile mood, impaired judgment, poor concentration, fatigue, confusion, impaired coordination and memory, respiratory depression and arrest, addiction
Benzodiazepines (Other Than Flunitrazepam)	Ativan, Halcion, Klonopin, Librium, ProSom, Restoril, Serax, Tranxene, Valium, Xanax, Doral; candy, downers, sleeping pills, tranks	Swallowed	Sedation, drowsiness, dizziness
Flunitrazepam [†]	Rohypnol; forget-me pill, Mexican Valium, R2, roach, Roche, roofies, roofinol, rope, rophies	Swallowed, snorted	Visual and gastrointestinal disturbances, urinary retention, amnesia while under drug's effects
Sleep Medications	Ambien (zolpidem), Sonata (zaleplon), Lunesta (eszopiclone)	Swallowed	Sedation, drowsiness, dizziness
Barbiturates	Amytal, Nembutal, phenobarbital, Seconal; barbs, reds, red birds, phennies, tooies, yellows, yellow jackets	Injected, swallowed	Sedation, drowsiness, depression, unusual excitement, fever, irritability, poor judgment, slurred speech, dizziness
GHB [†]	γ -hydroxybutyrate; G, Georgia home boy, grievous bodily harm, liquid ecstasy, soap, scoop, goop, liquid X	Swallowed	Drowsiness, dizziness, nausea and vomiting, headache, loss of consciousness, hallucinations, peripheral vision loss, nystagmus, loss of reflexes, seizures, coma, death
DISSOCIATIVE DRUGS			Increased heart rate and blood pressure, impaired function, memory motor loss, numbness, nausea and vomiting
PCP and Analogues	Phencyclidine; angel dust, boat, hog, love boat, peace pill	Injected, smoked, swallowed	Possible decrease in blood pressure and heart rate, panic, aggression, violence, suicidal ideation; loss of appetite, depression
Ketamine*	Ketalar SV; cat Valiums, K, Special K, vitamin K	Injected, smoked, snorted	At high doses: delirium, depression, respiratory depression and arrest, amnesia while under drug's effects
Salvia Divinorum	Salvia, shepherdess's herb, maria pastora, magic mint, sally-d	Chewed, smoked, swallowed	
Dextromethorphan (DXM)	Found in some cough and cold medications: Robo, Robotripping, Triple C	Swallowed	Euphoria, slurred speech, confusion, dizziness, distorted visual perceptions
HALLUCINOGENS			Altered states of perception and feeling, nausea, chronic mental disorders, persisting perception disorder (flashbacks)
LSD	Lysergic acid diethylamide; acid, blotter, cubes, microdot, yellow sunshines, blue heaven	Swallowed, absorbed through mouth tissues	LSD: flashbacks, hallucinogen persisting perception disorder LSD and mescaline: increased body temperature, heart rate, blood pressure, loss of appetite, sleeplessness, numbness, weakness, tremors, impulsive behavior, rapid shift in emotion
Mescaline	Buttons, cactus, mesc, peyote	Smoked, swallowed,	
Psilocybin	Magic mushrooms, purple passion, shrooms, little smoke	Swallowed	nervousness, paranoia, panic
OPIOIDS AND MORPHINE DERIVATIVES			Pain relief, euphoria, drowsiness, respiratory depression and arrest, pinpoint pupils, nausea, confusion, constipation, sedation, unconsciousness, seizures, coma, tolerance, addiction
Codeine	Empirin with Codeine, Fiorinal with Codeine, Robitussin A-C, Tylenol with Codeine, OxyContin, Roxicodone, Vicodin; Captain Cody, Cody, schoolboy (with glutethimide: doors and fours, loads, pancakes and syrup)	Injected, swallowed	Less analgesia, sedation, and respiratory depression than morphine

Continued

TABLE 126-4 COMMONLY ABUSED DRUGS—cont'd

SUBSTANCE: CATEGORY AND NAME	EXAMPLES OF COMMERCIAL AND STREET NAMES	HOW ADMINISTERED*	INTOXICATION EFFECTS AND POTENTIAL HEALTH CONSEQUENCES
Other Opioid Pain Relievers			
Oxycodone, hydrocodone bitartrate hydromorphone, oxymorphone, meperidine, propoxyphene	Tylox, Oxycontin, Percodan, Percocet; Oxy, O.C., oxycotton, oxycet, hillbilly, heroin, perc Vicodin, Lortab, Lorcet; vike, Watson-387 Dilaudid; juice, smack, D, footballs, dillies Opana, Numorphan, Numorphone; biscuits, blue heaven, blues, Mrs. O, octagons, stop signs, O bomb Demerol, meperidine hydrochloride; demmies, pain killer Darvon, Darvocet	Chewed, injected, snorted, suppositories, swallowed	For oxycodone—muscle relaxation/twice as potent an analgesic as morphine; high abuse potential
Fentanyl	Actiq, Duragesic, Sublimaze; apache, China girl, China white, dance fever, friend, goodfella, jackpot, murder 8, TNT, Tango and Cash	Injected, smoked, snorted	80-100 times more potent an analgesic than morphine
Heroin	Diacetylmorphine; brown sugar, dope, H, horse, junk, skag, skunk, smack, white horse, China white, cheese (with OTC cold medicine and antihistamine)	Injected, smoked, snorted	Staggering gain
Morphine	Roxanol, Duramorph, M, Miss Emma, monkey, white stuff	Injected, smoked, swallowed	
Opium	Laudanum, paregoric; big O, black stuff, block, gum, hop	Smoked, swallowed	
STIMULANTS			Increased heart rate, blood pressure, body temperature; feelings of exhilaration, increased energy and mental alertness, tremors, rapid or irregular heart beat; reduced appetite, irritability, anxiety, panic, paranoia, violent behavior, psychosis, weight loss, insomnia, heart failure, seizures, coma
Amphetamine	Adderall, Biphphetamine, Dexedrine; bennies, black beauties, crosses, hearts, LA turnaround, speed, truck drivers, uppers	Injected, smoked, snorted, swallowed	Rapid breathing, hallucinations, loss of coordination, restlessness, delirium, panic, impulsive behavior, Parkinson's disease, tolerance, addiction
Methamphetamine	Desoxyn; chalk, crank, crystal, fire, glass, go fast, ice, meth, speed, yaba, fire, tina, tweak, uppers, trash, yellow barn, methlies quick, stove top, go fast	Injected, smoked, snorted, swallowed	Memory loss, cardiac and neurologic damage, impaired memory and learning, tolerance, addiction, severe dental problems
Methylphenidate	Ritalin, Concerta; JIF, MPH, R-ball, Skippy, the smart drug, vitamin R	Injected, snorted, swallowed	Increase or decrease in blood pressure, psychotic episodes, digestive problems,
Cocaine	Cocaine hydrochloride; blow, bump, C, candy, Charlie, coke, crack, flake, rock, snow, toot	Injected, smoked, snorted	Chest pain, respiratory failure, nausea, abdominal pain, stroke, malnutrition, nasal damage from snorting
MDMA[†] (Methylenedioxymethamphetamine)	Adam, clarity, ecstasy, Eve, lover's speed, peace, uppers, Molly	Injected, snorted, swallowed	Mild hallucinogenic effects, increased tactile sensitivity, empathic feelings, chills, sweating, nystagmus, ataxia, teeth clenching, muscle cramping, impaired memory and learning, lowered inhibition
Synthetic Cathinone (Methylenedioxypyrovalerone (MDPV), Mephedrone ("Drone," "Meph," or "Meow Meow"), and Methylone)	Bath salts, drone, meph, meow meow, ivory wave, bloom, cloud nine, lunar wave, vanilla sky, white lightning, scarface	Injected, smoked, swallowed	Chest pain, paranoia, hallucinations, panic attacks, excited delirium, rhabdomyolysis, renal failure, high abuse and addiction potential
OTHER COMPOUNDS			
Inhalants	Solvents (paint thinners, gasoline), glues, gases (butane, propane, aerosol propellants, nitrous oxide), nitrites (isoamyl, isobutyl, cyclohexyl); laughing gas, poppers, snappers, whippets	Inhaled through nose or mouth	Stimulation, loss of inhibition, headache, nausea or vomiting, slurred speech, loss of motor coordination, wheezing, unconsciousness, cramps, weight loss, muscle weakness, depression, memory impairment, damage to cardiovascular and nervous systems, sudden death
Anabolic Steroids	Anadrol, Oxandrin, Durabolin, Depo-Testosterone, Equipoise; roids, juice, gym candy, pumpers	Injected, swallowed, topical	No intoxication effects. Hypertension, blood clotting and cholesterol changes, hostility and aggression, acne, prostate cancer, reduced sperm production, shrunken testicles, breast enlargement. In females: menstrual irregularities, beard development, and other masculine characteristics

CNS, Central nervous system.

*Taking drugs by injection can increase the risk of infection through needle contamination with staphylococci, human immunodeficiency virus, hepatitis, and other organisms.

[†]Associated with sexual assaults (e.g., date rapes).

intoxicated (DWI). In national surveys, the strategy of the *designated driver* appears to be effective at preventing unsafe driving by drinkers at risk for DWI. Complete abstinence is recommended for people with a history of alcohol use disorder, other serious medical conditions (e.g., liver disease), and pregnancy.

Nonpharmacologic Therapies

Pharmacologic agents are complementary and adjunctive to the traditional approaches of abstinence, group therapy, coping mechanisms, and behavior modification. The most widely employed behavioral approach is the 12-step program administered by Alcoholics Anonymous (AA), with which the recovering alcoholic moves through 12 specific steps aided by his or her attendance at regular meetings within a self-help peer group. Cognitive behavioral therapy is based on the principle that the alcoholic first must identify the internal and external cues to drinking so that he or she can develop effective countermeasures for drinking behavior. Motivation enhancement therapy is a four-session, brief contact intervention program that encourages self-awareness and behavioral changes in the alcoholic. These therapies provide similar efficacy.

Considerations for Drug Interventions

If desired, medications can be administered in conjunction with behavioral modification. Disulfiram, naltrexone, and acamprosate have been approved by the U.S. Food and Drug Administration (FDA) for adjunctive therapy.

Disulfiram (Antabuse) inhibits aldehyde dehydrogenase (i.e., the enzyme that converts acetaldehyde to acetate), resulting in a 5- to 10-fold increase in serum acetaldehyde concentrations when alcohol is consumed. This produces uncomfortable symptoms (e.g., facial flushing, tachycardia, nausea, vomiting, and headache), which act to deter alcohol consumption. Because of low medication compliance and limited efficacy, disulfiram is rarely prescribed.

Naltrexone is an opioid receptor antagonist. In clinical trials, a combination of naltrexone and psychosocial intervention reduced the number of drinking days, induced a longer period of abstinence from ethanol, and decreased the relapse rate in heavy drinkers when compared with psychosocial intervention alone. Naltrexone is administered orally in a dose of 50 mg daily for 12 weeks, although larger doses (i.e., 100 to 150 mg daily) and a longer duration of administration may improve its success in preventing relapse. In 2006, the FDA approved a once-a-month injectable form of naltrexone (380 mg) for the treatment of alcohol use disorders; this form appears to be more effective than the pill form at maintaining abstinence, since it eliminates the problem of medication compliance.

Naltrexone can be initiated while the individual is still drinking, thereby permitting treatment to be provided in a community-based setting without the need for enforced abstinence or detoxification. Some recovering alcoholics develop nausea when it is initiated. Because hepatic toxicity may occur at high doses (≥ 300 mg), periodic testing of liver function is recommended. Naltrexone is contraindicated in subjects receiving opioids, given that opiate withdrawal is an unintended adverse effect of the drug.

Acamprosate (Campral), a structural analog of γ -amino butyric acid (GABA), decreases excitatory glutamatergic neurotransmission during alcohol withdrawal. The recommended dosage is 666 to 1000 mg 3 times daily, and its most common side effects are diarrhea and intestinal cramping. In placebo-controlled trials involving almost 7000 alcoholic patients, acamprosate reduced relapse rates and increased abstinence from ethanol. In comparative trials, it did not appear to be as efficacious as naltrexone. Acamprosate should be used once abstinence is achieved; since it is not metabolized by the liver, it can be given safely to individuals with alcoholic liver disease.

The use of several other pharmacologic agents has been associated with a reduction in alcohol consumption, including ondansetron (a selective serotonin reuptake inhibitor), topiramate (an anticonvulsant), baclofen (a GABA agonist), nalmefene (an opioid antagonist), and varenicline (a nicotinic acetylcholine-receptor and dopamine partial agonist), but none of these agents has been approved by the FDA for treatment of alcohol dependence.

Fetal Alcohol Spectrum Disorders

Alcohol freely crosses the placenta and is teratogenic. It is a leading preventable cause of birth defects with mental deficiency, with up to 1 in 100 children in the United States being born with fetal alcohol spectrum disorders (FASDs). The scope of disabilities and malformations varies and depends on the amount of alcohol consumed, the frequency of exposure, the stage of fetal development when alcohol is present, maternal parity, nutrition, genetic susceptibility, and individual variation in maternal and fetal alcohol metabolism.

The term *fetal alcohol spectrum disorder* (FASD) is used to characterize the full range of prenatal alcohol damage, varying from mild to severe and encompassing a broad array of physical defects and cognitive, behavioral, and emotional deficits. It includes conditions such as fetal alcohol syndrome (FAS), alcohol-related neurodevelopmental disorder (ARND), and alcohol-related birth defects (ARBDS).

FAS, the most severe form of FASD, is characterized by (a) growth retardation (i.e., height or weight ≥ 10 th percentile); (b) neurodevelopmental abnormalities (i.e., microcephaly, hyperactivity, irritability, altered motor skills, learning disabilities, seizure disorders, and mental retardation), and (c) dysmorphic facial features (i.e., short palpebral fissures, smooth philtrum, and a thin upper lip). Children with typical dysmorphic facial features who lack the other features have partial FAS. Children with ARBDs have typical facies associated with FAS as well as anomalies in other organs (i.e., cardiac, renal, skeletal, auditory) but no growth retardation or neurodevelopmental abnormalities. Children with ARND exhibit behavioral or cognitive abnormalities in the absence of dysmorphic facial features.

Although the damage from prenatal exposure to alcohol cannot be reversed, children with FASDs benefit from early diagnosis and aggressive intervention with physical, occupational, speech and language, and educational therapies. Early recognition can also benefit the impaired mother, resulting in access to alcohol treatment and a better social situation for the entire family.

Although the recognition of FASD is important, its prevention is essential. Given that no safely established level of alcohol consumption in pregnancy exists, recommendations suggest that pregnant women maintain abstinence. In addition, women who are considering pregnancy or are already pregnant must be counseled about the effects of alcohol on the fetus.

Medical Management of Alcohol Withdrawal and Delirium Tremens

For the patient with probable alcohol withdrawal, comorbid conditions that may coexist or mimic the symptoms of withdrawal (e.g., infection, trauma, hepatic encephalopathy, drug overdose, gastrointestinal bleeding, and metabolic derangements) should be excluded. Once this has been accomplished, the patient should be placed in a quiet and protective environment and should receive parenteral thiamine and multivitamins to decrease the risk of Wernicke encephalopathy or Korsakoff amnestic syndrome.

The Revised Clinical Institute for Withdrawal Assessment for Alcohol (CIWA-Ar) scale (available at https://umem.org/files/uploads/1104212257_CIWA-Ar.pdf), a measure of withdrawal severity, is useful in guiding symptom-triggered therapy in medically stable (i.e., non ICU or postoperative) patients. Benzodiazepines are the only medications proved to ameliorate symptoms and to decrease the risk of seizures and DTs in patients with alcohol withdrawal. Typically, diazepam (5 to 20 mg), chlordiazepoxide (50 to 100 mg), or lorazepam (1 to 2 mg) is administered intravenously every 5 to 10 minutes until symptoms subside, with the last of these medications preferred in patients with advanced cirrhosis, considering that the liver minimally metabolizes it. All benzodiazepines appear to be similarly efficacious in treating alcohol withdrawal, but long-acting agents may be more effective in preventing withdrawal seizures and are associated with fewer rebound symptoms. Conversely, short-acting agents may offer a lower risk of oversedation. For the patient who is resistant to benzodiazepines, intravenous phenobarbital (130 to 260 mg administered intravenously every 15 minutes until symptoms are controlled) may be given.

PRESCRIPTION DRUG ABUSE

According to the National Survey on Drug Use and Health, an estimated 6.1 million Americans aged 12 years or older used prescription-type psychotherapeutic drugs nonmedically in the past month (Fig. 126-3). This estimate represents 2.4% of the population aged 12 years or older. In 2011, the illicit drug category with the largest number of recent initiates was marijuana use (2.6 million), followed by nonmedical use of pain relievers (1.9 million) and nonmedical use of tranquilizers (1.2 million). More people in the United States now die of prescription drug overdose (i.e., the nonmedical use of prescription-type pain relievers, tranquilizers, stimulants, and sedatives) than accidental vehicular trauma.

Sedatives and Hypnotics

Benzodiazepines and barbiturates are the major sedative-hypnotic drugs among the commonly abused agents that are listed in Table 126-4. The patient with sedative-hypnotic intoxication may have slurred speech, incoordination, unsteady gait,

FIGURE 126-3 Past-month illicit drug use among persons aged 12 or older, according to the National Survey on Drug Use and Health (2011). (From Substance Abuse and Mental Health Services Administration: Results from the 2011 National Survey on Drug Use and Health: Summary of National Findings, NSDUH Series H-44, HHS Publication No. [SMA] 12-4713, Rockville, Md., 2012, Substance Abuse and Mental Health Services Administration.)

impaired attention or memory, stupor, and coma. The psychiatric manifestations of intoxication include inappropriate behavior, labile mood, and impaired judgment and social functioning. On physical examination, the person may have respiratory depression or even arrest, nystagmus, and hyper-reflexia. Although benzodiazepines rarely depress respiration to the extent that barbiturates do (and, as a result, have a much wider margin of safety), the effects of these drugs are additive with those of other CNS depressants, such as ethanol. Chronic use may produce physical and psychological dependence and a potentially dangerous withdrawal syndrome.

Benzodiazepines potentiate the effects of GABA, which inhibits neurotransmission. They are available as short-acting agents (temazepam [Restoril] and triazolam [Halcion]), intermediate-acting agents (alprazolam [Xanax], chlordiazepoxide [Librium], estazolam [ProSom], lorazepam [Ativan], and oxazepam [Serax]), and long-acting agents (clorazepate [Tranxene], clonazepam [Klonopin], diazepam [Valium], flurazepam [Dalmane], halazepam [Paxipam], Prazepam [Centrax], and quazepam [Doral]). Flunitrazepam (Rohypnol, also known as *roach*, *roofies*, *circles*, *Mexican valium*, or *rope*) is a popularly abused benzodiazepine that is not legally available in the United States but is often smuggled here from other countries. It has been implicated in cases of date rape and is known as a club drug because adolescents and young adults often use it at nightclubs and bars or during all-night dance parties called raves.

In persons with an acute benzodiazepine overdose, respiratory depression is the major danger. Flumazenil (Romazicon), a competitive antagonist of benzodiazepines, can be given intravenously for acute overdose. Although it reverses the sedative effects of benzodiazepines, flumazenil may not completely reverse respiratory depression, and it may cause seizures in patients with

physical dependence or concurrent tricyclic antidepressant poisoning.

Benzodiazepine cessation may precipitate withdrawal symptoms, depending on the half-life of the specific agent, the duration of use, and the dose. Such withdrawal is characterized by intense anxiety, insomnia, irritability, perceptual changes, hypersensitivity to light and sound, psychosis, hallucinations, palpitations, hyperthermia, tachypnea, diarrhea, muscle spasms, tremors, and seizures. Withdrawal symptoms usually peak 2 to 4 days after the discontinuation of a short-acting agent and 5 to 6 days after discontinuation of a longer-acting one; however, panic attacks and nightmares may recur for months. In general, agents with shorter half-lives produce more intense withdrawal symptoms compared with agents with longer half-lives. Detoxification requires a change to a longer-acting benzodiazepine (e.g., clonazepam, diazepam) or phenobarbital and a tapering regimen of 7 to 10 days for short-acting agents or 10 to 14 days for longer-acting ones. For hemodynamically unstable patients who require very rapid medication titration to control withdrawal symptoms and for those with severe hepatic failure, short-acting medications are indicated in lieu of phenobarbital. Propranolol can be given to decrease tachycardia, hypertension, and anxiety.

Barbiturates may be short acting (pentobarbital and secobarbital), intermediate acting (amobarbital, aprobarbital, and butabarbital), or long acting (mephobarbital and phenobarbital). The symptoms of acute intoxication with the withdrawal from barbiturates are similar to those of benzodiazepines. For acute barbiturate overdose, oral charcoal and alkalization of the urine (to a pH >7.5) with forced diuresis are effective in lowering the blood concentration. For patients with hemodynamic compromise refractory to aggressive supportive therapy, barbiturate elimination can be increased by hemodialysis or charcoal hemoperfusion. The effective treatment of withdrawal symptoms requires estimating the daily dose of the abused drug and substituting an equivalent phenobarbital dose to stabilize the patient, after which the dose of phenobarbital is tapered over 4 to 14 days, depending on the half-life of the abused drug. Benzodiazepines may also be used for detoxification, and propranolol and clonidine may help reduce symptoms.

Abuse of γ -hydroxybutyrate (GHB) has increased substantially over the last decade in the United States. This drug is abused for its sedative, euphoric, and bodybuilding effects. GHB is a metabolite of the neurotransmitter GABA, and it also influences the dopaminergic system. It potentiates the effects of endogenous or exogenous opiates. The ingestion of GHB results in immediate drowsiness and dizziness, with the feeling of a *high*. These effects can be potentiated by the concomitant use of alcohol or benzodiazepines. Similar to flunitrazepam and ketamine, GHB is a popular club drug, and it has been implicated in cases of date rape. Its street names include *G*, *liquid E*, *liquid X*, *fantasy*, *Georgia home boy*, and *grievous bodily harm*. Adverse effects that may occur within 15 to 60 minutes of its ingestion include headache, nausea, vomiting, hallucinations, loss of peripheral vision, nystagmus, hypoventilation, cardiac dysrhythmias, seizures, and coma. In rare instances, these adverse effects have led to death. The withdrawal from GHB becomes clinically apparent within 12 hours and may last up to 12 days.

Opioids

Opioids include the natural and semisynthetic alkaloid derivatives of opium as well as the purely synthetic drugs that mimic heroin. They bind to opioid receptors in the brain, spinal cord, and gastrointestinal tract; in addition, they act on several other CNS neurotransmitter systems, including dopamine, GABA, and glutamate, to produce analgesia, CNS depression, and euphoria. With continued opioid use, tolerance and physical dependence develop. As a result, the user must use larger amounts of the drug to obtain the desired effect, and withdrawal symptoms may occur if use is discontinued. The commonly abused opioids include heroin, morphine, codeine, oxycodone (OxyContin, OxyIR, Oxecta, Roxicodone, or combination products, such as Percocet, Percodan, Tylox, Combunox), meperidine (Demerol), propoxyphene (Darvon), hydrocodone (Vicodin, Lortab, Lorcet), hydromorphone (Dilaudid), buprenorphine (Temgesic) and fentanyl (Sublimaze). In 2000, retail pharmacies dispensed 174 million prescriptions for opioids; by 2009, 257 million prescriptions were dispensed, an increase of 48%. The 2011 National Survey on Drug Use and Health reported that over 70% of subjects who abused prescription pain relievers obtained them from friends or relatives, whereas approximately 5 percent procured them from a drug dealer or over the internet.

Acute opioid overdose produces pulmonary congestion, with resultant cyanosis and respiratory distress, and changes in mental status that may progress to coma. Other manifestations include fever, pinpoint pupils, and seizures. Unsterile intravenous practices can lead to skin abscesses, cellulitis, thrombophlebitis, wound botulism, meningitis, rhabdomyolysis, endocarditis, hepatitis, or human immunodeficiency virus (HIV) infection. Neurologic complications from intravenous heroin use include transverse myelitis, inflammatory polyneuropathy, and peripheral nerve lesions.

For acute opioid overdose, the patient's respiratory status must be assessed and supported. Naloxone should be administered intravenously and repeated at 2- to 3-minute intervals, often in escalating doses; the patient should respond within minutes with increases in pupil size, respiratory rate, and level of alertness. If no response occurs, opioid overdose is excluded, and other causes of somnolence and respiratory depression must be considered. Naloxone should be titrated carefully, since it may precipitate acute withdrawal symptoms in opioid-dependent patients.

Withdrawal symptoms may appear as early as 6 to 10 hours after the last injection of heroin. Initially the individual often has feelings of drug craving, anxiety, restlessness, irritability, rhinorrhea, lacrimation, diaphoresis, and yawning; these signs are followed by dilated pupils, piloerection, anorexia, nausea, vomiting, diarrhea, abdominal cramps, bone pain, myalgia, tremors, muscle spasms, and, in rare cases, seizures. These symptoms and signs peak at 36 to 48 hours and then subside over 5 to 10 days, if untreated. A protracted abstinence syndrome characterized by bradycardia, hypotension, mild anxiety, sleep disturbance, and decreased responsiveness may occur for up to 5 months.

Withdrawal from opioids can be managed with methadone, a long-acting synthetic agonist drug; withdrawal symptoms of methadone develop more slowly and are less severe than those

caused by heroin. Methadone can be given twice daily and tapered over 7 to 10 days. Methadone use, in both therapeutic doses and overdoses, has been associated with QTc interval prolongation and torsade de pointes, which, in some cases, has been fatal. Alternatively, buprenorphine, a partial agonist, can be given; it is combined with naloxone in a formulation (Suboxone) developed to decrease the potential for abuse. Clonidine reduces autonomic hyperactivity and is particularly effective if combined with a benzodiazepine. Patients with repeated relapses can be maintained on methadone or buprenorphine.

Naltrexone, a long-acting opioid antagonist that blocks impulsive opioid use, is an option for maintenance treatment to prevent relapse. It can be given orally daily or via injectable depot and implantable formulations every 60 to 90 days. It should only be administered after the patient is thoroughly detoxified because it may precipitate withdrawal. Pharmacotherapy must be combined with psychotherapy and structured rehabilitation to achieve an optimal outcome.

Amphetamines

Amphetamines have been used therapeutically for weight reduction and treatment of attention-deficit disorder and narcolepsy. Similar to cocaine, they cause a release of monoamine neurotransmitters (dopamine, norepinephrine, and serotonin) from presynaptic neurons. In addition, however, they have neurotoxic effects on dopaminergic and serotonergic neurons. Their euphoric and reinforcing effects are mediated through dopamine and the mesolimbic system, whereas their cardiovascular effects are caused by the release of norepinephrine. Chronic use leads to neuronal degeneration in dopamine-rich areas of the brain, which may increase the risk for the eventual development of Parkinson's disease.

Amphetamines can be abused orally, intranasally, intravenously, or by smoking. The most frequently used drugs are dextroamphetamine (Dexedrine), methamphetamine (Desoxyn), and methylphenidate (Ritalin). Methamphetamine is known on the street as *ice*, *crank*, *meth*, *crystal*, *tina*, *glass*, and *yaba*. Illicit use of amphetamines has increased substantially, in part because (a) it is easily and quickly synthesized from ephedrine or pseudoephedrine (Fig. 126-4), and (b) its psychotropic effects persist for up to 24 hours. The anorexiant, phenmetrazine and phentermine, which are structurally and pharmacologically similar to amphetamine, also have been used illicitly.

Tolerance to the stimulant effects of amphetamines develops rapidly, and toxic effects can occur with higher doses. Acute amphetamine toxicity is characterized by excessive sympathomimetic effects, including tachycardia, hypertension, hyperthermia, cardiac tachyarrhythmia, tremors, seizures, and coma. The patient may experience irritability, hypervigilance, paranoia, stereotyped compulsive behavior, and tactile, visual, or auditory hallucinations. The clinical picture may simulate an acute schizophrenic psychosis. The symptoms of withdrawal are similar to those seen with cocaine (see discussion of cocaine), but the acute psychosis and paranoia are often pronounced.

The treatment of amphetamine abuse centers on a quiet environment, benzodiazepines for anxiety, and sodium nitroprusside for severe hypertension. Antipsychotics, such as haloperidol, can reduce the agitation and psychosis by blocking the effect of

FIGURE 126-4 The chemical structures of amphetamine and methamphetamine, which can be easily manufactured from ephedrine or pseudoephedrine given that they are structurally similar and widely available.

dopamine on the CNS receptor. Urine acidification with ammonium chloride accelerates amphetamine excretion.

ILLCIT DRUG ABUSE

Cocaine

Among individuals 12 years old or older in 2011, 1.4 million had used cocaine within the previous month, and 670,000 had used it for the first time within the previous 12 months. Cocaine can be taken orally or intravenously; alternatively, because it is well absorbed through all mucous membranes, abusers may achieve a high blood concentration after intranasal, sublingual, vaginal, or rectal administration. Its freebase form (called *crack* because of the popping sound it makes when heated) is heat stable, and it can be smoked. Crack cocaine is considered to be the most potent and addictive form of the drug. Euphoria occurs within seconds after crack cocaine is smoked, and is short lived. Compared with smoking crack cocaine or intravenous injection of the drug, mucosal administration results in a slower onset of action, a later peak effect, and a longer duration of action. The blood half-life is approximately 1 hour. The drug's major metabolite is benzoylecgonine, which can be detected in the urine for 2 to 3 days after a single dose.

An intense, pleasurable reaction lasting 20 to 30 minutes occurs after cocaine use, after which rebound depression, agitation, insomnia, and anorexia occur, which are then followed by fatigue, hypersomnolence, and hyperphagia (the *crash*). This crash usually lasts 9 to 12 hours but occasionally may last up to 4 days. Users often ingest the drug repetitively at relatively short intervals to recapture the euphoric state and to avoid the crash. On occasion, sedatives or alcohol are ingested concomitantly to reduce the intensity of anxiety and irritability associated with the crash. The combination of cocaine and intravenously administered heroin (so-called *speedball*, *snowball*, *blanco*, *boy-girl*, *Bombita*, *Belushi*, or *dynamite*) is often used so that the abuser can experience the cocaine-induced euphoria and then *float* down on the opiate. Unfortunately, this combination has been reported to cause sudden death. People who use cocaine in temporal

proximity to the ingestion of ethanol produce the metabolite cocaethylene, which has also been implicated in cocaine-related deaths.

Cocaine blocks the presynaptic reuptake of norepinephrine and dopamine, producing an excess of these neurotransmitters at the site of the postsynaptic receptor. Thus, cocaine acts as a powerful sympathomimetic agent, resulting in tachycardia, hypertension, tachypnea, hyperthermia, agitation, pupillary dilation, peripheral vasoconstriction, and seizures. Cocaine causes potent vasoconstriction of cerebral arteries and, therefore, may result in a stroke. It is associated with myocardial ischemia and arrhythmias and, in rare cases, with myocardial infarction in young persons with normal or only minimally diseased coronary arteries. The principal mechanisms of ischemia and infarction are coronary arterial vasoconstriction, thrombosis, platelet aggregation, tissue plasminogen activator inhibition, increased myocardial oxygen demand, and accelerated atherosclerosis (Fig. 126-5).

For patients with cocaine-induced hypertension or tachycardia, labetalol and benzodiazepines are usually effective in lowering systemic arterial pressure and heart rate. Patients with acute myocardial infarction should receive aspirin, heparin, nitroglycerin, and, if indicated, reperfusion therapy (with a thrombolytic agent or primary coronary intervention). The use of β -adrenergic blockers should be avoided, since ischemia may be worsened by unopposed α -adrenergically mediated coronary arterial vasocon-

striction. Patients with a normal electrocardiogram or nonspecific changes can be managed safely with observation.

The immediate treatment of acute cocaine intoxication includes obtaining vascular and airway access, if needed, and careful electrocardiographic monitoring. Benzodiazepines can be given to control CNS agitation; haloperidol or risperidone can be used in the severely agitated patient. A supportive environment is needed, but detoxification is not required, given that few physical signs of true dependence are present.

Most chronic cocaine abusers have psychological dependence and an intense craving for cocaine. Personal and group therapies are important adjuncts to pharmacologic treatment, but relapse is common and is difficult to manage. Although no medication is FDA approved for treatment of cocaine addiction, disulfiram, modafinil, anticonvulsants (e.g., topiramate and tiagabine), serotonin reuptake inhibitors (e.g., citalopram), serotonin receptor antagonists (e.g., ondansetron), and GABA receptor agonists (e.g., baclofen) have shown some promise in promoting cocaine abstinence.

Cannabis

The cannabinoid drugs include marijuana (the dried flowering tops and stems of the hemp plant) and hashish (a resinous extract of the hemp plant). Marijuana is the most commonly used illicit drug in the United States. (It has been recently legalized for recreational use in Alaska, Colorado, Oregon, and Washington.) In

FIGURE 126-5 The mechanisms by which cocaine may induce myocardial ischemia or infarction. Cocaine may cause increases in the determinants of myocardial oxygen demand when oxygen supply is limited (*top*), when intense vasoconstriction of the coronary arteries occurs (*middle*), or when accelerated atherosclerosis and thrombosis are present (*bottom*).

2011, an estimated 18.1 million Americans had used it in the past month. Between 2007 and 2011, the rate of use increased from 5.8 to 7.0%, and the number of users increased from 14.5 million to 18.1 million. Nearly 5.0 million persons used marijuana on a daily or almost daily basis over a 12-month period. Marijuana and hashish are among the drugs most commonly used by adolescents, with approximately one half of 12th graders admitting use at least once and 20% reporting that they are current users. Most of their pharmacologic effects come from metabolites of δ -9-tetrahydrocannabinol, which bind to specific cannabinoid receptors located in the CNS, spinal cord, and peripheral nervous system. The primary mode of use is smoking, with mood-altering and intoxicating effects noted within 3 minutes and peak effects in approximately 1 hour. The acute physiologic effects are dose-related and often include increased heart rate, conjunctival congestion, dry mouth, fine tremor, muscle weakness, and ataxia. Psychoactive effects include euphoria, enhanced perception of colors and sounds, drowsiness, inattentiveness, and inability to learn new facts. Tolerance and physical dependence occur, and chronic users may experience mild withdrawal symptoms of irritability, restlessness, anorexia, insomnia, or mild hyperthermia. Rarely, acute psychosis with panic reactions occurs. The treatment of withdrawal is supportive and includes reassurance; benzodiazepines may be used in severely agitated patients. Cannabinoids have been used as antiemetic agents in patients with cancer receiving chemotherapy, for weight stimulation (in patients with cancer or HIV infection), and in the treatment of glaucoma.

Synthetic marijuana is a psychoactive designer drug composed of a mixture of herbs, spices, or shredded plant material that is sprayed with synthetic chemicals that mimic the effects of cannabis when smoked or prepared as a tea. They have been sold widely in “head shops” as well as through the internet and are best known by the brand names K2 and Spice. Spice products are popular among young people; of the illicit drugs most used by high school seniors, they are second only to marijuana. Synthetic cannabis can precipitate acute psychosis or a worsening of previously stable psychotic disorders; they also may trigger a chronic (long-term) psychotic disorder among vulnerable individuals, such as those with a family history of mental illness. K2 ingestion has been associated with myocardial infarction and death. Regular users may experience withdrawal and addiction symptoms.

Hallucinogens and Dissociative Drugs

Hallucinogens (drugs that cause hallucinations) include lysergic acid diethylamide (LSD), mescaline, psilocybin, and ibogaine. *Dissociative drugs* distort perceptions of sight and sound and produce feelings of detachment (dissociation) without causing hallucinations. They include phencyclidine (PCP), ketamine, salvia, and dextromethorphan (a widely available cough suppressant).

LSD is the most potent of the hallucinogenic drugs. Although it is known to interact with serotonin receptors in the cerebral cortex and *locus ceruleus*, its precise psychoactive mechanism is unknown. Within 30 minutes of its oral ingestion, sympathomimetic effects appear, including mydriasis, hyperthermia, tachycardia, elevated blood pressure, diaphoresis, dry mouth, increased

alertness, tremors, and nausea. Within 2 hours, the psychoactive effects become apparent, with heightened perceptions (highly intensified colors, smells, sounds, and other sensations), body distortions, mood variations, and visual hallucinations. An acute panic reaction may occur, sometimes leading to self-injury or suicide. After approximately 12 hours, the syndrome begins to subside, but fatigue and tension may persist for another day. Flashbacks (brief recurrences of the hallucinations) may occur days or even weeks after the last dose but tend to disappear without treatment. Acute panic reactions are best treated in a supportive environment; benzodiazepines can be given to severely agitated patients.

PCP is a potent, addictive hallucinogen that produces a prompt stimulant effect similar to that of amphetamines, with feelings of euphoria, power, and invincibility. Patients may have hypertension, tachycardia, hyperthermia, bidirectional nystagmus, slurred speech, ataxia, hallucinations, extreme agitation, and rhabdomyolysis. With more severe reactions, patients may be brought to medical attention in a coma-like state, with open eyes and pupils that are partially dilated, a decreased pain response, brief periods of excitation, and muscle rigidity. On occasion, PCP users may have hypertensive urgency, seizures, and bizarre (often violent) behavior, which lead to suicide or extreme violence toward others. Tolerance and mild withdrawal symptoms have been seen in daily users, but the major problem is drug craving. Treatment entails a quiet environment, sedation with benzodiazepines, hydration, haloperidol for terrifying hallucinations, and suicide precautions. Continuous gastric suction and acidification of the urine with intravenous ammonium chloride or ascorbic acid may aid in the drug's excretion, but acidification may increase the risk of renal failure if rhabdomyolysis is present.

Ketamine is a rapidly acting general anesthetic; unlike most anesthetics, it produces only mild respiratory depression and appears to stimulate the cardiovascular system. Adverse effects, including delirium and hallucinations, limit its use as a general anesthetic in humans. Similar to PCP, ketamine is a dissociative anesthetic. In addition, it has both analgesic and amnesic properties and is associated with less confusion, irrationality, and violent behavior than PCP. Ketamine is one of the club drugs that have been implicated in date rape.

Inhalants

The inhalants may be classified as (1) *organic solvents*, including toluene (airplane glue and spray paint), paint thinners, kerosene, gasoline, carbon tetrachloride, shoe polish, acetone (nail polish removers and Liquid Paper), xylene (permanent markers), and degreasers (dry cleaning fluids); (2) *gases*, such as butane, propane, aerosol propellants, and anesthetics (ether, chloroform, halothane, and nitrous oxide); and (3) *nitrites*, such as cyclohexyl nitrite, amyl nitrite, and butyl nitrite (room deodorizer). These substances are most often inhaled by children or young adolescents, after which they produce dizziness and intoxication within minutes. Prolonged exposure or daily use may lead to hearing loss, bone marrow depression, cardiac arrhythmias, cerebral degeneration, peripheral neuropathies, and damage to the liver, kidneys, or lungs. A characteristic “glue sniffer's rash” around the nose and mouth is sometimes seen after prolonged use. In rare

instances, death may occur, most likely from hypoxemia, cardiac arrhythmias, pneumonia, or aspiration of vomit while unconscious. Detoxification is rarely required for the patient who has abused these substances, but psychiatric treatment may be needed to prevent relapse.

Designer Drugs

The term *designer drug* refers to illicit synthetic drugs, many of which have increased potency in comparison with their parent compounds. The most common designer drugs include analogs of fentanyl, meperidine, piperazine, and methamphetamines. The best-known fentanyl derivatives are α -methyl fentanyl (*China white*), parafluorofentanyl, and 3-methyl fentanyl. Because these drugs are approximately 1000 times as potent as heroin, it is not surprising that fatal overdoses from respiratory depression have been reported.

The major meperidine derivatives are 1-methyl-4-phenyl-4-propionoxypiperidine (MPPP) and 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP), each of which produces euphoria similar to that caused by heroin. In some users, MPTP causes neuronal degeneration in the substantia nigra, which produces an irreversible form of Parkinson's disease.

Piperazines, a new class of designer drugs of abuse, are commonly sold as party pills in the form of tablets, capsules, or powders on the drug black market and in so-called head shops or over the internet under the names of Frenzy, Bliss, Charge, Herbal ecstasy, A2, Legal X and Legal E. 1-Benzylpiperazine (BZP) is the most prevalent of these compounds. Aside from BZP and 1-(3,4-methylenedioxybenzyl) piperazine (MDBP), the phenylpiperazine derivatives 1-(3-trifluoromethylphenyl) piperazine (TFMPP), 1-(3-chloro phenyl) piperazine (mCPP), and 1-(4-methoxyphenyl) piperazine (MeOPP) are often abused. Because piperazines and amphetamines cause similar pharmacologic symptoms, piperazine poisoning can easily be wrongly diagnosed as amphetamine poisoning. Furthermore, piperazines are not detected by routinely used immunochemical screening procedures for drugs of abuse, but they require an appropriate toxicologic analysis (e.g., by gas chromatography-mass spectrometry). The methylenedioxy synthetic derivatives of amphetamine and methamphetamine are generally referred to as *ecstasy* and include 3, 4-methylenedioxy methamphetamine (MDMA, also known as *Adam*); 3, 4-methylenedioxy-ethylamphetamine (MDEA, also known as *Eve*); and N-methyl-1-(3, 4-methylenedioxyphenyl)-2-butanamine (MBDB, also known as *Methyl-J* or *Eden*). These drugs have CNS stimulant and hallucinogenic properties. They produce elevated mood and increased self-esteem and may cause acute panic, anxiety, paranoia, hallucinations, tachycardia, nystagmus, ataxia, and tremor. Deaths in some users have been attributed to cardiac arrhythmias, hyperthermia with seizures, and intracranial hemorrhage.

Prospectus for the Future

Recent research is focused on so-called vaccine strategies, whereby protein-conjugated analogues of cocaine would be

administered to produce anti-cocaine antibodies that bind cocaine, thereby preventing its passage across the blood-brain barrier. A novel pharmacokinetic approach to the treatment of drug toxicity involves the development of compounds that can be administered safely to humans and that accelerate the metabolism of the drug to inactive components. For example, catalytic antibodies have been developed to accelerate cocaine metabolism and are administered parentally. In experimental animals, mutations of human butyrylcholinesterase (one of the enzymes responsible for the metabolism of cocaine) accelerate cocaine metabolism and antagonize cocaine's behavioral and toxic effects.

for heart failure, 62
for hypertension, 173t
in renal artery stenosis, 341-342
in myocardial infarction, 105, 108-109
perioperative, with noncardiac surgery, 275-276
for scleroderma renal crisis, 348
side effects of, 174t
- Angiotensin I, 182, 644f
- Angiotensin II, 58, 182, 642, 644f
- Angiotensin-receptor blockers (ARBs), 62
in chronic kidney disease, 363-364
contraindications to, 174t
in coronary artery disease, 94
for hypertension, 173t
for Raynaud's phenomenon, 791
side effects of, 174t
- Angiotensinogen, 642, 644f
- Anhidrosis, 990
- Animal bites, 887
treatment for, 889-890
- Animal exposure, febrile syndromes associated with, 838t, 841-842
- Anion gap
in chronic kidney disease, 363
metabolic acidosis and, 306, 308-310
- Anisocoria, 1002-1003, 1004f
- Ankle-brachial index, 53-54, 159, 159t
- Ankylosing spondylitis
clinical features of, 777
epidemiology of, 775
inflammatory bowel disease with, 419
- Anomia, 976
- Anorchia, bilateral, 653
- Anosmia, in Kallmann's syndrome, 653
- Anosognosia, 978-979
- Antacids
in critically ill patients, 412
for gastroesophageal reflux disease, 397
in peptic ulcer disease, 407
- Anterior cerebral artery (ACA), stroke associated with, 1035, 1038t
- Anterior horn cell disease, 1015
- Anterior uveitis, spondyloarthritis and, 776, 777f
- Anterograde amnesia, 984
- Anti-glomerular basement membrane antibody, glomerulonephritis and, 321, 322f
- Antiarrhythmic drugs
for atrial fibrillation, 127-128, 128f
characteristics of, 114t
class I, 113
class II, 113
class III, 114-115
- Antiarrhythmic drugs (*Continued*)
class IV, 113
classification of, 112-113, 113t
heart failure and, 64
side effects of, 115t
- Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, 131
- Antibiotic prophylaxis
for infective endocarditis, 882
long-term, neutropenic patients, 946
- Antibiotics, 214
for acute bacterial otitis media, 871
for acute bacterial sinusitis, 868
for acute pancreatitis, 430
in bone and joint infections, 907
for central venous catheter-related bloodstream infections, 883
hepatotoxicity of, 452-453
for infective endocarditis, 881
for peritonitis, 897-898
for pneumonia, 875
- Antibodies, 826
anti- β_2 -glycoprotein I, 568, 570-571
antimicrosomal, 634
platelet, 550
structure of, 826, 827f
- Anticardiolipin antibodies, 568
serologies for, 570-571
thrombocytopenia with, 551
- Anticholinergic agents
for benign prostatic hyperplasia, 722
in chronic obstructive pulmonary disease, 213
for irritable bowel syndrome, 374
- Anticoagulants
endogenous, 539f, 540
natural, inherited deficiency of, 566-567
- Anticoagulation. *see also* Heparin; Warfarin.
in acute limb ischemia, 160-161
in atrial fibrillation, 125-126, 1044
during breast-feeding, 573
in cancer patient, hospitalized, 618
for deep vein thrombosis, 165
in heparin-induced thrombocytopenia, 569
for mitral stenosis, 81-82
perioperative, 573
during postpartum period, 573
with prosthetic heart valves, in pregnancy, 157
in pulmonary arterial hypertension, 164
idiopathic, 241
for pulmonary embolism, 167
in renal vein thrombosis, 351
for spinal cord injury, 1049
in stroke patients, 1044
for stroke prevention, secondary, 1044
venous hemostasis and, 537f
for venous thromboembolism, 571, 572t
- Anticodon, 3
- Anticonvulsants, for neuropathic pain, 1084t
- Anticyclic citrullinated peptide antibodies, in rheumatoid arthritis, 773
- Antidepressant medications
for bipolar disorders, 986
for depression, 987t
for fibromyalgia syndrome, 812
- Antidiarrheal agents, in inflammatory bowel disease, 423
- Antidiuretic hormone (ADH), 287
pituitary gland and, 624
- Antiemetic drugs, with cancer chemotherapy, 591
- Antiepileptic drugs, discontinuing of, 1063
- Antifungal prophylaxis, in neutropenic patients, 946
- Antigen-presenting cells, 284, 825, 827, 828f
for T-lymphocytes, 517
- Antigens, short-chain peptide, 827
- Antiglomerular basement membrane syndrome, 233
- Antihypertensive agents, 173t
for acute severe hypertension, 178, 179t
contraindications and side effects of, 174t
in hypertensive emergencies, 179t
lifetime protection from, 179
- Antimalarial chemoprophylaxis, 953
- Antimicrobial regimen, empirical, in septic patients, 851, 851t
- Antimicrobial stewardship, importance of, 916
- Antimicrobial therapy
for diarrhea, 901t, 903-904
for meningitis, 858-859, 859t
in neutropenia patients, 945-946
- Antimicrosomal antibodies, 634
- Antimyeloma therapy, for amyloidosis, 323-324
- Antineutrophil cytoplasmic antibodies (ANCA), 794-795
associated vasculitides with, 793
diffuse alveolar hemorrhage and, 233
in pulmonary vasculitides, 233
in ulcerative colitis, 420
vasculitides and, 320-321, 321t
- Antinuclear antibodies (ANAs)
low specificity of, 768
in systemic lupus erythematosus, 782
- Antiphospholipid antibodies (APAs), in systemic lupus erythematosus, 781
- Antiphospholipid antibody syndrome (APS), 350, 568
diagnosis of, 568
pregnancy and, 572-573
thrombocytopenia in, 551
thrombosis in, 568
- Antiplatelet therapy, 565, 565t. *see also* Aspirin; Clopidogrel.
in acute coronary syndrome, 101
in coronary artery disease, 94
in myocardial infarction, 108
platelet dysfunction caused by, 554t
for stroke prevention, 1041
- Antipsychotic medications, 988
for bipolar disorders, 986
- Antisense strand, 3
- Antithrombin (AT), 540
deficiency of, 566, 566t
functional, 570-571

CLINICAL **KEY**[™]

Smarter search. Faster answers.

Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ClinicalKey.com for more information and subscription options.
