The main purpose of the gastrointestinal (GI) tract is to digest and absorb major nutrients (fat, carbohydrate, and protein), essential micronutrients (vitamins and trace minerals), water, and electrolytes. Impaired absorption of these nutrients is defined as malabsorption. Under normal conditions, the digestion and absorption of nutrients requires both mechanical and enzymatic breakdown of food. Mechanical processes include chewing, gastric churning, and the to-and-fro mixing in the small intestine. Enzymatic hydrolysis is initiated by intraluminal processes requiring salivary, gastric, pancreatic, and biliary secretions and is completed at the intestinal brush border. The final products of digestion are then absorbed through the intestinal epithelial cells and transported into the portal circulation. The coordinated regulation of gastric emptying, normal intestinal progression, and the presence of adequate intestinal surface area are all important factors. The human gut microbiome, which comprises the communities of microorganisms that inhabit the GI tract, has been recognized to play an important role in nutrient utilization as well. From birth, interactions between the microbiota and the intestinal mucosa contribute to maturation of the host immune system. Disruptions to the homeostasis between the microbiota and the host immune system can lead to increased inflammation and decreased absorption.

Most dietary components can be absorbed anywhere along the length of the small intestine, but there are important exceptions in which absorption is limited to specific areas (e.g., vitamin B₁₂ and cholesterol are absorbed only in the terminal ileum). Diseases associated with diffuse mucosal involvement, such as celiac disease, can lead to impaired absorption of many nutrients, whereas diseases affecting only the terminal ileum can lead to decreased vitamin B₁₂ absorption. Bile acids are necessary for fat absorption; they undergo an enterohepatic circulation with release into bile and reabsorption from the terminal small intestine. Diseases interfering with this mechanism deplete the bile acid pool and can lead to fat malabsorption. Water and electrolytes are absorbed primarily by the colon. In addition, there is

caloric salvage of much of the carbohydrate from indigestible fiber through bacterial enzymatic activity in the colon. The following sections discuss normal assimilation of the major nutrients and the approach to evaluation of patients with suspected malabsorption.

DIGESTION AND ABSORPTION OF FAT

Dietary fat is composed predominantly of triglycerides (~95%) with long-chain fatty acids (16- and 18-carbon molecules). In animal fat, the constituent fatty acids are mostly saturated (e.g., palmitic acid, stearic acid), whereas those of vegetable origin are rich in unsaturated fatty acids (i.e., having one or more double bonds in the carbon chain, such as oleic and linoleic acids). Fats are insoluble in water (hydrophobic), and digestion begins with a process of emulsification, wherein larger fat droplets are dispersed in the aqueous medium of the lumen. In the proximal small intestine, bile salts from liver and pancreatic enzymes are released into the intestinal lumen; there, they mix with and bind to the surface of these globules, where colipase activity results in the release of fatty acids and a monoglyceride. These are taken up as mixed micelles with bile salts, and these hydrophobic particles cross the unstirred water layer that overlies the epithelial brush border.

Within the cell, fatty acids are resynthesized into triglycerides, and, together with cholesterol and phospholipids, they are packaged into chylomicrons and very-low-density lipoproteins to be exported via lymphatic channels. Bile salts remain in the intestinal lumen, are recycled into new micelles, and are finally reabsorbed in the terminal ileum with 95% efficiency. Most dietary lipids are absorbed in the jejunum, together with the fat-soluble vitamins A, D, E, and K. It is recommended that dietary fat account for no more than 35% of calories because higher levels are associated with increased risk of cardiac disease, obesity, and some cancers.

DIGESTION AND ABSORPTION OF CARBOHYDRATES

Most dietary carbohydrates consist of starch (a glucose polymer) and the disaccharides sucrose and lactose, but only monosaccharides are absorbed. Salivary and pancreatic amylases release

oligosaccharides from starch. The final hydrolysis to glucose monomers occurs at the brush border and includes disaccharide hydrolysis by sucrase and lactase. Glucose and galactose are actively transported in conjunction with sodium, whereas fructose absorption occurs by facilitated diffusion. About one half of dietary energy is derived from carbohydrate, with a nutritional goal of 55% and an increased component of insoluble fiber (i.e., that which is indigestible by mammalian enzymes but variably broken down by colonic bacteria.)

DIGESTION AND ABSORPTION OF PROTEINS

Dietary proteins are the major source for amino acids and the only source for the essential amino acids. Digestion starts in the stomach with pepsins secreted by the gastric mucosa, but most of the hydrolysis is accomplished by pancreatic enzymes in the proximal small bowel. The pancreas secretes the proteases trypsin, elastase, chymotrypsin, and carboxypeptidase as inactive proenzymes. Enterokinase (more properly, enteropeptidase) is secreted by the intestinal brush border; it splits trypsinogen to its active form, trypsin, which in turn converts the other proenzymes to their active forms. The products of luminal brush border peptidase digestion consist of amino acids and oligopeptides, which are transported across the epithelial cell. The transfer of most amino acids is sodium dependent and takes place in the proximal small bowel. Dietary requirements for amino acid nitrogen are met with about 15% of calories from protein.

MECHANISMS OF MALABSORPTION

The term *maldigestion* refers to defective hydrolysis of nutrients, whereas *malabsorption* refers to impaired mucosal absorption. In clinical practice, however, *malabsorption* refers to all aspects of impaired nutrient assimilation. Malabsorption can involve multiple nutrients, or it can be more selective. Therefore, the clinical manifestations of malabsorption are highly variable. The complete process of absorption consists of a *luminal phase*, in which

various nutrients are hydrolyzed and solubilized; a *mucosal phase*, in which further processing takes place at the brush border of the epithelial cell with subsequent transfer into the cell; and a *transport phase*, in which nutrients are moved from the epithelium to the portal venous or lymphatic circulation. Impairment in any of these phases can result in malabsorption (Table 33-3).

Luminal Phase

Digestion is accomplished for the most part by pancreatic enzymes, particularly lipase, colipase, and trypsin; the gastric digestive enzymes do not play a major role. As a consequence, chronic pancreatitis can result in malabsorption, particularly for fat and protein. Deficiency in bile salts also contributes to fat malabsorption and may result from cholestatic liver disorders (impaired secretion of bile), bacterial overgrowth (resulting in luminal bile salt deconjugation), or ileal disease or resection with loss of effective enterohepatic circulation of the bile acids. The major part of the luminal phase of digestion occurs in the duodenum and the proximal jejunum.

Mucosal Phase

Mucosal disease is a more common cause of malabsorption. It can result from diffuse small intestinal diseases such as celiac disease or Crohn's disease or from a decrease in surface area (e.g., after surgical resection for small bowel infarction). The net effect is a smaller effective mucosal surface and a relative loss of mucosal absorption. Selective defects in an otherwise normal intestine may result in specific entities such as lactase deficiency or abetalipoproteinemia.

Transport Phase

After absorption, nutrients leave the cells through venous or lymphatic channels. Consequently, malabsorption may be associated with mesenteric venous obstruction, lymphangiectasia, or lymphatic obstruction due to malignancy or infiltrative processes such as Whipple's disease.

TABLE 33-3 PATHOPHYSIOLOGIC MECHANISMS IN MALABSORPTION

LUMINAL PHASE	MUCOSAL PHASE	TRANSPORT PHASE
Reduced nutrient availability	Extensive mucosal loss (resection or infarction)	Vascular conditions (vasculitis; atheroma)
Cofactor deficiency (pernicious anemia; gastric surgery)	Diffuse mucosal disease (celiac disease)	Lymphatic conditions (lymphangiectasia; irradiation; nodal tumor, cavitation, or infiltrations)
Nutrient consumption (bacterial overgrowth)	Crohn's disease; irradiation; infection; infiltrations; drugs: alcohol, colchicine, neomycin, iron salts	
Impaired fat solubilization	Brush border hydrolase deficiency (lactase deficiency)	
Reduced bile salt synthesis (hepatocellular disease)	Transport defects (Hartnup cystinuria; vitamin B ₁₂ and folate uptake)	
Impaired bile salt secretion (chronic cholestasis)	Epithelial processing (abetalipoproteinemia)	
Bile salt inactivation (bacterial overgrowth)		
Impaired cholecystokinin release (mucosal disease)		
Increased bile salt losses (terminal ileal disease or resection)		
Defective nutrient hydrolysis		
Lipase inactivation (Zollinger-Ellison syndrome)		
Enzyme deficiency (pancreatic insufficiency or cancer)		
Improper mixing or rapid transit (resection; bypass; hyperthyroidism)		

Modified from Riley SA, Marsh MN: Maldigestion and malabsorption. In Feldman M, Scharshmidt BF, Sleisenger MH, editors: Sleisenger and Fordtran's gastrointestinal and liver disease: pathophysiology/diagnosis/management, ed 6, Philadelphia, 1998, WB Saunders, pp 1501–1522.

The absorptive process can be impaired at many stages. For example, patients with subtotal gastrectomy or bariatric surgery often experience malabsorption. There are resultant defects at all phases: impaired gastric churning, premature emptying, and impaired mixing (in the jejunum) of food with bile and pancreatic enzymes. The impaired mixing is a consequence of anatomic changes (gastrojejunostomy bypassing the duodenum) and reduced production of pancreatic enzymes (because cholecystokinin and secretin release is blunted when gastric contents bypass the duodenum). Moreover, stasis may lead to bacterial overgrowth in the afferent loop with changes in the bile acids needed for fat absorption. Another example of manifold mechanisms is diabetes mellitus, which may lead to delayed gastric emptying, abnormal intestinal motility, bacterial overgrowth, and pancreatic exocrine insufficiency.

CLINICAL PRESENTATION

The clinical manifestations of malabsorption are usually nonspecific, particularly in the early stages. A change in bowel movements, usually with diarrhea, and weight loss despite adequate food intake may occur in more severe cases. Usually, however, patients have relatively mild symptoms such as bloating and flatulence. Clinical manifestations related to a specific micronutrient deficiency can occur. For example, iron deficiency anemia may be the only manifestation of celiac disease in some patients. Muscle wasting and edema result from protein malabsorption. Nutritional anemia, caused by deficiencies of iron, folate, and vitamin B₁₂, contributes to fatigue. Bleeding tendency (e.g., ecchymosis) may be attributed to prolonged prothrombin time resulting from vitamin K deficiency related to fat malabsorption. Bulky, oily stools are the hallmark of steatorrhea resulting from fat malabsorption, whereas bloating (abdominal distention) and soft diarrheal movements occur as a result of carbohydrate malabsorption. Signs associated with malabsorption are presented in Table 33-4.

DIAGNOSIS

Malabsorption can be caused by a large number of disorders, and some of the more common of which are listed in Table 33-4. The cause of malabsorption can often be determined by a very detailed patient history. However, because the clinical symptoms are varied, more specific assays of albumin, cobalamin, iron, cholesterol, calcium, folic acid, and prothrombin time are useful to support the diagnosis of malabsorption. These tests are helpful in assessing the severity of malabsorption, but they are not specific for the differential diagnosis. Many tests are available in the work-up of malabsorption; those that have been most useful clinically are discussed in the following sections (Fig. 33-3).

Fecal Fat Analysis

If fat malabsorption is suspected, the simplest qualitative method for detecting fat in stool is microscopic examination with Sudan staining of a drop of stool. Sensitivity is limited, but the test is quick and easy, and it correlates well with the quantitative measurement of fecal fat when moderate to severe steatorrhea is present. To quantify fat, stool is collected for three consecutive days while the patient is on a diet containing 100 g of fat per day,

TABLE 33-4 SIGNS ASSOCIATED WITH MALABSORPTION SYNDROMES

SIGNS	ASSOCIATED SYNDROMES
GASTROINTESTINAL	
Mass	Crohn's disease, lymphoma, tuberculosis, glands
Distention	Intestinal obstruction, gas, ascites, pseudocyst (pancreatic), motility disorder
Steatorrheic stool	Mucosal disease, bacterial overgrowth, pancreatic insufficiency, infective or inflammatory, drug induced
EXTRAINTESTINAL	
Skin	
Nonspecific	Pigmentation, thinning, inelasticity, reduced subcutaneous fat
Specific	Blisters (dermatitis herpetiformis), erythema nodosum (Crohn's disease), petechiae (vitamin K deficiency), edema (hypoproteinemia)
Hair	
Alopecia	Gluten sensitivity
Loss or thinning	Generalized inanition, hypothyroidism, gluten sensitivity
Eyes	
Conjunctivitis, episcleritis	Crohn's disease, Behçet's syndrome
Paleness	Severe anemia
Mouth	
Aphthous ulcers	Crohn's disease, gluten sensitivity, Behçet's syndrome
Glossitis	Deficiencies of vitamin B ₁₂ , iron, folate, niacin
Angular cheilosis	Deficiencies of vitamin B ₁₂ , iron, folate, B complex
Dental hypoplasia (pitting, dystrophy)	Gluten sensitivity
Hands	
Raynaud's phenomenon	Scleroderma
Finger clubbing	Crohn's disease, lymphoma
Koilonychia	Iron deficiency
Leukonychia	Inanition
Musculoskeletal	
Monoarthropathy and polyarthropathy	Crohn's disease, gluten sensitivity, Whipple's disease, Behçet's syndrome
Back pain (osteomalacia, osteoporosis, sacroiliitis)	Crohn's disease, malnutrition, gluten sensitivity
Muscle weakness (low potassium, magnesium, vitamin D, generalized inanition)	Diffuse mucosal disease, bacterial overgrowth, lymphoma
Nervous System	
Peripheral neuropathy (weakness, paresthesias, numbness)	Vitamin B ₁₂ deficiency
Cerebral (seizures, dementia, intracerebral calcification, meningitis, pseudotumor, cranial nerve palsies)	Whipple's disease, gluten sensitivity, diffuse lymphoma

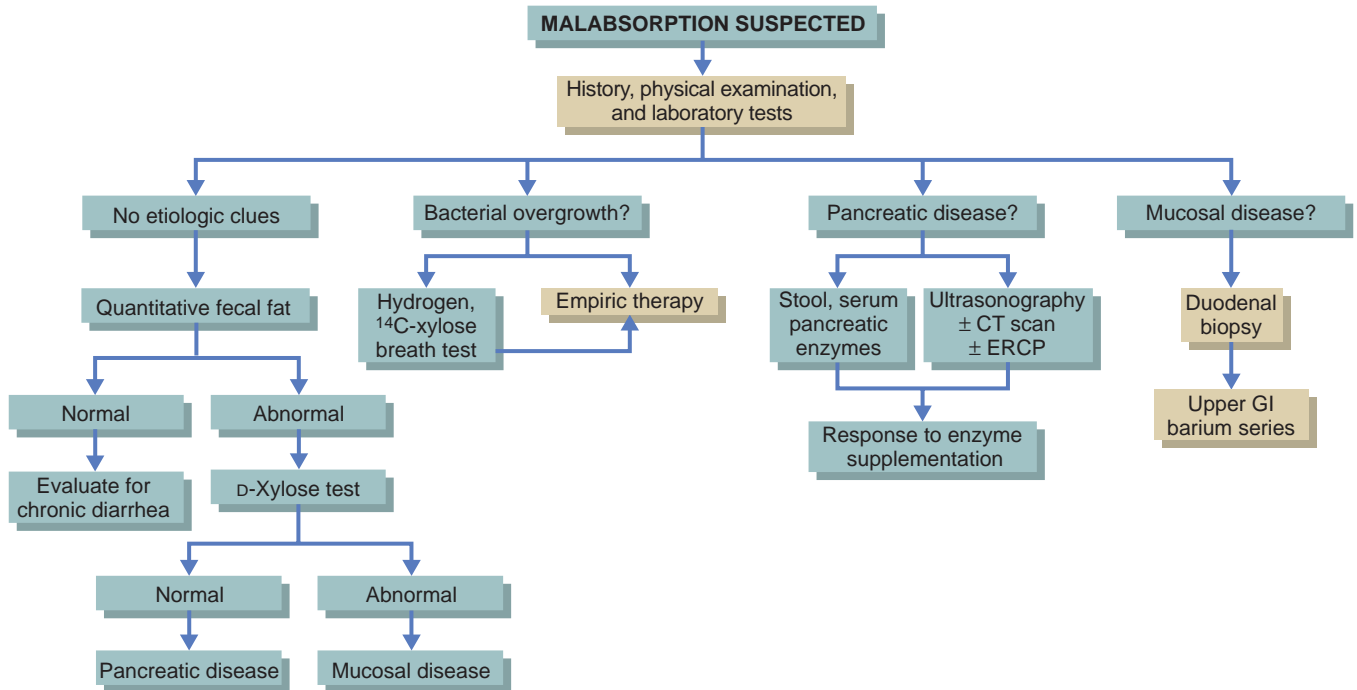

FIGURE 33-3 Approach to the patient with suspected malabsorption. CT, Computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; GI, gastrointestinal. (Modified from Riley SA, Marsh MN: Maldigestion and malabsorption. In Feldman M, Scharschmidt BF, Sleisenger MH, editors: Sleisenger and Fordtran's gastrointestinal and liver disease: pathophysiology/diagnosis/management, ed 6, Philadelphia, 1998, WB Saunders, pp 1501–1522.)

and the specimen is analyzed for fat content. Normal fat excretion should not exceed 6 g/day. Although this test is cumbersome and nonspecific, it offers an accurate quantification of fecal fat excretion provided fat consumption is appropriate.

Tests of Pancreatic Exocrine Function

Aspiration of duodenal contents for evaluation of bicarbonate and enzyme output after stimulation of the pancreas may be the best index of pancreatic exocrine function. However, the test is invasive, is time-consuming, and is performed only in a few specialized centers. The measurement of pancreatic enzymes (i.e., fecal elastase 1) in the stool is simple and provides helpful laboratory evidence for the diagnosis of moderate to severe pancreatic insufficiency. Pancreatic calcifications seen on abdominal films or computed tomography (CT) scans indicate the presence of chronic pancreatitis. Magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) can help outline abnormal duct anatomy and may supplement CT scanning for diagnostic purposes to evaluate the sequelae of chronic pancreatitis. However, normal findings on pancreatography do not exclude the presence of pancreatic exocrine insufficiency.

Small Intestinal Biopsy

Whereas the gross appearance of the mucosa during upper GI endoscopy can provide some clues regarding the presence of a disease causing malabsorption, biopsy of the small intestinal mucosa is a key diagnostic test for diseases that affect the cellular phase of absorption. In some diseases, the histologic features are diagnostic; in others, the findings may be highly suggestive (Table 33-5). Several tissue samples should be taken from the

TABLE 33-5 UTILITY OF SMALL BOWEL BIOPSY SPECIMENS IN MALABSORPTION

FINDINGS OFTEN DIAGNOSTIC	FINDINGS ABNORMAL BUT NOT DIAGNOSTIC
Whipple's disease	Celiac disease
Amyloidosis	Systemic sclerosis
Eosinophilic enteritis	Radiation enteritis
Lymphangiectasia	Bacterial overgrowth syndrome
Primary intestinal lymphoma	Tropical sprue
Giardiasis	Crohn's disease
Abetalipoproteinemia	
Agammaglobulinemia	
Mastocytosis	

Data from Trier JS: Diagnostic value of peroral biopsy of the proximal small intestine, *N Engl J Med* 285:1470, 1971.

duodenal bulb and from the distal duodenum to enhance the diagnostic accuracy.

Imaging Studies

In patients with malabsorption, barium studies of the small bowel are usually nonspecific. Occasionally, however, distinct anatomic changes are seen, such as in jejunal diverticulosis, lymphoma, Crohn's disease, strictures, or enteric fistulas. Also, there may be a distinctive barium pattern of thin-walled, dilated loops suggestive of celiac disease. CT and magnetic resonance enterography provide a more detailed imaging of the small intestine and are more sensitive in identifying abnormalities such as active bowel inflammation, mesenteric stranding and edema, strictures, fibrofatty proliferation of the mesentery, and fistula formation.

Wireless capsule endoscopy is a noninvasive method that permits direct visualization of the small bowel mucosa and can provide a more detailed evaluation of small bowel disease

compared with radiographic studies. However, capsule endoscopy should be avoided in patients in whom a stricture is suspected because of the risk of retention. The detection of mucosal lesions by the capsule endoscopy can often be followed by deep enteroscopy (double-balloon endoscopy, single-balloon endoscopy, or spiral enteroscopy), allowing for tissue biopsy, tattoo placement before surgery, balloon dilatation, and foreign body retrieval.

Schilling Test

Vitamin B₁₂ is an essential micronutrient, and its absorption requires several steps. First, the ingested vitamin binds to salivary R-factor protein. In the stomach, gastric parietal cells secrete intrinsic factor, which mixes with the ingested meal. In the duodenum, pancreatic trypsin hydrolyzes the R protein, freeing the vitamin to bind with intrinsic factor. The vitamin B₁₂-intrinsic factor complex is then absorbed by specific receptors that are found only on enterocytes in the distal ileum. Malabsorption of vitamin B₁₂ can occur because of lack of intrinsic factor (e.g., pernicious anemia, gastric resection), pancreatic insufficiency, bacterial overgrowth, or ileal resection or mucosal disease (e.g., Crohn's disease).

The Schilling test quantifies vitamin B₁₂ absorption using radiolabeled vitamin B₁₂ as a marker. The test may be expanded to several stages to amplify its diagnostic spectrum. In stage 1, after the injection of 1000 µg of unlabeled vitamin B₁₂ to saturate hepatic storage, the patient ingests 0.5 µg of radiolabeled vitamin. Urine is then collected for the measurement of radioactivity; reduced radioactivity suggests B₁₂ malabsorption. The test is repeated (stage 2) with the addition of oral intrinsic factor to the ingested vitamin B₁₂. If urinary excretion of the radiolabel is corrected, pernicious anemia is diagnosed. If malabsorption is still present, the patient is given a short course of oral antibiotics (stage 3), and the test is repeated; correction of radiolabeled B₁₂ excretion establishes bacterial overgrowth. If the test result remains abnormal, oral pancreatic enzymes are given (stage 4), and the test is repeated; correction of the abnormality at this stage implies pancreatic deficiency. Finally, if all these interventions fail, ileal disease or absence of transcobalamin protein is determined by other diagnostic tests. This long outline serves as merely an example of an algorithm of clinical analysis; the usual routine in clinical settings is to administer parenteral vitamin B₁₂ while the etiology is delineated by other modalities.

D-Xylose Test

The D-xylose test serves as an indicator of mucosal absorption in the proximal small bowel and is used to determine whether defects in the epithelium of the intestine are responsible for malabsorption. D-Xylose is a 5-carbon monosaccharide that is transported across the intestinal mucosa largely by passive diffusion. In this test, the subject ingests 25 g of D-xylose, and urine is collected for the next 5 hours. Healthy subjects excrete more than 4.5 g of D-xylose in 5 hours (or ≥20% of the ingested load). Excretion of a lower amount of D-xylose suggests abnormal absorption. However, an abnormally low (false-positive) result may occur in the presence of impaired renal excretory function, gastroparesis, massive peripheral edema, or ascites. Abnormal results can also be seen in the presence of bacterial overgrowth

as a result of bacterial degradation of D-xylose in the lumen, but this "pseudomalabsorption" may be corrected after treatment with antibiotics serving as a therapeutic trial.

Breath Tests

Breath tests rely on bacterial degradation of luminal compounds, which releases metabolic byproduct gases (e.g., hydrogen, methane, carbon dioxide) that can be measured in the exhaled breath. In the case of disaccharidase deficiency, a specific disaccharide (e.g., lactose) that is orally ingested but not properly absorbed in the small intestine is delivered to the colon, where bacterial fermentation liberates metabolites; hydrogen gas is the marker assayed in the breath. In the presence of bacterial overgrowth of the small intestine, orally ingested glucose ferments in the proximal small bowel (instead of being absorbed), resulting in increased hydrogen in the breath; here, the timing of exhaled hydrogen aids in the diagnosis. The measurement of radioactive carbon dioxide in the breath after ingestion of a nutrient labeled with carbon 14 (¹⁴C) has been used to estimate the malabsorption of fat or bile acids and for measurement of bacterial overgrowth (¹⁴C-xylose). The radioactive tests are cumbersome, and their usefulness in clinical practice is limited.

The overlap of symptoms and the large number of diagnostic tests available for evaluation of malabsorption necessitate the use of a systematic approach and a rational algorithm (see Fig. 33-3). The most accurate test for fat malabsorption remains the 72-hour fecal fat analysis; however, the test is difficult to carry out in clinical practice. Surrogate screening for steatorrhea is done with the qualitative stool fat examination (Sudan stain) and measurement of serum carotene. If the stool fat content is normal, the patient may still have selective impairment of absorption of a specific carbohydrate. This latter condition should be suspected if the primary symptoms are cramps, flatulence, and diarrhea. The most common example of carbohydrate malabsorption is lactose intolerance; specific tests include the oral lactose tolerance test, but measurement of breath hydrogen is more sensitive and more specific.

More generally, an osmotic gap in fecal water suggests a dietary (rather than a secretory) cause of the diarrhea related to luminal short-chain fatty acids or carbohydrates. The osmotic gap is calculated by the following formula:

$$\text{Osmotic gap} = \text{Plasma osmolality} - [2 \times (\text{fecal } [\text{Na}^+] + \text{fecal } [\text{K}^+])]$$

The osmotic gap is not calculated by directly measuring stool osmolality because it increases with time in the specimen container. In addition, luminal osmolality is equal to serum osmolality because the colon cannot establish a gradient against the serum concentration of solutes.

When fat malabsorption is demonstrated (>6 g/24 hours, or increased qualitative stool fat and decreased serum carotene), a D-xylose absorption-excretion test should be performed next. A normal D-xylose test result makes diffuse mucosal disease unlikely and suggests maldigestion, principally pancreatic enzyme or bile salt deficiency. Clues to chronic pancreatitis include a history of alcohol abuse or previous episodes of pancreatitis. Unusual causes of pancreatic malabsorption, such as cystic fibrosis, micro-lithiasis, or drug toxicity, require specific testing and a detailed history. Serum enzyme tests and abdominal imaging (plain films

or, with much greater sensitivity, abdominal CT scans) can be obtained next to identify pancreatic disease. If the urinary D-xylose excretion is abnormal, the breath hydrogen test may be used to diagnose bacterial overgrowth using glucose for the carbohydrate load. If no bacterial overgrowth is present, a mucosal biopsy should be performed (see Table 33-5). Imaging studies of the small bowel may be helpful on occasion.

If the cause of malabsorption remains unclear, other considerations should include parasitic infection, such as *Giardia lamblia*, or ascariasis involvement of the pancreatic duct (more common in undeveloped countries). These diagnoses require a careful stool examination for ova and parasites or fecal antigen studies.

TREATMENT

The specific treatment of malabsorption depends on identification of the underlying condition. Occasionally, therapeutic trials for treatable conditions should be instituted, such as a gluten-free diet for celiac disease, pancreatic enzyme replacement for pancreatic exocrine malfunction, metronidazole for *G. lamblia* infection, or broad-spectrum antibiotics for suspected bacterial overgrowth. Parenteral nutrition may have a role in maintaining adequate nutritional status. Treatment modalities are discussed in later chapters focusing on specific diseases. Two disorders, celiac disease and bacterial overgrowth, are discussed here as illustrative of the pathophysiology.

Celiac Disease

Celiac disease (also called celiac sprue, nontropical sprue, or gluten-sensitive enteropathy) is characterized by intestinal mucosal injury resulting from gluten-related immunologic damage in persons genetically predisposed to this condition. The prevalence of the disease among relatives of patients with celiac disease is approximately 10%. There is a strong association of celiac disease with human leukocyte antigen (HLA) class II molecules, particularly HLA-DQ2 and HLA-DQ8. The disease is induced by exposure to storage proteins found in grain plants such as wheat (which contains gliadin), barley, and rye and their products. Oats are implicated, not because of gliadin, but because of contamination with wheat during packaging and transportation. The exposure initiates a cellular immune response that results in mucosal damage, particularly in the proximal intestine. Results of investigations suggest that an enzyme, tissue transglutaminase, may be the autoantigen of celiac disease.

Clinical Presentation

Celiac disease can manifest with the classic constellation of symptoms and signs of a malabsorption syndrome. Not uncommonly, however, the manifestation is atypical, with nonspecific GI symptoms such as bloating, chronic diarrhea (with or without steatorrhea), flatulence, lactose intolerance, or deficiencies of a single micronutrient (e.g., iron deficiency anemia). Extraintestinal complaints such as depression, weakness, fatigue, arthralgias, osteoporosis, or osteomalacia may predominate. A number of diseases, including dermatitis herpetiformis, type 1 diabetes mellitus, autoimmune thyroid disease, and selective immunoglobulin A (IgA) deficiency, are found in significant association with celiac disease.

Diagnosis

Celiac disease is a leading consideration in every patient with the malabsorption syndrome, and it should be included as well in the differential of atypical manifestations. Fiberoptic or capsule endoscopy may show the typical features of broad and flattened villi; with the former instrument, tissue can be sampled for histologic analysis. Intestinal biopsy is the most valuable test in establishing the diagnosis. The spectrum of pathologic changes ranges from normal villous architecture with an increase in mucosal lymphocytes and plasma cells (the infiltrative lesion) to partial blunting or total villous flattening. Although abnormal biopsy findings are not specific, they are highly suggestive, particularly because most other conditions that can mimic celiac disease (e.g., Crohn's disease, gastrinoma, lymphoma, tropical sprue, graft-versus-host disease, immune deficiency) may be distinguished clinically. A clinical response to a gluten-free diet establishes the diagnosis and precludes the need, in adults, to document healing by repeated biopsies. Serologic blood tests (antigliadin, antiendomysial, and reticulin antibodies) are helpful in screening of patients with atypical symptoms and asymptomatic relatives of patients with celiac disease.

Treatment

Strict, lifelong adherence to a gluten-free diet is the only treatment for celiac disease. Specific nutritional supplementation should be provided to correct deficiencies, particularly those of iron, vitamins, and calcium. A clinical response may be seen within a few weeks. Patients should be monitored to ensure adequate response and proper adherence to the diet. The long-term prognosis is excellent for patients who adhere to the diet, although there may be a slight increase in the incidence of malignancies, particularly lymphoma.

Bacterial Overgrowth Syndrome

The proximal small bowel normally contains fewer than 10^4 bacteria per milliliter of fluid, with no anaerobic *Bacteroides* organisms and few coliforms. Overgrowth of luminal bacteria can result in diarrhea and malabsorption by a number of mechanisms, including (1) deconjugation of bile salts, which leads to impaired micelle formation and impaired uptake of fat; (2) patchy injury to the enterocytes (small intestinal epithelial cells); (3) direct competition for the use of nutrients (e.g., uptake of vitamin B₁₂ by gram-negative bacteria or the fish tapeworm *Diphyllobothrium latum*); and (4) stimulated secretion of water and electrolytes by products of bacterial metabolism, such as hydroxylated bile acids and short-chain (volatile) organic acids.

Conditions Associated with Bacterial Overgrowth

The most important factors maintaining the relative sterility of the upper gut are gastric acidity, peristalsis, and intestinal immunoglobulins (IgA). Conditions that impair these functions can result in bacterial overgrowth. Impaired peristalsis may be caused by motility disorders (e.g., scleroderma, amyloidosis, diabetes mellitus) or by anatomic changes (e.g., surgically created blind loops, obstruction, jejunal diverticulosis). Achlorhydria, pancreatic insufficiency, and hypogammaglobulinemia are also

associated with bacterial overgrowth but uncommonly result in clinical steatorrhea.

Diagnosis

Direct culture of jejunal aspirate is the most definitive diagnostic test, but it is invasive, uncomfortable, and costly. The ^{14}C -xylose breath test is an accurate and sensitive laboratory test; measurement of breath hydrogen after an oral challenge with glucose is simpler but not as sensitive or as specific. An empirical therapeutic trial with antibiotics is an acceptable alternative to diagnostic testing.

Treatment

When appropriate, specific therapy, such as surgery for intestinal obstruction, should be provided. More commonly, patients are treated with antibiotics, most appropriately those that are effective against aerobic and anaerobic enteric organisms. Tetracycline, trimethoprim-sulfamethoxazole, or metronidazole, in combination with a cephalosporin or quinolone,

are suitable agents. A single course of therapy for 7 to 10 days may be therapeutic for months. In other patients, intermittent therapy (one week of every four) or even an extended period of continuous therapy proves to be most effective.

MALABSORPTIVE THERAPY

Cardiovascular disease and other consequences of obesity have reached epidemic proportions in the United States, and one approach to this problem has been the deliberate induction of malabsorption (primarily of fats) to reduce a patient's lipid levels and body mass index. Medications used for this purpose includes bile acid-binding resins, such as cholestyramine and colestipol, and the lipase inhibitors, orlistat (Xenical) and ezetimibe (Zetia). Surgical treatment (bariatric operations) usually consists of gastric partition combined with some degree of small intestinal bypass, which induces significant weight loss by several proposed mechanisms, including malabsorption, improved nutrient deposition, and enhanced satiety.

D. Diarrhea

John S. Maxwell and M. Michael Wolfe

DEFINITION

The average number of bowel movements for the normal adult can range from three per day to three per week. Diarrhea can be defined as increased frequency of stools with decreased consistency and increased volume, but the subjective nature of these complaints and lack of fixed normal values make the definition difficult. The 1997 position statement by the American Gastroenterological Association on chronic diarrhea defines diarrhea as the production of loose stools with or without increased stool frequency. There are also definitions that include fecal weight, which in the United States averages less than 200 g/24 hours but varies according to the type of diet. The 2003 guidelines for the investigation of chronic diarrhea define diarrhea as the abnormal passage of loose or liquid stool more than three times a day or a stool volume greater than 200 g/day or both. Because of the subjective nature of the complaints, a detailed history is needed to arrive at a diagnosis (Table 33-6).

The duration of symptoms is useful in the differential diagnosis of diarrhea and is a part of the necessary history. Acute diarrhea is limited to 2 weeks or less and is usually infectious in origin. Persistent diarrhea persists for longer than 14 days, and chronic diarrhea is considered to last longer than 4 weeks. As time goes on, its etiology is less likely to be infectious.

PHYSIOLOGY

Approximately 8 to 9 L of fluid enters the small bowel in a 24-hour period. This includes 1 to 2 L from dietary consumption, with the remainder produced by salivary, gastric, biliary, pancreatic, and intestinal secretions. All but 1 to 2 L is absorbed in the small intestine and then enters the colon. Almost all of this fluid is absorbed as it travels through the colon, leaving less than 200 g/day of stool. Disruption of the absorption of ions, solutes,

and water or increased secretion of electrolytes results in water accumulation in the lumen and therefore diarrhea.

ACUTE DIARRHEA

Most cases of acute diarrhea are caused by viral or bacterial infections and are self-limited, resolving without specific therapy. Acute diarrhea in Western countries is common and occurs at a rate of about one episode per person per year. It tends to occur in outbreaks involving food or waterborne contamination or recurrently in specific groups, such as people who care for infants, small children, travelers, and immunocompromised individuals.

TABLE 33-6 CLASSIFICATION OF DIARRHEA

TYPE	PRESENTATION	CAUSE
Acute (duration <2 wk)	Usually mild; wide range of symptoms	Most commonly infectious
Chronic (duration >4 wk)		
Secretory	Large volume, watery stool No change with fasting	Cholera, neuroendocrine tumors, drugs, nonosmotic laxatives, bile salts, bacterial toxins
Osmotic	Watery stool Stops with fasting	Carbohydrate malabsorption laxatives (Mg, PO ₄)
Inflammatory	Bloody, mucous diarrhea Frequent, urgent small stools	Infectious colitis IBD, invasive bacteria
Motility	Soft to watery stools	IBS Bacterial overgrowth Hyperthyroidism Scleroderma
Steatorrhea	Greasy, malodorous	Malabsorption: celiac disease, short bowel syndrome, maldigestion, fistula

IBD, Inflammatory bowel disease; IBS, irritable bowel syndrome.

Most of the deaths associated with acute diarrhea occur in elderly persons because of the physiologic changes of aging that include abnormalities in water homeostasis and decreased thirst perception. Because of volume depletion, elderly patients are at increased risk for falls due to orthostatic hypotension, electrolyte disturbances, and delirium.

Most cases of acute diarrhea are caused by viral infection; studies of acute diarrhea show positive bacterial cultures in only 1.5% to 5.6% of cases. Viruses commonly causing acute infectious diarrhea include noroviruses, rotaviruses, and adenoviruses. The symptoms typically last approximately 48 hours and clear spontaneously.

Bacterial causes of acute infectious diarrhea include *Salmonella*, *Campylobacter*, *Shigella*, enterotoxigenic *Escheria coli*, and *Clostridium difficile*. These are the likely causes of most severe cases of acute diarrhea. Among patients with diarrhea lasting longer than 3 days and high outputs, a bacterial cause was found in 87% of cases. Protozoa are infrequent causes of acute diarrhea.

Because of the short duration of symptoms, good prognosis, and high frequency of viral etiologies found in acute diarrhea, clinical investigation is not needed and is not cost-effective in most cases. The indications warranting a complete evaluation involve clinical signs of severe illness: profuse watery diarrhea and hypovolemia; frequent passage of small-volume, bloody stools containing mucus; bloody diarrhea; fever greater than 101° F; illness lasting longer than 48 hours; severe abdominal pain; hospitalization; recent use of antibiotics; age greater than 70 years; immunocompromise; and systemic illness and diarrhea in pregnancy (listeriosis).

Items from the history that might be helpful to the diagnosis include information regarding travel, work exposure, and pets. Fever usually indicates an invasive organism, such as *Salmonella*, *Shigella*, *Campylobacter*, certain viruses, *Entamoeba histolytica*, or *C. difficile*. Risk factors include food consumption or preparation involving raw or undercooked meats and dairy products or contaminated fruits and vegetables. Pregnant women have a 20-fold increased risk of developing listeriosis from meat or unpasteurized milk, and this bacterial infection always needs to be considered in a pregnant woman with diarrhea and systemic complaints. Ingestion of preformed bacterial toxins from *Staphylococcus aureus*, *Bacillus cereus*, or *Clostridium perfringens* typically causes diarrhea within 6 hours. Acute traveler's diarrhea is most commonly caused by enterotoxigenic *E. coli*.

Infectious agents sometimes can cause mucosal inflammation ranging from mild to severe. These include noroviruses, rotaviruses, and the human immunodeficiency virus (HIV). Bacterial mucosal invasion can be present with *Salmonella*, enteroinvasive *E. coli*, *Campylobacter jejuni*, and *Yersina enterocolitica*; *E. histolytica*, *C. difficile*, *Shigella* spp., *E. coli* O157:H7, *Vibrio*, and *Aeromonas* secrete toxins and invade the mucosa. Patients often relate a history of initially watery diarrhea later progressing to bloody diarrhea.

Noninfectious causes of acute diarrhea are less common. They can include irritable bowel syndrome (IBS), inflammatory bowel disease (IBD), ischemic bowel disease (either ischemic colitis or mesenteric vascular insufficiency), partial bowel obstruction, fecal impaction with overflow diarrhea, and bacterial overgrowth. Most often, these disorders manifest as persistent or

chronic diarrhea, but they do have a specific onset. Medications and over-the-counter supplements can be a cause of acute or chronic diarrhea, and the diagnosis may be suggested by introduction of a new medication or an increase in dose. Frequently, oral magnesium replacement, donepezil hydrochloride (Aricept), tube feedings, liquid medications, and chewing gum made with nonabsorbable sugars (e.g., sorbitol) are associated with diarrhea. An accurate medication history (prescription and over-the-counter), including supplements, is necessary.

Evaluation of Acute Diarrhea

Most patients with acute diarrhea do not require a detailed evaluation because their illness is neither severe nor prolonged. There is significant cost involved in laboratory testing, cultures, and procedures, and because a viral infection is responsible for most cases, the results will be unrevealing. These patients typically have watery, nonbloody diarrhea and are not systemically ill. Many patients with traveler's diarrhea have large-volume watery diarrhea due to enterotoxigenic *E. coli*. Some patients who have severity indicators in their history or examination findings, or who are elderly or immunocompromised, should have a laboratory evaluation.

Patients with bloody, frequent, small-volume stools should be evaluated for potential bacterial causes. The same is true for patients who have systemic symptoms (e.g., abdominal pain, fever), fecal leukocytes, an elevated fecal lactoferrin level (a marker for leukocytes), or occult blood in the stool. Stool cultures should be done to look for *Shigella*, *Samonella*, *Campylobacter*, and enterohemorrhagic *E. coli*. Identification of *Listeria*, *Yersinia*, and *Vibrio* may require additional testing. Stool should be evaluated for ova and parasites if cultures are negative and if there is persistent diarrhea or a history HIV/AIDS. *Giardia* and *Cryptosporidium* immunoassays and staining for *Microsporidium* are also indicated in these individuals and in patients with a possible exposure history. Because of the risk of community-acquired *C. difficile* infection, testing should be done for the presence of this organism even without a history of antibiotic use.

Finally, if there are no definitive results from the stool studies, endoscopic imaging with either flexible sigmoidoscopy or colonoscopy may be required to evaluate for IBD, ischemic colitis, or cytomegalovirus colitis in immunocompromised patients. Despite an extensive evaluation, no cause can be determined in 20% to 40% of cases.

Treatment

Treatment of acute diarrhea begins with general supportive measures. The most important therapy is hydration, which is best accomplished by the oral route, although intravenous hydration is more frequently used in the United States. Proper oral hydration could decrease the admission rate for children in the United States by at least 100,000 patients per year. Oral hydration solutions are effective because in many small bowel diarrheal illnesses, the intestine remains able to absorb water if glucose and salt are present to allow transport of water from the lumen. The World Health Organization formula that is recommended for oral rehydration consists of the following components:

NaCl 2.6 g (0.092 ounce)

Trisodium citrate dihydrate 2.9 g (0.10 ounce)

KCl 1.5 g (0.053 ounce)

Anhydrous glucose 13.5 g (0.48 ounce) or sucrose 27 g (0.96 ounce)

1 L water

This formula can easily be made and also is commercially available. Drinks made for perspiration replacement, such as Gatorade, are not the same as the hydration fluid but can be used if the individual is not volume depleted.

Antibiotics are not required in most cases but are a consideration in specific circumstances. The inability to obtain immediate results from cultures for enteric pathogens often necessitates a decision regarding empiric antibiotic therapy. In general, empiric antibiotics do not significantly affect the course of acute diarrhea. In one study in which all patients were culture positive, there was a 1-day benefit for those receiving antibiotic treatment compared with nontreatment. Among those who were severely ill, the results were better: 1.5 days for resolution in the treated group compared to 3.4 days in the untreated group.

Antibiotics should be avoided in patients with enterohemorrhagic *E. coli* because no benefit has been demonstrated and there may be an increased risk of hemolytic-uremic syndrome related to increased release of Shiga toxin. These patients often have bloody diarrhea and abdominal pain but no fever. If antibiotics have been started, they should be discontinued if culture results show *E. coli* O157:H7. There is also no clinical improvement with antibiotic treatment of nontyphoid *Salmonella* gastroenteritis, and the clearance of bacteria from the stool may be prolonged.

Symptomatic Therapy

Dietary changes usually do not need to be drastic. The patient should be encouraged to take clear liquids and perhaps soft and low-fiber foods, which will aid in hydration and supply some calories for baseline energy requirements and enterocyte renewal. Milk should be avoided because of possible temporary lactose intolerance due to mucosal injury. Caffeine and ethanol should also be avoided because they stimulate intestinal motility.

In patients with acute diarrhea who do not have bloody diarrhea or fever, loperamide (Imodium), diphenoxylate-atropine (Lomotil), or tincture of opium can decrease the frequency of watery stools. These agents also possess antisecretory properties, and they inhibit intestinal motility, thereby allowing more intestinal absorption. The usual dose of loperamide should not exceed 8 2-mg tablets per day and diphenoxylate should not exceed 8 5-mg tablets per day. Diphenoxylate and tincture of opium have central-acting opioid effects and can cause unwanted side effects, particularly in the elderly. These drugs also are associated with increased risk of hemolytic-uremic syndrome in patients with enterohemorrhagic *E. coli* infections. The use of probiotics to repopulate intestinal flora in infectious diarrhea has not been well studied.

CHRONIC DIARRHEA

The evaluation of chronic diarrhea is more variable, and the establishment of universal guidelines is more difficult, reflecting in part the many potential causes. Diarrhea may result from colonic inflammation, colonic neoplasia, small bowel inflammation, malabsorption due to small bowel mucosal disorders,

malabsorption due to pancreatic insufficiency, motility disorders, and functional bowel disorders.

Chronic diarrhea is a common reason for referral to a gastroenterology clinic, but the true incidence is difficult to estimate because of differing definitions and populations. In one study, the estimated prevalence of chronic diarrhea in the elderly population was between 7% and 14%, but that study also included functional bowel disorders. Another estimate excluding abdominal pain placed the prevalence at 4% to 5%. Chronic diarrhea certainly can affect the quality of life, and any clinician who cares for these patients has heard of patients being housebound because of a fear of diarrhea and incontinence.

Evaluation of Chronic Diarrhea

Because of the myriad causes and differing severities, optimal guidelines are not established. Most recommendations are based on expert opinion and may include bias as a result of the types of referrals or regional differences. A thorough history and physical examination are essential. The history should try to establish the likelihood of organic versus functional disorders, to differentiate malabsorptive from inflammatory etiologies, and to determine the cause of the diarrhea. Consequently, important parts of the history include the following:

1. Character of the onset of diarrhea—sudden or gradual
2. Continuous versus intermittent symptoms
3. The presence of nocturnal diarrhea
4. Duration of diarrhea
5. Epidemiology—travel, exposure to contaminated food or water, family members with similar illness
6. Stool characteristics—watery, bloody, greasy
7. Fecal incontinence versus diarrhea or both
8. Abdominal pain—IBD, IBS, mesenteric vascular insufficiency
9. Weight loss—often significant in malabsorption, IBD, ischemia, and neoplasm
10. Aggravating factors—stress, specific foods (e.g., milk)
11. Prior evaluations to avoid repeating tests
12. Mitigating factors—what the patient has tried to control the diarrhea
13. Previous operations, radiation therapy, medications, supplements
14. Factitious diarrhea—always a consideration in eating disorders, malingering, or secondary gain
15. Review of systems—hyperthyroidism, scleroderma, tumor syndromes, diabetes mellitus
16. Risk factors for HIV and other immunosuppressed states

Physical examination rarely provides a specific diagnosis, but it does allow an assessment of fluid status and nutritional status. Some helpful findings include mouth ulcers or perianal disease that suggest the possibility of IBD, rashes or flushing, abdominal mass, and findings of hyperthyroidism.

Some causes are related to socioeconomic status. In contrast to acute diarrhea, infectious causes of chronic diarrhea are unusual in the United States, although they are frequently encountered in developing countries. Infectious causes are a concern in newly arrived immigrants or travelers. Occasionally,

persisting infections such as *Giardia*, *Entamoeba*, *C. difficile*, *Aeromonas*, *Plesiomonas*, *Cryptosporidium*, *Tropheryma whipplei* (Whipple's disease), *Blastocystis hominis*, and *Cyclospora* can cause chronic diarrhea. In addition, up to 30% of patients with these infections develop postinfectious IBS as a cause of their chronic diarrhea.

Patients with diarrhea-predominant IBS can have a wide variety of symptoms, but the main complaints are usually chronic abdominal pain and altered bowel movements. These patients complain of small-volume, frequent diarrhea, often with interspersed normal or constipated stools. They may report marked urgency as well as a feeling of incomplete evacuation. Approximately one half of these patients have mucus in the stools. Large-volume diarrhea, bloody diarrhea, nocturnal diarrhea, and greasy stools are not compatible with IBS and raise the probability of organic disease. The Rome III criteria, a consensus statement on functional bowel disorders established for research purposes, may help establish the diagnosis of IBS as well as functional diarrhea. The criteria for IBS are recurrent abdominal pain or discomfort occurring on at least 3 days per month in the last 3 months and associated with two or more of following: (1) improvement of pain with bowel movement; (2) onset associated with a change in frequency of stool; and (3) onset associated with a change in form or consistency of stool.

IBS can be diagnosed based on a typical history and clinical findings and does not usually require an extensive evaluation. If there are potentially serious symptoms that are not consistent with IBS, additional testing is undertaken. Functional diarrhea is defined by the Rome III criteria as continuous or recurrent passage of loose or watery stools without abdominal pain or discomfort, occurring in at least 75% of stools for at least 3 months. This criterion is somewhat ambiguous in guiding the evaluation because it does not help to exclude other causes of chronic diarrhea.

Inflammatory bowel diseases, such as ulcerative colitis and Crohn's disease, are classic causes of chronic diarrhea. Radiation enterocolitis (usually based on the history) and ischemic colitis are more unusual causes. *Crohn's disease* can involve any portion of the GI tract, from the mouth to the anus. Patients with Crohn's disease typically have abdominal pain, diarrhea, weight loss, and fever; gross bleeding is not common with Crohn's disease. There is frequently a delay in presentation and diagnosis of several months from the onset of symptoms to the diagnosis of Crohn's disease. Anemia, leukocytosis, and elevated inflammatory markers are common laboratory findings.

The presentation of *ulcerative colitis* varies a great deal because of variable involvement of the colon. Typically, if the inflammation is limited to the rectum or rectosigmoid region, the symptoms are relatively mild. The onset may be gradual, and there may be episodes of bloody mucus and intermittent diarrhea with fewer than four stools per day. Urgency, mild cramping, and a sensation of incomplete evacuation (tenesmus) are commonly reported, and constipation may also be a complaint. More serious symptoms are often associated with greater involvement of the colon (left-sided colitis or sometimes pancolitis). Patients have frequent loose, bloody stools (up to 10 per day) with mucus. Mild anemia and leukocytosis, mild-to-moderate cramping abdominal pain, and low-grade fever may be present. Weight loss is not

common in mild disease. Severe disease with more than 10 bloody stools per day usually indicates pancolitis. There is severe cramping pain, fever, leukocytosis, and anemia, which often requires transfusion. There can be rapid weight loss leading to malnutrition. Overall, approximately one third of these patients have rectosigmoid disease, one third have left-sided disease, and the remainder have pancolitis. Fulminant disease is present in about 10% of patients at presentation. For information regarding the treatment of IBD, see [Chapter 37](#).

Microscopic colitis is most commonly seen in middle-aged women but can be found at all ages and in men as well. It usually manifests with chronic watery diarrhea. There can be mild cramping and weight loss, but dehydration and malnutrition are rare. The name implies that this is a histologic diagnosis, and indeed, the mucosal appearance of the colon at the time of endoscopy is frequently entirely normal, and biopsies are necessary to document its presence. Disease is present throughout the colon but is often more severe on the right side. There are two types of microscopic colitis: lymphocytic and collagenous. Although the underlying cause of the colitis is not known, it is associated with autoimmune disease in up to 50% of cases. Treatment starts with trials of symptomatic pharmacotherapy. Loperamide and cholestyramine may be useful in mild disease; budesonide, a poorly absorbed steroid, may be used, although relapses are frequent after weaning. Mesalamine and sulfasalazine have been used, but there is little information indicating effectiveness.

Malabsorption can result in diarrhea, most commonly from malabsorption of fat and nutrients. The bowel movements are classically described as greasy or oily, foul smelling, and large volume, although not usually watery. There may be associated weight loss. Malabsorption can be congenital, caused by membrane transport defects of small bowel enterocytes, or acquired due to extensive damage or resection of the small bowel resulting in decreased absorptive area. Celiac disease, Crohn's disease, and short bowel syndrome after resection can be causes. The jejunal-ileal bypass procedure, which was performed for patients with morbid obesity in the 1960s and 1970s but is no longer done due to extensive and serious complications, created severe malabsorption resulting in weight loss. Maldigestion resulting from lack of pancreatic enzymes (chronic pancreatitis or, occasionally, pancreatic tumor) and lack of bile salts for fat absorption also can occur.

Laboratory findings depend on the severity of malabsorption and which specific nutrient is deficient. The most common malabsorptive process is lactose intolerance that results in gas, bloating, and diarrhea. Lactose intolerance can be diagnosed by lactose breath testing or the more simple lactose avoidance trial. Celiac disease and tropical sprue can result in a wide spectrum and severity of symptoms, from iron deficiency to calcium and magnesium deficiency, fat-soluble vitamin deficiencies, and weight loss. The rare Whipple's disease can cause not only malabsorption but also systemic findings. Bacterial overgrowth, such as in some gut motility disorders and small bowel diverticula as well as surgically created blind loops, can also result in malabsorption. Breath testing is available for the evaluation of bacterial overgrowth.

Other cases of chronic, but usually self-limited, diarrhea occur in about 10% of patients who have undergone gallbladder

removal. The likely cause is the continuous presentation of bile to the intestine that results from the loss of storage capacity in the gallbladder; this continuous flow increases the level of bile salts in the colon, leading to diarrhea. Postcholecystectomy diarrhea usually responds to bile acid-binding agents such as cholestyramine and often resolves over time.

Secretory diarrhea is uncommon and typically manifests with large-volume (>1 L/day), watery diarrhea that occurs both day and night and continues in spite of fasting. Although this diagnosis can usually be established by the history and a trial of stool monitoring while fasting, calculation of the stool osmolar gap from measured stool electrolytes can be helpful (see previous discussion). A secretory diarrhea will have an osmolar gap of less than 50 mOsm/kg, whereas the gap in an osmotic diarrhea will be greater than 125 mOsm/kg. Causes of secretory diarrhea are rarely infectious. They include fairly uncommon but often quite dramatic syndromes such as Zollinger-Ellison syndrome (gastrinoma), vasoactive intestinal peptide-producing tumor (VIPoma), and carcinoid syndrome. For the evaluation of chronic secretory diarrhea, stool cultures should be done. Imaging of the small bowel and colon should be considered, and appropriate testing for hormones and other secretagogues should be based on the history and findings.

Endoscopic and Imaging Procedures

Christopher S. Huang and M. Michael Wolfe

INTRODUCTION

Since Mikulicz first used a prototype esophagoscope to visualize the lumen of the esophagus in 1880, physicians have been attempting to peer into every portion of the gastrointestinal (GI) tract in order to understand disease and to restore their patients to health. This goal has become more achievable than ever as a result of the wide variety of invasive and noninvasive endoscopic and imaging procedures that are currently available. This chapter reviews the various endoscopic and radiographic procedures currently in use, including their indications and basic information regarding their performance.

GASTROINTESTINAL ENDOSCOPY

GI endoscopy is the primary modality for directly visualizing the GI tract and for obtaining tissue samples to establish definitive diagnoses. In addition, a wide variety of therapeutic maneuvers can be performed endoscopically to deal with a host of disease processes, such as hemostasis for bleeding ulcers or varices, resection or ablation of neoplastic tissue, dilation or stenting of strictures, and removal of bile duct stones.

Over the years, endoscopes have evolved from early rigid types with limited capabilities to more sophisticated flexible instruments with advanced imaging capabilities, specialized features for therapeutic maneuvers, and various designs to enable examination of specific areas of the GI tract and biliopancreatic systems. Endoscopes come in varying lengths and in diameters ranging from 3.1 mm to 15 mm (Fig. 34-1). They consist of a control handle, an insertion tube, and a connector section that attaches to the light source and image processing unit. The control handle comprises dials that deflect the scope tip in all directions as well as buttons for suction, air or water insufflation, and image capture. The control handle also includes the entry port to the “working channel,” which runs down the length of the insertion tube, through which a wide array of accessories such as biopsy forceps, snares, and balloon dilators can be passed. The tip of the insertion tube houses a charge-coupled device for color image generation, a light guide illumination system, and an objective lens, which may be oriented for forward viewing, side viewing, or oblique viewing, depending on the type of endoscope.

Technologic advances continue to improve the quality of endoscopic imaging. These include the introduction of high-definition instruments, magnification endoscopy (from a baseline of 30× or 35× up to 150×), and enhanced imaging technologies such as narrow band imaging (NBI) and multiband imaging.

GI endoscopy can be performed in dedicated endoscopy suites or at a patient’s bedside in emergency situations. After positioning the patient appropriately and providing sedation, if necessary, the endoscopist passes the lubricated endoscope through the intended orifice and advances it manually. The angulations of the GI lumen are navigated by deflecting the endoscope tip and by applying torque to the instrument shaft (i.e., rotating the shaft along the long axis of the instrument). Endoscopy is generally safe, with complications that include bleeding (0.3% to 1% after colonoscopic polypectomy), perforation (0.05% in general, but 0.1% to 0.5% after polypectomy), and sedation-associated hypotension and hypoxia (1% to 5%). Death related to endoscopic procedures is exceedingly rare (0% to 0.01%).

Esophagogastroduodenoscopy

Esophagogastroduodenoscopy (EGD), often referred to as *upper endoscopy*, is performed with a *gastroscope* and allows the

FIGURE 34-1 Endoscopes used for endoscopy of the upper gastrointestinal tract. Endoscopes of varying sizes are available for use in different situations. The uppermost endoscope (6-mm diameter) can be used for unsedated endoscopy. The middle endoscope (9-mm diameter) is used for standard diagnostic endoscopy. The lowermost endoscope (12-mm diameter) is used for therapeutic endoscopy, such as the placement of enteral stents. (Courtesy Brian C. Jacobson, Boston, Mass.)

endoscopist to visualize the esophagus, the stomach, and the duodenum as far as its third and sometimes fourth portions (Fig. 34-2). Common indications for EGD include evaluation of upper GI symptoms (e.g., dyspepsia, heartburn, nausea, vomiting, dysphagia, odynophagia), screening for and surveillance of Barrett's esophagus, screening for gastroesophageal varices, evaluation of suspected upper GI bleeding (acute or chronic), and investigation of malabsorptive diarrhea (as in celiac sprue or protein-losing enteropathy). A partial list of the therapeutic interventions that can be performed during EGD includes treatment of esophageal varices; dilation of esophageal strictures, rings, and webs; removal or ablation of neoplastic tissue; hemostasis therapy for upper GI bleeding; and the placement of palliative stents for malignant obstruction of the esophagus, pylorus, or duodenum.

Enteroscopy

Examination of the small intestine beyond the ligament of Treitz is not feasible with a standard gastroscope. Recent advances have

allowed direct visualization of the 6 meters or so of the small intestine. *Push* enteroscopy using a long (>200 cm) endoscope allows the endoscopist to both image and biopsy or cauterize lesions in the small intestine. However, because of looping of the endoscope and tortuosity of the small intestine, advancing this instrument beyond the first 50 cm of jejunum can be difficult. Balloon-assisted enteroscopy is a newer technique that provides endoscopic access to most of the small bowel. This method employs balloons, incorporated into overtubes or the endoscope itself, to permit pleating of the small bowel onto the endoscope. By inflating and deflating the balloons in sequence, the enteroscope can be advanced through extremely long stretches of small intestine. With a combined anterograde (through the mouth) and retrograde (through the anus) approach, the entire small intestine can be visualized. Spiral enteroscopy, another novel technique, uses a spiral overtube device that retracts the small bowel over the scope, allowing for deep enteroscopy.

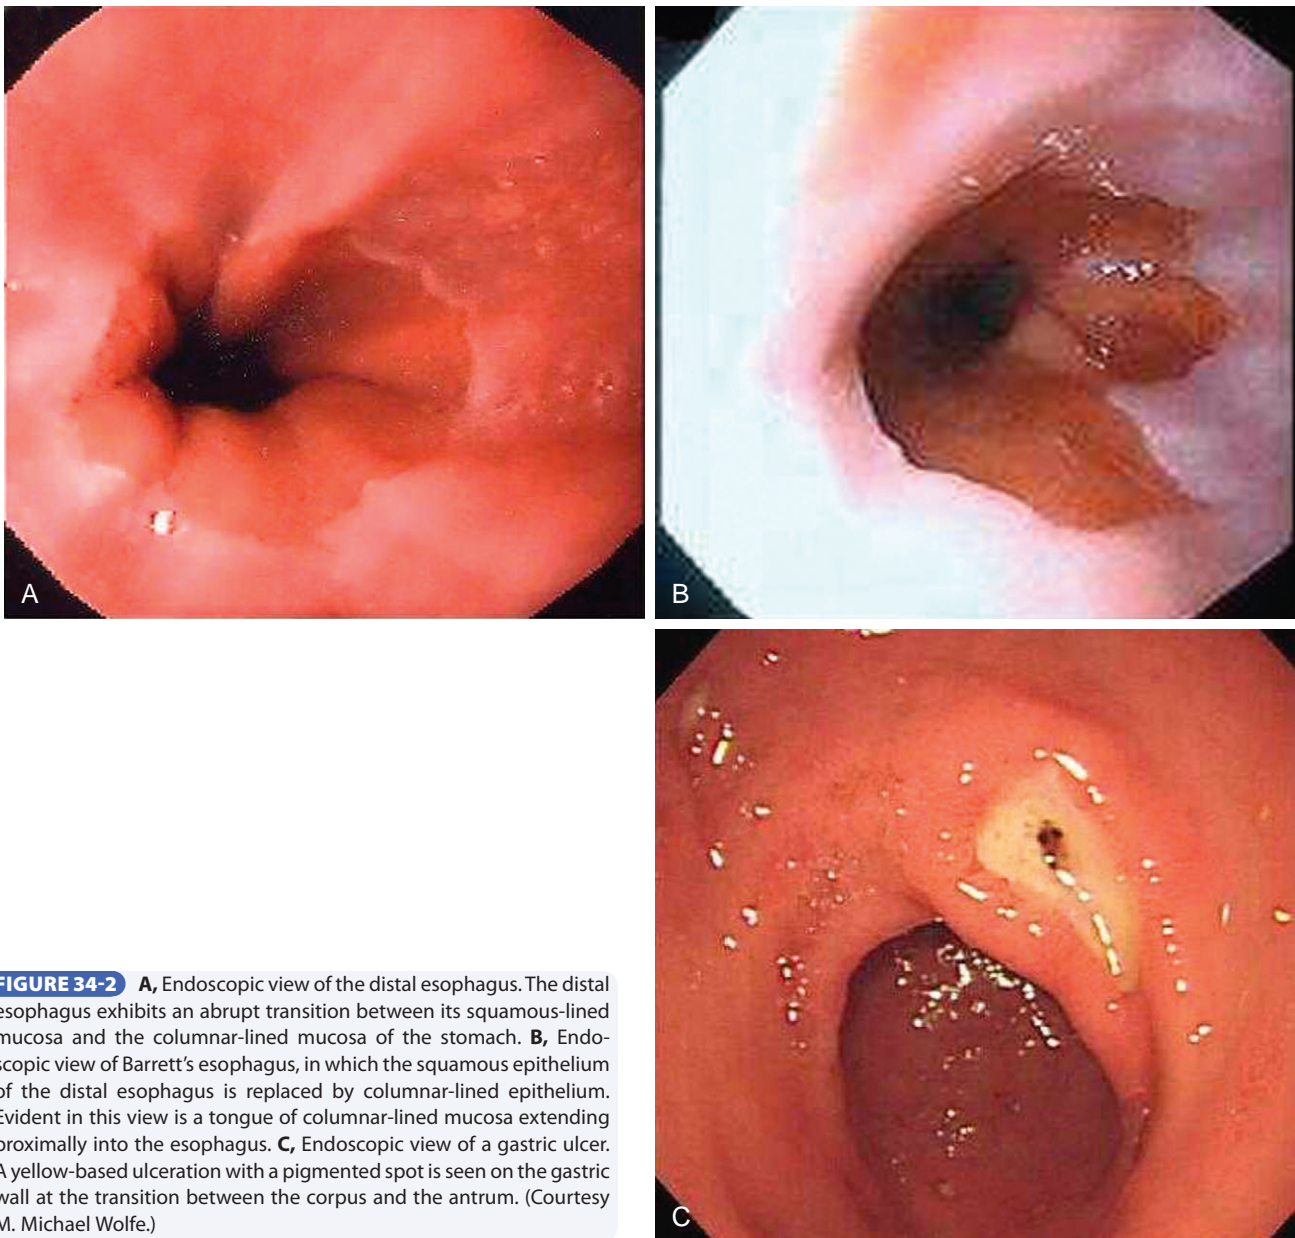

FIGURE 34-2 **A**, Endoscopic view of the distal esophagus. The distal esophagus exhibits an abrupt transition between its squamous-lined mucosa and the columnar-lined mucosa of the stomach. **B**, Endoscopic view of Barrett's esophagus, in which the squamous epithelium of the distal esophagus is replaced by columnar-lined epithelium. Evident in this view is a tongue of columnar-lined mucosa extending proximally into the esophagus. **C**, Endoscopic view of a gastric ulcer. A yellow-based ulceration with a pigmented spot is seen on the gastric wall at the transition between the corpus and the antrum. (Courtesy M. Michael Wolfe.)

The most invasive approach for visualization of the entire small bowel is intraoperative enteroscopy. In this procedure, a surgeon makes an incision in the patient's abdomen and then pleats the small bowel onto the enteroscope while the endoscopist visualizes the lumen. Once a lesion has been identified, the surgeon may elect to proceed directly to a resection of the affected segment of small intestine if the lesion is not amenable to endoscopic treatment.

Video Capsule Endoscopy

The desire to obtain visualization of the GI lumen in the least invasive way has resulted in the development of video capsule endoscopy, in which the patient swallows a pill-sized wireless camera (E-Fig. 34-1; Video 34-1). Capsule endoscopes are now available for evaluation of the esophagus and small intestine, and development of colon capsule endoscopes is underway. Capsules are 11 × 26 mm and can transmit images wirelessly to a data recorder as they travel through a patient's GI tract, without the need for sedation. At the end of the study, the stored images are uploaded into a computer for viewing while the capsule is ultimately passed in the patient's stool.

The esophageal capsule is helpful in patients being screened for esophageal varices and in those with suspected complications of acid reflux, such as reflux esophagitis or Barrett's esophagus. The small bowel capsule has become the "gold standard" for visualization of the small intestine, most commonly for the purpose of investigating obscure GI bleeding (E-Figs. 34-2 and 34-3; Videos 34-2 and 34-3) or suspected inflammatory bowel disease (E-Figs. 34-4 and 34-5). Retention of the capsule within the small bowel, usually at a site of pathology, occurs rarely but is the main potential complication of capsule endoscopy.

Sigmoidoscopy and Colonoscopy

Flexible sigmoidoscopy allows visualization of the rectum, sigmoid colon, and descending colon to the level of the splenic flexure. Enemas are given before the procedure to clear stool from the distal colon. Because sigmoidoscopy is quick (<10 minutes) and not particularly painful, sedation typically is not necessary, making it a convenient tool for colorectal cancer screening. Sigmoidoscopy may also be useful for evaluating chronic diarrhea and rectal bleeding suspected to arise from the distal colon or rectum and for assessing response to therapy in patients with inflammatory bowel disease involving the rectosigmoid colon.

Colonoscopy allows direct visualization of the entire large bowel and the terminal ileum. Bowel cleansing for colonoscopy requires the ingestion of osmotically active solutions, such as polyethylene glycol, coupled with a clear liquid diet for 24 hours before the procedure. Colonoscopy can be more uncomfortable for the patient than sigmoidoscopy due to stretching and distention of the colon, so sedation and analgesia are typically provided. In recent years, colonoscopy has become widely performed as a first-line colorectal cancer screening test. Other indications for colonoscopy include evaluation of chronic diarrhea, iron deficiency anemia, and overt or occult GI blood loss, as well as assessment of inflammatory bowel disease, including surveillance for dysplasia. Therapeutic interventions that can be performed during colonoscopy include polypectomy, thermal ablation of vascular ectasias, decompression of colonic dilation associated

with pseudo-obstruction, stenting of malignant obstruction, and control of lower GI bleeding.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is a combined endoscopic and radiographic procedure for imaging the biliary and pancreatic ducts. A *duodenoscope* is an instrument specially designed for use during ERCP that includes an imaging lens oriented on the side of the endoscope's tip, allowing a direct view of the ampulla of Vater on the medial wall of the second portion of the duodenum. An adjustable instrument *elevator* located at the tip of the duodenoscope helps the endoscopist guide a catheter into the duct of interest. Contrast material is then injected through the catheter, filling the duct, and fluoroscopic images are obtained (Fig. 34-3).

Indications for ERCP include evaluation and treatment of bile duct obstruction due to benign or malignant causes (e.g., bile duct stones, strictures, bile duct or pancreatic malignancies), cholangitis, postoperative or traumatic bile leaks and pancreatic duct leaks, drainage of pseudocysts, and evaluation of idiopathic pancreatitis. With the use of a special manometry catheter, sphincter of Oddi pressures can be measured in cases of suspected sphincter of Oddi dysfunction. Therapeutic interventions that are possible during ERCP include sphincterotomy (an incision through the sphincter of Oddi using a catheter with an electrocautery cutting wire), removal of bile duct stones, and placement of biliary or pancreatic duct stents to alleviate signs and symptoms of obstruction or to promote healing of duct leaks. ERCP carries a significant (5%) risk for complications, including pancreatitis, postsphincterotomy bleeding, and perforation. Therefore, ERCP should be performed only if therapeutic benefits are anticipated.

Choledochoscopy and *pancreatoscopy* are techniques in which an endoscope 3 mm or less in diameter is passed through the accessory channel of a duodenoscope and into the bile or pancreatic duct. The use of this small endoscope permits direct visualization of ductal abnormalities, guides electrohydraulic lithotripsy of large stones, and allows for direct sampling of ductal lesions.

Endoscopic Ultrasound

Endoscopic ultrasound (EUS), or endosonography, is performed with an endoscope containing an ultrasound transducer in its tip. Because this transducer can be placed within the GI lumen, high-resolution images of the bowel wall can be obtained, revealing distinct layers that correspond to the mucosa, submucosa, muscularis propria, and serosa (Fig. 34-4). This technique allows the endoscopist to stage tumor depth and determine the layer of origin of a subepithelial mass. In addition, EUS can penetrate the luminal wall, providing sonographic images of adjacent structures within the mediastinum and upper abdomen, including the pancreas, liver, gallbladder, mesenteric vessels, and adrenal glands. High-frequency EUS catheter probes can be passed through the accessory channel of a duodenoscope and into the biliary or pancreatic duct to provide sonographic images of small tumors and stones. They can likewise be used through a standard endoscope to evaluate diminutive subepithelial lesions and to stage obstructing esophageal cancers.

E-FIGURE 34-1 Capsule endoscopy of the normal small intestine. The ingested small bowel capsule captures still images of the small intestinal mucosa that enable visualization of the normal villi and plicae circulares.

E-FIGURE 34-3 Capsule endoscopy image of an ulcerated small intestinal tumor. As the capsule passes near an ulcerated mass protruding into the small bowel lumen (See Video 34-3). The ulcerated lesion is seen originating from the bottom righthand side of the lumen. Surgical pathology diagnosed this neoplasm as a carcinoid tumor.

E-FIGURE 34-2 Capsule endoscopy image of an actively bleeding vascular ectasia. An area of active bleeding was identified on capsule endoscopy performed for unexplained gastrointestinal blood loss. It was later identified as vascular ectasia and ablated during push enteroscopy.

E-FIGURE 34-4 Capsule endoscopy image of an ulceration and stricture of the small intestine consistent with Crohn's disease. This abnormal area exhibits evidence of mucosal narrowing consistent with a stricture (S) and an irregularly bordered ulceration (U) that appears to be circumferential. Crohn's disease was proven on biopsy. (Courtesy Daniel S. Mishkin, Boston, Mass.)

Contrast material injected into the biliary tree during ERCP demonstrates the intraductal anatomy of the common bile duct (CBD), right hepatic duct (RHD), left hepatic duct (LHD), and smaller intrahepatic biliary radicals. **B**, Normal pancreatogram. Contrast material injected into the pancreatic duct during ERCP defines the intraductal anatomy throughout the length of the pancreas. (Courtesy Brian C. Jacobson, Boston, Mass.)

FIGURE 34-4 Endoscopic ultrasound of the gastrointestinal wall. A 12-MHz ultrasound probe, passed through the accessory channel of an endoscope, demonstrates the normal layers of the rectal wall. The mucosa (*m*) appears as a superficial, hyperechoic (*white*) band and a deeper hypoechoic (*black*) band. The submucosa (*sm*) appears as the next hyperechoic layer. The muscularis propria (*mp*) appears hypoechoic, and the serosa (*s*) appears as the outermost, hyperechoic layer. (Courtesy Brian C. Jacobson, Boston, Mass.)

Fine-needle aspiration (FNA) as well as core biopsy can be performed under EUS guidance, and FNA is the preferred approach to obtaining a tissue diagnosis in many circumstances (e.g., pancreatic masses or cysts, subepithelial lesions of the GI tract, intra-abdominal or paraesophageal lymphadenopathy).

Recent advances such as elastography and contrast-enhanced harmonic EUS have further enhanced the diagnostic capability of EUS, particularly in terms of distinguishing malignant from benign processes. However, EUS is more than just a diagnostic modality, and the spectrum of EUS-guided therapies is rapidly expanding. Therapeutic maneuvers that can be performed via EUS guidance include pseudocyst drainage, celiac axis neurolysis, fiducial placement into solid tumors to guide stereotactic radiotherapy, drainage of pelvic abscesses, and achievement of bile duct access (when initial attempts at ERCP have failed).

NONENDOSCOPIC IMAGING PROCEDURES

Plain Abdominal Radiographs

Plain abdominal radiographs include upright, supine, and lateral decubitus films obtained with standard radiographic equipment and without the use of contrast agents. Plain films are most useful in the initial evaluation of abdominal pain or nausea and vomiting, particularly when perforation or obstruction is suspected, and they may reveal evidence of a pneumoperitoneum, dilated bowel loops and air-fluid levels, excessive amounts of stool, or displacement of bowel loops. These findings are indicative of a perforation, obstruction or ileus, constipation or fecal impaction, and volvulus or organ enlargement, respectively (Fig. 34-5). Calcifications, such as those seen in chronic pancreatitis and gallstone disease, may also be visible on these radiographs.

Contrast Studies

Contrast agents such as barium or the water-soluble diatrizoate (e.g., Gastrografin) can be administered by mouth or rectum to detect mucosal abnormalities (ulcerations and masses),

FIGURE 34-5 Upright plain radiograph of the abdomen. Air in dilated loops of colon and air-fluid levels can be seen in this patient with a sigmoid volvulus. (Courtesy Brian C. Jacobson, Boston, Mass.)

strictures, herniations, diverticula, and abnormal peristalsis. Contrast agents can be used alone (*single contrast*) or along with instillation of air or ingestion of gas-forming agents (*double contrast*). The former method is more useful for detecting obstructing lesions and motility disturbances, whereas the latter aids in detecting more subtle findings such as small ulcerations or polyps.

A *video esophagogram* (also known as a modified barium swallow) entails the filming of a patient's oral cavity and pharynx during the ingestion of contrast materials of various thicknesses and textures. This imaging modality permits careful assessment of a patient's ability to manipulate a food bolus, swallow effectively, and avoid aspiration events. A video esophagogram is indicated for evaluating patients with oropharyngeal dysphagia and recurrent aspiration pneumonia. A standard *barium esophagogram* (barium swallow) focuses attention on the esophagus during the ingestion of a bolus of contrast material. This study can detect esophageal rings, webs, strictures, and motility problems that endoscopy might miss. A barium esophagogram may be useful for evaluating esophageal dysphagia as well as odynophagia.

An *upper GI series* includes serial radiographic images as an ingested contrast agent travels through the esophagus, stomach, and duodenum. This study can define gastric abnormalities such as masses, ulcerations, and mucosal thickening. It is indicated in the evaluation of abdominal pain and suspected gastric outlet obstruction. If radiographic imaging continues as the contrast agent traverses the jejunum and ileum, the study is called a *small bowel follow-through* (Fig. 34-6). Indications for a small bowel

FIGURE 34-6 Small bowel follow-through. Ingested barium defines the contours of the small and large bowel lumen. A long stricture of the terminal ileum (S) can be seen in this patient with Crohn's disease. (Courtesy Brian C. Jacobson.)

follow-through include suspected small bowel obstruction or partial obstruction from any cause, suspected small bowel mucosal disease (e.g., Crohn's disease), and obscure GI blood loss. During this more involved procedure, a radiologist obtains multiple films, including *spot films*, or close-up views of regions that appear abnormal. Fluoroscopy can be used to follow a contrast agent during the journey through the small bowel. Attention is paid not only to structural findings but also to the length of time required for the contrast agent to reach and enter the colon. For more detailed small bowel images, *enteroclysis* can be performed. This method requires the infusion of concentrated contrast material directly into the small bowel through a nasojejunal tube placed under fluoroscopic guidance. Because of its invasive nature, enteroclysis is becoming less common in this era of wire-less capsule endoscopy.

Single- and double-contrast barium enemas can detect colonic strictures, diverticula, polyps, and colonic ulcerations, and they can be therapeutic in reducing a sigmoid volvulus. Double-contrast barium enema may be used for colorectal cancer screening as a stand-alone test or in conjunction with flexible sigmoidoscopy, or it may be used to visualize the proximal colon when colonoscopy cannot be completed for various reasons. However, it is now infrequently used for these purposes given its relatively poor sensitivity and the availability of computed tomography colography (discussed later). In general, the upper GI series and barium enema have been superseded by upper endoscopy and colonoscopy because the endoscopic procedures offer increased sensitivity for detecting mucosal abnormalities, the ability to obtain mucosal biopsies, and the potential for resection of identified lesions.

Transabdominal Ultrasound

Ultrasonography is often the first imaging study obtained in the evaluation of suspected biliary colic, jaundice, or abnormal liver test results. Its use of sound waves to create an image obviates the need for radiation exposure, and the addition of Doppler techniques permits the assessment of vascular flow. Ultrasound can detect parenchymal abnormalities such as fatty liver or cirrhosis,

focal masses or cysts, ascites, biliary ductal dilation, gallstones, and large vessel thromboses. It may detect thickening of the gut wall and areas of intussusception. Ultrasound is also used to guide needle placement for biopsies or fluid aspiration. Ultrasound cannot penetrate bone or air, preventing its use as a more general diagnostic tool for the GI tract.

Computed Tomographic Methods

Computed tomography (CT) uses computer-aided reconstruction of multiple radiographic images obtained in a circular or helical course around a patient's vertical axis. Internal organs are visualized based on their inherent tissue densities compared with their surroundings. The GI lumen is usually opacified by having the patient drink an oral contrast agent. In addition, intravenous contrast agents can be administered to highlight regions with increased blood flow, thereby improving detection of pathologic lesions such as tumors and areas of active inflammation.

CT can detect parenchymal lesions, such as tumors, cysts, and abscesses, and can define the size, shape, and characteristics of organs such as the liver and spleen. Vascular abnormalities (e.g., perigastric varices, large vessel thromboses) and intra-abdominal fluid (e.g., ascites) can also be seen with CT. The caliber and contour of the GI tract wall are demonstrated by CT, aiding in the diagnosis of inflammatory lesions such as colitis, diverticulitis, and appendicitis. CT may also be used to guide needle biopsies of abdominal masses and to place electrodes into tumors for ablative therapies such as radiofrequency ablation. The use of CT to guide placement of drainage catheters has made possible the percutaneous treatment of intra-abdominal abscesses, pseudocysts, and pancreatic necrosis.

CT enteroclysis and CT enterography are two emerging techniques that were developed to provide better images of the small intestine. CT enteroclysis uses a nasojejunal tube to deliver contrast material into the small intestine, whereas CT enterography uses an orally ingested low-density intraluminal contrast agent to distend the lumen and highlight the small intestinal mucosa (Fig. 34-7). With the advancement of this technology and its ability to reconstruct images in multiple planes, both luminal and extraluminal information can be obtained.

CT can also be used to obtain high-resolution images of the colon. CT colography, or *virtual colonoscopy*, makes use of special

FIGURE 34-7 Computed tomography enterography. A long segment of inflamed terminal ileum is demonstrated in this patient with Crohn's disease. (Courtesy Christopher S. Huang.)

image reconstruction software to create accurate visualization of the colonic lumen, provided that the patient has completed a bowel-cleansing regimen identical to that used for colonoscopy (although techniques that do not require such preparation are being developed). These CT images are 70% to 90% sensitive for detecting polyps or masses within the colon, helping to determine which patients need therapeutic colonoscopy. Virtual colonoscopy is being used in some centers to complete colonic visualization in the setting of an incomplete colonoscopy.

Magnetic Resonance Methods

Similar to CT, magnetic resonance imaging (MRI) provides multiple cross-sectional images of the abdomen and pelvis. These images are created using powerful field magnets to orient small numbers of nuclei within the body in such a way as to produce a measurable magnetic moment. MRI avoids radiation exposure but requires the patient to lie almost motionless, often within a small enclosed tube, for prolonged periods. MRI can visualize parenchymal lesions such as masses and cysts and may better characterize abnormalities seen on CT, such as hemangiomas, hepatic focal nodular hyperplasia, and fatty liver. MRI is also helpful in better characterizing perirectal abscesses and fistulas in patients with Crohn's disease. Special rectal MRI probes or coils can provide detailed images of rectal cancer used for tumor staging and can evaluate anal sphincters in patients with fecal incontinence.

MRI of the biliary and pancreatic ducts (*magnetic resonance cholangiopancreatography*, or MRCP) is a noninvasive method that can detect ductal dilation, strictures, stones (Fig. 34-8), pancreatic parenchymal changes in chronic pancreatitis, and congenital ductal abnormalities such as pancreas divisum. *Magnetic resonance angiography* is a magnetic resonance method for visualizing blood vessels that serves as an important noninvasive tool in patients with suspected mesenteric ischemia, vasculitis, or other vascular anomalies.

Visceral Angiography

Angiography is an invasive technique whereby a catheter is introduced into a blood vessel and intravascular contrast material is

FIGURE 34-8 Magnetic resonance cholangiopancreatography. Several stones are visualized within the common bile duct, appearing as hypointense filling defects on T2-weighted images. (Courtesy Christopher S. Huang.)

injected during fluoroscopic imaging to visualize the vessel's lumen. Visceral angiography is used to evaluate mesenteric vessels in the setting of GI bleeding or suspected mesenteric ischemia. For GI bleeding, angiography is sensitive enough to detect blood loss of as little as 1 to 1.5 mL/minute. Once the site of bleeding has been localized, the radiologist can infuse vasopressin (a vasoconstrictor) or embolize the vessel using tiny coils or gelatin sponges to ensure hemostasis. In the setting of mesenteric ischemia, angiography permits localization of a vascular stenosis or obstruction, followed by possible therapeutic interventions such as balloon angioplasty, stent placement, or infusion of vasodilators and thrombolytics. Other indications for angiography include the placement of transjugular intrahepatic portosystemic shunts (TIPS) in cirrhotic patients with intractable variceal bleeding or refractory ascites and the chemoembolization of liver tumors.

Radionuclide Imaging

Technetium-99m (^{99m}Tc) is currently the major radionuclide used in GI imaging. Its 6-hour half-life and ready availability make it ideal for clinical use. ^{99m}Tc can be used to label various substances for use in several imaging techniques. ^{99m}Tc -sulfur colloid scanning and ^{99m}Tc -labeled red blood cell scanning are two distinct methods that can be used to detect active GI bleeding. The latter uses the patient's own blood cells to carry the radionuclide throughout the body. These methods can detect as little as 0.05 to 0.4 mL/minute of blood loss. However, localization of the site of bleeding is less accurate than with angiography. ^{99m}Tc scans are often performed before angiography to document ongoing bleeding before subjecting a patient to the more invasive, less sensitive study. A ^{99m}Tc -labeled red blood cell scan can also be used to diagnose hepatic hemangioma with an almost 100% positive predictive value.

Cholescintigraphy using ^{99m}Tc -iminodiacetic acid (IDA) analogues is the most commonly performed liver study in nuclear medicine. The radionuclide is taken up by the liver, is excreted into bile, and passes through the biliary tree into the gallbladder and duodenum. Failure to visualize the gallbladder during a hepatobiliary IDA scan may indicate cholecystitis secondary to cystic duct obstruction by a gallstone. Meckel's diverticulum can be a source of abdominal pain and bleeding, but it may be difficult to visualize with standard endoscopic and radiographic imaging. The agent ^{99m}Tc -pertechnetate has a high affinity for gastric mucosa and is therefore used to demonstrate the presence of this congenital anomaly.

Gastric emptying studies are useful for the evaluation of suspected gastroparesis. Patients are given a ^{99m}Tc -sulfur colloid-labeled standardized meal (consisting of liquid egg whites, toast, jam or jelly, and water) and are imaged at 0, 1, 2 and 4 hours after meal ingestion. Gastric retention of more than 10% of contents at 4 hours is highly sensitive and specific for delayed gastric emptying.

PROSPECTUS FOR THE FUTURE

Through continued technologic advances, endoscopic and radiologic image quality and resolution will also continue to improve. In addition, the GI lumen will no longer be regarded as a boundary to therapeutic endoscopy. Examples of expected innovations include the following.

- *The implementation of natural orifice transluminal, endoscopically guided surgical procedures.* With the use of recently introduced instruments, an endoscopist will be able to incise the GI tract wall, advance an endoscope into the peritoneal cavity, and then perform surgical procedures such as cholecystectomy. Endoscopic bariatric procedures for the treatment of obesity are also on the horizon and are likely to be in high demand given the obesity epidemic. A new field of *endosurgery* will develop to accompany these advances and will require training in both surgical principles and gastroenterology.
- *Commercial availability of new endoscopic imaging methods, such as confocal microscopy and fluorescence endoscopy.* Confocal microscopy allows an endoscopist to obtain magnified endoscopic images similar to those seen with a low-power microscope. Fluorescence endoscopy entails the use of special wavelengths of light to excite naturally occurring fluorophores in benign and neoplastic tissue. These fluorophores, such as collagen and nicotinamide adenine dinucleotide plus hydrogen (NADH), then fluoresce in a predictable manner, providing a means of identifying, by endoscopy, otherwise microscopic changes (e.g., dysplasia) without the need for a biopsy.
- *Video capsule endoscopes with advanced diagnostic and possibly therapeutic capabilities.* Through further advances in nanotechnology, video capsule endoscopes will be able to sample GI secretions, measure intraluminal pressures, take biopsy samples, and perhaps even provide focal ablation of lesions using thermal energy or radiofrequency ablation.

For a deeper discussion on this topic, please see Chapter 134, "Gastrointestinal Endoscopy," in Goldman-Cecil Medicine, 25th Edition.

Esophageal Disorders

Carla Maradey-Romero, Ronnie Fass, and M. Michael Wolfe

INTRODUCTION

The esophagus appears to be a simple organ with a single function—the transmission of ingested food and fluids to the stomach. This task is achieved, however, by a tightly coordinated pattern of motility, coupled with protective barriers that prevent gastric secretions from entering the esophagus and pharynx. Derangement of these activities can cause a significant number of distressing symptoms that, taken together, are among the most commonly reported gastrointestinal symptoms that are sufficient to cause patients to seek medical care.

NORMAL FUNCTION OF THE ESOPHAGUS

The tubular esophagus begins after the cricopharyngeus muscle and consists of a muscular tube averaging 20 to 22 cm in length (range, 17 to 30 cm). It is composed proximally of skeletal muscle and distally of smooth muscle. Autopsy studies indicate that the proximal 5% or so of tubular esophagus is skeletal muscle, the middle 35% is mixed, and the distal 60% is smooth muscle. The muscular layers are arranged in circular and longitudinal bundles. The esophagus has no serosal layer. Situated between the muscular layers is the myenteric plexus, and between the circular muscle layer and the muscularis mucosa is the submucosal or Meissner's plexus. The ganglia of the myenteric plexus are more prominent in the smooth muscle areas of the tubular esophagus and are thought to integrate messages from the vagus nerve to the muscles of the esophagus.

At the junction of the esophagus and the stomach is a zone of higher resting pressure referred to as the lower esophageal sphincter (LES). This sphincter has no clearly defined anatomic structure, and the current thinking is that it is principally composed of the circular muscle of the distal 2 to 3 cm of the esophagus in conjunction with the oblique muscle fibers running from the lesser curvature to the greater curvature of the stomach (the gastric sling fibers). The right crus of the diaphragm supports the LES in its barrier by physically encircling it and providing mechanical support, particularly during physical exertion.

The process of swallowing is complex and requires fine coordination involving multiple muscle groups. The process begins with the tongue and pharynx, both of which are densely innervated. The pharyngeal musculature is controlled by the trigeminal, facial, glossopharyngeal, vagus, and hypoglossal nerves. Vagal neurons controlling the pharynx and skeletal muscle of the esophagus originate from the nucleus ambiguus. Although the smooth muscle portions of the tubular esophagus are innervated by the vagus nerve—and it is the vagus nerve that controls peristalsis under physiologic conditions—peristalsis in this portion

of the esophagus will continue even if vagal innervation is removed. The neural plexuses of the smooth muscle esophagus control its activity via excitation of circular and longitudinal muscle bundles by muscarinic receptors or via inhibition of the circular muscle layer by nonadrenergic, noncholinergic neurotransmitters: nitric oxide and vasoactive intestinal polypeptide.

Swallowing begins when a food bolus is propelled into the pharynx from the mouth under voluntary muscle control. In rapid sequence and with precise coordination, the larynx is elevated and the epiglottis seals the airway; the upper esophageal sphincter opens; and the bolus is propelled into the tubular esophagus. Peristaltic pressures ranging 40 to 180 mm Hg are generated. The measured pressure tends to be lower in the more proximal portions of the esophagus and greater in the distal smooth muscle portions. The pressures vary not only by location but also by consistency (i.e., solid or highly viscous boluses require greater pressures), volume, and temperature of the bolus itself. Movement through the tubular esophagus is controlled by the vagus nerve, concomitantly with initiation of the swallow. The LES relaxes to gastric baseline and remains relaxed (deglutitive inhibition) as the bolus is propelled distally. Once the bolus has been propelled into the stomach, the LES returns to its state of tonic contraction, preventing movement back into the esophagus.

SYMPTOMS OF ESOPHAGEAL DISEASE

Heartburn (pyrosis) is the most common symptom of esophageal disease, occurring in 44% of Americans at least once a month. About 10% of persons in the United States experience heartburn every day. It is most often described as a burning sensation in the epigastrium that rises into the chest. Patients often move their hand up and down between the xiphoid and sternal angle when describing this symptom. Given that heartburn is a cardinal sign of gastroesophageal reflux, it tends to occur after meals, when the patient is lying supine, or after an increase in intra-abdominal pressure (e.g., bending or lifting). Specific types of food, including fatty or spicy foods and chocolate, may also induce heartburn. Symptoms are often relieved temporarily by antacid preparations. Heartburn may be accompanied by regurgitation of bitter or sour fluid into the back of the throat or by excessive saliva production (so-called *water brash*), which is caused by a vagal reflex.

Dysphagia refers to a sensation of difficulty swallowing; patients report that a food bolus “gets stuck” or “goes down slowly.” Although patients may point to their neck or chest when describing where the bolus gets held up, the location to which

they point is poorly correlated with the actual level of obstruction. Dysphagia may result from a mechanical obstruction of the esophagus, from inflammation of the esophageal mucosa, or from an abnormality of esophageal motility.

Odynophagia, or pain on swallowing, needs to be differentiated from dysphagia in the patient history because it can be an important clue to the cause of the swallowing disorder. Painful swallowing is most often associated with infectious esophagitis or pill-induced esophageal ulcers but is only rarely present in acid-mediated esophageal disease.

Chest pain may also be a sign of esophageal disease, most often caused by gastroesophageal reflux or esophageal dysmotility. Unfortunately for the clinician, the symptoms of cardiac and esophageal chest pain overlap because of the shared neural pathways mediating pain sensation to these organs. Typical features of angina may occur in reflux-induced chest pain, including radiation to the neck and jaw; relief with nitrates, which modulate esophageal motility; and onset of symptoms with exertion. Chest pain that awakens a patient from sleep, however, is uncommon in true cardiac disease and suggests an esophageal disorder, as does pain that is relieved with antacids or pain that lasts for several hours without associated symptoms. Esophageal chest pain is often thought to occur in response to esophageal spasm, but data suggest that gastroesophageal reflux is responsible for most cases.

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) is the most common disorder of the esophagus. It causes occasional heartburn in almost one half of the population and daily symptoms in almost 7% of adult Americans. GERD is responsible for about \$10 billion to \$12 billion in direct medication costs per year, and related acid antisecretory therapies are among the most commonly prescribed drugs in the United States.

Gastroesophageal reflux is defined as the reflux of gastric contents back into the esophagus. There are three main underlying mechanisms that can result in gastroesophageal reflux. First, in both healthy subjects and those with GERD, reflux of gastric contents occurs primarily in the postprandial period (physiologic reflux) due to transient relaxation of the LES. Two additional mechanisms of gastroesophageal reflux are low baseline LES pressures and stress reflux. The latter indicates an inability to mount sufficient LES pressures to prevent reflux in response to sudden increases in intra-abdominal pressure. Other pathophysiologic mechanisms also bear a role in GERD, including esophageal dysmotility, delayed gastric emptying, duodenogastroesophageal reflux, impaired local defense mechanisms, and decreases in salivation.

Hiatal hernia is another important factor in the pathogenesis of GERD. The size of the hernia tends to correlate with the severity of the reflux. The presence of a nonreducible hiatal hernia disrupts the sphincter mechanism and prolongs esophageal clearance, leading to increased duration of esophageal acid exposure.

Patients with impaired esophageal motility have more severe reflux, slower acid clearance, worse mucosal injury, and more frequent extraesophageal manifestation of GERD. The importance of esophageal dysmotility is best illustrated by scleroderma, in which a hypotensive LES and impaired or absent esophageal

peristalsis contribute to reflux that is often severe. Further, many patients with scleroderma have an associated sicca syndrome and therefore have reduced acid-neutralizing capacity as a result of the absence of saliva.

Heartburn is the cardinal clinical feature of GERD, and when it is present, the diagnosis of GERD is made easily. Complaints of bitter regurgitation or water brash add to the diagnostic accuracy, but these features are not always present. In some cases, atypical symptoms dominate in patients with no history of heartburn. Most cases of noncardiac chest pain, which can mimic angina, are thought to be caused by GERD. A significant number of additional symptoms, including chronic cough, asthma, hoarseness, chronic sore throat, and globus sensation, may also result from occult gastroesophageal reflux.

Diagnosis

When heartburn is the predominant or sole symptom, gastroesophageal reflux is the cause in at least 75% of individuals, indicating that the presence of heartburn is specific for the diagnosis of GERD. Other GERD-related symptoms include acid regurgitation, belching, water brash, dysphagia, odynophagia, chest pain, globus sensation, chronic cough, hoarseness, and asthma.

A presumptive diagnosis of GERD based on symptoms commonly leads to a trial of empiric antireflux treatment without further diagnostic testing. In first-time health care seekers, more detailed diagnostic evaluation is definitely indicated if alarm symptoms are present (i.e., dysphagia, odynophagia, anorexia, weight loss, or evidence of upper gastrointestinal bleed). Presently, most physicians accept the concept that a marked symptomatic response to antireflux treatment is highly suggestive of GERD as the underlying cause of the patient's symptoms.

Endoscopy has a low sensitivity for diagnosis of GERD, because 50% to 70% of patients with GERD-related symptoms have no evidence of esophageal mucosal injury on endoscopy. However, upper endoscopy remains the "gold standard" for diagnosis of erosive esophagitis, Barrett's esophagus (BE) (E-Fig. 35-1), and other important complications of GERD, such as ulceration and stricture. The test is indicated in patients with alarm symptoms and to exclude BE in those with long-standing symptoms of GERD. Endoscopy is also warranted if there is diagnostic uncertainty (e.g., persistence of symptoms on appropriate empiric therapy).

Presently, pH monitoring is best reserved for patients who are considered to be candidates for antireflux surgery; those who report relapse of GERD symptoms after antireflux surgery; and those with atypical or extra-esophageal symptoms that are poorly responsive to an adequate trial of antireflux therapy. Measurement of esophageal impedance and pH has a role in identifying nonacidic reflux as the cause of residual GERD-related symptoms in patients being treated with proton pump inhibitors (PPIs) at least twice daily.

Treatment

For patients with mild or infrequent symptoms, it is reasonable to use antacids and lifestyle modification such as weight loss, cessation of smoking, and elevation of the head of the bed. For patients with more severe reflux symptoms, a definitive treatment is required. Treatment of GERD is summarized in Table 35-1.

E-FIGURE 35-1 Endoscopic image of the gastroesophageal junction demonstrates a “tongue” of Barrett’s mucosa (*red*) extending above the Z-line.

TABLE 35-1 TREATMENT OF GASTROESOPHAGEAL REFLUX DISEASE

Lifestyle modifications	Selective serotonin reuptake inhibitors
Antireflux medications	Serotonin-norepinephrine reuptake inhibitors
Histamine-2 receptor antagonists	
Proton pump inhibitors	
Transient LES relaxation reducers	Antireflux surgery
Baclofen	Endoscopic treatment
Visceral pain modulators	Alternative and complementary medicines
Tricyclic antidepressants	Acupuncture
Trazadone	Psychological intervention

LES, Lower esophageal sphincter.

The initial aims of GERD management are confirmation of the diagnosis of GERD, adequate relief of GERD symptoms, and healing of esophagitis, if present. Among patients with mild-to-moderate erosive esophagitis (Los Angeles grades A and B), PPIs are superior to histamine-2 receptor antagonists in providing healing of mucosal erosions and relief of GERD symptoms. For patients with severe erosive esophagitis (Los Angeles grades C and D), PPIs are the sole treatment; in some of these patients, even doubling of the dose of PPI is not infrequently required. Failure of a 4-week course of initial therapy with a PPI should prompt a review of the diagnosis if it is based solely on symptoms. For patients without adequate response to once-daily PPI, addition of a second daily dose before the evening meal is a reasonable next step.

The aims of long-term management of GERD are satisfactory control of reflux symptoms, maintenance of healing of erosive esophagitis, prevention of complications, and improvement of quality of life. Because GERD is predominantly a chronic relapsing disorder, the balance of priorities for long-term care differs from that of initial therapy.

Patients with atypical or extraesophageal manifestations of GERD should be offered double doses of PPI as the initial course of therapy. A response lag of up to 6 months may be encountered.

For patients who are unwilling to take medications for long periods and those who cannot tolerate the side effects of antireflux treatment, surgery is a reasonable alternative, provided that they are fully informed about the risks and possible complications of the procedure (e.g., increased flatulence, dysphagia, diarrhea, early satiety).

SEQUELAE OF GASTROESOPHAGEAL REFLUX DISEASE

Common complications of GERD include esophagitis, ulceration, and esophageal stricture. Strictures typically produce progressive dysphagia to solids and often require endoscopic dilatation to relieve the obstruction followed by intensive antisecretory therapy to prevent recurrence.

Barrett's Esophagus

BE is defined as a change in the esophageal epithelium of any length that can be recognized at endoscopy and confirmed to involve intestinal metaplasia by biopsy of the tubular esophagus (E-Fig. 35-2A). It is considered to be an acquired condition associated with GERD. Of those individuals undergoing endoscopy for any reason, up to 2% may have BE; among those undergoing

an endoscopy for GERD-related symptoms, 3.5% to 9.6% are found to harbor this premalignant lesion. Both BE and esophageal adenocarcinoma are much less common in non-Caucasian populations; the reasons are not defined. There are data suggesting that obesity and smoking contribute to the risk of adenocarcinoma arising from BE.

Many authors divide these lesions into short-segment and long-segment BE, based on the length of the metaplastic epithelium (<3 cm and ≥3 cm, respectively). Another approach is the Prague circumference and maximum length criteria: The length: The length of BE is divided to the part (if any) in which the columnar-like epithelium is circumferential (C) and the part that is composed only of metaplastic tongues (M). It is more common to find dysplasia in patients with long-segment BE, and there is a correlation between the length of Barrett's epithelium and the risk of developing dysplasia and adenocarcinoma of the esophagus.

Given the increased risk of adenocarcinoma development, surveillance of patients with known BE is recommended (see E-Fig. 35-2B). The lack of large-scale studies on which to base these recommendations has led to a variety of guidelines based on presumed risk. Because inflammation can mimic the cellular and nuclear changes that are often seen with dysplasia, all patients with BE should be adequately treated with acid suppression therapy (i.e., PPI) before endoscopy. Even if antireflux surgery has been performed, a surveillance program is still warranted.

Under most circumstances, patients with BE without dysplasia should have endoscopic surveillance at 3- to 5-year intervals or if their symptom pattern changes. Multiple biopsies, taken every 2 cm in four quadrants, are recommended. Biopsies should be reviewed by a pathologist familiar with Barrett's metaplasia. If dysplasia of any degree is found, the biopsy specimens should be forwarded to another pathologist who specializes in Barrett's histopathology.

Dysplasia is typically categorized as low-grade, high-grade, or indefinite for dysplasia (see E-Fig. 35-2C). Current recommendations suggest that patients with high-grade or low-grade dysplasia confirmed by an expert pathologist should undergo repeat endoscopy within 6 months. If there is no change, radiofrequency ablation of the Barrett's mucosa is recommended. Various mucosal ablative techniques are available, including photodynamic therapy, radiofrequency ablation, cryoablation, and argon plasma coagulation.

DYSPHAGIA

Dysphagia means difficulty in swallowing. Dysphagia may result from any alteration of the swallowing process, from bolus entry into the mouth to entry into the stomach. Given the complexity of this process, a wide array of abnormalities may be involved and the symptoms are poorly discriminating. Dysphagia may be divided into abnormalities related to the movement of a food bolus from the mouth to the esophagus (transfer or oropharyngeal dysphagia) and alterations of movement from entry into the esophagus to the stomach (transport or esophageal dysphagia) (Fig. 35-1).

Oropharyngeal Dysphagia

The process of moving a food bolus, particularly liquids, from the mouth to the esophagus, coming as it does in close proximity to

E-FIGURE 35-2 **A**, Barrett's esophagus. A pathologic image demonstrates intestinal metaplasia of the esophagus abutting the normal squamous mucosa—the pathologic lesion that defines Barrett's esophagus. **B**, Adenocarcinoma of the esophagus (*at right*), arising in an area of dysplastic Barrett's mucosa. **C**, Low-grade dysplasia in a patient with Barrett's esophagus.

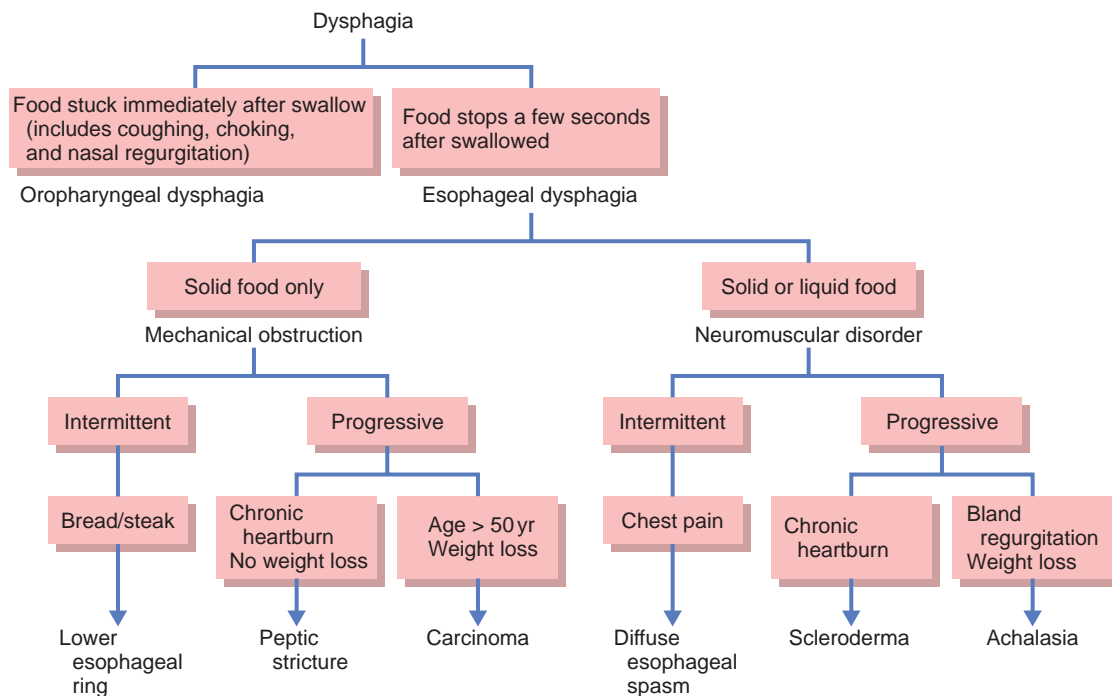

FIGURE 35-1 Algorithm for the differential diagnosis of dysphagia.

the airway, requires a fine coordination of events happening at a very rapid rate. Disruption of this phase of swallowing may be caused by structural defects or, more commonly, by neuromuscular dysfunction. Structural abnormalities that may be encountered in the hypopharynx include cervical osteophytes, hypopharyngeal diverticulum (Zenker's diverticulum), head and neck tumors, radiation injury, and postcricoid webs. In these settings, patients may have difficulty when a solid bolus leaves the mouth and enters the tubular esophagus.

Much more commonly, symptoms of transfer dysphagia result from neuromuscular injury causing disruption of this finely coordinated act of swallowing. In these situations, problems are much more commonly associated with attempts to swallow liquids. Sensory or motor injury may lead to an inability to accomplish the transfer of a bolus from the mouth to the esophagus. Stroke (particularly involving the brain stem) is one of the most common causes of oropharyngeal dysphagia. This scenario is associated with a higher patient mortality rate because of a higher risk of aspiration pneumonia and dehydration.

Essentially, any disease process that affects the brain can result in dysphagia. The more common associations are amyotrophic lateral sclerosis, Parkinson's disease, and brain tumors. Primary muscular diseases may also result in oropharyngeal dysphagia. These include oculopharyngeal muscular dystrophy, myotonic dystrophy, myasthenia gravis, and tardive dyskinesia. Patients with oropharyngeal dysphagia commonly complain that food gets "stuck" immediately upon swallowing; this sensation may be associated with choking, coughing, or nasal regurgitation.

Esophageal Dysphagia

Once the food bolus enters the esophagus, passage may be impeded by structural abnormalities or alterations in esophageal motility. These alterations range from congenital abnormalities to acquired conditions, and they constitute a rather large differential diagnosis. Solid food dysphagia alone is more commonly

seen in patients with mechanical obstruction, whereas solid and liquid dysphagia is typically encountered in esophageal motility disorders such as achalasia. Patients with esophageal dysphagia usually report the onset of symptoms several seconds after initiation of a swallow.

ESOPHAGEAL MOTILITY DISORDERS

The more common disorders of esophageal motility are achalasia, diffuse esophageal spasm, and scleroderma, and their key features are outlined in [Table 35-2](#).

Primary Motility Disorders

The term *primary motility disorders* refers to a number of conditions in which there is some disruption in the neuromuscular control of esophageal peristalsis.

Achalasia

The prototype of esophageal dysmotility is achalasia. This condition, characterized by loss of esophageal peristalsis and failure of LES relaxation, is the most widely recognized primary motility disorder. A variety of changes have been described in patients with this condition: loss of ganglion cells from the myenteric plexus; degenerative changes in the vagus nerve; degenerative changes in the dorsal motor nucleus of the vagus, including occasional evidence of intracytoplasmic inclusions (Lewy bodies); loss of small intramuscular nerve fibers; and reduction in vesicles of small nerve fibers. The initial site of injury is unknown, and 98% of cases are idiopathic. Achalasia may occur at any age from childhood to late adulthood. The peak occurrence is between the ages of 30 and 60 years.

The hallmark symptom of achalasia is dysphagia, typically for both solids and liquids. Other commonly noted symptoms include regurgitation, chest pain, and what patients describe as "heartburn." Symptoms typically have been present for years before diagnosis, and this may especially be true if patients are

**TABLE 35-2** ESOPHAGEAL MOTOR DISORDERS

FEATURE	ACHALASIA	SCLERODERMA	DIFFUSE ESOPHAGEAL SPASM
Symptoms	Dysphagia Regurgitation of nonacidic material	GERD Dysphagia	Substernal chest pain (angina-like) Dysphagia with pain
Radiographic appearance	Dilated, fluid-filled esophagus Distal “bird-beak” stricture	Aperistaltic esophagus Free reflux Peptic stricture	Simultaneous noncoordinated contractions
CONVENTIONAL MANOMETRIC FINDINGS			
LES	High resting pressure Incomplete or abnormal relaxation with swallow	Low resting pressure	Normal pressure
Body	Low-amplitude, simultaneous contractions after swallowing	Low-amplitude peristaltic contractions or no peristalsis	Some peristalsis Diffuse and simultaneous nonperistaltic contractions, occasionally high amplitude

GERD, Gastroesophageal reflux disease; LES, lower esophageal sphincter.

carefully interviewed. Weight loss may be encountered as well. Achalasia may result in pulmonary symptoms, a complication suggested by the presence of cough resulting from aspiration of esophageal contents. Neuronal denervation is the underlying mechanism of achalasia. This results in failure of esophageal body peristalsis and failure of the LES to relax in response to swallowing.

High-resolution manometry has been used to define three subtypes of achalasia. Each is associated with incomplete LES relaxation. Type 1 (classic achalasia) is devoid of any significant decreases in esophageal pressurization. Type 2 is associated with simultaneous pressurization throughout the esophagus after a swallow. Type 3 (spastic achalasia) is associated with luminal obliterating contractions after a swallow.

When achalasia is identified, its treatment can progress through several stages: (1) medical therapy with nitrates and calcium channel blockers to lower sphincter pressures and with PPIs; (2) botulinum toxin injection to lower LES pressures; (3) pneumatic dilation to facilitate luminal opening; and (4) esophageal myotomy, performed either laparoscopically or in the traditional transthoracic approach (Heller myotomy).

Secondary Achalasia

A number of conditions may result in a syndrome resembling achalasia. The most common and important of these causes is malignancy involving the region of the gastroesophageal junction (e.g., adenocarcinoma of the cardia, gastric lymphoma) or, less commonly, metastatic involvement from a distant primary malignancy (e.g., small cell lung cancer, Hodgkin's lymphoma, hepatocellular carcinoma). The result is a syndrome that radiographically and manometrically resembles primary achalasia. Such involvement is typically seen in older patients in whom the development of dysphagia is rapid. Most of these cases are identified by endoscopic examination. Other diseases that may mimic achalasia include Chagas' disease (South American trypanosomiasis) and intestinal pseudo-obstruction, which may be caused by a host of conditions ranging from familial neuropathies and myopathies to disorders such as muscular dystrophy.

Rings and Webs

Nosology is critical when discussing rings and webs. An esophageal *ring* is a distal esophageal structure that occurs at the esophago-gastric junction; it is covered on one side by squamous mucosa

and on the other by columnar mucosa. One exception to this rule is Schatzki's ring, which is typically located radiographically about 2 cm proximal to the esophagogastric mucosal junction, as described later. An esophageal *web* is a ring-like structure along the entire length of the esophagus that is covered entirely by squamous mucosa. Cervical esophageal webs are typically diaphragm-like structures found in the immediate postcricoid area. They may be identified incidentally on radiographic or endoscopic imaging, although they can easily be missed if care is not taken to carefully examine this area of the esophagus. The pathogenesis of cervical webs is unknown. Pathologically, they are composed of normal squamous tissue overlying connective tissue; this bland histology separates these typical cervical webs from those changes found in the proximal esophagus associated with dermatologic diseases (e.g., epidermolysis bullosa, pemphigoid, chronic graft-vs-host disease). Symptomatic patients are more likely to be female. Typically, the symptom complex is intermittent solid food dysphagia. The association between iron deficiency anemia and esophageal webs is referred to as Paterson-Kelly or Plummer-Vinson syndrome.

Treatment of the typical cervical web is usually simple. Most can be disrupted during the performance of endoscopy. Esophageal bougienage may be required in some patients.

A lower esophageal ring (Schatzki's ring) is thought to be the most common cause of dysphagia (E-Fig. 35-3). The history tends to be characteristic. Patients are typically older than 40 years of age and report intermittent, solid food dysphagia occurring early in a meal. The dysphagia is usually transient, and if the bolus passes, the remainder of the meal can be consumed. Patients may go for many weeks without symptoms. The dysphagia is not progressive, and constitutional symptoms such as bleeding or weight loss are absent. Occasionally, patients with Schatzki's ring may have food impaction at presentation.

Rings can be visualized either radiographically or endoscopically, and they cause varying degrees of luminal narrowing. Rings with a luminal diameter of 13 mm or less are more likely to be symptomatic, although other factors, including bolus size and effectiveness of esophageal peristalsis, contribute to the intermittent episodes of dysphagia.

The pathogenesis of esophageal rings is not established. Current research has focused on the likely contribution of acid reflux. Evidence suggests that many patients respond to acid suppression with PPIs, in terms of both increased luminal size of the

E-FIGURE 35-3 A Schatzki ring in the distal esophagus. Presenting symptoms include intermittent dysphagia to solids with long periods of normal swallowing between symptomatic episodes. Endoscopic dilatation of the ring is usually effective in eliminating symptoms.

ring and reduction in symptoms. In some patients, esophageal bougienage or more aggressive endoscopic manipulation (four-quadrant needle knife incision) may be required.

EOSINOPHILIC ESOPHAGITIS

Eosinophilic esophagitis was originally described in the pediatric population, but in the last decade it has been recognized increasingly in adults as well. This inflammatory process is characterized on biopsy by dense eosinophilic infiltration of the submucosa that over time leads to structural abnormalities in most patients. The underlying etiology is proposed to be delayed hypersensitivity reaction to food allergens or immunologic response to allergens outside of the gastrointestinal tract, although identification of a specific allergen is often elusive.

Dysphagia is the most commonly encountered symptom, but patients also may complain of heartburn, chest pain, nausea, and other symptoms. Food impaction may occur, sometimes as a presenting symptom. Endoscopic findings include a uniform small-caliber esophagus, single or multiple corrugations, esophageal mucosal furrows, and stricture formation. Tearing of the esophagus can occur with simple passage of the endoscope, during biopsy, or after dilatation. Diagnosis is established after biopsies from the distal and middle esophagus demonstrate dense infiltrate of 15 to 25 eosinophils per high-power field.

All patients with eosinophilic esophagitis should be treated first with a PPI, possibly twice daily, regardless if there is evidence for GERD. Subsequent treatment relies primarily on swallowed topical steroids. Fluticasone inhalers are used, for example, but the contents are sprayed into the mouth and swallowed to coat the esophagus. This approach has proved to be effective in reducing symptoms and improving histologic findings. If this approach is used, patients should be instructed to wash their mouths out with water after each treatment to prevent the development of oral candidiasis. Budesonide or other oral systemic steroids may be considered in severe cases. All patients with eosinophilic esophagitis should be evaluated for allergic reactions to food or other allergens. The relationship between GERD and eosinophilic esophagitis remains to be elucidated.

ESOPHAGEAL INFECTIONS

Infections of the esophagus are uncommon in immunocompetent individuals. They are, however, a major source of morbidity in those with compromised immunity related to immunosuppression, human immunodeficiency virus (HIV) infection, and other causes of immune suppression. Infectious esophagitis typically manifests with odynophagia as the most common symptom, and dysphagia is common as well. New onset of these symptoms in an immunocompromised individual warrants a detailed

evaluation; symptoms do not readily discriminate among the different etiologies, and therapy must be targeted and can be intensive depending on the overall setting.

Candida is perhaps the most common cause of infectious esophagitis. It may or may not be associated with oral thrush, and it tends to produce dysphagia with only mild pain on swallowing. *Candida* has a characteristic appearance on endoscopic examination, and esophageal brushings and biopsies demonstrate fungal hyphae (E-Fig. 35-4). Treatment with oral fluconazole is usually effective.

Herpes simplex virus is associated with more severe odynophagia and causes esophageal ulcers that are often multiple. Acyclovir is the treatment of choice for herpes esophagitis. Cytomegalovirus (CMV) also causes esophageal ulceration and odynophagia. Endoscopic examination usually demonstrates a single large ulcer in the distal esophagus, and biopsies reveal viral inclusions that confirm the diagnosis. Both ganciclovir and foscarnet are effective treatments for CMV esophagitis.

There may be more than one infectious process involved in an individual patient. HIV infection is associated with esophageal ulceration and odynophagia, although much less commonly in the present era of effective antiretroviral therapy. As the overall immune system improves, the esophagitis typically recovers as well.

For a deeper discussion on this topic, please see Chapter 138, "Diseases of the Esophagus," in Goldman-Cecil Medicine, 25th Edition.

Diseases of the Stomach and Duodenum

Robert C. Lowe and M. Michael Wolfe

INTRODUCTION

The stomach acts as a reservoir for recently ingested food and initiates the process of digestion. By storing large quantities of food (1.5 to 2 L in the adult), the stomach allows intermittent feeding. Once solid particles have been reduced in size to accommodate the much smaller capacity of the duodenum, the gastric contents are released through the pylorus in a controlled fashion. This chapter focuses on the anatomy and physiology of the stomach and duodenum as well as on the most common disease processes that involve these organs.

GASTRODUODENAL ANATOMY

The stomach is in continuity with the esophagus proximally and the duodenum distally. The *lower esophageal sphincter*, a circular smooth muscle structure located at the distal end of the esophagus, creates a high-pressure zone that under normal conditions prevents gastric contents from refluxing into the esophagus. Similarly, the pyloric sphincter, the most distal portion of the stomach, plays an important role in the trituration of solid food particles and ensures the downstream propulsion of the food bolus, preventing duodenogastric reflux. The stomach is divided into four regions (Fig. 36-1; Video 36-1). The cardia is a poorly defined transition from the esophagogastric junction to the fundus. The dome-shaped fundus projects upward above the cardia and is the most superior part of the stomach in contact with the left hemidiaphragm and the spleen. The body, or corpus, located immediately below and continuous with the fundus, is the largest part of the stomach and is characterized by the presence of longitudinal folds known as rugae. The antrum extends from the incisura angularis, a fixed sharp indentation that marks the end of the gastric body, to the *pylorus*, or *pyloric channel*, a tubular structure that joins the stomach to the duodenum.

The mucosa, or inner lining of the stomach, is formed by a layer of columnar epithelium. The submucosa, immediately deep to the mucosa, provides a skeleton of dense connective tissue in which lymphocytes, plasma cells, arterioles, venules, lymphatics, and the myenteric plexus are contained. The third tissue layer, the muscularis propria, is a combination of an inner oblique, middle circular, and an outer longitudinal smooth muscle layer. The serosa, a thin, transparent continuation of the visceral peritoneum, is the final layer of the stomach wall. The autonomic innervation of the stomach stems from both sympathetic and

parasympathetic nervous systems. The anterior and posterior trunks of the vagus nerve provide parasympathetic innervation, whereas the celiac plexus, coursing along the vascular supply of the stomach, provides sympathetic innervation.

The gastric mucosal surface is composed of a single layer of mucus-containing columnar epithelial cells. The surface lining is invaginated by gastric pits, which provide access to the gastric lumen for gastric glands. The gastric glands of different regions

FIGURE 36-1 Anatomic regions of the stomach and duodenum. Agents that affect lower esophageal sphincter (LES) tone and gastro-duodenal motility.

of the stomach are lined with different types of specialized cells. The oxyntic or acid-producing region of the stomach is found in the fundus and body, where gastric glands contain characteristic parietal cells, which secrete both acid and intrinsic factor. These glands also contain zymogen-rich chief cells, which synthesize pepsinogen, and enterochromaffin-like endocrine cells, which secrete histamine. Antral glands have different endocrine cells, including gastrin-secreting G cells and somatostatin-secreting D cells.

The duodenum, the most proximal portion of the small intestine, forms a C-shaped loop around the head of the pancreas and is in continuity with the pylorus proximally and the jejunum distally (see Fig. 36-1 and Video 36-1). Angular changes in course divide the duodenum into four portions. The first part of the duodenum is the duodenal bulb or cap and is characterized by a smooth, featureless luminal surface. The remainder of the duodenum has characteristic circular folds known as the *plica circularis* or *valvulae conniventes*, which increase the surface area available for digestion. Similar to the stomach, the duodenal wall is formed by mucosa, submucosa, muscularis, and serosa layers. The duodenal mucosa is lined with columnar cells forming villi surrounded by crypts of Lieberkühn. The submucosa includes characteristic Brunner glands that produce bicarbonate-rich secretions involved in acid neutralization. The innervation of the duodenum is similar to the stomach.

GASTRODUODENAL MUCOSAL SECRETIONS AND PROTECTIVE FACTORS

Although hydrochloric acid (HCl) is the primary gastric secretion, the stomach also secretes water, electrolytes (hydrogen [H⁺], sodium [Na⁺], potassium [K⁺], chloride [Cl⁻], and bicarbonate [HCO₃⁻]), enzymes (pepsin and gastric lipase), and glycoproteins (intrinsic factors and mucin) to assist in a wide variety of physiologic functions. The digestion of proteins and triglycerides, as well as the complex process of vitamin B₁₂ absorption, begins in the gastric lumen. Gastric acid also prevents the development of enteric microbial colonization and systemic infections. The normal human stomach contains about 1 billion parietal cells that are stimulated to secrete H⁺ ions by three different pathways: neurocrine, paracrine, and endocrine (Fig. 36-2). The neurocrine pathway involves the vagal release of acetylcholine, which stimulates H⁺ ion generation through a parietal cell muscarinic M₃ receptor. The paracrine pathway is mediated by release of histamine from mast cells and enterochromaffin-like (ECL) cells in the stomach. Histamine binds to histamine-2 receptors on parietal cells, activating adenylate cyclase, which, in turn, leads to an increase in adenosine 3',5'-cyclic monophosphate (cAMP) levels and subsequent generation of H⁺ ions. The secretion of gastrin from antral G cells constitutes the endocrine pathway, which acts both directly on the parietal cell and indirectly by stimulating histamine secretion from ECL cells. The hydrogen-potassium adenosine triphosphatase (H⁺, K⁺-ATPase) enzyme, or proton pump, located at the apical surface of the parietal cell, is the final step of acid secretion. A negative feedback loop governs both gastrin release and acid secretion, preventing postprandial acid hypersecretion. Somatostatin, produced by D cells in the gastric corpus and fundus, inhibits release of gastrin from G cells and may also reduce acid secretion from parietal

FIGURE 36-2 Schematic representation of acid secretion by the parietal cell. Each transmitter has a specific receptor located on the basolateral surface of the parietal cell. Stimulation of these receptors leads to activation of intracellular second messenger systems. Gastrin and acetylcholine promote the accumulation of intracellular calcium, whereas histamine causes a stimulatory G protein (G_s) to activate adenylate cyclase, which, in turn, generates cyclic adenosine monophosphate (cAMP). These intracellular messengers then activate protein kinases, which activate the proton pump (the H⁺, K⁺-ATPase enzyme), located at the apical surface of the parietal cell, to secrete H⁺ ion in exchange for K⁺ ions. Prostaglandins and somatostatin inhibit parietal cell function by binding to receptors that act through inhibitory G proteins (G_i) to inhibit adenylate cyclase. Long arrows indicate sites of action of various drugs that inhibit acid secretion. ECL, Enterochromaffin-like endocrine cells.

cells and histamine release from ECL cells. Acid is necessary to convert pepsinogen, secreted from gastric chief cells, into pepsin, a proteolytic enzyme that is inactive at a pH greater than 4. Parietal cells also secrete intrinsic factor, a glycoprotein that binds to ingested vitamin B₁₂, allowing its absorption in the terminal ileum.

Several mechanisms are involved in maintaining the protective mucosal barrier. Mucus and HCO₃⁻ constitute the first line of defense. Mucus forms a stable layer that prevents H⁺ ion back-diffusion and lubricates the mucosa, protecting against mechanical damage and maintaining a significant pH gradient between the gastric lumen and the epithelial cell surface. Endogenous epithelial defensive factors, such as cell migration and proliferation, permit a constant and rapid renewal of the mucosa and ensure the continuity of the epithelium and the integrity of the tight intercellular junctions. Subepithelial defensive factors such as an adequate mucosal blood flow constitute a second line of protection and play a crucial role in maintaining a normal pH environment and thereby the integrity of the gastroduodenal mucosa.

GASTRODUODENAL MOTOR PHYSIOLOGY

Based on electrophysiologic and functional characteristics, the stomach can be divided into two functional compartments. The proximal stomach (fundus and proximal third of the body) acts as a reservoir for recently ingested food, whereas the distal stomach grinds, mixes, and sieves food particles. The smooth muscle of the proximal stomach has a characteristic tonic contraction that allows for gastric accommodation, a process by which the fundus relaxes in response to incoming food and fluid, with little increase in intragastric pressure. In contrast, the distal stomach produces high-amplitude contractions originating from the pacemaker region in the midportion of the greater curvature.

Gastroduodenal motor events vary in response to fasting and food intake. During fasting, gastric motility is characterized by a pattern of phasic contractions known as the migrating motor complex (MMC). The MMC clears the stomach and small intestine of undigested food particles, mucus, and sloughed epithelial cells. The MMC begins in the stomach and migrates down the length of the small bowel with a combined duration of 84 to 112 minutes. Following a meal, irregular contractile activity propels the ingested material distally.

Gastric emptying of a mixed solid and liquid meal involves the coordinated actions of the distinct regions of the stomach with feedback from the small intestine. Although liquids empty from the stomach at a relatively linear rate, solids are propelled forward by gastric contractions toward the antrum, where particles are triturated by high-amplitude contractions. Once solids have been reduced in size to particles of 1 to 2 mm, they are emptied into the pylorus.

A variety of medications and foods that exert significant effects on gastroduodenal motility are described in [Figure 36-1](#) (see [Video 36-1](#)). Agents that modify the lower esophageal sphincter and esophageal motility are explained in [Chapter 36](#).

PEPTIC ULCER DISEASE

Definition and Epidemiology

Peptic ulcer disease (PUD) is a common clinical problem characterized by mucosal defects of the stomach or duodenum. The proteolytic enzyme pepsin and gastric acid were initially identified as key factors involved in their pathogenesis, leading to the concept of *no acid, no ulcer*. However, in the past two decades, factors other than acid and pepsin that contribute to the development of ulcers have been recognized. Men and women are at equal risk for developing PUD, and the overall lifetime risk is ~10%. Peptic ulcers are uncommon in children, but the risk increases with age. More than 70% of all ulcer cases occur in individuals between the ages of 25 and 64 years. Whereas the incidence of PUD is decreasing in younger age groups, more persons 65 years of age and older are developing ulcers. These trends are likely related to the overall decrease in the prevalence of *Helicobacter pylori* infection in the general population and the increasing use of NSAIDs by older persons. The most important risk factors for the development of peptic ulcers are infection with *H. pylori* and use of NSAIDs. If neither of these factors is present, an alternative cause must be sought, including

hypersecretory states (e.g., Zollinger-Ellison syndrome [ZES]) or one of the other less common causes of ulcer disease such as Crohn disease, vascular insufficiency, viral infection, radiation therapy, and cancer chemotherapy. Although a significant number of environmental factors, including stress, personality type, occupation, alcohol consumption, and diet, have been linked to the development of ulcers, there is no convincing evidence suggesting that any of these factors by itself can cause PUD.

Pathology

By killing ingested bacteria and other microorganisms, gastric acid prevents the development of enteric colonization and ensures both efficient absorption of nutrients and prevention of systemic infections. Gastric acid is also an important factor in protein hydrolysis and digestion and, under various conditions, may play an etiologic role in inciting gastroduodenal mucosal injury. Postprandial gastric acid secretion is regulated primarily by increases in gastrin expression, which is controlled by a negative feedback loop wherein postprandial gastrin-mediated acid secretion stimulates the release of somatostatin from antral D cells. Somatostatin appears to act by a paracrine mechanism to inhibit further release of gastrin from G cells. Somatostatin produced by D cells in the gastric corpus and fundus may also directly inhibit acid secretion from parietal cells and may suppress histamine release from ECL cells. Although the presence of acid is necessary for the formation of ulcers, acid secretion is normal in nearly all patients with gastric ulcers and is increased in only one third of patients with duodenal ulcers. Therefore, acid is clearly not the only factor involved in the pathogenesis of peptic ulcers, and the balance between aggressive factors that act to injure the gastroduodenal mucosa and defensive factors that normally protect against corrosive agents is also important. When this delicate balance is disrupted for any reason, an ulcer may result.

In addition to the regulation of intragastric acidity, mechanisms involved in maintaining the protective mucosal barrier include mucus and HCO_3^- secretion, mucosal blood flow, cell restitution and repair, and changes in local immune factors. The mucosal defensive properties appear to be mediated to a large extent by endogenous prostaglandins, nitric oxide, and trefoil proteins. When the synthesis of these mediators is diminished, even normal rates of acid secretion may be sufficient to injure the mucosa.

Helicobacter pylori Infection

Helicobacter pylori (*H. pylori*) are curved, flagellated, gram-negative rods found only in gastric epithelium or in regions of gastric metaplasia. It is the most common worldwide cause of microbial infection, involving an estimated 50% of the world's population. *H. pylori* organisms clearly cause histologic gastritis and are found in 50% to 95% of patients with gastroduodenal ulcers. However, only a minority of patients with *H. pylori* gastritis develop peptic ulcer disease (PUD) or gastric cancer. In the Western world, there is a clear age-related prevalence of *H. pylori* infection in healthy individuals, increasing from 10% in those younger than 30 years to 60% in those older than 60 years. The mode of transmission appears to be by the fecal-oral route. Improvements in sanitation and standards of living appear to

account for the decline in the rate of infection. *H. pylori* colonization is more common in individuals in lower socioeconomic strata compared with other groups. In the developing world, infection is far more common, with more than 80% of the population being infected by age 20 years. *H. pylori* infection is typically lifelong unless antimicrobial treatment is instituted.

H. pylori organisms reside in the mucus layer overlying gastric epithelium and are characterized as noninvasive organisms. Factors important in the organism's ability to colonize the stomach include its motility, the production of urease, and bacterial adherence. Ammonia generated from urea by *H. pylori* urease neutralizes acid, creating a more hospitable microclimate in which the bacteria can survive. *H. pylori* also have the ability to bind specifically to gastric-type epithelium, which prevents the organisms from being shed during cell turnover, mucus secretion, or gastric motility. Tissue injury is mediated by the production of lipopolysaccharide, leukocyte-activating factors, and vacuolating toxins, which have been associated with cytotoxic effects, inflammation, and cytokine activation. About 65% of *H. pylori* isolates produce a vacuolating toxin. Toxin-producing strains may be more pathogenic than those that do not produce toxins, and their presence correlates with a more intense polymorphonuclear cell infiltration. A cytotoxin-associated gene (*cagA*) is a marker for strains that make the vacuolating toxin, and patients infected with *cagA*-positive strains are more likely to develop ulcers (Fig. 36-3). Colonization causes acute and chronic inflammation consisting of neutrophils, plasma cells, T cells, and macrophages accompanied by varying degrees of epithelial cell injury, all of which resolve after effective treatment.

Although predicting the ultimate outcome of *H. pylori* infection is impossible, the clinical manifestations can be correlated with the distributions of gastric histopathologic states. Antral-predominant *H. pylori* gastritis is associated with duodenal ulcers; individuals infected with *H. pylori* have been shown to have a diminished number of somatostatin-secreting D cells, which decreases the magnitude of the response to luminal acidification. Thus, in patients with *H. pylori* infection limited to the antrum, the negative inhibition of gastrin release is disrupted, resulting in higher postprandial gastrin levels and hypersecretion

of acid. Corporal and fundic colonizations, by contrast, are more likely to cause atrophic gastritis.

Other important factors that may influence the outcomes of the infection include the host response, environmental factors, and age at the time of infection. Virtually all patients with *H. pylori* infection have a chronic superficial gastritis; however, duodenal and gastric ulcers develop in only 20% of infected patients. Patients with *H. pylori* infection and severe atrophic gastritis, corpus-predominant gastritis, or both, along with intestinal metaplasia, are at increased risk for intestinal-type gastric cancer. Finally, the mucosal lymphocytic response to *H. pylori* infection may lead to a monoclonal B-cell proliferation in mucosa-associated lymphoid tissue (MALT). MALT lymphomas, also known as *maltomas*, are rare, with about 1 in 1 million infected patients developing the disease. Complete histologic regression has been demonstrated in 50% to 80% of *maltomas* following eradication of *H. pylori*. Flat, localized, nonbulky lesions of the distal stomach are associated with greater rates of cure after antibiotic therapy.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are one of the most widely used classes of drugs. Although generally well tolerated, NSAIDs are associated with a small but significant percentage of adverse gastrointestinal (GI) events. Concepts regarding NSAID-induced gastroduodenal mucosal injury have evolved from a simple notion of topical injury to theories involving multiple mechanisms by which NSAIDs induce both local and systemic effects. According to the dual-injury model, NSAIDs have direct toxic effects on the gastroduodenal mucosa and indirect effects through active hepatic metabolites and decreased synthesis of mucosal prostaglandins. Hepatic metabolites are excreted into the bile and subsequently into the duodenum, where they may cause mucosal damage to the stomach by duodenogastric reflux and to the small intestine by antegrade passage through the GI tract. Prostaglandin inhibition, in turn, leads to reduction in epithelial mucus, decreased secretion of HCO_3^- , impaired mucosal blood flow, reduced epithelial proliferation, and decreased mucosal resistance to injury. The impairment in mucosal resistance facilitates mucosal injury by endogenous factors, including acid, pepsin, and bile salts.

Prostaglandins are derived from arachidonic acid, which originates from cell membrane phospholipids through the action of phospholipase A_2 . The metabolism of arachidonic acid to prostaglandins and leukotrienes is catalyzed by the cyclooxygenase (COX) pathway and the 5-lipoxygenase (LOX) pathway, respectively (Fig. 36-4). Two related but unique isoforms of COX, designated COX-1 and COX-2, have been demonstrated in mammalian cells. Despite their structural similarities, each is encoded by distinct genes that differ with regard to their distribution and expression in tissues; the COX-1 gene is primarily expressed constitutively, whereas the COX-2 gene is inducible. COX-1 appears to function as a housekeeping enzyme in most tissues, including the gastric mucosa, whereas the expression of COX-2 can be induced by inflammatory stimuli and mitogens in many different types of tissue. It is postulated that the anti-inflammatory properties of NSAIDs are mediated through the inhibition of COX-2, whereas adverse effects, such as gastroduodenal ulceration, occur as a result of the effects on COX-1. The discovery of the two COX

FIGURE 36-3 Mechanisms by which *Helicobacter pylori* may cause gastric ulcers (A) and duodenal ulcers (B). IL-8, interleukin-8. (From Peek RM, Blaser MJ: Pathophysiology of *Helicobacter pylori*-induced gastritis and peptic ulcer disease, *Am J Med* 102:200-207, 1997.)

isoforms led to the development of COX-2–specific inhibitors (e.g., celecoxib, rofecoxib, valdecoxib), drugs that maintain their anti-inflammatory properties while preserving the biosynthesis of protective prostaglandins (Fig 36-5). Unfortunately, adverse cardiovascular effects of COX-2 inhibitors have limited the use of these drugs.

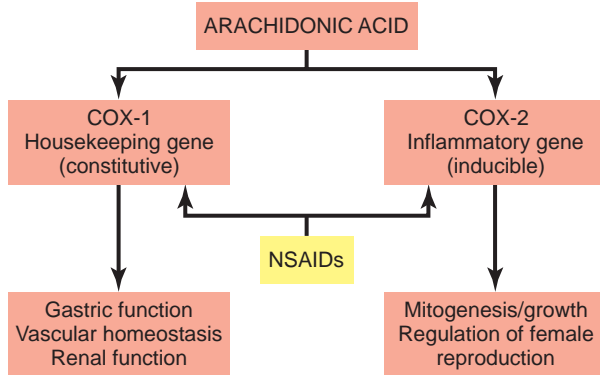

FIGURE 36-4 Biosynthesis of prostaglandins and leukotrienes through the cyclooxygenase and lipoxygenase pathways.

The spectrum of NSAID-related mucosal injury includes a combination of subepithelial hemorrhages, erosions, and ulcerations that is often referred to as *NSAID gastropathy*. Erosions are likely to be small and superficial, whereas ulcers tend to be larger (more than 5 mm in diameter) and deeper. Although no area of the stomach is resistant to NSAID-induced mucosal injury, the most frequently and severely affected site is the antrum. Microscopically, a *reactive* pattern of injury can be found that is characterized by mucin depletion and little or no increase in inflammatory cells. Endoscopic studies have shown a prevalence of gastroduodenal ulcers of 10% to 25% in patients with chronic arthritis treated with NSAIDs, which is 5 to 15 times the expected prevalence in an age-matched healthy population.

In addition, at least 60% of individuals with complicated ulcers (e.g., hemorrhage, perforation) report the use of NSAIDs, including aspirin. NSAID-induced ulceration occurs with all traditional NSAIDs, regardless of enteric coating or delivery as a prodrug formulation. The risk for NSAID-induced ulceration and complications is dose related and increases with age older than 60 years, concurrent corticosteroid use, increasing duration and dose of therapy, anticoagulant therapy, and a history of prior ulcer disease.

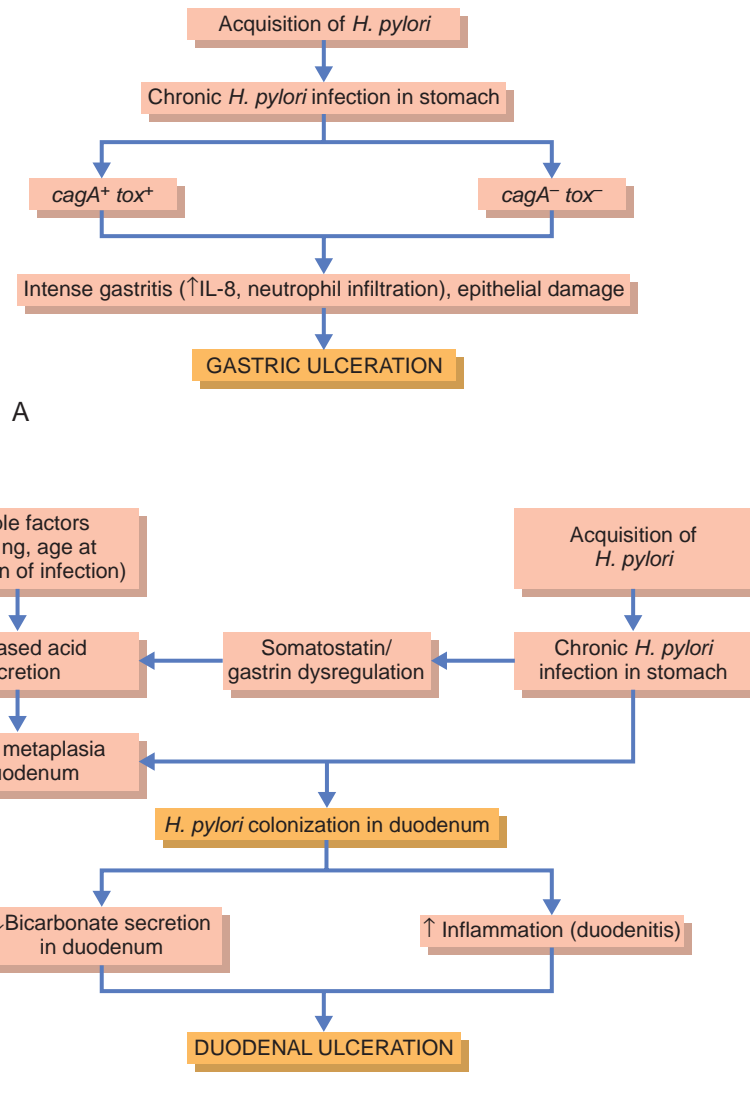

FIGURE 36-5 Depiction of the two cyclooxygenase isoenzymes that catalyze the synthesis of tissue prostaglandins from arachidonic acid.

Zollinger-Ellison Syndrome

ZES, an acid hypersecretory state caused by gastrin-secreting tumors, accounts for 0.1% of patients who have PUD and should be considered in patients with ulcers in unusual sites (e.g., distal duodenum, jejunum); multiple, recurrent, or complicated duodenal ulcers; or ulcers associated with chronic diarrhea. This disorder is discussed in detail below.

Clinical Presentation

Peptic ulcer disease can be clinically silent or can exhibit a variety of manifestations ranging from iron deficiency anemia to abdominal pain, obstruction, perforation, and hemorrhage. Symptoms may mimic those of other diseases, including cholecystitis, pancreatitis, gastric cancer, and gastroesophageal reflux. Myocardial ischemia or infarction, especially of the inferior wall, can cause abdominal pain that resembles peptic ulcer. Abdominal pain in PUD is generally epigastric and is usually described as a dull ache but may be sharp or burning. Less than 20% of patients report the hunger-like pain traditionally associated with both gastric and duodenal ulcers. Similarly, the character of the symptoms and their relation with meals, specifically pain relief after food intake for duodenal ulcer and pain worsening for gastric ulcer, do not always correlate with endoscopic diagnosis and are less useful in predicting ulcer location. Nocturnal pain and pain relief with milk or antacids are common with duodenal ulcers but can also occur with gastric ulcers. NSAID-associated ulcers typically produce painless bleeding. Nausea and vomiting are commonly associated with peptic ulcers, being slightly more common with gastric ulcers. Gastric outlet obstruction may be caused by antropyloric or duodenal ulcers but should be differentiated from malignant obstruction resulting from gastric or pancreatic cancer. Weight loss, while suggestive of malignancy, is reported frequently by patients with peptic ulcer disease.

Diagnosis

Because the clinical features of gastroduodenal ulcers may overlap with other disorders, and the physical examination is often not helpful in the diagnosis, imaging studies of the GI tract are required to confirm the presence of peptic ulcers. Although contrast radiology (barium upper GI series) can be used, endoscopy is preferred because, in addition to characterizing the ulcer, it allows tissue sampling to exclude malignancy, assessment of *H. pylori* infection, and, in cases of acute ulcer hemorrhage, delivery of endoscopic therapy for the control of hemorrhage.

Diagnostic Tests for *Helicobacter pylori*

Eradication of *H. pylori* infection is associated with a significant reduction in ulcer recurrence. *H. pylori* testing is thus essential in all patients with PUD, and the diagnostic options and the indications for their use are summarized in Figure 36-6. Immunoglobulin G serologic testing is the noninvasive test of choice for diagnosing *H. pylori* infection in the untreated patient. However, because the antibodies may persist for several years, serologic analysis is not useful as a means to document cure of the infection since positive results may reflect past exposure but not necessarily current infection with *H. pylori*. Another noninvasive approach to detecting *H. pylori* is the ¹³C- or ¹⁴C-labeled urea breath test.

When present, *H. pylori* urease splits the urea, which may be detected as labeled carbon dioxide in the breath of a patient. The urea breath test is more accurate than serologic tests, and although more expensive and less widely available, it is the noninvasive test of choice to document successful *H. pylori* eradication after antibiotic therapy. Patients should not receive PPIs for at least 14 days before administration of breath tests to avoid false-negative results. Stool antigen testing is also available and useful in the initial diagnosis of *H. pylori* infection. If endoscopic examination is performed, the diagnosis is made by the rapid urease test or histologic testing. In the rapid urease test, mucosal biopsies are placed in a urea-containing medium with a pH-sensitive indicator that changes color when ammonia is produced from urea by the urease of the organism. The rapid urease test has high sensitivity and specificity, equivalent to histologic analysis, and is inexpensive. Recent treatment with antibiotics or PPIs, however, may decrease the yield of the test. Histologic analysis is frequently the standard for detecting *H. pylori* infection and can establish the degree, type, and location of inflammation. Gastric biopsy specimens should be taken from both the antrum and the corpus because the bacteria are not uniformly distributed throughout the stomach. The presence of chronic active gastritis is strongly suggestive of *H. pylori* infection, even if bacteria are difficult to identify.

Treatment

Treatment of Peptic Ulcer Disease

Healing Ulcers by Suppressing Acid Secretion

Regardless of the cause, inhibition of gastric acid secretion continues to be the cornerstone of therapy for PUD. Antacids are effective agents for healing ulcers and may provide some symptom relief. However, because of the need to take these drugs multiple times each day, and the associated adverse effects, antacids are now rarely used as initial therapy.

H₂ receptor antagonists reduce acid secretion by competitively and selectively inhibiting histamine receptors on the parietal cell. H₂ receptor antagonists increase intragastric pH and inhibit pepsin activity. In general, H₂ receptor antagonists are safe and well tolerated, although the occurrence of adverse effects is slightly increased with cimetidine because of binding to cytochrome P-450 and hence increased risk for drug interactions. H₂ receptor antagonists heal 90% to 95% of duodenal ulcers and 88% of gastric ulcers after 8 weeks. Given as a single full dose at bedtime, cimetidine (800 mg), ranitidine and nizatidine (300 mg), and famotidine (40 mg) have comparable efficacies for ulcer healing. The recommended duration of treatment is 4 weeks for duodenal ulcers and 8 weeks for gastric ulcers.

Proton pump inhibitors, or PPIs, are the most potent inhibitors of gastric acid secretion available and heal gastroduodenal ulcers more rapidly than H₂ receptor antagonists. However, because they are most effective when the parietal cell is stimulated to secrete acid in response to a meal, PPIs should only be taken before a meal and should not be used in conjunction with H₂ receptor antagonists or other antisecretory agents. Moreover, because acid secretion must be stimulated for maximal efficacy, PPIs are administered before the first meal of the day. These agents are safe and well tolerated; adverse effects are unusual and include headache, diarrhea, and nausea. Single daily doses

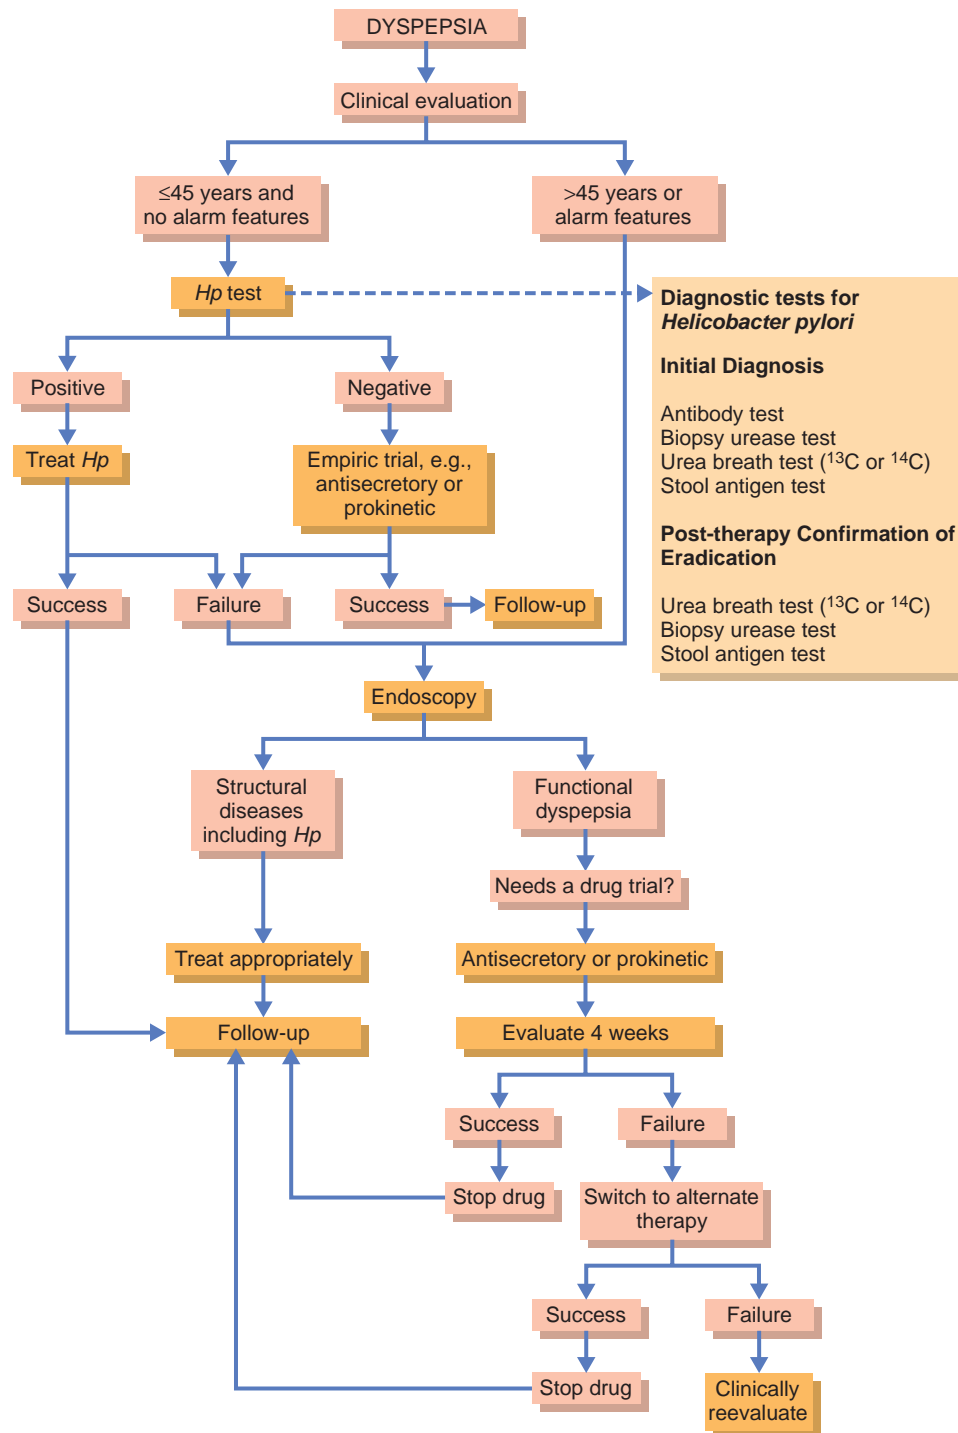

FIGURE 36-6 Diagnostic approach to patients presenting with uninvestigated dyspepsia. Alarm features include weight loss, vomiting, dysphagia, evidence of anemia, gastrointestinal bleeding, or an abdominal mass or lymphadenopathy. *Hp*, *Helicobacter pylori*. (Modified from American Gastroenterological Association medical position statement: evaluation of dyspepsia, *Gastroenterology* 114:579-581, 1998.)

of omeprazole (20 mg), pantoprazole (40 mg), rabeprazole (20 mg), lansoprazole (30 mg), or esomeprazole (40 mg), all before breakfast, are effective in healing gastroduodenal ulcers. The recommended duration of treatment is again 4 weeks for duodenal ulcers and 8 weeks for gastric ulcers.

Healing by Enhancing Mucosal Defense

Sucralfate, a complex salt of sucrose sulfate and aluminum hydroxide, appears to be as effective as H₂ receptor antagonists

in the treatment of duodenal ulcer disease. The evidence for efficacy in healing of gastric ulcers is less compelling. Sucralfate has little or no effect on acid secretion and acts through several different mucosal protective mechanisms. In the gastroduodenal lumen, sucralfate becomes a gel-like substance that binds to both defective and normal mucosa, acting as a physical barrier to the diffusion of acid, pepsin, and bile acids. The recommended dose is 1 g 4 times daily, which makes it less convenient than other agents for treating PUD.

Although bismuth compounds and prostaglandin analogues have been shown to provide protective effects on the gastroduodenal mucosa and may have some effect on ulcer healing, these agents are not routinely used in the initial treatment of peptic ulcers.

Treatment of *Helicobacter pylori* Infection

Eradication of *H. pylori* should be attempted in all patients with documented current or past PUD and evidence of infection. Successful therapy requires a combination of drugs that prevents the emergence of resistance and effectively reaches the bacteria, and must be of sufficient duration to ensure eradication. Combinations of two antibiotics, plus either a PPI or ranitidine bismuth citrate, are used to maximize the chance of eradication. Current treatment regimens for *H. pylori* are shown in Table 36-1. Factors such as antibiotic resistance and noncompliance with therapy have been identified as predictors of treatment failure. Metronidazole resistance is most common, and both metronidazole and clarithromycin resistance are increasing in frequency, with rates of 37% and 10%, respectively. Because compliance is essential for treatment success, the current regimens offer simpler dosing than earlier options. A failed initial course of antibiotic therapy suggests antibiotic resistance, and it may be assumed that, if the patient received metronidazole or clarithromycin in the original regimen, resistance to that antibiotic is present. When possible, repeat use of the same antibiotic should be avoided. The recommended duration for repeat treatment courses is 14 days. An alternative initial approach involves a shorter, 10-day treatment course with PPI and sequential dosing of amoxicillin and clarithromycin, but further validation studies are needed before this can be recommended as standard therapy.

Maintenance Therapy

Before embarking on long-term maintenance therapy for PUD, careful attention must be paid to eliminating the most important risk factors for ulcer recurrence: *H. pylori* infection and NSAID use. Moreover, hypersecretory states, including gastrinoma, should be excluded in individuals with recurrent ulcers without *H. pylori* infection. Patients with a history of ulcer complications,

frequent ulcer recurrence, continued NSAID use, or *H. pylori*-negative ulcers, and those who fail to clear *H. pylori* infection despite appropriate therapy, should be considered candidates for maintenance antisecretory therapy. However, even patients who have had a complicated ulcer may not require maintenance therapy, provided *H. pylori* infection is cured. Maintenance regimens include an H₂ receptor antagonist at bedtime at one half the dose required for initial healing or a full-dose PPI taken before breakfast.

Treatment and Prophylaxis of NSAID-Induced Ulceration

The optimal treatment of patients with NSAID-induced gastroduodenal ulcers is the discontinuation of the offending agent. If NSAIDs must be continued, therapy with an antisecretory agent should be instituted. Based on their superior safety profile and their ability to heal gastroduodenal ulcers at an accelerated rate whether or not NSAID use is continued, PPIs are preferred over both H₂ receptor antagonists and misoprostol.

Because of the significant rate of serious complications associated with NSAIDs and the poor correlation between dyspeptic symptoms (e.g., abdominal pain, distention, nausea, heartburn) and the presence of gastroduodenal mucosal injury, prevention of ulceration has become the principal goal in the management of NSAID-related GI toxicity. Risk factors for NSAID-related injury include advanced age (>60 years), prior history of PUD or ulcer hemorrhage, concomitant use of anticoagulants or corticosteroids, significant comorbid conditions, and use of high NSAID doses (Table 36-2). Two strategies have been used to prevent ulcers: (1) the concomitant use of medications such as misoprostol or PPIs, and (2) the development of safer anti-inflammatory agents, such as COX-2-specific inhibitors. Misoprostol, a prostaglandin E₁ analogue, significantly reduces the development of both gastric and duodenal ulcers in patients using NSAIDs. By augmenting prostaglandin-dependent pathways, misoprostol reduces gastric acid secretion and enhances mucosal defenses. However, misoprostol is associated with significant adverse effects and a high frequency of therapy discontinuation as a result of these effects, especially when administered 4 times a day. The most frequent symptom is diarrhea, although symptoms such as abdominal pain, nausea, and bloating may also occur. A lower dose of misoprostol (200 mcg 3 times daily) is nearly as effective as 4 times daily dosing for preventing duodenal and gastric ulcers, with a slight reduction in the occurrence of adverse effects.

The second strategy to prevent NSAID-induced ulcers involves the co-administration of an antisecretory agent, usually a PPI, or the substitution of the traditional NSAID with one of the newer

TABLE 36-1 TREATMENT REGIMENS FOR *HELICOBACTER PYLORI* INFECTION

Triple therapy (cure rate, 85% to >90%)
BMT triple therapy for 14 days
Bismuth subsalicylate, 524 mg by mouth 4 times daily
Metronidazole, 250 mg by mouth 4 times daily
Tetracycline HCl, 500 mg by mouth 4 times daily + H ₂ -RA for additional 4 weeks
LAC for 10 or 14 days
Lansoprazole, 30 mg by mouth twice daily
Amoxicillin, 1 g by mouth twice daily
Clarithromycin, 500 mg by mouth twice daily
OAC for 10 or 14 days
Omeprazole, 20 mg by mouth twice daily
Amoxicillin, 1 g by mouth two times daily
Clarithromycin, 500 mg by mouth twice daily
RBC-AC (cure rate, >90%)
Ranitidine bismuth citrate + amoxicillin + clarithromycin
MOC (cure rate, >90% in the absence of metronidazole resistance)
Metronidazole + omeprazole + clarithromycin
H ₂ -RA, histamine-2 receptor antagonist; HCl, hydrochloric acid.

COX-2–specific inhibitors. According to available evidence, PPIs are superior to H₂ receptor antagonists in preventing gastroduodenal ulceration and improving dyspeptic symptoms during continued NSAID use. Similarly, PPIs provide protection against endoscopic NSAID ulcers at a rate at least comparable with that of misoprostol, with fewer associated GI symptoms. However, misoprostol, but not PPIs, has been shown in a prospective analysis to decrease the prevalence of ulcer complications.

COX-2–specific inhibitors (e.g., celecoxib, rofecoxib, valdecoxib) have suggested an improved GI safety profile with reduced incidence of ulcers and ulcer complications and at least similar effectiveness when compared with traditional NSAIDs. However, recent evidence suggesting an increased risk for cardiovascular events, specifically myocardial infarctions and strokes, associated with the use of selective COX-2 inhibitors, has led to significant public concern with subsequent market withdrawal of some of these agents and restricted use of others. These adverse effects are thought to be related, at least in part, to the inhibition of prostacyclin with the resultant unopposed *thrombogenic* effects of thromboxane A₂. Concern over this issue led to the withdrawal of rofecoxib and valdecoxib from the US market in 2005. Recommendations for the use of nonselective NSAID versus celecoxib and the use of either PPI or misoprostol involve risk stratification of the patient's cardiovascular risk and GI risk by the clinician.

More recent meta-analyses have suggested that concomitant *H. pylori* infection and NSAID use increase the risk for ulcer complications. Therefore, in patients who require chronic NSAID use, the current recommendation is to test for and eradicate *H. pylori*, given that it is a treatable risk factor.

Surgery

Because of the remarkable progress in pharmacologic acid suppression therapy and the recognition that ulcer disease can be cured by eliminating *H. pylori* infection and NSAIDs, surgery now plays a marginal role in treating uncomplicated PUD. Surgical intervention is now mostly reserved for managing the complications of peptic ulcers, especially gastric outlet obstruction and perforation. Some of the different surgical approaches are shown in Figure 36-7.

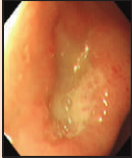

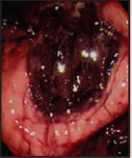

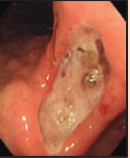

Complications of Peptic Ulcer Disease

Bleeding

PUD is the leading cause of upper GI bleeding, accounting for about 50% of cases and more than 150,000 hospital admissions

annually in the United States. Although bleeding ceases spontaneously in 80% of patients, the mortality rate associated with bleeding ulcers is 5% to 10%. Patients with bleeding ulcers exhibit hematemesis, melena, or hematochezia, often without abdominal pain. The major risk factor for bleeding ulcers is NSAID use. Predictors for an adverse outcome include hemodynamic instability at presentation, bright red blood from the rectum or through the nasogastric tube, age older than 60 years, ongoing transfusion requirements, and an increasing number of underlying medical illnesses. All patients with upper GI bleeding should undergo early upper endoscopic examination, which allows for both therapeutic intervention and the determination of other predictors for rebleeding. Rebleeding rates are about 5% for clean-based ulcers, 10% for ulcers with flat spots, 22% for adherent clots, 43% for nonbleeding visible vessels, and 55% for active oozing or spurting from an ulcer (Fig. 36-8). Patients with large ulcers, greater than 1 to 2 cm in diameter, also have increased rebleeding and mortality rates. Endoscopic therapy with techniques such as multipolar or thermal coagulation, injection with epinephrine, or placement of hemostatic clips, clearly improves the outcome in patients with bleeding ulcers by decreasing mortality, length of hospital stay, number of blood transfusions, and need for emergency surgery.

Because most ulcer bleeding recurs within 3 days of initial presentation, patients with active bleeding or stigmata of hemorrhage, such as raised pigmented spots in an ulcer crater, can be discharged within 2 to 3 days if they are stable. Given the excellent prognosis for patients with clean-based ulcers, discharge within 24 hours of presentation or immediately after endoscopic examination appears to be safe. About 20% of patients rebleed after endoscopic therapy, and 50% of these can be successfully retreated. The remainder may be treated angiographically with either intra-arterial vasopressin or embolization techniques. Surgery is generally reserved for instances in which all other measures have failed. Although endoscopic therapy is the first treatment modality in the management of actively bleeding gastroduodenal ulcers, some evidence also suggests that adjuvant use of acid suppression therapy can reduce recurrent bleeding after initial endoscopic control. A continuous infusion of an intravenous PPI has been shown to reduce the incidence of recurrent ulcer hemorrhage following endoscopic therapy. Thus, patients with significant upper GI bleeding in whom a peptic ulcer is suggested should be treated with an intravenous PPI using a loading dose (80 mg of pantoprazole) followed by a continuous infusion (8 mg per hour of pantoprazole). If at the time of endoscopic

	Clean base	Flat spot	Adherent clot	NBVV*	Active bleed

examination, no evidence of recent or active bleeding can be found, and after feeding has been initiated, oral administration can be substituted for the parenteral route.

Perforation

Perforation, which occurs when a peptic ulcer erodes through the full thickness of the stomach or duodenum, is far less common than bleeding. Ulcer perforation usually leads to peritonitis, which, if untreated, may result in sepsis and death. Patients exhibit a sudden onset of severe abdominal pain that typically begins in the epigastrium and radiates throughout the entire abdomen. When peritonitis is present, physical examination is remarkable for abdominal pain, guarding, rebound tenderness, and boardlike rigidity. The clinical suggestion of perforation may be confirmed in most cases by the presence of free intra-abdominal air (pneumoperitoneum) with either an upright chest radiograph or upright and supine abdominal radiographs. In less obvious instances, computed tomography (CT) or an upper GI water-soluble contrast study may be helpful. Perforation mandates surgical intervention. A perforated duodenal ulcer is typically repaired with an omental patch, whereas a perforated gastric ulcer necessitates either an omental patch or a partial resection.

Gastric Outlet Obstruction

In the era before acid suppression and *H. pylori* therapy, PUD accounted for 60% of the cases of gastric outlet obstruction.

More recently, the incidence of both ulcers and obstruction requiring surgery has declined, and estimates indicate that fewer than 5% of patients with duodenal ulcer and less than 1% to 2% with gastric ulcer develop significant gastric outlet obstruction. Gastric outlet obstruction is typically caused by either pyloric channel or duodenal ulcers and may be seen in the setting of acute ulceration, in which edema, spasm, and inflammation lead to obstruction, or as a consequence of chronic ulceration with scarring and fibrosis. Patients usually exhibit symptoms of early satiety, bloating, nausea, vomiting, and weight loss. Endoscopy is the diagnostic test of choice but visualization of the lesion is frequently obscured by the presence of retained food residue. Patients in whom gastric outlet obstruction is suggested should undergo gastric decompression and lavage to remove retained gastric contents before endoscopic examination. Malignancy may now account for 50% of instances of gastric outlet obstruction and should be excluded with adequate biopsy and cytology samples. Occasionally, imaging techniques such as barium upper GI series and radionuclide gastric-emptying scans can also be used to determine the length of the obstructed area and to evaluate gastric emptying. In addition to the correction of fluid, electrolyte, and pH imbalances resulting from persistent vomiting, patients with gastric outlet obstruction should undergo nasogastric decompression for 3 to 5 days. During that time, acid suppression with an intravenous H_2 receptor antagonist or PPI should also be instituted. Adequacy of response may be assessed

empirically with a trial of refeeding. For patients failing to respond to medical therapy, treatment options include endoscopic balloon dilation and surgery.

GASTRITIS

Clinical Presentation

Gastritis represents a nonspecific inflammation of the mucosal surface of the stomach. Clinically, the three most common causes of gastritis are *Helicobacter pylori*, nonsteroidal anti-inflammatory drugs (NSAIDs), and stress-related mucosal changes. The approach to *H. pylori* and NSAID induced gastritis is similar to that for PUD, and is detailed above.

Stress-Related Gastric Mucosal Damage

During critical illness, events such as shock, hypotension, and catecholamine release are associated with reduced blood flow to the GI tract and mucosal ischemia. When blood flow to the mucosa is inadequate, the normal mucosal protective mechanisms, including epithelial turnover and mucus and HCO₃ secretion, are altered. In addition, mediators such as cytokines and oxygen-free radicals are released. The combination of these events reduces the mucosal resistance to acid back-diffusion, causing erosions that may progress to ulceration and bleeding. Although mucosal damage develops in most critically ill patients, stress ulcers usually remain superficial and do not erode through the stomach wall to cause perforation. The major problem is blood loss, which is occult in most instances. Although occult stress ulcer bleeding occurs in 20% of patients in long-term intensive care units, gross hemorrhage occurs in only 5%.

Treatment

Aggressive volume resuscitation, control of sepsis, and adequate oxygenation in critically ill patients are important measures that may reduce the occurrence of low-flow states and subsequent mucosal damage. A wide variety of prophylactic strategies are used to prevent GI bleeding in critically ill patients. Pharmacologic agents used in this setting exert their effects through three main mechanisms: (1) acid neutralization, (2) mucosal protection, and (3) inhibition of gastric acid secretion. Acid neutralization with antacids is effective but requires administration every 1 to 2 hours through a nasogastric tube, which is inconvenient and increases nursing time. The side effects of magnesium-containing antacids include diarrhea, hypermagnesemia, and alkalemia, whereas aluminum-based antacids cause hypophosphatemia, constipation, and metabolic alkalosis, as well as potentially toxic plasma aluminum levels in patients with renal insufficiency. Mucosal protective agents such as sucralfate, an aluminum salt of sucrose sulfate, may improve mucosal blood flow through a prostaglandin-mediated mechanism. Sucralfate is well tolerated at doses of 1 g every 4 to 6 hours. Constipation occurs in 2% to 4% of patients, and aluminum toxicity has occurred in patients with chronic renal failure. Prostaglandin analogues (e.g., misoprostol) exert a protective effect on the gastric mucosa but have not been carefully studied for stress ulcer prophylaxis, and their use in this setting cannot be recommended. Antisecretory agents inhibit gastric acid secretion and are

frequently used in the prevention of stress-induced mucosal damage in critically ill patients. Histamine-2 (H₂) receptor antagonists (e.g., cimetidine, ranitidine, famotidine, nizatidine), given either as a continuous infusion or by bolus injection, have been shown to reduce the incidence of clinically significant stress bleeding. An increase in intragastric pH to greater than 4 has been demonstrated with these agents; however, tolerance occurs rapidly and may limit their clinical efficacy. Although H₂ receptor antagonists are considered safe, they do possess both class-specific and individual side-effect potentials. The most prominent class-specific effect is central nervous system toxicity, which occurs more frequently in elderly patients compared with other age groups. Proton pump inhibitors (PPIs) irreversibly block parietal cell H⁺, K⁺-ATPase. These agents (e.g., omeprazole, lansoprazole, rabeprazole, pantoprazole, esomeprazole) are prokinetic agents that are normally activated following systemic absorption and localization to the highly acid milieu of the secretory canaliculus of *activated* parietal cells. Activation occurs after a meal, and because critically ill patients are generally fasting, PPIs administered orally or by nasogastric tube are significantly less active in this setting and are thus not recommended. However, in patients receiving enteral feeding, PPIs administered by the enteral route suppressed acid more effectively than intravenous PPIs. Pantoprazole, the first intravenous PPI available in the United States, has shown promising results in several small studies and may prove beneficial in stress bleeding prophylaxis. Intravenous preparations of lansoprazole and esomeprazole have recently become available.

Prophylaxis is recommended in patients with coagulopathy and those with respiratory failure requiring mechanical ventilation for more than 48 hours. Other patients in whom stress bleeding prophylaxis is indicated include those with central nervous system trauma, burns, organ transplantation, a history of PUD with or without bleeding, multiorgan failure, trauma, and major surgery (Table 36-3).

Other Causes of Gastritis

Autoimmune atrophic gastritis exhibits an autosomal-dominant inheritance pattern and is associated with autoantibody formation. Histologically, autoimmune atrophic gastritis is characterized by chronic inflammation, gradual atrophy of glands, and loss of parietal cells. The process is usually confined to the corpus and fundus, where the gastric glands tend to undergo intestinal metaplasia. Loss of parietal cells results in achlorhydria, vitamin B₁₂ deficiency, and megaloblastic anemia (pernicious anemia). These patients have an increased risk for carcinoma, seen especially in Scandinavian countries. No overall increased cancer risk has been documented in American patients, and routine surveillance has not been advocated in the United States.

Respiratory failure	
Central nervous system trauma	
Burns	
Organ transplantation	

Lymphocytic gastritis is characterized by a mononuclear infiltration of T cells, usually antral predominant, and is often associated with celiac disease, collagenous and lymphocytic colitis, and Ménétrier disease. *Eosinophilic gastritis* is characterized by an eosinophilic infiltration of the stomach, especially the antrum. All layers of the gastric wall may be affected, but selective predominance of eosinophilic infiltrates may be found in the submucosa, muscle layers, or subserosa, making biopsy diagnosis difficult. Clinical manifestations include delayed gastric emptying or manifestations of anemia from chronic blood loss caused by associated mucosal ulceration. Corticosteroids are used to control symptoms.

Ménétrier disease is a rare disease characterized by giant gastric folds in the fundus and the body of the stomach. Histologically, increased mucosal thickness, glandular atrophy, and an increase in the size of the gastric pits are characteristic findings. Hypochlorhydria and hypoalbuminemia are commonly seen. In children, Ménétrier disease is thought to be caused by cytomegalovirus (CMV), whereas overexpression of a tissue growth factor has been implicated in the adult form of the disease.

In addition to *H. pylori*, a variety of infectious pathogens may involve the stomach. Gastric infections are typically seen in patients who are immunocompromised in the settings of HIV infection, chemotherapy, and organ transplantation. Bacterial infections such as tuberculosis and syphilis rarely involve the stomach. CMV and herpesvirus infection, as well as fungal (e.g., *Candida*, histoplasmosis, mucormycosis, cryptococcosis, aspergillosis), and parasitic infections (e.g., *Cryptosporidium*, *Strongyloides*) are also possible. Other diseases such as sarcoidosis and Crohn disease may involve the stomach. The presence of granulomas on histologic specimens, along with systemic manifestations of the disease, confirms the diagnosis.

The stomach is occasionally involved by acute *graft-versus-host* disease. Gastric erosions or ulcers may be encountered in the investigation of bone marrow transplantation patients with abdominal pain or GI bleeding. Biopsy specimens should be obtained to rule out opportunistic infections (e.g., CMV).

Alcohol, drugs (e.g., cocaine, iron, potassium chloride), and physical agents (nasogastric tubes) are also associated with nonspecific forms of gastritis. Similarly, ischemia as a result of vascular injuries, embolization, vasculitis, and amyloidosis has been described as a cause of gastritis.

NONULCER DYSPEPSIA

Dyspepsia, defined as pain or discomfort in the upper abdomen, is a common clinical problem and may be seen at some time in 25% to 40% of adults. Though dyspepsia is a classic manifestation of PUD, only 15% to 25% of patients with dyspepsia are found to have a gastric or duodenal ulcer. The remainder of patients have nonulcer or functional dyspepsia, a condition most likely related to an abnormal perception of events in the stomach caused by afferent visceral hypersensitivity. Abnormal gastric motility may also play a role in nonulcer dyspepsia (NUD), and recent evidence suggests that about 40% of patients with NUD have impairment in the fundic accommodation response of the stomach. Dyspeptic symptoms may be chronic, recurrent, or of new onset. The diagnostic evaluation should focus on excluding other causes of dyspepsia such as gastroparesis and gastric cancer.

Management

Three possible strategies for managing patients with NUD have been formulated (see Fig. 36-6). Immediate endoscopic evaluation is indicated for individuals older than 45 years and persons exhibiting alarm features (*red flags*) such as weight loss, recurrent vomiting, dysphagia, GI bleeding, anemia, a strong family history of GI cancer, or an abdominal mass. Urgent endoscopic examination is indicated to exclude a serious underlying disease process, particularly gastric and esophageal carcinoma. If a gastric ulcer is found during endoscopic examination, multiple biopsies and cytologic analysis should be obtained to exclude malignancy. Ulcer treatment is subsequently employed, and ulcer healing should be confirmed with a follow-up endoscopic examination because nonhealing ulcers can occasionally be a manifestation of gastric carcinoma. Barium radiography offers poor sensitivity and specificity and is thus no longer recommended in the evaluation of dyspepsia.

The second option when treating patients younger than 45 years with NUD but without alarm features is an empirical trial of antisecretory therapy for 1 to 2 months. Endoscopy is indicated in patients who fail to respond to this regimen. Avoiding the introduction of long-term drug use in this situation is important, particularly because of the considerable benefit of placebo in such individuals.

The third strategy for managing NUD involves initial noninvasive testing for *H. pylori* followed by antimicrobial therapy in patients with positive tests. This strategy is presumed to heal ulcers if present, eliminate the ulcer diathesis, and save on resources, particularly in patients younger than 45 years without alarm symptoms. The frequency of *H. pylori* infection in the community should also be taken into account because noninvasive tests show decreased accuracy when the prevalence of *H. pylori* is less than 10%. This approach, although advocated by some physicians, has shown variable effectiveness in relieving NUD. Moreover, indiscriminate use of antimicrobial therapy may be associated with altering normal intestinal flora, increasing resistance of *H. pylori* and other bacteria that are not a target of therapy, and producing a series of adverse events such as antibiotic-associated and *Clostridium difficile* colitis.

ZOLLINGER-ELLISON SYNDROME

Zollinger-Ellison Syndrome (ZES) is characterized by elevated levels of serum gastrin produced by gastrin-secreting tumors that are most often located in the pancreas and duodenum. Hypergastrinemia stimulates hypersecretion of gastric acid and pepsin, which may produce peptic ulcers, duodenojejunitis, esophagitis, and diarrhea. ZES is an uncommon cause of PUD, accounting for less than 1% of the instances. The gastrin-secreting tumor in ZES, referred to as a *gastrinoma*, is frequently located in the *gastrinoma triangle*, an area encompassed by the second and third portions of the duodenum, the junction of the head and neck of the pancreas, and the cystic duct. Seventy-five percent of all gastrinomas are sporadic; the remaining 25% are part of the type I multiple endocrine neoplasia (MEN-I) syndrome, an autosomal-dominant condition with a locus on chromosome 11, typically associated with hyperparathyroidism and pituitary tumors. All patients with sporadic gastrinomas without evidence of liver

metastases should be surgically explored with the intent of removing local and regional disease. Unfortunately, despite careful diagnostic testing, no tumor is found in at least 10% of diagnosed instances of ZES.

ZES should be considered in patients with recurrent PUD in the absence of *H. pylori* infection or NSAID use, as well as in patients with multiple duodenal ulcers, ulcers in unusual locations (distal duodenum or jejunum), or severe or refractory diarrhea or gastroesophageal reflux disease. Although peptic ulcer occurs in more than 90% of patients with ZES, as many as 35% of individuals exhibit only diarrhea. The diagnosis of ZES is made when a fasting gastrin concentration of more than 1000 pg/mL exists in the setting of gastric acid hypersecretion. In equivocal cases (e.g., gastrin <1000 pg/mL), a positive secretin provocative test will confirm the diagnosis. The secretin test is positive (≥ 200 pg/mL increase over the preinjection fasting gastrin level) in about 90% of patients with ZES and moderately elevated gastrin levels. Basal acid output is elevated (>15 mmol per hour without previous gastric acid-reducing surgery and >5 mmol per hour with prior surgery) in more than 90% of patients with ZES. Because gastrinomas constitute a relatively uncommon cause of hypergastrinemia, other causes of an elevated gastrin level should be considered. The most common causes of hypergastrinemia are antrum-dominant *H. pylori* infection or achlorhydria related to either decreased intraluminal acid in the setting of atrophic gastritis or antisecretory therapy with PPIs. Hypergastrinemia may be related to other causes, including retained gastric antrum (after ulcer surgery), massive small bowel resection, chronic gastric outlet obstruction, and chronic renal failure. Therefore, the presence of acid hypersecretion, as documented by gastric acid analysis, may be necessary to establish the diagnosis.

Once hypergastrinemia has been established and obvious causes have been excluded, efforts should focus on localizing and resecting the gastrin-secreting tumor. The single best imaging test for gastrinoma is somatostatin-receptor scintigraphy (SRS), which is more sensitive than conventional imaging studies, including CT, magnetic resonance imaging (MRI), and ultrasonography, although endoscopic ultrasonography (EUS) is equally sensitive for localizing primary tumors of the pancreas. If liver metastasis is present, a CT- or ultrasound-guided liver biopsy should be performed. In patients without liver metastasis, SRS will localize a possible primary tumor in 60% of cases. If the patient is a surgical candidate and SRS is positive for a primary tumor, no additional localization studies are required. If the SRS is negative for a possible primary tumor, the use of MRI, angiography, or EUS will detect a possible primary tumor in an additional 15% of patients. Multiple pancreatic or duodenal tumors are generally detected in patients with MEN-I syndrome, and although the precise role of surgery in these patients is less certain, some physicians recommend surgery if a lesion larger than 3 cm is identified with preoperative imaging techniques to decrease the possibility of hepatic metastasis. However, successful and long-lasting remission of MEN-I syndrome occurs rarely, if at all.

All patients with ZES, whether sporadic or familial, require antisecretory therapy after the diagnosis is established and during initial evaluation as attempts are made to localize the gastrinoma. Patients with ZES should be treated initially with a PPI using

twice the dose normally employed to treat common gastroduodenal ulcers. Intravenous PPIs such as pantoprazole in daily doses ranging from 80 to 240 mg can be used in patients who are unable to take medications by mouth, including those undergoing surgery. The goal of therapy is a basal acid output of less than 10 mmol per hour in the hour preceding the next dose of the drug. Chronic therapy with PPIs uniformly results in continued inhibition of acid secretion, good symptom control, complete healing of any mucosal lesions, and few adverse effects.

GASTROPARESIS

Gastroparesis is a syndrome characterized by delayed gastric emptying, resulting in impaired transit of food from the stomach to the duodenum in the absence of mechanical obstruction. Symptoms of gastric stasis include early or easy satiety, bloating, nausea and vomiting, and abdominal discomfort. Because eating exacerbates symptoms, patients frequently exhibit anorexia, weight loss, and nutritional deficiencies. A wide range of clinical disorders is associated with impaired gastric emptying (Table 36-4).

Diabetes mellitus is the most common cause of gastroparesis, and up to 60% of patients with diabetes complain of symptoms consistent with gastric stasis. Although gastroparesis is typically seen in individuals with long-standing (>10 years) type 1 diabetes who have other complications, such as peripheral and autonomic neuropathy, nephropathy, and retinopathy, GI complaints are also common within the first decade of diagnosis. Diabetic gastroparesis appears to occur as a result of permanent neuropathy of autonomic and enteric nerves, transitory variations in glycemic control, or a combination of both. Idiopathic gastroparesis is also common and comprises those instances with no clearly identifiable cause. Up to one third of these patients have virus-induced gastroparesis, with viral infiltration of the myenteric plexus in the stomach. Patients who have undergone gastric

surgery, especially those having had preoperative gastric outlet obstruction as a complication of PUD, are also commonly affected by gastroparesis. Finally, Parkinson's disease, rheumatologic disorders, hypothyroidism or hyperthyroidism, chronic intestinal pseudo-obstruction, and a variety of paraneoplastic syndromes can also produce gastroparesis.

The diagnostic evaluation of delayed gastric emptying should focus on excluding structural and metabolic abnormalities. Endoscopy is the preferred initial test to rule out mechanical gastric outlet obstruction, and a CT enterography or capsule endoscopic study may be useful to exclude small bowel lesions. Serum electrolytes, blood cell counts, and thyroid studies should also be performed. When these studies are negative, radionuclide scintigraphy (gastric-emptying scan) using a mixed solid-liquid meal can quantitate delayed gastric emptying. Assessment of solid emptying is more clinically relevant than liquid emptying. In especially difficult cases, GI manometry and electrogastrography may help in the diagnosis.

Managing gastroparesis begins with identifying and treating potentially correctable causes. Medications that reduce gastric emptying, such as narcotics, anticholinergics, and tricyclic antidepressants, should be avoided. Because liquids empty easier than solids, and because liquid emptying is often preserved in patients with gastroparesis, simple dietary modifications may be helpful in treatment. The diet should be modified to include blenderized foods and liquid supplements. High-fat and fiber-rich foods should be avoided because they inhibit gastric emptying under normal conditions and are less likely to empty. Medical options are limited and involve the use of prokinetic drugs, which are agents that improve transit in the GI tract.

Metoclopramide is a dopamine-2 receptor antagonist that also facilitates the release of acetylcholine from cholinergic nerve terminals in the gut, thereby accelerating gastric emptying. The efficacy of metoclopramide is inconsistent, and adverse effects and the development of tolerance complicate long-term therapy. Adverse effects occur in up to 20% of patients and include drowsiness, anxiety, fatigue, insomnia, restlessness, agitation, extrapyramidal effects, galactorrhea, and menstrual irregularities. The typical dosage is 10 mg, 20 to 30 minutes before meals and at bedtime, although doses as high as 80 mg or as low as 20 mg may be used daily. Doses should be reduced for patients with renal failure. Domperidone, another dopamine receptor antagonist with prokinetic properties, has similar efficacy to metoclopramide in the treatment of delayed gastric emptying but is currently not available in the United States.

Erythromycin is a macrolide antibiotic that stimulates smooth muscle motilin receptors located at all levels of the GI tract. The prokinetic effects of erythromycin are related to its ability to mimic the effect of the GI peptide motilin to stimulate smooth muscle contraction, which accounts for the acceleration of solid and liquid gastric emptying. Erythromycin may dramatically improve gastric emptying in patients with severe diabetic gastroparesis when given acutely at an intravenous dose of 1 to 3 mg/kg every 8 hours. Long term use of the drug at a dose of 250 to 500 mg orally every 8 hours in patients with gastric stasis is of limited efficacy because of tachyphylaxis and side effects.

Endoscopic botulinum toxin A injection into the pyloric sphincter has also been reported in the treatment of delayed

gastric emptying in small studies, but larger clinical trials have not shown this procedure to be effective.

In patients who are refractory to these measures, surgical placement of a jejunal tube, with or without a venting gastrostomy, may be necessary. Total parenteral nutrition is rarely indicated. Surgical gastrectomy should only be considered in patients with refractory postsurgical gastric stasis. Gastric pacemakers and other prokinetics, specifically new serotonin-receptor agonists, are under investigation and may be options in the future.

● RAPID GASTRIC EMPTYING

Rapid gastric emptying is a far less common clinical problem than delayed gastric emptying. *Dumping syndrome* describes the alimentary and systemic manifestations of early delivery of large amounts of osmotically active food to the small intestine. Dumping syndrome is usually seen when the normal reservoir, grinding, and sieving properties of the stomach are disrupted, most commonly following surgery for obesity (Roux-en-Y gastric bypass) or PUD. The accelerated emptying of hypertonic boluses of nutrient material into the small intestine results in splanchnic vasodilation and release of vasoactive peptides. Early dumping symptoms, occurring about 30 minutes after a meal, include epigastric fullness and pain, nausea, vomiting, early satiety, and vasomotor features such as flushing, palpitations, and diaphoresis. Later symptoms, such as diaphoresis, tremulousness, and weakness, occur about 2 hours after a meal and may be caused by hypoglycemia from rebound hyperinsulinemia. Treatment of dumping syndrome involves dietary manipulation to decrease the volume and osmotic load emptied into the intestine. Frequent small feedings of meals low in carbohydrates, separation of liquid and solid intake, and avoidance of hypertonic fluids and lactose are usually helpful. When these measures fail, administration of octreotide at a dose of 25 to 50 mcg subcutaneously 30 minutes before meals may be helpful. Octreotide acts by slowing gastric emptying and intestinal transit as well as by inhibiting the release of insulin. Surgical procedures to slow gastric emptying have limited success.

● GASTRIC VOLVULUS

Gastric volvulus occurs when the stomach rotates within the abdominal or thoracic cavity, compromising its emptying and its vascular supply. This event may be transient, producing few if any symptoms, or may lead to obstruction or even ischemia and necrosis. *Primary gastric volvulus*, seen in one third of the patients, occurs below the diaphragm when the stabilizing ligaments are too lax as a result of congenital or acquired causes. *Secondary gastric volvulus* occurs above the diaphragm in association with paraesophageal hernias or other diaphragmatic defects. Acute gastric volvulus produces sudden, severe pain of the upper abdomen or chest, and persistent retching producing scant vomitus; this is often associated with the inability to pass a nasogastric tube by medical personnel. This combination of symptoms, also known as Borchardt triad, should lead to a strong clinical suggestion of acute gastric volvulus. Chronic gastric volvulus may be associated with mild and nonspecific symptoms, such as epigastric discomfort, heartburn, abdominal fullness or bloating, and borborygmi, especially after meals. The diagnosis of gastric volvulus is made by upper GI series demonstrating an

abrupt obstruction at the site of the volvulus. Acute gastric volvulus requires emergency surgical evaluation because of the substantial risk for mortality related to gastric ischemia or perforation. Treatment consists of surgical gastropexy and repair of any associated paraesophageal hernia.

Inflammatory Bowel Disease

Hannah L. Miller and Francis A. Farraye

INTRODUCTION

Inflammatory bowel disease (IBD) comprises two disorders: ulcerative colitis and Crohn's disease. The diagnosis of IBD is based on review of clinical, endoscopic, radiologic, and histologic data. Despite the chronic nature of these two diseases and the fact that their causes have not yet been defined, new and emerging targeted anti-inflammatory treatments hold great promise in helping to reduce morbidity and improve the quality of life of individuals with IBD.

DEFINITION AND EPIDEMIOLOGY

Ulcerative colitis (UC) is characterized by inflammatory changes that involve the colonic mucosa in a continuous superficial fashion, typically starting in the rectum and extending proximally. Depending on the extent of the disease, UC can be divided into proctitis (rectum only), proctosigmoiditis (rectum and sigmoid), left-sided colitis (extending to the splenic flexure), and pancolitis (inflammation extends proximal to the splenic flexure). This classification is significant for both prognosis and therapy. Unlike UC, Crohn's disease can involve any segment of the gastrointestinal tract from the mouth to the anus, often in a discontinuous fashion. It is characterized by transmural inflammation, which results in complications such as abscesses, fistulas, and strictures.

In the United States, about 1.4 million individuals have IBD, and the overall annual incidence is about 20 new cases per 100,000 persons years. Although the incidence of UC has remained stable for several decades, the incidence of Crohn's disease has been increasing; it now seems to have plateaued at levels approximately equivalent to those of UC. The prevalence of IBD in the United States is between 249 to 319 per 100,000 persons. A bimodal age at presentation exists, with an initial peak between the second and fourth decades of life and another peak in the sixth decade. The sexes are equally affected.

The incidence and prevalence of IBD reflects the interplay of complex genetic and environmental factors that contribute to these disorders. For example, both diseases are more common in northern climates and among whites, particularly populations with Northern European ancestry such as North Americans, South Africans, and Australians. Individuals of Ashkenazi Jewish descent also have a twofold to eightfold increased risk for these disorders compared with non-Jews. Although incidence rates of IBD are lowest among Hispanics and Asians, IBD can occur in any ethnic or racial group from anywhere in the world. The cause of IBD remains unknown, but it is believed that a combination of genetic, immunologic, infectious, and environmental factors

plays a role. In addition, state-of-the-art research points toward a relationship between the human microbiome and dysfunction of the immune system in patients with IBD.

Approximately 5% to 20% of patients with IBD have a first-degree relative with the disease, and first-degree relatives of IBD patients have about a 10- to 15-fold increased risk for developing IBD, predominantly with the same disease as the proband. A positive family history is more frequently observed in patients with Crohn's disease compared with UC, suggesting that genetic factors contribute more significantly in the etiology of Crohn's disease.

Through advances in genome-wide association studies, several susceptibility loci on multiple chromosomes have been linked to IBD, supporting a polygenic cause for these disorders. Polymorphisms in the *NOD2* gene (previously known as *CARD15*), located on chromosome 16, were the first definitive genetic risk factors identified for Crohn's disease. Homozygous mutations of the *NOD2* gene are associated with a greater than 20-fold increase in susceptibility for Crohn's disease. Defects in the *NOD2* protein appear to result in abnormal intestinal immune responses to bacterial cell wall components. These gene mutations are estimated to account for 15% to 25% of the cases of Crohn's disease and are linked predominantly to fibrostenotic terminal ileal disease. In addition to *NOD2*, other genes associated with Crohn's disease have been identified that regulate autophagy; they include *ATG16L1*, *IRGM*, and *LRRK*. Genes that regulate the interleukin-17 (IL-17) and IL-23 receptor pathways have been found to increase the risk for both UC and Crohn's disease; they include *IL23R*, *IL12B*, *STAT3*, *JAK2*, and *TYK2*. *IL27* and *TNFSF15* have been implicated only in Crohn's disease. Genes regulating epithelial barrier function have also been discovered for IBD, including members of the *OCTN/IBD5* susceptibility locus (*SLC22A4* and *SLC22A5*), *ECM1*, *CDH1*, *HNF4A*, *LAMB1*, and *GNA12*.

Currently, it is believed that IBD results from an inappropriate, overactive mucosal immune response to commensal intestinal bacteria or the microbiome in genetically susceptible individuals. Profound alterations in mucosal immunology have been demonstrated in patients with IBD. In the normal immunologic state of the intestine, recently activated lymphoid tissue is abundant within the mucosal compartment. This state has been described as controlled or *physiologic* inflammation, and it likely develops in response to constant encounters with antigenic substances (derived from host microbial flora or dietary and environmental sources) that have crossed the epithelial barrier from the luminal environment. Indeed, one of the main functions of the intestinal immune system is to discriminate noxious or harmful substances

and organisms from nonharmful ones. As a result, a large and well-maintained network of many different mucosal immune cells exists, including cells involved in reducing immune responses (regulatory cells) and those involved in activating immune responses. In IBD, this homeostatic balance, or immune tolerance, is dysregulated, resulting in overactivation of the immune system.

In Crohn's disease, there is an excessive and persistent CD4-positive helper T lymphocyte subtype 1 (T_H1) immune response to components of commensal bacterial flora. The T_H1 cytokine profile, which includes interferon- γ , IL-2, IL-12, and tumor necrosis factor- α (TNF- α), is elevated in patients with Crohn's disease. Patients with UC demonstrate greater expression of IL-5 and IL-13, cytokines characteristically associated with a T_H2 response. In addition, non- T_H1/T_H2 pathways have been identified as being potentially important in the pathogenesis of IBD. IL-23, for example, has been recognized as an inducer of a subset of proinflammatory T cells (T_H17) that secrete high levels of IL-17 and play an important role in mediating inflammation in murine models of colitis. IL-17 expression has been shown to be upregulated in active IBD, both Crohn's disease and UC.

Environmental factors also are believed to play a role in the pathogenesis of IBD, because the disease is more common in industrialized countries. Moreover, the frequency has tended to increase in countries as they become more industrialized. It has been postulated that poor sanitation, food contamination, and crowded living conditions are associated with helminthic infection, which leads to regulatory T-cell conditioning and stimulation of IL-10 and transforming growth factor- β production by mononuclear cells, thereby preventing intestinal inflammation. However, the only environmental factor clearly associated with IBD is tobacco smoking. Smoking seems to be protective against UC, whereas smoking in Crohn's disease causes a more aggressive disease. No dietary triggers have been found to cause IBD, but elemental diets and diversion of the fecal stream can reduce inflammation in Crohn's disease.

PATHOLOGY

Mucosal biopsies in IBD reveal acute and chronic inflammation with infiltration by plasma cells, neutrophils, lymphocytes, and eosinophils; focal ulcerations; crypt architectural distortion; and crypt abscesses (Figs. 37-1 and 37-2). In Crohn's disease, the inflammation is transmural and more commonly focal. Granulomas are found in 25% to 30% of histologic specimens in Crohn's disease, but not in UC. The presence of granulomas is not required but can assist in making the diagnosis of Crohn's disease in the right clinical setting (Fig. 37-3). Granulomas are not diagnostic because they can be found in many other diseases, such as Beçhet's disease, tuberculosis, *Yersinia* infection, and lymphoma.

CLINICAL PRESENTATION

Intestinal Manifestations

UC is characterized by chronic inflammation of the mucosal surface that involves the rectum and extends proximally through the colon in a continuous manner. The extent and severity of the colonic inflammation determine prognosis and presentation

FIGURE 37-1 Normal colonic mucosa (hematoxylin and eosin stain).

FIGURE 37-2 Mucosal biopsy specimen demonstrates crypt branching and a crypt abscess characteristic of ulcerative colitis (hematoxylin and eosin stain).

(insidious versus acute onset). Most patients initially exhibit diarrhea, abdominal pain, urgency to defecate, rectal bleeding, and the passage of mucus per rectum. At presentation, approximately 40% to 50% of patients have proctitis or proctosigmoiditis, 30% to 40% have left-sided colitis (disease extending to the splenic flexure), and the remaining 20% to 25% have pancolitis. Of the patients who initially present with proctitis or proctosigmoiditis, about 15% develop more extensive disease over time.

The typical clinical course of UC is one of chronic intermittent exacerbations followed by periods of remission. Signs of a worsening clinical course include the development of abdominal pain, dehydration, fever, and tachycardia. Clinical features that have been used to assess severity of UC include bowel frequency, fever, increased heart rate, and hematochezia (blood in the stool), as well as the presence of anemia and an elevated erythrocyte

FIGURE 37-3 Colonic biopsy specimen demonstrates a chronic inflammatory infiltrate with a granuloma in a patient with Crohn's colitis (hematoxylin and eosin stain).

sedimentation rate (ESR) or C-reactive protein (CRP) level. Anemia commonly occurs and is caused by chronic blood loss from the involved colonic mucosa as well as bone marrow suppression from the inflammatory condition. Perforation can occur in patients with severe or fulminant colitis, especially those taking corticosteroids, and in the setting of toxic megacolon. Toxic megacolon is characterized by gross dilation of the large bowel associated with fever, abdominal pain, dehydration, tachycardia, and bloody diarrhea.

The clinical presentation of Crohn's disease depends on the section of gastrointestinal tract involved and the type of inflammation. Crohn's disease can involve any portion of the gastrointestinal tract; the most common site is ileocecal (40% of patients), followed by isolated small bowel disease (30%) and isolated colonic involvement (25%). The remaining sites of Crohn's disease are rare (5%) and include the esophagus, stomach, and duodenum.

Symptoms in Crohn's disease often include right lower quadrant abdominal pain, fever, weight loss, diarrhea, and sometimes a palpable inflammatory mass. Hematochezia is less common than in UC. The disease is often present for months or years before diagnosis, and in children, growth retardation may be the sole presenting sign. In contrast to UC, the inflammation in Crohn's disease is transmural and can result in microperforations and the formation of fistulous tracts. Fistulas may form between different segments of bowel (e.g., enteroenteric, enterocolonic) or between bowel and skin (enterocutaneous), bowel and bladder (enterovesicular), or rectum and vagina (rectovaginal). Over time, as many as 30% to 40% of patients develop disabling perianal involvement with fissures, fistulas, and abscesses.

Chronic inflammation can cause fibrosis and stricture formation, which in turn may result in partial or complete intestinal obstruction, with the patient complaining of abdominal pain, distention, nausea, and vomiting. Strictures can also lead to stasis with subsequent small intestinal bacterial overgrowth. Extensive ileal mucosal disease may lead to malabsorption of vitamin B₁₂ (resulting in a megaloblastic anemia and neurologic side effects

if not corrected) and malabsorption of bile salts (resulting in diarrhea induced by unabsorbed bile salts and potential fat-soluble vitamin deficiency). Depletion of the bile salt pool can lead to the formation of gallstones. Weight loss may result from generalized malabsorption caused by loss of absorptive surfaces. Chronic fat malabsorption leads to luminal binding of free fatty acids to calcium; this allows oxalate, which normally is poorly absorbed because it complexes to calcium in the gut lumen, to be absorbed. The increase in oxalate absorption increases the risk for urinary calcium oxalate stone formation. Patients with an ileostomy or chronic volume loss from diarrhea are also at increased risk for uric acid stones.

Extraintestinal Manifestations

Although both UC and Crohn's disease primarily involve the bowel, they are also associated with inflammatory manifestations in other organ systems. This reflects the systemic nature of these disorders (Table 37-1). Extraintestinal manifestations can occur in parallel or independently of colonic activity, and they can become more difficult to treat than the bowel disease itself.

The most common extraintestinal manifestation is arthritis, which is seen in about 9% to 50% of patients and is divided into two major types. The first is a peripheral, large-joint, asymmetrical, seronegative, oligoarticular, nondeforming arthritis that may involve the knees, hips, wrists, elbows, and ankles. This *peripheral arthropathy* usually parallels the course of the large bowel disease and typically lasts for only a few weeks. The second type of IBD-related arthritis is axial in location, consisting of sacroiliitis or ankylosing spondylitis, and does not parallel the activity level of the bowel disease. Ankylosing spondylitis occurs in 5% to 10% of IBD patients and manifests with low back pain and stiffness that is usually worse during the night, in the morning, or after inactivity. Sacroiliitis alone (without ankylosing spondylitis) is common in IBD (up to 20% of patients), but in many cases is asymptomatic.

Liver complications of IBD include both intrahepatic and biliary tract diseases. Intrahepatic diseases include fatty liver, pericholangitis, and chronic active hepatitis. Pericholangitis, also known as small-duct sclerosing cholangitis, is the most common of these diseases. It usually is asymptomatic, identified only by abnormalities in alkaline phosphatase and γ -glutamyl transpeptidase on laboratory tests and histologically by portal tract

inflammation and bile ductule degeneration. Small-duct sclerosing cholangitis may progress to cirrhosis.

Biliary tract disease includes an increased incidence of gallstones and of primary sclerosing cholangitis (PSC). PSC is a chronic cholestatic liver disease marked by fibrosis of the intrahepatic and extrahepatic bile ducts; it occurs 1% to 4% of patients with UC and less often in those with Crohn's disease. Overall, about 70% of patients with PSC have UC. Fibrosis leads to strictures of the bile ducts, which in turn may lead to recurrent cholangitis (with fever, right upper quadrant pain, and jaundice) and progression to cirrhosis. In addition, about 10% of patients develop cholangiocarcinoma. Medical or surgical therapy for the IBD does not modify the course of PSC, and most patients progress to cirrhosis and may require liver transplantation.

The two classic dermatologic manifestations of IBD are pyoderma gangrenosum and erythema nodosum. Pyoderma gangrenosum occurs in about 5% of patients and is characterized by a discrete ulcer with a necrotic base, usually on the legs. The ulcer may spread and become large and deep, destroying soft tissues. Pyoderma parallels the bowel activity in 50% of cases. Treatment is usually with systemic or intralesional steroids, or both. Other treatment options include dapson, cyclosporine, and the anti-TNF agents. Erythema nodosum occurs in 10% of IBD patients, usually with peripheral arthropathy, and produces raised, tender nodules, usually over the anterior surface of the tibia. Erythema nodosum responds to treatment for the underlying bowel disease. A less common dermatologic manifestation of IBD is Sweet's syndrome, or acute febrile neutrophilic dermatosis. This condition is characterized by the sudden onset of fever, leukocytosis, and tender, erythematous, well-demarcated papules and plaques that show dense neutrophilic infiltrates on histologic examination.

Ocular manifestations of IBD, including uveitis and episcleritis, occur in 1% to 5% of patients. Uveitis (or iritis) is an inflammatory lesion of the anterior chamber that produces blurred vision, photophobia, headache, and conjunctival injection. Local therapy includes steroids and atropine. Episcleritis produces burning eyes and scleral injection without vision deficits and is treated with topical steroids.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of IBD is based on a constellation of clinical features, laboratory tests, and endoscopic, radiographic, and histologic findings. Laboratory tests are not specific and usually reflect inflammation (leukocytosis) or anemia. Perinuclear antineutrophil cytoplasmic antibody (pANCA) is positive in up to 70% of patients with UC but is rarely positive in patients with Crohn's disease, whereas anti-*Saccharomyces cerevisiae* antibodies (ASCA) are common in Crohn's disease but rarely found in UC (Table 37-2). Additional markers have improved the sensitivity and specificity of serologic testing, including antibodies to OmpC (*Escherichia coli* outer membrane porin C) and antibodies to bacterial flagellins CBir1, FlaX, and A4-Fla2.

Colonoscopy in patients with UC reveals a granular mucosa, decreased vascular markings, decreased mucosal reflection, exudate, and superficial ulcerations (Fig. 37-4). In more severe cases, the mucosa is friable, with deeper ulcerations. Patients with long-standing disease have *pseudopolyps*, which represent islands

TABLE 37-2 DIFFERENTIATING FEATURES OF ULCERATIVE COLITIS AND CROHN'S DISEASE

	ULCERATIVE COLITIS	CROHN'S DISEASE
Site of involvement	Involves colon only Rectum almost always involved	Any area of the gastrointestinal tract Rectum usually spared
Pattern of involvement	Continuous	Skip lesions
Diarrhea	Bloody	Usually nonbloody
Severe abdominal pain	Rare	Frequent
Perianal disease	No	In 30% of patients
Fistula	No	Yes
Endoscopic findings	Erythematous and friable Superficial ulceration	Aphthoid and deep ulcers Cobblestoning
Radiologic findings	Tubular appearance resulting from loss of haustral folds	String sign of terminal ileum RLQ mass, fistulas, abscesses
Histologic features	Mucosa only Crypt abscesses	Transmural Crypt abscesses, granulomas (about 30%)
Smoking	Protective	Worsens course
Serology	pANCA more common	ASCA more common

ASCA, Anti-*Saccharomyces cerevisiae* antibodies; pANCA, perinuclear antineutrophil cytoplasmic antibody; RLQ, right lower quadrant.

FIGURE 37-4 Endoscopic image of ulcerative colitis demonstrates diffuse inflammation characterized by erythema, edema, friability, and hemorrhage.

of normal tissue in regions of previous ulceration. In Crohn's disease (Fig. 37-5), endoscopic examination may show aphthoid erosions, deep linear or stellate ulcers, edema, erythema, exudate, and friability with intervening areas of normal mucosa (skip lesions). However, a diagnosis of *indeterminate* colitis is occasionally made because of an overlap of findings. For example, colonic Crohn's disease may produce superficial continuous rectal involvement similar to that seen in UC. Similarly, chronic UC can infrequently result in inflammation of the terminal ileum, called *backwash ileitis*. In many patients with indeterminate colitis,

FIGURE 37-5 Endoscopic image of Crohn's disease demonstrates linear ulcers in areas of otherwise normal mucosa.

FIGURE 37-6 Video capsule endoscopic image shows ulcerated stenosis in a patient with Crohn's disease (arrows).

repeated examination is necessary, or complications may develop that help identify the disease form.

Several types of radiologic studies can be used to diagnose IBD. In Crohn's disease, the most sensitive test to diagnose small bowel disease is video capsule endoscopy. Small erosions and ulcerations on the mucosa, as well as strictures, can be visualized best on video capsule endoscopy (Fig. 37-6). Patients with known or suspected strictures should be evaluated for risk of capsule retention before undergoing capsule endoscopy. On traditional small bowel radiography, segments of edematous bowel appear thickened next to uninvolved mucosa, a characteristic pattern referred to as *cobblestoning*. Tight, long strictures in the small bowel can be identified and are called a *string sign*. Cross-sectional imaging with computed tomographic (CT) enterography and magnetic resonance enterography has replaced traditional small bowel radiography. Cross-sectional imaging can identify bowel wall thickening with surrounding inflammation, as well as intra-abdominal abscesses and fistulas (Figs. 37-7 and 37-8). A characteristic finding on cross-sectional imaging in Crohn's disease is infiltration of the mesentery with fat, commonly known as *creeping fat*.

The differential diagnosis of IBD includes infectious colitis, ischemic colitis, radiation enteritis, enterocolitis induced by non-steroidal anti-inflammatory drugs, diverticulitis, appendicitis, gastrointestinal malignancies, and irritable bowel syndrome. In patients with acute onset of bloody diarrhea, infectious causes that must be excluded with stool testing include *Salmonella enteritidis*, *Shigella* species, *Campylobacter jejuni*, *Escherichia coli* O157, and *Clostridium difficile*. Among the infectious causes, *Yersinia enterocolitica* can mimic Crohn's disease because the pathogen causes ileitis, mesenteric adenitis, fever, diarrhea, and right lower quadrant abdominal pain. *Mycobacterium tuberculosis* infection, strongyloidiasis, and amebiasis must be excluded in high-risk populations, because these infections can mimic IBD, and

FIGURE 37-7 Computed tomographic enterography shows inflammatory stricture (arrow) and small bowel wall thickening in a patient with Crohn's disease.

treatment with corticosteroids can lead to disseminated infection and death.

TREATMENT

The goal of treatment is induction and maintenance of remission. As part of the initial management of IBD, the clinician must

FIGURE 37-8 Computed tomographic enterography shows extensive Crohn's disease with fistula (arrow).

TABLE 37-3 TREATMENT OPTIONS

DISEASE SEVERITY	ULCERATIVE COLITIS	CROHN'S DISEASE
Mild	Oral and topical 5-ASA compounds	5-ASA compounds Antibiotics Elemental diet
Moderate	Oral and topical 5-ASA compounds Oral steroids or budesonide MMX Azathioprine, 6-MP Infliximab, adalimumab, golimumab	5-ASA compounds Antibiotics Oral steroids or budesonide EC Azathioprine, 6-MP Methotrexate Infliximab, adalimumab, certolizumab natalizumab
Severe	Intravenous steroids Cyclosporine Infliximab, adalimumab, golimumab Vedolizumab Surgery	Intravenous steroids Methotrexate Infliximab, adalimumab, certolizumab Natalizumab, vedolizumab Surgery

5-ASA, 5-Aminosalicylic acid; 6-MP, 6-mercaptopurine.

determine the extent and assess the severity of the disease. Patients with mild or moderate disease can be managed as outpatients. Patients with severe or fulminant disease—with abdominal pain, fever, tachycardia, anemia, and leukocytosis—require hospital admission and multidisciplinary team management. Because IBD is a chronic recurrent illness, treatment is centered on controlling the acute attack with induction of remission, followed by maintenance of remission. Treatment options for UC and Crohn's disease are summarized in [Table 37-3](#).

5-Aminosalicylic Acid

The aminosalicylates are given either orally or topically (suppository and enema). They are safe and effective for treatment (i.e., induction of remission) of mild to moderate UC and for maintenance of remission (Level of evidence III, A). The efficacy of the 5-aminosalicylic acid (5-ASA) agents in induction or maintenance of remission in Crohn's disease has not been clearly shown in studies, although they are commonly used off-label for this purpose (level of evidence III, A for induction and III, B for maintenance). This class of anti-inflammatory medications includes sulfasalazine (Azulfidine) at a dose of 4 to 6 g/day in divided doses. This drug consists of 5-ASA linked to a sulfapyridine moiety; the 5-ASA is released after bacterial lysis of an azo bond in the colon.

Side effects, including headache, nausea, and skin reactions, require discontinuation of sulfasalazine in about 30% of patients. Reversible oligospermia may occur, and rare serious side effects include pleuropericarditis, pancreatitis, agranulocytosis, interstitial nephritis, and hemolytic anemia. Patients who take sulfasalazine need folic acid supplementation. Derivatives of oral 5-ASA compounds include mesalamine (Pentasa, 4 g/day in divided doses; Delzicol, 2.4 g/day in divided doses; Asacol HD, 2.4 to 4.8 g/day in divided doses; Lialda, 2.4 to 4.8 g once daily; Apriso, 1.5 g once a day), olsalazine (Dipentum, 1 to 2 g/day in divided doses), and balsalazide (Colazal, 6.75 g/day in divided doses; Giazio 3.3 g/day in divided doses). Topical forms of mesalamine (Canasa suppositories, 1000 mg once daily; Rowasa enemas, 4 g once nightly) are commonly used because of a more favorable side-effect profile. In addition to their use in the primary treatment of IBD, several studies suggest that long-term use of 5-ASA medications may reduce the risk for colorectal cancer in patients with UC.

Corticosteroids

Corticosteroids may be used topically, orally, or intravenously. They are effective for controlling active disease but not for maintaining remission (level of evidence I,A for induction and III, A for maintenance). They are indicated for moderate or severe disease in UC patients for whom treatment with 5-ASA has failed. The most commonly used agent is oral prednisone, started in doses between 40 and 60 mg/day. Patients typically improve rapidly, and the medication is usually tapered down slowly (i.e., by 5 to 10 mg/week until discontinuation). Patients who do not improve after 1 week of oral treatment and those with more severe disease are best treated in the hospital with intravenous corticosteroids, such as intravenous hydrocortisone (300 mg/day), or methylprednisolone (which can be given either by continuous infusion or in three divided doses).

Corticosteroids have numerous side effects with long-term use. Controlled trials have shown that budesonide EC (Entocort EC) is more effective than placebo or oral 5-ASA and has similar efficacy to prednisolone for the induction of remission in Crohn's disease (level of evidence I, A). Entocort EC (9 mg given once daily) undergoes extensive first-pass hepatic metabolism, is available for inducing and maintaining remission of ileal and ileocolonic Crohn's disease (level of

evidence III, A), and may offer long-term benefits with decreased corticosteroid side effects. Budesonide MMX (Uceris 9 mg given once daily) has an extended release that targets the colon and is available for the treatment of mild to moderate UC (level of evidence I, A for induction and III, A for maintenance).

Immunomodulators

The immunomodulators used in IBD include azathioprine (Imuran, 2 to 2.5 mg/kg/day) and its active metabolite, 6-mercaptopurine (6-MP) (Purinethol, 1 to 1.5 mg/kg/day), as well as methotrexate and cyclosporine. Azathioprine and 6-MP are effective therapies for maintaining remission in both Crohn's disease and UC and are used primarily as steroid-sparing agents (level of evidence I, A). They have a slow onset of action (weeks to months). Side effects include nausea, abnormal liver enzymes, bone marrow suppression, opportunistic infections, and an increased risk of lymphoma and nonmelanoma skin cancer.

Methotrexate can be used for induction (25 mg subcutaneously once weekly) and maintenance of remission (15 to 25 mg subcutaneously once weekly) in active Crohn's disease (level of evidence IIa, B for induction and I, B for maintenance); the side effect profile is similar but also includes interstitial pneumonitis. Intravenous cyclosporine (2 mg/kg/day given over 24 hours) is used as a rescue medicine and, in severe UC refractory to intravenous steroids, as a *bridge* treatment to one of the above immunomodulators or biologic agents. Given the potential for both short-term and long-term side effects, as well as the need for close follow-up, patients needing these medications are best managed by gastroenterologists.

Biologic Agents

Biologics are a class of medications that target specific aspects of the immune system. The first such agent to be used in IBD was infliximab (Remicade), a chimeric monoclonal antibody to TNF- α , which has been shown to be effective in the treatment of both moderate to severe Crohn's disease, including fistulizing disease, and UC (level of evidence I, A). Because infliximab is a chimeric antibody, its toxicities include infusion reactions, delayed-type hypersensitivity reactions, and formation of autoantibodies (which can reduce its efficacy). Anti-TNF agents that are administered subcutaneously include adalimumab (Humira) and golimumab (Simponi), which are fully human monoclonal antibodies, and certolizumab pegol (Cimzia), which is a humanized anti-TNF antibody Fab fragment. Adalimumab and certolizumab are efficacious in patients with moderate to severe Crohn's disease, whereas adalimumab and golimumab are approved to treat moderate to severe UC.

Natalizumab (Tysabri), a humanized anti- α_4 -integrin antibody, blocks inflammatory cell migration and adhesion, and has been approved for the treatment of moderate to severe Crohn's disease in patients who have had an inadequate response to, or are unable to tolerate, conventional Crohn's disease therapies including inhibitors of TNF- α (level of evidence IIa, B for induction and IIa, A for maintenance). Vedolizumab (Entyvio), a humanized monoclonal antibody to $\alpha_4\beta_7$ integrin, has been recently approved for the treatment and maintenance of both Crohn's and ulcerative colitis (level of evidence I, A).

Because of the potent effects these biologic agents have on the immune system, careful patient selection and monitoring for complications are necessary. Reactivation of latent tuberculosis and other serious infections have been reported with the anti-TNF agents. Other rare but serious complications include non-Hodgkin's lymphoma, exacerbation of congestive heart failure, abnormal complete blood count (CBC) and liver function test results, and demyelinating disease. Natalizumab has been linked to rare cases of progressive multifocal leukoencephalopathy caused by the human JC virus.

Future biologic agents with alternate mechanisms of action are being discovered and developed. Ustekinumab (Stellara), an IL-12/IL-23 inhibitor already approved for psoriasis, has shown promise and is in clinical trials for Crohn's disease. Tofacitinib, a JAK inhibitor, already approved for rheumatoid arthritis, is now being investigated for Crohn's disease.

Other Agents

Other agents for treatment of IBD include antibiotics, probiotics, antidiarrheals, bile salt resin binders, and nutritional support.

Antibiotics are used primarily in patients with Crohn's disease who have perianal or fistulizing disease. In colonic Crohn's disease, antibiotics can be used in combination with immunosuppressive drugs as an alternate strategy. The role of antibiotics in UC is unclear, and further studies are required. However, intravenous antibiotics are used in the initial treatment of severe, toxic, or fulminant colitis.

Probiotics are viable nonpathogenic organisms that, after ingestion, may prevent or treat intestinal diseases and have been explored in the treatment of IBD. Multiple studies have found them to be effective in treating pouchitis after ileal pouch-anal anastomosis. One probiotic mixture, termed VSL#3, includes four strains of *Lactobacillus* (*L. paracasei*, *L. plantarum*, *L. acidophilus*, and *L. delbrueckii* subsp *bulgaricus*), three strains of *Bifidobacteria* (*B. longum*, *B. breve*, and *B. infantis*), and one strain of *Streptococcus* (*S. thermophiles*). It has been shown in randomized clinical trials to be a safe and effective adjunct modality for achieving clinical response and remission in patients with mild to moderately active UC. So far, none of the probiotics has been shown to be effective in induction or maintenance of remission in patients with Crohn's disease.

Antidiarrheal agents and bile salt resin binders can be used as adjuncts for management of diarrhea in patients with IBD, but antidiarrheal agents should be used cautiously during exacerbations of colitis because they can precipitate toxic megacolon. The main role of antidiarrheal medications involves controlling diarrhea in patients who have undergone previous resections. Patients with Crohn's disease who have had less than 100 cm of terminal ileum removed can develop a bile salt malabsorptive state, during which bile salts enter the colon and cause a secretory diarrhea. Bile salt resin binders such as cholestyramine are an effective treatment in these cases. When patients have undergone one or more extensive resections amounting to more than 100 cm of ileum, the bile salt pool is depleted and fat malabsorption develops. These patients may require a low-fat diet supplemented with medium-chain triglycerides and antidiarrheal agents, but bile salt resin binders should not be used.

Nutritional support is an important adjunctive aspect in the management of IBD. However, the role of nutrition as a primary treatment has been limited to patients with small bowel Crohn's disease. These patients may achieve and maintain remission with total parenteral nutrition or elemental diets after prolonged periods (at least 4 weeks). Many patients with Crohn's disease or UC experience weight loss during exacerbations of their illness and need caloric supplements. Vitamins and minerals can be given orally as a multivitamin with folic acid. Vitamin B₁₂ should be supplemented parenterally in patients who have extensive ileal disease or an ileal resection. Patients taking corticosteroids require supplemental calcium and vitamin D, and individuals with extensive small bowel involvement can also develop malabsorption of fat-soluble vitamins (A, D, E, and K), iron, and, rarely, trace minerals. Lactose-free diets and low-fiber diets may be necessary in patients with active disease or strictures.

Surgical Management

Surgical intervention is indicated for patients with severe complications such as obstruction, perforation, massive gastrointestinal hemorrhage, or toxic megacolon not responsive to medical treatment. The other main indication for surgical treatment is the presence of dysplasia or cancer. For patients with UC, regardless of the extent of disease, the entire colon must be removed. Historically, the initial operation for UC was a total proctocolectomy and Brooke ileostomy, but ileal pouch–anal anastomosis has become the procedure of choice in most patients. In this operation, the colon is removed and the small bowel is constructed into a reservoir (ileal pouch) that is anastomosed to the anus, allowing defecation through the anus. Complications include the development of pouchitis, fecal incontinence, reduced fertility, and need for reoperation. Surgery is not curative in Crohn's disease. Many surgical procedures in patients with Crohn's disease are performed to manage complications of the disease, including segmental resection, stricturoplasty, fistulectomy, and abscess drainage.

PROGNOSIS

The prognosis in a patient with IBD is determined by the relapse rate, the rate of surgery, and the incidence of colon cancer. Approximately two thirds of patients with UC have at least one relapse in the 10 years after their diagnosis. About 20% to 30% of patients with pan-UC will require colectomy within their lifetime. Only 5% of individuals with proctitis undergo colectomy by 10 years after diagnosis. In contrast, more than 60% of Crohn's patients require surgery within the 10 years after their diagnosis. The rate of recurrence in Crohn's disease is high, with 70% of patients having an endoscopic recurrence within 1 year after surgery and 50% having a symptomatic recurrence within 4 years. Predictors of a severe course in Crohn's disease include stricturing or penetrating disease and perianal disease.

The risk for colon cancer is increased in patients with UC, and its magnitude is related to the extent and duration of disease. The colon cancer risk is increased 10- to 20-fold after 8 to 10 years of disease in pancolitis, and after 15 to 20 years in left-sided colitis. The cumulative incidence of colorectal cancer is 2.5% after 20 years and 7.6% after 30 years of disease. Proctitis is not associated

with an increased risk of colorectal cancer. In colonic Crohn's disease, the risk of colorectal cancer is equivalent to that in patients with UC of similar extent and duration. Patients with only small bowel Crohn's disease are not thought to be at increased risk for colorectal cancer. The rates of small bowel carcinoma and lymphoma are increased in patients with Crohn's disease.

Screening for dysplasia and colon cancer should be performed by colonoscopy 8 to 10 years after the onset of symptoms. Surveillance examinations are performed every 1 to 3 years. Proctitis does not require endoscopic surveillance. Patients with IBD and PSC appear to have a particularly increased risk for colon cancer, and yearly surveillance is recommended after the initial diagnosis of PSC. It is recommended that a minimum of 33 "random" mucosal biopsy samples be obtained during the colonoscopic examination, in addition to targeted samples of circumscribed lesions. The use of chromoendoscopy and other enhanced imaging techniques increases the detection of dysplastic lesions in patients with UC and may replace the performance of random biopsies in the future. Colectomy is indicated in patients with flat high-grade dysplasia, multifocal flat low-grade dysplasia, or evidence of colorectal cancer. Polypoid dysplasia entirely removed by polypectomy without flat dysplasia elsewhere in the colon can be managed with continued surveillance colonoscopy.

As understanding of the etiologic and pathophysiologic aspects of IBD increases, major advances in diagnosis and treatment are anticipated. These will be based on better use of molecular, genetic, and serologic tests to differentiate among the subtypes of disease; earlier and more targeted use of biological agents to manage inflammation; and improvements in the detection and prevention of colorectal cancer in those at risk.

Diseases of the Pancreas

David R. Lichtenstein

ACUTE PANCREATITIS

Definition and Epidemiology

Acute pancreatitis is an acute inflammatory process of the pancreas that may also involve peripancreatic tissues and remote organ systems. It is the leading cause of hospitalization of patients with gastrointestinal disorders in the United States, with more than 200,000 admissions annually. This translates into an overall incidence of 1 case per 4000 people in the general population.

Pathology

The pancreas is located in the retroperitoneum and has exocrine and endocrine functions (Fig. 38-1) derived from the pancreatic acinus and the pancreatic islet, respectively. As an exocrine gland, the pancreas participates in normal digestion and nutrient absorption. The enzymes secreted by the pancreas digest starch (i.e., amylase), fats (i.e., lipase), and protein (i.e., trypsin and other proteolytic enzymes). Within acinar cells, proteolytic digestive enzymes are synthesized and packaged separately in the Golgi region into condensing vacuoles and transported in an inactive form referred to as zymogens to the apical portions of the cell. When stimulated, they are discharged into the central ductule of the acinus by exocytosis.

Normal physiology involves secretion of inactive enzymes into the duodenum, where they are converted to an active form by enterokinase, a brush border enzyme secreted by small bowel enterocytes. Trypsinogen conversion to active trypsin is the trigger enzyme that subsequently converts the other zymogens to active enzymes (E-Fig. 38-1).

The pathogenesis of acute pancreatitis remains incompletely understood. Based on experimental models, the initiating event appears to involve intra-acinar activation of trypsin from trypsinogen, resulting in acute intracellular injury, pancreatic autodigestion, and the potential for profound systemic complications after activated enzymes are leaked into the bloodstream. Initiating events may include obstruction of the pancreatic duct (e.g., gallstones, pancreatic tumor), overdistention of the pancreatic duct (e.g., from endoscopic retrograde cholangiopancreatography [ERCP]), reflux of biliary or duodenal juices into the pancreatic duct, changes in permeability of the pancreatic duct, ischemia of the organ, and toxin-induced cholinergic hyperstimulation (Fig. 38-2).

During the initial hospitalization for acute pancreatitis, reasonable attempts to determine the cause are appropriate, particularly those that may affect acute management. The cause of acute pancreatitis is readily identified in 70% to 90% of patients after an initial evaluation consisting of the history, physical examination, focused laboratory testing, and routine radiologic studies. Gallstones account for 45%, alcohol for 35%, miscellaneous causes for 10%, and idiopathic causes for 10% to 20% of acute pancreatitis cases (Table 38-1).

Gallstone Pancreatitis

Among patients with gallstones, the incidence of acute pancreatitis is 0.17% per year. Gallstones increase the relative risk of pancreatitis 25- to 35-fold. It is theorized that gallstone passage causes transient obstruction of the pancreatic duct, precipitating acute pancreatitis. Acute gallstone pancreatitis should be suspected when associated with a transient elevation in liver-associated enzymes, particularly alanine aminotransferase (ALT) levels greater than 150 IU/L. Most stones pass spontaneously from the ampulla and do not require intervention (discussed later).

Alcoholic Pancreatitis

Acute alcoholic pancreatitis is the second most common cause of pancreatitis in the United States. Approximately 10% of chronic alcoholics develop attacks of pancreatitis that are indistinguishable from other forms of acute pancreatitis. Alcoholics with acute pancreatitis most commonly have underlying

FIGURE 38-1 Normal anatomy of the pancreas.

E-FIGURE 38-1 Mechanism of proenzyme activation in the intestinal lumen. (Modified from Solomon TE: Exocrine pancreas: pancreatitis. In the Undergraduate teaching project in gastroenterology and liver disease, unit 24, Bethesda, Md., 1984, American Gastroenterological Association.)

FIGURE 38-2 The pathophysiology of acute pancreatitis is not fully understood, but as the schematic shows, a cascade of events seems likely, beginning with the release of toxic substances into the parenchyma and ending with shock and death. Damage to the ductal epithelium or acinar cell injury may result from bile reflux, increased intraductal pressure, alcohol, or trauma. (Modified from Grendell JH: The pancreas. In Smith LH Jr, Thier SO, editors: Pathophysiology: the biological principles of disease, ed 2, Philadelphia, 1985, WB Saunders, p 1228.)

chronic disease. However, some have true acute alcoholic pancreatitis because not all patients progress to chronic pancreatitis, even with continued alcohol abuse. The mechanism of pancreatic injury, the genetic and environmental factors that influence its development in alcoholics, and the reason only a small proportion of alcoholics develop pancreatitis are unclear (see [Chronic Pancreatitis](#)).

Heredity

Hereditary causes of pancreatitis include mutations in the genes encoding cationic trypsinogen (*PRSS1*), pancreatic secretory trypsin inhibitor (serine protease inhibitor Kazal type 1 [*SPINK1*]), cystic fibrosis transmembrane conductance regulator (*CFTR*), chymotrypsin C (i.e., caldecrin) (*CTRC*), and the calcium-sensing receptor (*CASR*).

The role of genetic testing in idiopathic acute pancreatitis is controversial. Diagnosis of these genetic disorders contributes little to direct management because specific therapy is unavailable. Similarly, inadvertent disclosure of the results of genetic testing protects patients' healthcare insurance but may impact other financial decisions such as disability and

life insurance. However, identification of an underlying genetic cause may obviate the need for further testing, allow more informed family planning, and enable better surveillance for complications, including pancreatic cancer. The decision to pursue genetic testing is one that should be made only with the advice and involvement of an experienced counselor.

Neoplasia

Primary pancreatic ductal adenocarcinoma, ampullary tumors, metastasis to the pancreas, and intraductal papillary mucinous neoplasms are uncommon causes of acute pancreatitis. These causes should be considered for patients older than 40 years. Pancreatitis has been reported in up to 10% of patients with pancreatic cancer.

Smoking

Smoking was once thought to be a risk factor due to its synergism with alcohol. However, studies have suggested that cigarette smoking is an independent risk factor for acute and chronic pancreatitis by mechanisms that are unclear.

TABLE 38-1 CAUSES OF ACUTE PANCREATITIS**OBSTRUCTION**

Gallstones
 Tumors: ampullary or pancreatic tumors
 Parasites: *Ascaris* or *Clonorchis* species
 Developmental anomalies: pancreas divisum, choledochocoele, annular pancreas
 Periapillary duodenal diverticula
 Hypertensive sphincter of Oddi
 Afferent duodenal loop obstruction

TOXINS

Ethyl alcohol
 Methyl alcohol
 Scorpion venom: excessive cholinergic stimulation causes salivation, sweating, dyspnea, and cardiac arrhythmias; seen mostly in the West Indies
 Organophosphorus insecticides

DRUGS

Definite associations (documented with rechallenges): azathioprine or 6-mercaptopurine, valproic acid, estrogens, tetracycline, metronidazole, nitrofurantoin, pentamidine, furosemide, sulfonamides, methyl dopa, cytarabine, cimetidine, ranitidine, sulindac, dideoxycytidine
 Probable associations: thiazides, ethacrynic acid, phenformin, procainamide, chlorthalidone, L-asparaginase

METABOLIC DISORDERS

Hypertriglyceridemia, hypercalcemia, end-stage renal disease

TRAUMA

Accidental: blunt trauma to the abdomen (e.g., car accident, bicycle)
 Iatrogenic: postoperative, endoscopic retrograde cholangiopancreatography

INFECTIOUS DISEASES

Parasitic: ascariasis, clonorchiasis
 Viral: mumps, rubella, hepatitis A, hepatitis B, hepatitis C, coxsackievirus B, echovirus, adenovirus, cytomegalovirus, varicella virus, Epstein-Barr virus, human immunodeficiency virus
 Bacterial: mycoplasma, *Campylobacter jejuni*, tuberculosis, *Legionella* species, leptospirosis

VASCULAR DISORDERS

Ischemia: hypoperfusion (e.g., postcardiac surgery) or atherosclerotic emboli
 Vasculitis: systemic lupus erythematosus, polyarteritis nodosa, malignant hypertension

IDIOPATHIC DISORDERS

Between 10% and 30% of patients have pancreatitis
 Up to 60% have occult gallstone disease (e.g., biliary microlithiasis, gallbladder sludge)
 Less common causes: sphincter of Oddi dysfunction, mutations in the cystic fibrosis transmembrane regulator

MISCELLANEOUS DISORDERS

Penetrating peptic ulcer
 Crohn's disease of the duodenum
 Pregnancy-associated disorders
 Pediatric associations: Reye's syndrome, cystic fibrosis

Autoimmune Pancreatitis

Autoimmune pancreatitis (AIP) is a benign disease with a unique histology of lymphoplasmacytic sclerosing pancreatitis, which is characterized by a periductal lymphoplasmacytic infiltrate, storiform fibrosis, obliterative phlebitis, and abundant immunoglobulin G4 (IgG4) immunostaining (>10 IgG4-positive cells per high-power field).

The most common manifestation of AIP is obstructive jaundice, which closely mimics pancreatic cancer with focal enlargement of the pancreatic head. AIP can also manifest with acute

pancreatitis in up to 15% to 30% of individuals, and about 5% of patients evaluated for acute or chronic pancreatitis have AIP. AIP has a peak incidence in the sixth or seventh decades of life and tends to affect men twice as often as women.

Computed tomography (CT) typically demonstrates diffuse enlargement of the pancreas with delayed (rim) enhancement and a diffusely irregular, attenuated main pancreatic duct. More than 60% of individuals have clinical and histologic involvement of other organs, including the biliary tree, retroperitoneum, lacrimal and salivary glands, lymph nodes, periorbital tissues, kidneys, thyroid, lungs, meninges, aorta, breast, prostate, pericardium, and skin. Patients with AIP frequently respond favorably to corticosteroid treatment.

Pancreas Divisum

At approximately 4 weeks' gestation, the dorsal pancreas forms as an evagination from the duodenum, and shortly thereafter, the ventral pancreas forms from the hepatic diverticulum (E-Fig. 38-2). At approximately the eighth intrauterine week of life, the ventral pancreas rotates posterior to the duodenum and comes to rest posterior and inferior to the head portion of the dorsal pancreas with associated fusion of the main ducts. If fusion is incomplete, the duct of Wirsung drains only the ventral pancreas through the major ampulla, and the duct of Santorini drains the bulk of the pancreas (i.e., dorsal pancreas) through the relatively small accessory (minor) ampulla. This anomaly, called *pancreas divisum*, occurs in 5% to 10% of the general population and is associated with acute and chronic pancreatitis.

Theories suggest that pancreatitis results from relative outflow obstruction of the main dorsal duct through the small accessory ampulla. Endoscopic papillotomy and surgical sphincteroplasty are therapeutic maneuvers that may reduce the incidence of recurrent pancreatitis by increasing drainage through the accessory papilla.

Clinical Presentation

The hallmark of acute pancreatitis is persistent abdominal pain. In atypical cases, patients may have unexplained organ failure or postoperative ileus. The onset of pain is typically sudden, severe, and worse when supine. Pain is usually located in the upper abdomen and may radiate to the back, chest, and flanks. Nausea and vomiting are common. Physical examination usually reveals severe upper abdominal tenderness that is sometimes associated with guarding.

Pancreatic enzymes, vasoactive substances (e.g., kinins), and other toxic substances (e.g., elastase, phospholipase A₂), are liberated by the inflamed pancreas and extravasate along fascial planes in the retroperitoneal space, lesser sac, and peritoneal cavity. These materials cause chemical irritation and contribute to the development of ileus, chemical peritonitis, third-space losses of protein-rich fluid, hypovolemia, and hypotension. The toxic molecules may reach the systemic circulation by lymphatic and venous pathways and contribute to subcutaneous fat necrosis and end-organ damage, including shock, renal failure, and respiratory insufficiency (i.e., atelectasis, effusions, and acute respiratory distress syndrome [ARDS]). Grey Turner's sign (i.e., ecchymosis of the flank) or Cullen's sign (i.e., ecchymosis in the periumbilical region) may be associated with hemorrhagic pancreatitis.

E-FIGURE 38-2 Endoscopic retrograde cholangiopancreatography shows the pancreatic ductal system in pancreas divisum. The upper duct (i.e., dorsal pancreas) was visualized by injecting contrast into the duct of Santorini. The lower duct (i.e., ventral pancreas) was highlighted by injecting the duct of Wirsung.

Metabolic problems, which are common in severe disease, include hypocalcemia, hyperglycemia, and acidosis. Hypocalcemia is most commonly caused by concomitant hypoalbuminemia. Other mechanisms include complexing of calcium to released free fatty acids, protease-induced degradation of circulating parathyroid hormone (PTH), and failure of PTH to release calcium from bone.

Acute pancreatitis is associated with a variety of local and vascular complications, including local spread of inflammation to contiguous organs. The most common include peripancreatic fluid collections, pseudocyst formation, obstruction of the duodenum or bile duct, and exocrine or endocrine insufficiency. Less common complications include pancreatic fistula formation, vascular thrombosis (i.e., splenic, portal and superior mesenteric veins), colonic necrosis, and development of an arterial pseudoaneurysm. Trypsin can activate plasminogen to plasmin and induce clot lysis. However, trypsin also can activate prothrombin and thrombin and produce thrombosis leading to disseminated intravascular coagulation.

Acute peripancreatic fluid collections are pools of peripancreatic fluid confined by normal peripancreatic fascial planes without a definable wall encapsulating the collection. These fluid collections occur during the first 4 weeks after interstitial pancreatitis. Most remain sterile and are reabsorbed spontaneously during the first several weeks after the onset of acute pancreatitis. When a localized acute peripancreatic fluid collection persists beyond 4 weeks, it is likely to develop into a pancreatic pseudocyst.

 Pancreatic pseudocysts (E-Fig. 38-3) are encapsulated fluid collections with well-defined inflammatory walls and are usually located outside the pancreas with minimal or no necrosis. They occur a minimum of 4 weeks after the onset of acute pancreatitis. In symptomatic patients, if the pseudocyst is mature and encapsulated, treatment can involve endoscopic, surgical, or percutaneous drainage. Although most pseudocysts remain asymptomatic, presenting symptoms may include abdominal pain, early satiety, nausea, and vomiting due to compression of the stomach or gastric outlet. Rapidly enlarging pseudocysts may rupture, hemorrhage, obstruct the extrahepatic biliary tree, erode into surrounding structures, and become infected. Indications for pseudocyst drainage include suspicion of infection or progressive enlargement with associated symptoms previously described. Asymptomatic pseudocysts should be followed.

The term *acute necrotic collection* describes a nonorganized accumulation of heterogeneous fluid and necrotic material in the setting of necrotizing pancreatitis. The necrosis may involve the pancreatic parenchyma or peripancreatic tissue, or both. Walled-off pancreatic necrosis is a mature, encapsulated collection of pancreatic or peripancreatic necrosis that usually occurs more than 4 weeks after the onset of necrotizing pancreatitis.

Abdominal compartment syndrome is diagnosed when the intra-abdominal pressure exceeds 20 mm Hg and there are signs of new respiratory, renal, or vascular organ failure. Intra-abdominal hypertension typically occurs early and is the result of pancreatic inflammation and fluid third spacing. Abdominal compartment syndrome is associated with mortality rates ranging up to 50% to 75% in various reports. Suggested treatment includes analgesics, sedation, nasogastric tube decompression, and fluid restriction. If these measures do not result in

improvement, percutaneous catheter decompression followed if unsuccessful by a surgical laparotomy is recommended. The ability of this approach to improve outcomes is the focus of ongoing research.

Diagnosis and Differential Diagnosis

The diagnosis of acute pancreatitis is based on a combination of clinical, biochemical, and radiologic factors. A diagnosis of acute pancreatitis requires two of the following three features: abdominal pain characteristic of acute pancreatitis; serum amylase or lipase levels, or both, at least three times the upper limit of normal; and characteristic findings of acute pancreatitis on imaging.

Elevated serum amylase levels may occur in a wide variety of other conditions, including bowel perforation, intestinal obstruction or ischemia, acute appendicitis, cholecystitis, tubo-ovarian disease, and renal failure. Serum amylase levels may be normal in patients with hypertriglyceridemia or alcohol-induced acute pancreatitis. Serum lipase is preferred because it is more sensitive and specific than serum amylase for the diagnosis of acute pancreatitis. The serum lipase level remains normal in some nonpancreatic conditions associated with an elevated serum amylase level, including macroamylasemia (i.e., formation of large molecular complexes between amylase and abnormal immunoglobulins), salivary gland disorders, and tubo-ovarian disease, but it may similarly rise in appendicitis, renal disease, and cholecystitis. The serum lipase concentration is more sensitive than that of amylase because it remains elevated longer and may be diagnostic even for patients seeking medical attention several days after symptom onset. Repeated measurements of serum pancreatic enzymes have little value in assessing clinical progress, and the magnitude of serum amylase or lipase elevation does not correlate with the severity of pancreatitis.

Contrast-enhanced computed tomography (CECT) or magnetic resonance imaging (MRI) of the pancreas should be used for patients whose diagnosis is unclear or who fail to improve within the first 48 to 72 hours after hospital admission. Imaging findings supporting acute pancreatitis include pancreatic enlargement, peripancreatic inflammatory changes, and extrapancreatic fluid collections. Imaging does not exclude the diagnosis of acute pancreatitis because the pancreas appears normal in 15% to 30% of those with mild disease. CECT is also useful for assessing disease severity based on the presence and extent of complications such as pancreatic necrosis and acute peripancreatic fluid collections. Pancreatic imaging should be performed after adequate fluid resuscitation to minimize the risk of contrast-induced nephrotoxicity.

MRI is preferred for patients with a contrast allergy and renal insufficiency because T2-weighted images without gadolinium contrast can similarly diagnose pancreatic necrosis. Early imaging (within 72 hours of symptom onset) can underestimate the existence and extent of pancreatic necrosis. Gallstone pancreatitis should be suspected in patients with transient elevation in liver function test results, particularly a serum ALT level elevated more than threefold. Transabdominal ultrasonography should be performed in all patients with acute pancreatitis when considering a diagnosis of gallstone pancreatitis.

E-FIGURE 38-3 Computed tomography scan shows a large pancreatic pseudocyst.

FIGURE 38-3 Contrast-enhanced computed tomography demonstrates interstitial pancreatitis (A) and necrotizing pancreatitis (B).

Prognosis

The distinction between interstitial and necrotizing acute pancreatitis has important prognostic implications (Fig. 38-3). *Interstitial pancreatitis* is characterized by an intact microcirculation and uniform enhancement of the gland on CECT. *Necrotizing pancreatitis* is characterized by disruption of the pancreatic microcirculation so that large areas (>3 cm or >30%) of pancreatic parenchyma do not enhance on CECT. Approximately 20% to 30% of patients with acute pancreatitis have necrotizing pancreatitis.

The finding of pancreatic necrosis predicts a more severe course, particularly infection in the necrotic pancreatic tissue, also called *infected necrosis*. Infection is a strong determinant of the severity of illness and accounts for a large percentage of the deaths from acute pancreatitis. Infected necrosis develops in 30% to 50% of patients with acute necrotizing pancreatitis but not in those with interstitial disease. Infected necrosis should be suspected in patients with persistent systemic inflammatory response syndrome (SIRS) or organ dysfunction. The diagnosis can be made if extraluminal gas is seen on CECT. More commonly, CT-guided needle aspiration is obtained for Gram stain and culture of necrotic material, or antibiotics are given empirically based on clinical suspicion after appropriate cultures are obtained. Antibiotics that penetrate pancreatic tissue, including cephalosporins, carbapenems, quinolones, and metronidazole, are used for treatment of infected necrosis.

Risk assessment should be performed for all patients to stratify the severity of illness. The current classification includes mild, moderate, and severe forms. Mild acute pancreatitis, the most common form, is characterized by the absence of organ failure and pancreatic necrosis. Mild pancreatitis usually does not require pancreatic imaging, and patients recover within several days with restoration of normal pancreatic function and gland architecture. Patients with mild acute pancreatitis account for 80% of all attacks and less than 5% of the overall mortality rate.

Moderately severe pancreatitis is transient organ failure or local or systemic complications in the absence of organ failure. Local complications include pancreatic necrosis (with or without

infection) and acute peripancreatic fluid collections. Death from moderately severe pancreatitis is much less common than in cases of severe pancreatitis.

Severe acute pancreatitis is defined by persistent organ failure extending for more than 48 hours. Severe acute pancreatitis occurs in 15% to 20% of patients. Most individuals with persistent organ failure have underlying necrotizing disease. The respiratory, cardiovascular, and renal systems are most commonly affected. Early deaths (within the first week) are most often the result of multiple organ failure caused by the release of inflammatory mediators and cytokines. Late deaths are more likely to result from local or systemic infection. The risks of infection and death correlate with disease severity and pancreatic necrosis.

Despite the importance of recognizing severe disease, most patients are initially admitted to the hospital without necrosis or organ failure, and methods to predict individuals more likely to progress to severe disease during the initial several days of hospitalization have been defined. A combination of clinical assessment, scoring systems, serum markers, and CECT scanning provides the most useful prognostic information (Table 38-2). Regardless of the prognostic factor chosen, there are significant limitations in predicting disease severity.

Clinical predictors of a poor outcome include severe comorbid illnesses, older age, and obesity. Laboratory findings associated with increased mortality include blood urea nitrogen elevation on admission or a rise during the first 24 hours of admission, hemoconcentration from third spacing of fluids reflected by an elevated hematocrit of 44 or greater on admission, and serum markers reflecting a robust systemic inflammatory response, such as a C-reactive protein level greater than 150 mg/dL (sensitivity of 80%, specificity of 76%, positive predictive value of 67%, and negative predictive value of 86%). Imaging studies predicting a severe outcome include a pleural effusion seen on chest radiography within the first 24 hours or pancreatic imaging identifying necrosis.

Severe pancreatitis is predicted by organ dysfunction, including shock (systolic blood pressure <90 mm Hg), respiratory failure ($\text{PaO}_2 \leq 60$ mm Hg), and acute renal injury (creatinine

TABLE 38-2 PREDICTORS OF SEVERE PANCREATITIS

CRITERIA	PROGNOSTIC INDICATORS
Signs*	Heart rate: >90 beats/min Temperature: >38° C or <36° C White blood cell count: >12,000 or <4,000 cells/ μ L or >10% bands Respiratory rate >20 beats/min or PaCO ₂ <32 mm Hg
Patient characteristics	Comorbid illnesses Age >55 yr Obesity (BMI >30 kg/m ²)
Laboratory values	BUN level of 20 mg/dL or higher and any rise in BUN during the first 24 hr of admission associated with increased mortality Serum creatinine >1.8 mg/dL within first 24 hr Hemoconcentration with Hct \geq 44 on admission or failure of Hct to decrease in first 24-48 hr with volume resuscitation predicts severe pancreatitis Serum marker reflecting a systemic inflammatory response, CRP >150 mg/dL
Imaging findings	Pleural effusion Pancreatic necrosis Acute extrapancreatic fluid collections
Scoring systems	
Ranson's criteria	Eleven prognostic indicators, including five available on admission (age >55 yr, WBC >16,000/mm ³ , glucose >200 mg/dL, LDH >350 IU/L, AST >250 U/L) and six measured at the end of the first 48 hr (Hct decreased >10, BUN >5 mg/dL, Po ₂ <60 mm Hg, base deficit >4 mEq/L, serum calcium <8 mg/dL, estimated fluid sequestration >6 L); mortality rate of 10-20% for three to five signs and >50% for six or more signs
Acute Physiologic and Chronic Health Evaluation (APACHE II) system	Calculated by assigning points based on age, heart rate, temperature, respiratory rate, mean arterial pressure, PaO ₂ , pH, potassium, sodium, creatinine, Hct, WBC, GCS, and previous health status
Bedside Index for Severity of Acute Pancreatitis (BISAP)	Five variables available in initial 24 hr: BUN >25 mg/dl, impaired mental status (GCS score <15), finding of SIRS, age >60 yr, and pleural effusion on imaging. Each variable adds 1 point to the total score, and scores of 3, 4, and 5 correspond to mortality rates of 5.3%, 12.7%, and 22.5%, respectively.

AST, Aspartate aminotransferase; BMI, body mass index; BUN, blood urea nitrogen; CRP, C-reactive protein; GCS, Glasgow Coma Scale; Hct, hematocrit; LDH, lactate dehydrogenase; SIRS, systemic inflammatory response syndrome; WBC, white blood cells.

*SIRS predisposes to multiple organ dysfunction and pancreatic necrosis. SIRS is defined by two or more of these criteria persisting for more than 48 hours.

>2.0 mg/L after rehydration). SIRS predisposes to multiple organ dysfunction and pancreatic necrosis.

Well-established scoring systems include Ranson's criteria, Acute Physiologic and Chronic Health Evaluation II (APACHE II), and Bedside Index for Severity of Acute Pancreatitis (BISAP). With increasing scores, the likelihood of a complicated, prolonged, and fatal outcome increases.

Treatment

Early steps in the management of patients with acute pancreatitis can decrease severity, morbidity, and mortality (Fig. 38-4). Prevention of complications depends largely on monitoring, vigorous hydration, and early recognition of pancreatic necrosis and choledocholithiasis. Patients with multiorgan dysfunction and those with predicted development of severe disease are at greatest risk for adverse outcomes and should be treated when possible

in a care unit with intensive monitoring capability and multidisciplinary input.

Supportive Care

Patients with acute pancreatitis are treated supportively with aggressive intravenous hydration, parenteral analgesics, and bowel rest. Supplemental oxygen is recommended initially for all patients. Nasogastric tube suction is indicated for symptomatic relief in patients with nausea, vomiting, and ileus. No specific treatments are effective in limiting systemic complications. Agents that put the pancreas to rest (e.g., somatostatin, calcitonin, glucagon, H₂-receptor antagonists) and enzyme inhibitors (e.g., aprotinin, gabexate mesylate) have not been shown to lower disease-related morbidity and mortality.

Antibiotics

Antibiotic therapy is no longer recommended for patients with sterile necrosis due to the lack of proven benefit. For patients with suspected infected necrosis, appropriate antibiotics are initiated before the confirmatory diagnosis, with the initial choice taking into consideration the likely pathogenic organisms and the ability of the antimicrobials to penetrate into necrotic pancreatic tissues. After culture results are available, the antibiotics can be tailored appropriately.

Fluid Management

Vigorous fluid resuscitation is important for maintaining the microcirculation and perfusion of the pancreas during the early phase of acute pancreatitis. Early aggressive intravenous hydration translates into a potential benefit of reduced pancreatic necrosis and organ failure. Crystalloid, the preferred intravenous fluid, is administered at an initial rate of 250 to 500 mL/hour with a preceding bolus infusion for individuals with severe volume depletion. Lactated Ringer's solution may be the preferred crystalloid replacement because in one comparative study, it reduced the incidence of SIRS by more than 80% compared with normal saline infusion. Fluids are adjusted every few hours based on the patient's hemodynamic and volume status. Caution must be used for the elderly and those with underlying cardiovascular or renal impairment.

Analgesia

Despite the theoretical concern that narcotic analgesia may result in sphincter of Oddi spasm and worsening pancreatitis, there is no evidence to support withholding narcotics from patients with acute pancreatitis. The physician should consider liberal use of patient-controlled analgesia, although this approach has not been compared prospectively with on-demand analgesia. There is no evidence to indicate superiority of a specific opiate. Patients administered repeated doses of narcotic analgesics should have oxygen saturation monitored due to risks of unrecognized hypoxia.

Nutritional Care

Patients with mild disease may initiate oral intake when pain resolves and appetite returns. Starting with a low-fat solid diet is as safe as a clear liquid diet. For patients with predicted severe pancreatitis or those unlikely to start oral intake within 5 to 7 days, providing supplemental nutrition is important.

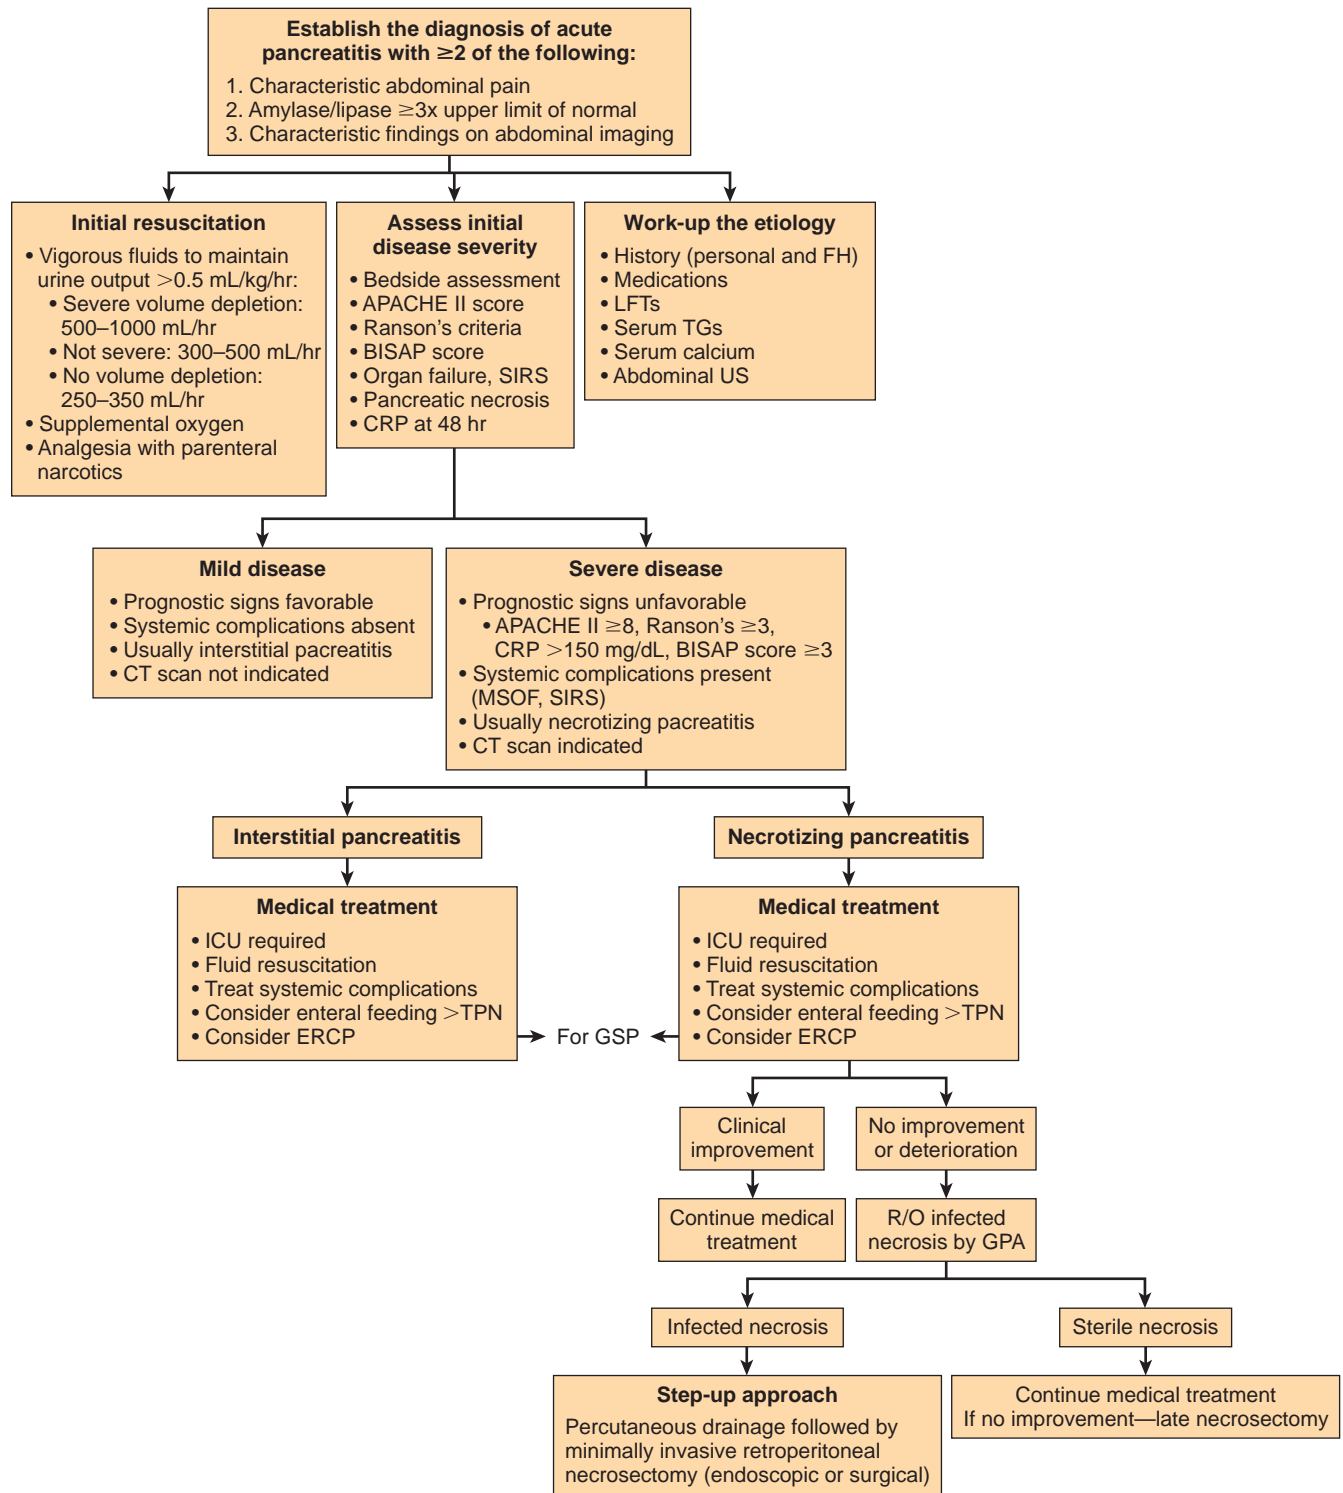

FIGURE 38-4 Management algorithm for acute pancreatitis. Some of the guidelines, such as the diagnostic utility of the C-reactive protein (CRP) level, require further validation. Antibiotic use, including the type and duration of treatment, continues to be examined, and these suggested approaches will likely be modified by the findings of future studies. APACHE II, Acute Physiologic and Chronic Health Evaluation II; BISAP, Bedside Index for Severity of Acute Pancreatitis; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; FH, family history; GPA, CT-guided percutaneous aspiration; GSP, gallstone pancreatitis; ICU, intensive care unit; LFTs, liver function tests; MSOF, multiple system organ failure; R/O, rule out; SIRS, systemic inflammatory response syndrome; TGs, triglycerides; TPN, total parenteral nutrition; US, ultrasound.

Options include total parenteral nutrition through central venous access or preferably as enteral feeding through a nasoenteric feeding tube. Enteral feeding is safer and less expensive than total parenteral nutrition and is associated with a reduction in systemic infection, need for surgical intervention, organ

failure, and mortality. Enteral feeding is usually well tolerated, even by patients with ileus. Nasogastric feeding may offer a safe alternative to nasojejunal feeding because it appears to be equally safe and effective. Parenteral nutrition should be reserved for patients who cannot achieve sufficient caloric intake through

the enteral route or those in whom enteral access cannot be maintained.

Management of Recurrence and Necrosis

Gallstone Pancreatitis

The risk of gallstone pancreatitis recurrence is as high as 50% to 75% within 6 months of the initial episode, and cholecystectomy before discharge is recommended for patients with mild attacks of pancreatitis. Cholecystectomy is often delayed in patients with severe pancreatitis to allow for better exposure of the ductal anatomy at the time of surgery. Urgent ERCP (Video 38-1) with identification and clearance of bile duct stones is recommended for patients with evidence of ongoing biliary obstruction, as suggested by imaging and laboratory data. Biliary sphincterotomy leaving the gallbladder in situ is considered an effective alternative for those who are not candidates for cholecystectomy.

Sterile Pancreatic and Extrapancreatic Necrosis

Sterile pancreatic necrosis usually is treated with supportive medical care during the first several weeks, even in patients with multiple organ failure. After the acute pancreatic inflammatory process has subsided and coalesced into an encapsulated structure (e.g., walled-off pancreatic necrosis), débridement may be required for intractable abdominal pain, vomiting caused by extrinsic compression of stomach or duodenum, or persistent systemic toxicity. Débridement is delayed for at least 4 to 6 weeks after the onset of pancreatitis and can be performed by a combination of endoscopic, radiologic, and surgical techniques. Asymptomatic pancreatic necrosis does not warrant intervention, regardless of the extent and location.

Infected Pancreatic and Extrapancreatic Necrosis

Infected pancreatic necrosis is best treated with drainage or débridement, or both. In most cases, the diagnosis of infected necrosis is confirmed by fine-needle aspiration before intervention, but because false-negative results can occur, débridement warrants consideration when infected necrosis is suspected, even if infection is not documented. The consensus is that the best outcomes are achieved when surgery is delayed for a minimum of 4 weeks after the onset of disease to allow liquefaction of necrotic tissues and a fibrous rim to form around the necrosis (i.e., walled-off pancreatic necrosis). Patients with infected necrosis are initially treated with broad-spectrum antibiotics and medical support to allow encapsulation of the necrotic collections, which may facilitate intervention and reduce complications of bleeding and perforation. When there is dramatic clinical deterioration, delay is not feasible, and early intervention is required.

Traditional management of infected pancreatic necrosis has been open surgical necrosectomy with closed irrigation by indwelling catheters, necrosectomy with closed drainage without irrigation, or necrosectomy and open packing. The open surgical approaches are associated with a high morbidity (34% to 95%) and mortality (11% to 39%) rates. A more conservative step-up approach using percutaneous catheter drainage as the initial treatment has gained favor. If the percutaneous approach fails, it is followed by a less invasive, video-assisted retroperitoneal débridement (VARD) or endoscopic transluminal drainage with

or without necrosectomy (Video 38-2), provided expertise is available.

CHRONIC PANCREATITIS

Definition and Epidemiology

Chronic pancreatitis is characterized by inflammation, fibrosis, and irreversible loss of acinar (exocrine) and islet (endocrine) cell function. This disorder contrasts with acute pancreatitis, which is usually nonprogressive. The two conditions may overlap because recurrent attacks of acute pancreatitis may lead to chronic pancreatitis, and individuals with chronic pancreatitis may experience exacerbations of acute pancreatitis. The annual incidence of chronic pancreatitis ranges from 5 to 12 cases per 100,000 people, and the prevalence is about 50 cases per 100,000 people.

Pathology

Chronic pancreatitis can be classified as nonobstructive or obstructive (Table 38-3). The most common cause of the non-obstructive type is chronic alcoholism (70%). Alcohol can cause episodes of acute pancreatitis, but at the time of the initial attack, structural and functional abnormalities often indicate underlying chronic pancreatitis.

Because most alcoholics do not develop pancreatitis, the presumption is that unidentified genetic, dietary, or environmental influences must coexist with alcohol abuse. For example, epidemiologic data have implicated smoking as a causal, dose-dependent cofactor in chronic pancreatitis. The combined effect of smoking and alcohol is synergistic and contributes profoundly to the development and progression of the disease.

If alcoholism is excluded, 20% of U.S. patients have chronic pancreatitis with no immediately demonstrable cause. Gallstone pancreatitis, the major cause of acute pancreatitis, rarely leads to chronic pancreatitis. Calcific pancreatitis is a major cause of chronic pancreatitis in South India and other parts of the tropics. Autoimmune pancreatitis, genetic mutations (*CFTR*, *SPINK1*, *PRSS1*, *CTRC*, *CASR*), obstruction (e.g., tumors, sphincter of Oddi dysfunction, pancreas divisum), hypertriglyceridemia, and hypercalcemia are potential causes of cases initially labeled idiopathic.

Clinical Presentation

Most patients with chronic pancreatitis experience episodic or continuous pain. Occasionally, patients exhibit exocrine or

TABLE 38-3 CAUSES OF CHRONIC PANCREATITIS

CFTR, Cystic fibrosis transmembrane conductance regulator; *SPINK1*, serine peptidase inhibitor Kazal type 1.

endocrine insufficiency in the absence of pain. Other patients are asymptomatic and are found to have chronic pancreatitis incidentally on imaging.

The pain of chronic pancreatitis is typically epigastric, often radiates to the back, is occasionally associated with nausea and vomiting, and may be partially relieved by sitting upright or leaning forward. The pain is often worse 15 to 30 minutes after eating. Early in the course of chronic pancreatitis, the pain may occur in discrete attacks; as the condition progresses, the pain tends to become continuous.

The pain of chronic pancreatitis is poorly understood. Possible causes include inflammation of the pancreas, increased intrapancreatic pressure, neural inflammation, and extrapancreatic causes, such as stenosis of the common bile duct and duodenum.

Glucose intolerance occurs with some frequency in chronic pancreatitis, but overt diabetes mellitus usually manifests late in the course of disease. Diabetes in patients with chronic pancreatitis is different from typical type 1 diabetes in that the pancreatic alpha cells, which produce glucagon, are also affected, increasing the risk of hypoglycemia.

Clinically significant endocrine or exocrine insufficiency (i.e., protein and fat deficiencies) does not occur until more than 90% of pancreatic function is lost. Steatorrhea usually occurs before protein deficiencies because lipolytic activity decreases faster than proteolysis. Malabsorption of fat-soluble vitamins (A, D, E, K) and vitamin B₁₂ may also occur, although clinically symptomatic vitamin deficiency is uncommon. Because reduced vitamin D absorption can result in osteoporosis, osteopenia, and fractures, periodic assessment of vitamin D levels and bone densitometry are recommended.

Diagnosis and Differential Diagnosis

Because direct biopsy of the pancreas has considerable risk, the diagnosis of chronic pancreatitis is typically based on indirect tests of pancreatic structure and function. Marked structural changes usually correlate with severe functional impairment. In early chronic pancreatitis, however, mild abnormalities of pancreatic function can precede the morphologic changes seen on imaging. Studies of pancreatic structure may remain normal even with advanced deterioration of pancreatic function.

Laboratory evaluations of serum pancreatic enzymes, such as amylase and lipase, are frequently normal in the setting of well-established chronic pancreatitis, even during painful exacerbations. Serum pancreatic enzymes neither confirm nor exclude the diagnosis.

Tests of Function

Function tests assess pancreatic secretory reserve of ductal function capacity for secretion of bicarbonate ions (HCO_3^-) in fluid or acinar function for secretion of digestive enzymes. Direct tests involve stimulation of the pancreas through the administration of hormonal secretagogues. Indirect tests measure the consequences of pancreatic insufficiency, and although more widely available, the results usually are not abnormal until enzyme output has declined by more than 90%. They are insensitive to early pancreatic insufficiency. Clinicians have preferentially relied on noninvasive methods to circumvent the challenges associated with direct pancreatic function tests. Clinically available indirect tests

of pancreatic function include analyses of fecal fat, fecal elastase, and serum trypsin.

The secretin stimulation test takes advantage of the normal response of pancreatic ductular cells to secrete HCO_3^- in response to physiologic and exogenously administered secretin. The observation that HCO_3^- production is impaired early in the course of chronic pancreatitis led to the use of this test to diagnose early-stage disease (sensitivity of 95%). The test involves oral placement of a double-lumen gastroduodenal catheter for aspiration and quantitative measurement of pancreatic enzyme and HCO_3^- production before and after stimulation with intravenous secretin. This quantitative measure of pancreatic secretion and enzyme activity is primarily performed for patients with suspected chronic pancreatitis who have chronic abdominal pain but negative or equivocal results of imaging studies. Peak pancreatic fluid HCO_3^- concentrations of less than 80 mEq/L represent pancreatic insufficiency.

The secretin stimulation test has been infrequently used in clinical practice because the study is labor intensive and is associated with discomfort. Endoscopic collection methods have simplified pancreatic fluid collection and made the test more suitable for clinical use.

The 72-hour fecal fat determination is sometimes used for detection of steatorrhea (fecal fat >7 g/24 hours), but the test is not specific for pancreatic exocrine insufficiency. The test also lacks sensitivity because steatorrhea occurs only in advanced chronic pancreatitis. Because the quantitative fecal fat test is inconvenient, unpleasant for patients, and prone to laboratory error, a qualitative assay is used preferentially in clinical practice to assess for malabsorption.

Determination of fecal elastase is the most commonly used noninvasive test for the diagnosis of pancreatic exocrine insufficiency. Elastase, a protease synthesized by pancreatic acinar cells, is useful for evaluating insufficiency because it is stable in stool, unaffected by pancreatic enzyme replacement, and correlates well with stimulated pancreatic function test results. Mild or severe exocrine insufficiency is based on fecal elastase values of less than 200 or 100 $\mu\text{g/g}$ of stool, respectively.

Low concentrations of serum trypsin are relatively specific for advanced chronic pancreatitis. However, they are not sensitive enough to be helpful for most patients with mild to moderate pancreatic disease.

Tests of Structure

Findings that suggest chronic pancreatitis include ductal abnormalities (e.g., dilation, stones, duct irregularity), parenchymal abnormalities (e.g., calcification, inhomogeneity, atrophy), gland contour changes, and pseudocysts. Imaging studies may be normal or inconclusive in the early stages of disease.

Plain film radiography of the abdomen can detect pancreatic calcifications in approximately 20% of individuals with alcohol-induced chronic pancreatitis. The study should be the first diagnostic test performed when pancreatitis is suspected because it is simple and inexpensive. Calcifications not detected on plain films are more readily apparent by CT (E-Fig. 38-4). CT scans may show supportive findings of pancreatic ductal dilatation, atrophy of the pancreas, and fluid collections (e.g., pseudocysts). Sensitivity and specificity

E-FIGURE 38-4 Computed tomography scan shows calcifications and small pseudocysts in the pancreas that are consistent with a diagnosis of chronic pancreatitis.

for the diagnosis of chronic pancreatitis are 75% to 90% and 85%, respectively.

ERCP can reliably evaluate structural abnormalities of the pancreatic ductular system. ERCP allows detection of pancreatic duct changes, including ductal dilation, strictures, abnormal side branches, communicating pseudocysts, and ductal stones and leaks. ERCP is highly effective for visualizing these ductal and duct-related findings, with a sensitivity for the diagnosis of chronic pancreatitis of 71% to 93% and a specificity of 89% to 100%. The major limitation of ERCP is the development of procedure-related acute pancreatitis in up to 5% of patients. ERCP should not be used for diagnostic purposes but instead reserved for patients with established chronic pancreatitis when endoscopic therapy is recommended (discussed later).

Magnetic resonance cholangiopancreatography is a noninvasive diagnostic imaging modality that provides visualization of the pancreatic duct with images similar to those of ERCP but without the risk of precipitating acute pancreatitis. However, limited visualization of pancreatic duct side branches makes this test useful only for patients with advanced changes of the main pancreatic duct. A modification of MRI imaging with secretin stimulation enhances side branch visualization, but whether it aids in the diagnosis of chronic pancreatitis remains to be determined.

Endoscopic ultrasound (EUS) as a diagnostic imaging study for chronic pancreatitis relies on quantitative and qualitative parenchymal tissue and ductal findings. EUS appears to be equally or more sensitive than other tests of structure and function. An international consensus panel proposed the Rosemont criteria for diagnosing chronic pancreatitis. Major criteria include hyperechoic foci with shadowing that indicates pancreatic duct calculi and parenchymal lobularity with honeycombing. Minor criteria include cysts, a dilated main duct (≥ 3.5 mm in diameter), irregular pancreatic duct contour, dilated side branches (≥ 1 mm in diameter), hyperechoic duct wall, parenchymal strands, non-shadowing hyperechoic foci, and lobularity with noncontiguous lobules. In the absence of any of these criteria, chronic pancreatitis is unlikely, whereas with detection of four or more criteria, the disease is likely, even when other imaging and pancreatic function tests may still be normal.

Treatment

Malabsorption

Treatment of pancreatic exocrine insufficiency is best achieved with pancreatic enzyme supplementation. Most commercial preparations consist of pancreatin, which is the shock-frozen powdered extract of porcine pancreas containing lipase, amylase, trypsin, and chymotrypsin. For most patients, the recommended dose depends on the size and nature of the meal (i.e., fat content), residual pancreatic function, and therapeutic goals (i.e., elimination of steatorrhea, reduction in the abdominal symptoms of maldigestion, or improvement in nutrition).

Approximately 90,000 USP units of lipase per meal are needed for optimal fat absorption. Due to residual pancreatic lipase secretion and physiologic gastric lipase secretion, it is appropriate to begin therapy with at least 50,000 USP units of lipase with each meal and one half of that amount with snacks.

Administration of acid-stable, encapsulated microspheres or microtablets filled with pancreatic enzymes has greatly increased the efficacy of enzyme supplementation.

In cases of gastric hyperacidity, proton pump inhibitors (PPIs) or histamine (H_2)-receptor antagonists should be used to reduce enzyme inactivation. If these methods do not provide improvement, the next step is to decrease dietary fat intake to less than 50 g per day and to substitute medium-chain triglycerides (MCTs), which do not require hydrolysis before absorption. Although clinically effective, patients usually do not like MCT fat because of poor palatability.

Other factors may accentuate steatorrhea, including concomitant small bowel bacterial overgrowth, which can occur in up to 25% of patients with chronic pancreatitis. Bacterial overgrowth may be caused by hypomotility due to inflammatory diseases of the head of the pancreas or chronic use of narcotic analgesics.

Pain

The greatest challenge in treating chronic pancreatitis is controlling abdominal pain. Pain may improve over time, but the course is not predictable, and improvement may take years. Therapy targets the mechanisms responsible for pancreatic pain, including pancreatic hyperstimulation, ischemia, obstruction of ducts, inflammation, and neuropathic hyperalgesia. Pain can develop in the early stages of chronic pancreatitis before morphologic changes can be demonstrated on imaging studies. Patients with chronic pancreatitis are at increased risk for pancreatic cancer, which may cause a change in the pain pattern, and extrapancreatic causes of pain must always be considered.

Pain management should proceed in a stepwise fashion and begin with lifestyle modifications such as alcohol and tobacco abstinence, a low-fat diet, and pancreatic enzyme supplementation, followed by a sequentially more aggressive and invasive approach for symptomatic failures, although it should be recognized that placebo alone is effective for up to 30% of patients. Several approaches can be considered for chronic pain relief.

1. Tobacco and alcohol abstinence. Abstention may decrease the frequency of painful attacks and reduce the likelihood pancreatic function deterioration and development of pancreatic cancer.
2. Nutrition and hydration. Small meals that are low in fat may help to some degree. Although the evidence is anecdotal, encouraging hydration may prevent exacerbations of pancreatitis. Supplementation of dietary fat with MCTs may be of benefit, possibly as a result of antioxidant effects of MCTs or the minimal increases in plasma cholecystokinin (CCK) levels associated with MCTs compared with other sources of dietary fat.
3. Analgesics. Most patients with pain require analgesics. Tramadol, a less potent opioid, is commonly used initially. The risk of addiction to opioids is not known, but studies of opioid use in other chronic pain syndromes suggest rates of less than 20%. Patients with previous addictive behaviors such as substance abuse (alcohol and tobacco included) are at greater risk for analgesic abuse and addiction.
4. Secretion suppression. Oral pancreatic enzyme replacement is thought to blunt pain by reducing endogenous CCK

secretion, which stimulates pancreatic acinar cells. Replacement therapy provides increased trypsin activity in the duodenum, which denatures CCK-releasing peptide, resulting in a reduction in endogenous CCK release and an attendant decrease in pancreatic stimulation and pain. Therapy is initiated with large doses of non-enteric-coated pancrelipases (i.e., pancreatic enzyme preparations) because the enteric-coated preparations theoretically release their enzymes further down the intestine, away from the stimulatory CCK enterocytes. Co-administration of acid suppressive therapy to prevent destruction of the enzymes by gastric acid may be helpful.

5. Neural transmission modification. Gabapentoids, including pregabalin, have been used effectively to treat neuropathic pain disorders, including diabetic neuropathy and neuropathic pain of central origin. Based on the finding that pancreatic pain is accompanied by similar alterations of central pain processing, studies suggest a benefit with pregabalin as an adjuvant treatment to decrease pain associated with chronic pancreatitis. Similarly, tricyclic antidepressants, selective serotonin reuptake inhibitors, and serotonin-norepinephrine reuptake inhibitors can be administered on a trial basis.
6. Antioxidants. Oxidative stress can cause direct pancreatic acinar cell damage through several pathways. Supplementation with antioxidants, such as selenium, vitamins C and E, and methionine, may relieve pain and reduce oxidative stress. In a randomized trial, the reduction in the number of painful days per month was higher for the patients who received antioxidants compared with those who received placebo (7.4 vs. 3.2 days). Patients who received antioxidants also were more likely to become pain free (32% vs. 13%).
7. Endoscopic decompression. Endoscopic decompression of the pancreatic duct is an option for obstruction of the main pancreatic duct caused by strictures, stones, or sphincter of Oddi dysfunction. Endoscopic therapies include pancreatic sphincterotomy, stricture dilation, stone removal with intracorporeal or extracorporeal shock wave lithotripsy, and temporary stent placement. Complete or partial pain relief is reported for approximately 50% to 80% of carefully selected patients during follow-up extending as long as 3 to 4 years.
8. Surgery. Surgical pancreatic ductal drainage, usually with lateral pancreaticojejunostomy (i.e., Puestow procedure), can be offered to those with a dilated (>6 mm in diameter) main pancreatic duct. Pain reduction is reported by approximately 80% of patients. This procedure is safe and has an operative mortality rate of less than 5%; however, only 35% to 60% of patients are free of pain at the 5-year follow-up. Individuals with nonobstructed, nondilated pancreatic ductal systems may be offered resection of focally diseased portions of the gland (i.e., Frey or Beger procedures) or total pancreatectomy with islet cell transplantation.

Management of Complications

The complications of chronic pancreatitis include pseudocysts, pancreatic fistulas, biliary obstruction, pancreatic cancer, small bowel bacterial overgrowth, and gastric varices due to splenic vein thrombosis.

Pancreatic Fistulas

Pancreatic fistulas occur as a result of duct disruption resulting in localized fluid collections, ascites, or pleural effusions. Treatment consists of bowel rest, endoscopic pancreatic duct stenting, and administration of a somatostatin analogue. Surgical intervention may be needed if this conservative approach is unsuccessful.

Vascular Complications

The splenic vein courses along the posterior surface of the pancreas, where it can be affected by inflammation from pancreatitis or malignancy that lead to thrombosis. Splenic vein thrombosis can result in isolated fundal gastric varices. Splenectomy is usually curative for patients who develop bleeding from gastric varices.

Pseudoaneurysm formation is a complication of acute and chronic pancreatitis. Affected vessels, including the hepatic, splenic, pancreaticoduodenal, and gastroduodenal arteries, lie close to the pancreas. CECT or MRI shows the pseudoaneurysm as a cystically dilated vascular structure in or adjacent to the pancreas. EUS with Doppler imaging can show blood flow within the pseudoaneurysm. Mesenteric angiography permits confirmation of the diagnosis and provides a means of therapy because selective embolization of the pseudoaneurysm can be accomplished during the procedure. Surgery for bleeding pseudoaneurysms is difficult and associated with high morbidity and mortality rates.

Biliary and Duodenal Obstruction

Symptomatic obstruction of the bile duct or duodenum, or both, develops in a few patients with chronic pancreatitis. Postprandial pain and early satiety are characteristic of duodenal obstruction, whereas pain and cholestasis (sometimes with resultant cholangitis) suggest a bile duct stricture. These complications most commonly result from inflammation or fibrosis in the head of the pancreas or an adjacent pseudocyst.

Endoscopic stenting may be attempted for bile duct strictures, but they are often refractory and typically require prolonged treatment. Endoscopic failures can be treated with surgical biliary decompression. The importance of decompression is underscored by the observation that it can reverse secondary biliary fibrosis associated with bile duct obstruction.

● CARCINOMA OF THE PANCREAS

Definition and Epidemiology

Carcinoma of the pancreas is the fourth leading cause of cancer-related death in the United States, with approximately 43,000 new cases diagnosed annually. The peak incidence of pancreatic carcinoma occurs in the seventh decade of life. There is a slight male-to-female predominance (relative risk of 1.4 : 1), and blacks have a 30% to 40% higher incidence of pancreatic carcinoma than whites in the United States.

Many environmental factors have been implicated as increasing the risk for pancreatic cancer. Cigarette smoking is the most consistent factor, with the increased risk attributed to the

aromatic amines found in cigarette smoke. Other risk factors include obesity, lack of physical activity, and diabetes mellitus. Studies evaluating the relationship between diet and pancreatic cancer are inconclusive. A Western diet (i.e., high intake of fat and meat, particularly smoked or processed meats) has been linked to the development of pancreatic cancer in many studies. Epidemiologic studies have failed to find a consistent association between alcohol or coffee consumption and the development of pancreatic cancer.

Up to 10% of patients with pancreatic cancer have a family history of the disease, but most cannot be identified with a known genetic disorder. Recognized genetic disorders that predispose to pancreatic cancer include hereditary pancreatitis (*PRSS1* gene), hereditary nonpolyposis colorectal cancer, familial adenomatous polyposis, *BRCA2* germline mutations, Peutz-Jeghers syndrome (*STK11* gene), familial atypical mole melanoma syndrome (*CDKN2A* gene, formerly *MTS1*), ataxia telangiectasia, and the Von Hippel–Lindau syndrome.

Although imaging surveillance of high-risk family cohorts is pursued at some centers, there is no consensus about the optimal methods or frequency of pancreatic cancer screening. Screening has not been shown to improve survival rates.

Pathology

The term *pancreatic cancer* usually refers to ductal adenocarcinoma of the pancreas, representing 85% to 90% of all pancreatic neoplasms. *Exocrine pancreatic neoplasm* is a more inclusive term that includes neoplastic pancreatic ductal and acinar cells and their stem cells and pancreatoblastoma.

More than 95% of malignant neoplasms of the pancreas arise from the exocrine elements. Neoplasms arising from the endocrine pancreas (i.e., islet cell or neuroendocrine tumors) comprise no more than 5% of pancreatic neoplasms. Pancreatic cancers are composed of several distinct elements, including pancreatic cancer cells, tumor stroma, and stem cells. The precursor lesion of pancreatic cancer is pancreatic intraepithelial neoplasia, which progresses from mild dysplasia (PanIN grade 1) to more severe dysplasia (PanIN grades 2 and 3) and eventually to invasive carcinoma.

Clinical Presentation

The clinical manifestations of pancreatic carcinoma may be non-specific and are often insidious. The tumor has usually reached an advanced stage by the time of diagnosis. Common presenting signs and symptoms of pancreatic cancer include jaundice, weight loss, and abdominal pain. The pain is usually constant, with radiation to the back. Because most cancers begin in the pancreatic head, patients may exhibit obstructive jaundice or a large, palpable gallbladder (i.e., Courvoisier's sign).

Painless jaundice is the most common manifestation in patients with a potentially resectable and curable lesion. Anorexia, nausea, and vomiting may also occur, along with emotional disturbances such as depression. Less common manifestations include superficial thrombophlebitis (i.e., Trousseau's sign), acute pancreatitis, diabetes, ascites, paraneoplastic syndromes (e.g., Cushing's syndrome), hypercalcemia, gastrointestinal bleeding, splenic vein thrombosis, and a palpable abdominal mass.

Diagnosis and Differential Diagnosis

The goal of imaging in the evaluation of suspected pancreatic carcinoma is to establish the diagnosis with a high degree of certainty and to determine resectability in patients who are otherwise candidates for operative resection. The diagnosis of pancreatic cancer is frequently suggested by a pancreatic mass seen on imaging studies. Evidence of a dilated pancreatic duct, hepatic metastases, invasion of vessels, or a dilated common bile duct in the setting of biliary obstruction may also be found. The imaging appearance may be impossible to distinguish from benign causes of pancreatic masses such as focal pancreatitis or autoimmune pancreatitis. Multiphase, multidetector, helical CT is the best initial study to define a mass and assess for liver metastasis or vascular invasion. Compared with CT, MRI, and angiography, EUS is the most accurate diagnostic and staging technique, providing information about tumor location, vascular invasion, and lymph node involvement.

The imaging techniques are highly accurate for recognizing unresectable disease, but they are somewhat limited for identifying resectable disease because occult metastases (<1 cm in diameter) may be on the surface of the liver or peritoneum. Staging laparoscopy is recommended for patients with the highest likelihood of occult metastatic disease: those with tumors of the body or tail of the pancreas who appear to have potentially resectable disease by CT (one half of whom have occult peritoneal metastases), those with large (>3 cm) primary tumors, those for whom imaging suggests occult metastatic disease, and those with a very high initial CA 19-9 level (>1000 units/mL).

The use of tumor markers to diagnose carcinoma of the pancreas has yielded disappointing results. The tumor marker CA 19-9 has a sensitivity of 70% to 80% and a specificity of 85% to 95% for diagnosing selected patients already exhibiting signs and symptoms that suggest pancreatic cancer. However, for early-stage cancers, CA 19-9 has limited sensitivity. Use of CA 19-9 requires the Lewis blood group antigen, which is absent in 5% to 10% of the population. The greatest utility for CA 19-9 is to identify occult metastasis in patients with seemingly resectable tumors, for monitoring patients after apparently curative surgery, and for following those receiving chemotherapy for advanced disease. Rising CA 19-9 levels suggest recurrent disease even in the absence of radiographically detectable lesions.

Unfortunately, only 10% to 20% of carcinomas in the head of the pancreas and rare cancers of the body and tail are resectable for cure. If evaluation is conclusive that a pancreatic tumor is not resectable, the first objective is to confirm the cell type, which can be done accurately by CT- or EUS-guided biopsy.

Treatment

Surgical Resection

The major determinant of operative resectability and long-term survival is vascular invasion or metastatic disease. Although practice varies across institutions, most surgeons consider a pancreatic cancer to be categorically unresectable if there is extrapancreatic involvement, including extensive peripancreatic lymphatic extension, nodal involvement beyond the peripancreatic tissues, or distant metastases (e.g., liver, peritoneum,

omentum, extra-abdominal sites). Other indications of unresectability include vascular encasement (i.e., more than one half of the vessel's circumference), occlusion or thrombus of the superior mesenteric vein (SMV) or the SMV–portal vein confluence, or direct involvement of the superior mesenteric artery, inferior vena cava, aorta, celiac axis, or hepatic artery, as defined by the absence of a fat plane between the tumor and these structures on CT. For tumors of the tail of the pancreas, encasement of the splenic vein does not necessarily obviate resectability.

Selective preoperative ERCP with biliary stent placement is recommended for patients with obstructive jaundice when symptoms of intractable pruritus or cholangitis occur or when surgery must be delayed for several weeks. At the time of stent placement, ERCP tissue sampling techniques can confirm a diagnosis of pancreatic malignancy (sensitivity of 30% to 60%), but the sensitivity is lower than that of EUS-guided fine-needle aspiration.

The standard operation for pancreatic cancer of the head or uncinata process is the Whipple procedure (i.e., pancreaticoduodenectomy). Whipple resection consists of removal of the pancreatic head, distal common bile duct, gallbladder, duodenum, proximal jejunum, gastric antrum, and regional lymph nodes. Reconstruction requires pancreaticojejunostomy, hepaticojejunostomy, and gastrojejunostomy. The surgical mortality rate for this procedure is approximately 3% when performed by experienced pancreatic surgeons. Patients who have undergone surgical resection should receive adjuvant treatment using gemcitabine alone or in combination with fluorouracil-based chemoradiation therapy, which improves progression-free and overall survival rates.

The term *borderline resectable* is reserved for cases with focal (less than one half of the circumference) tumor abutment of the visceral arteries or short-segment occlusion of the SMV or SMV–portal vein confluence or hepatic artery. Some centers are performing resection and reconstruction of a short segment of the portal vein or SMV in selected patients. Arterial resection and reconstruction (mostly of the superior mesenteric and hepatic arteries) are performed infrequently, and the morbidity and mortality rates for the operation increase markedly when these arteries are included. The use of preoperative neoadjuvant chemoradiation therapy in an effort to convert patients with unresectable locoregionally advanced disease to a resectable status has increased the overall resection rate, but no difference in survival has been demonstrated.

Palliation

For patients with inoperable cancers or poor performance status, palliative interventions to alleviate jaundice, pain, and intestinal obstruction often become the focus of therapy. When advanced disease is observed operatively, the surgeon must determine whether to perform additional palliative surgery. Biliary bypass is indicated in patients with obstructive jaundice. Duodenal

bypass is indicated when features suggest impending gastric outlet obstruction. Alternative palliative endoscopic approaches are available for patients not undergoing exploratory surgery.

Chemoradiation Therapy for Advanced Disease

Systemic chemotherapy provides benefit for patients with advanced pancreatic cancer, improving disease-related symptoms and survival compared with the best supportive care alone. Studies comparing gemcitabine with 5-fluorouracil indicate very low objective response rates for both single agents but superiority for gemcitabine in terms of clinical response based on improvement in symptoms (i.e., pain and weight loss) and performance status. For patients with advanced disease, gemcitabine may be combined with a platinum agent, erlotinib (i.e., epidermal growth factor receptor inhibitor), or a fluoropyrimidine.

Prognosis

Carcinoma of the pancreas accounts for approximately 5% of cancer deaths in the United States. The overall prognosis is poor because less than 20% of patients are alive beyond the first year after diagnosis, and only 1% to 3% are alive beyond the fifth year. Although 15% to 20% of patients have resectable disease at initial diagnosis, most have locally advanced or metastatic cancer. Median survival is 8 to 12 months for patients with locally advanced unresectable disease and 3 to 6 months for those with metastases at diagnosis.

A Whipple resection for pancreatic head cancers is the only chance for cure; however, the median survival after surgery is 15 to 20 months. The overall 5-year survival rate is 10% to 25%, and up to 50% of those who survive 5 years ultimately die of recurrent cancer. Poor prognostic factors include a high tumor grade, a large tumor, high levels of CA 19-9 before and after surgery, tumor-positive surgical margins, and lymph node metastases.

 For a deeper discussion of these topics, please see Chapter 144, "Pancreatitis," and Chapter 194, "Pancreatic Cancer," in Goldman-Cecil Medicine, 25th Edition.

Laboratory Tests in Liver Disease

Shaheryar A. Siddiqui and Michael B. Fallon

INTRODUCTION

The liver is the largest solid organ in the body, and it performs many metabolic, secretory, and nutritional functions that are vital to maintenance of a healthy human physiology. The liver is responsible for glucose homeostasis, plasma protein synthesis, lipid and lipoprotein synthesis, bile acid synthesis and secretion (for absorption of fats and vitamins), and vitamin storage (vitamins B₁₂, A, D, E, and K). In addition, the liver is the major site for biotransformation, detoxification, and excretion of a vast array of endogenous and exogenous compounds (e.g., drugs, toxins). As a result of these diverse roles, the clinical manifestations of liver disease are varied and can be quite subtle. Laboratory tests are designed to assess the various functions of the liver, which are then correlated with patient history and physical examination as part of a broader assessment. These tests may be ordered as part of a screening evaluation or to further evaluate clinical signs and symptoms prompting consideration of liver disease, such as hepatomegaly, ascites, jaundice, dark urine, light-colored stool, or gastrointestinal bleeding.

LIVER FUNCTION TESTS

Colloquially, the term *liver function tests* (LFTs) is used quite often when referring to a panel of measurements to assess the “function” of the liver. This panel typically includes measurements of total protein, albumin, aspartate aminotransferase (AST, formerly called serum glutamic-oxaloacetic transaminase or SGOT), alanine aminotransferase (ALT, formerly called serum glutamic-pyruvic transaminase or SGPT), alkaline phosphatase (ALP), γ -glutamyl transpeptidase (GGT), bilirubin (conjugated and unconjugated), and prothrombin time (PT). Unlike tests used to assess function in other organ systems (e.g., arterial blood gases, creatinine clearance), liver function tests do not directly measure hepatic function and may not accurately reflect the cause or severity of liver disease. Rather, they reflect certain patterns or types of liver and biliary cell injury that warrant further evaluation. The most widely available and useful liver function tests are outlined in [Table 39-1](#).

Hepatocellular Injury

AST and ALT are intracellular enzymes that catalyze the transfer of the α -amino group of aspartate or alanine to the α -keto group of ketoglutaric acid, resulting in formation of pyruvate or oxaloacetic acid, respectively. They are important enzymes that participate in gluconeogenesis. With cell injury, AST and ALT are released into the circulation, and higher values are used primarily as markers of liver inflammation. ALT is found predominantly in

hepatocytes, and an elevation in ALT is more specific than an elevated AST for liver disease. AST is found in the liver but also in heart, skeletal muscle, brain, kidney, pancreas, and lungs. After injury or death of liver cells, these enzymes are released into the circulation. They are measured indirectly with the use of a spectrophotometer.

In most hepatocellular disorders (e.g., viral hepatitis, acetaminophen toxicity), ALT levels are higher than or equal to AST levels. In alcoholic liver disease, however, the AST usually is more than two-fold higher than the ALT (AST/ALT ratio >2). An AST/ALT ratio greater than 3 is 97% specific for alcohol as the underlying cause. Extremely high transaminase levels (15 times the upper limit of normal) generally indicate acute hepatocellular necrosis from viral or toxic causes such as acetaminophen; less frequently, they indicate acute bile duct obstruction or hepatic ischemia (shock liver).

Patients who have isolated asymptomatic elevations of AST and ALT (usually ALT $>$ AST) may have nonalcoholic fatty liver disease (NAFLD), which is caused by obesity, insulin resistance and diabetes, hyperlipidemia, or excessive alcohol consumption. However, in some cases, the AST is higher than the ALT, mimicking the pattern seen in alcoholic liver disease. A careful history and evaluation are warranted, although the AST/ALT ratio in NAFLD rarely exceeds 2, thus distinguishing it from alcoholic liver disease.

Infiltrative hepatocellular disease (e.g., hemochromatosis) and chronic viral hepatitis are also part of the differential.

Cholestasis

Serum ALP comprises a group of isoenzymes derived from the liver, bone, intestine, and placenta. Hepatic ALP (isoenzyme ALP-1) is present mainly in the mucosal cells lining the bile ducts; the usual flow of bile into the small intestine maintains the normal serum level of ALP. In cholestasis related to biliary obstruction or duct injury, serum ALP levels rise as a result of retention of bile acids in the liver; the bile acids solubilize ALP from the hepatocyte plasma membrane and also stimulate its synthesis. Various other hepatocyte plasma membrane enzymes are simultaneously released, including 5'-nucleotidase (5'-NT) and GGT, confirming that the elevated ALP is caused by hepatobiliary disease. The measurement of ALP is thus correlated with integrity of the biliary system.

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are examples of obstructive diseases with predominant elevation of ALP. Other conditions, such as bone regeneration, pregnancy, and neoplastic, infiltrative, and granulomatous liver diseases are also associated with elevated ALP levels.

TABLE 39-1 LABORATORY TESTS OF HEPATIC FUNCTION

LIVER ASSAY*	LIVER FUNCTION	ABNORMALITY
Serum albumin (3.5-5.5 g/dL)	Assess the biosynthetic capacity of the liver (days to weeks)	Decreased synthetic capacity Protein malnutrition Nephrotic syndrome Protein-losing enteropathy
Prothrombin time (11-14 sec)	Assess the biosynthetic capacity of the liver (hours to days)	Decreased synthetic capacity (especially factors II and VII) Vitamin K deficiency Consumptive coagulopathy
Serum bilirubin (0.2-1.3 mg/dL) (3.4-22.2 μmol/L)	Extraction of bilirubin from blood; conjugation and excretion into bile	Hemolysis Diffuse liver disease Cholestasis Extrahepatic bile duct obstruction Congenital disorders of bilirubin metabolism
Serum alkaline phosphatase (39-136 units/L)	Present in the cells lining the biliary tree	Bile duct obstruction Cholestasis Infiltrative liver disease (neoplasms, granulomas)
γ-glutamyl transpeptidase (7-45 units/L)	Highly sensitive to hepatocyte damage and cholestasis	Bone destruction, remodeling
5'-nucleotidase (2-17 units/L)	More specific for the liver and for cholestasis than GGT	Pregnancy
Aspartate aminotransferase (AST) or SGOT (5-40 Units/L)	Represent hepatocyte inflammation and damage	Hepatocellular necrosis Cardiac or skeletal muscle necrosis
Alanine aminotransferase or SGPT (5-65 Units/L)	Represent hepatocyte inflammation and damage	Same as AST; however, more specific for liver cell damage

*The reference intervals given here in conventional metric units and in SI units are from several large medical centers. Always use the reference intervals provided by your clinical laboratory, since intervals may be method-dependent.

An isolated elevated ALP level may be the only clue to obstruction of the common bile duct or neoplastic or granulomatous hepatic disease. Elevated serum ALP levels with normal 5'-NT and GGT usually suggests a nonhepatic cause (e.g., bone disease, pregnancy, chronic renal failure, lymphoma, congestive heart failure). Electrophoretic fractionation of ALP isoenzymes may be useful to confirm alternative sources.

Elevated bilirubin levels also are characteristic of cholestasis. Bilirubin is present in the serum in two forms: unconjugated (indirect) and conjugated (direct). Under normal conditions, total serum bilirubin levels are less than 1 mg/dL, with the conjugated fraction representing up to 30% of the total. The serum bilirubin level reflects a balance between bilirubin production and its conjugation and excretion into bile by the liver.

The differential diagnosis for hyperbilirubinemia (see [Chapter 42](#)) requires consideration of an extensive list of disorders in which there are alterations of bilirubin production (hematologic disorders with predominantly unconjugated hyperbilirubinemia), hepatic metabolism (congenital abnormalities of bilirubin conjugation, liver disease), or excretion (congenital abnormalities of bilirubin excretion or biliary obstruction with predominantly conjugated hyperbilirubinemia). Hence, an ele-

vated serum bilirubin is not specific but should initiate a more detailed evaluation for more specific causes.

Importantly, individual tests often do not indicate the nature of the underlying liver disease; hence, the common use of the LFT panel of tests. The overall pattern of liver test abnormalities and the relative magnitudes of abnormalities in individual tests often provide significant insights, including categorization as to whether the liver disease is primarily hepatocellular or cholestatic. [Figure 39-1](#) outlines common patterns of liver test abnormalities and common accompanying diagnostic evaluation.

Hepatic Synthetic Function

The serum albumin level and the PT (expressed as the international normalized ratio [INR]) reflect the hepatic capacity for protein synthesis. The PT is dependent on coagulation factors II, V, VII, and X and responds rapidly to altered hepatic function because of the short serum half-lives of factors II and VII (about 6 hours). This makes measurement of PT a useful marker of hepatic synthetic function that can be measured as frequently as daily. However, because serum levels of factors II, VII, IX, and X are dependent on vitamin K, coexistent vitamin K deficiency must be excluded or treated before PT can be used as a measure of intrinsic hepatic function. In contrast, the serum half-life of albumin is 14 to 20 days, and serum levels fall with prolonged liver dysfunction or acute liver impairment. Malnutrition and renal or gastrointestinal losses merit consideration in the evaluation of significant hypoalbuminemia, especially if the PT is relatively well preserved.

QUANTITATIVE TESTS OF LIVER FUNCTION

Quantitative liver tests that depend on the capacity of the liver to transform or transport a test agent have been developed but have not received widespread application. These include indocyanine green clearance, galactose elimination capacity, aminopyrine breath test, antipyrine clearance, monoethylglycine xylidide, and caffeine clearance. They may be superior to conventional biochemical tests in predicting prognosis, but their clinical utility has not been established, and they are limited primarily to research centers.

Specific Disease Markers

Elevations of individual γ-globulins can be suggestive of specific diseases. For example, autoimmune hepatitis is associated with an elevated total immunoglobulin G (IgG) level and the presence of autoantibodies such as antinuclear antibody (ANA), anti-smooth muscle antibody (ASMA), and anti-liver/kidney microsomal antibody type 1 (anti-LKM1). IgG4-related disease is an autoimmune phenomenon in which increased IgG4 levels cause dysfunction in multiple organs, including autoimmune cholangitis and autoimmune pancreatitis. Alcoholic cirrhosis is associated with high IgA levels, and primary biliary cirrhosis is associated with elevated IgM levels.

Viruses are detected by polymerase chain reaction (PCR), enzyme assays, and genotyping. Screening can be performed for specific diseases such as hemochromatosis (iron panels and *HFE* gene mutation testing). Levels of α₁-antitrypsin and serum ceruloplasmin are measured to evaluate patients with liver disease

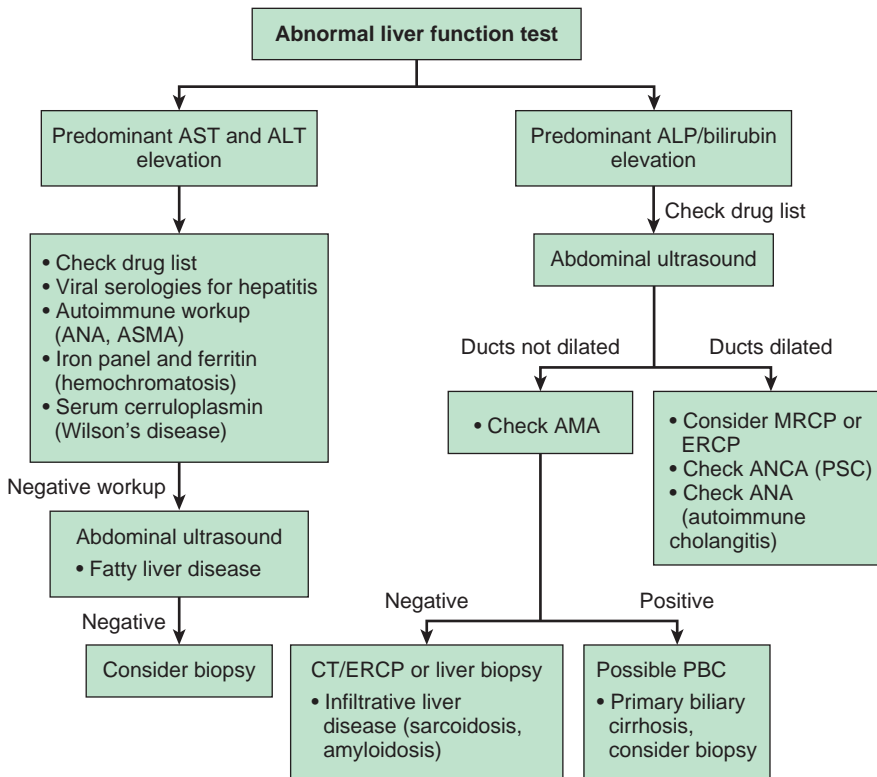

FIGURE 39-1 Diagnostic approach to abnormal liver function test. ACE, Angiotensin-converting enzyme; ALP, alkaline phosphatase; ALT, alanine aminotransferase; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; AMA, antimitochondrial antibody; ASMA, anti-smooth muscle antibody; AST, aspartate aminotransferase; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis.

for possible α_1 -antitrypsin deficiency and Wilson's disease, respectively. Serum ammonia is a poor marker of hepatic function. However, it is used frequently as an aide in the evaluation of possible portosystemic encephalopathy. Carbohydrate-deficient transferrin (CDT) is a marker used to identify chronic alcohol use.

Biomarkers of Liver Histology

Liver biopsy remains the “gold standard” for detection and quantitation of liver cirrhosis, fibrosis, inflammation, steatosis, tumors, and necrosis. Biopsy of the liver is a straightforward procedure that can be performed by either a percutaneous or a transjugular approach. Although it is generally safe, serious complications such as bleeding (1 per 1000) and death (1 per 10,000) may occur. There is also a finite risk of introducing an infection.

Given these potential concerns, noninvasive alternatives to liver biopsy would be attractive if validated. Both noninvasive serum markers and ultrasonographic elastography have been evaluated as potential alternatives to liver biopsy to assess hepatic fibrosis. FibroTest (known as FibroSure in the United States) is the most studied biomarker panel. Other patented biomarker panels include the Enhanced Liver Fibrosis (ELF) test, Hepascore, Fibro Meter, and FIBROSpect by Western blotting. The FibroTest panel incorporates six serum markers: α_2 -macroglobulin, haptoglobin, apolipoprotein A-I, GGT, total bilirubin, and ALT. An algorithm is used to calculate a score, represented as a range from F0 to F4, that indicates the probability of fibrosis (F0, no cirrhosis; F4, liver cirrhosis).

Another scoring system, called the NAFLD fibrosis score, uses six variables (age, body mass index [BMI], AST, ALT, platelet count, and serum albumin) to predict advanced fibrosis in

patients with NAFLD. The utility of this scoring system in routine clinical practice is not clearly established.

Imaging modalities such as real-time shear wave elastography (SWE) on the Aixplorer ultrasound machine, transient elastography (FibroScan), and acoustic radiation force imaging (ARFI) are sonographic techniques based on the theory that a “shear wave” moves faster in a less elastic liver (i.e., one with more fibrosis and scarring) than in a normal or less fibrotic liver. These imaging modalities have a high specificity in detecting liver fibrosis, comparable to that of serum biomarkers.

Liver Biopsy

Biopsy and histologic examination of liver tissue is still the standard protocol for patients who are undergoing induction therapy for chronic viral hepatitis or are on the transplant list for any other cause of liver failure. Contraindications for biopsy include an uncooperative patient, impaired hemostasis (INR >1.5), thrombocytopenia (fewer than 50,000 to 60,000 platelets per microliter), use of nonsteroidal anti-inflammatory drugs (NSAIDs) within the previous 7 to 10 days, and suspected echinococcal cysts in the liver.

For a deeper discussion on this topic, see Section XIII: Disease of the Liver, Gallbladder, and Bile Ducts in Goldman-Cecil Medicine, 25th Edition.

Jaundice

Klaus Mönkemüller, Helmut Neumann, and Michael B. Fallon

INTRODUCTION

The term *jaundice* refers to yellow pigmentation of the skin, the conjunctival membranes over the sclera, and other mucous membranes that is caused by elevated serum bilirubin levels (hyperbilirubinemia). The word derives from the French word *jaune*, which means “yellow,” and the condition also is known as *icterus* (Greek for “yellow”). Normal serum bilirubin levels range from 0.5 to 1.0 mg/dL, and plasma bilirubin concentrations typically must exceed 2.5 mg/dL before jaundice becomes evident clinically. In most cases, jaundice or hyperbilirubinemia per se is not a pathologic condition but rather a sign of one or more illnesses originating from or affecting the liver and blood. However, there is one notable exception: In newborns, high bilirubin levels can lead to pathologic cerebral changes. In this condition, which is known as *kernicterus* (the word *kern* derives from German and means “nucleus”), sustained high levels of unconjugated bilirubin lead to deposition of unconjugated bilirubin in the cerebral basal ganglia (or nuclei). This process is preventable and treatable and therefore merits special recognition to prevent damage to the developing brain.

BILIRUBIN METABOLISM

Hyperbilirubinemia can be classified based on the three phases of hepatic bilirubin metabolism: uptake, conjugation, and excretion into the bile (the rate-limiting step). In addition, jaundice can be classified into prehepatic, hepatic, and posthepatic causes (Table 40-1). Although the approaches are complementary, we believe that the latter classification is more useful for the practicing clinician.

The main source of bilirubin is the hemoglobin released from senescent red blood cells, and the liver serves as its primary site of metabolism and excretion. Abnormalities at any step—bilirubin production, metabolism, or excretion—can lead to increases in serum bilirubin and clinical jaundice. Under normal conditions, human red blood cells have a life span of about 120 days. As they age, erythrocytes are broken down and removed from the circulation by phagocytes. Most bilirubin (80%) is derived from the breakdown of hemoglobin released from these cells; the remainder is derived from ineffective erythropoiesis and from catabolism of myoglobin and hepatic hemoproteins such as the cytochrome P-450 isoenzymes. The normal rate of bilirubin production is approximately 4 mg/kg body weight per day

(E-Fig. 40-1).

TABLE 40-1 CLASSIFICATION OF JAUNDICE AND REPRESENTATIVE CAUSES

PREHEPATIC CAUSES

Predominantly Unconjugated Hyperbilirubinemia

Hemolysis (e.g., sickle cell disease, autoimmune hemolytic anemia, mechanical cardiac valve with accelerated red cell destruction)
 Microbe-induced hemolysis (malaria, leptospirosis)
 Ineffective erythropoiesis (e.g., megaloblastic anemias)
 Hematoma resolution

HEPATIC CAUSES

Unconjugated Hyperbilirubinemia

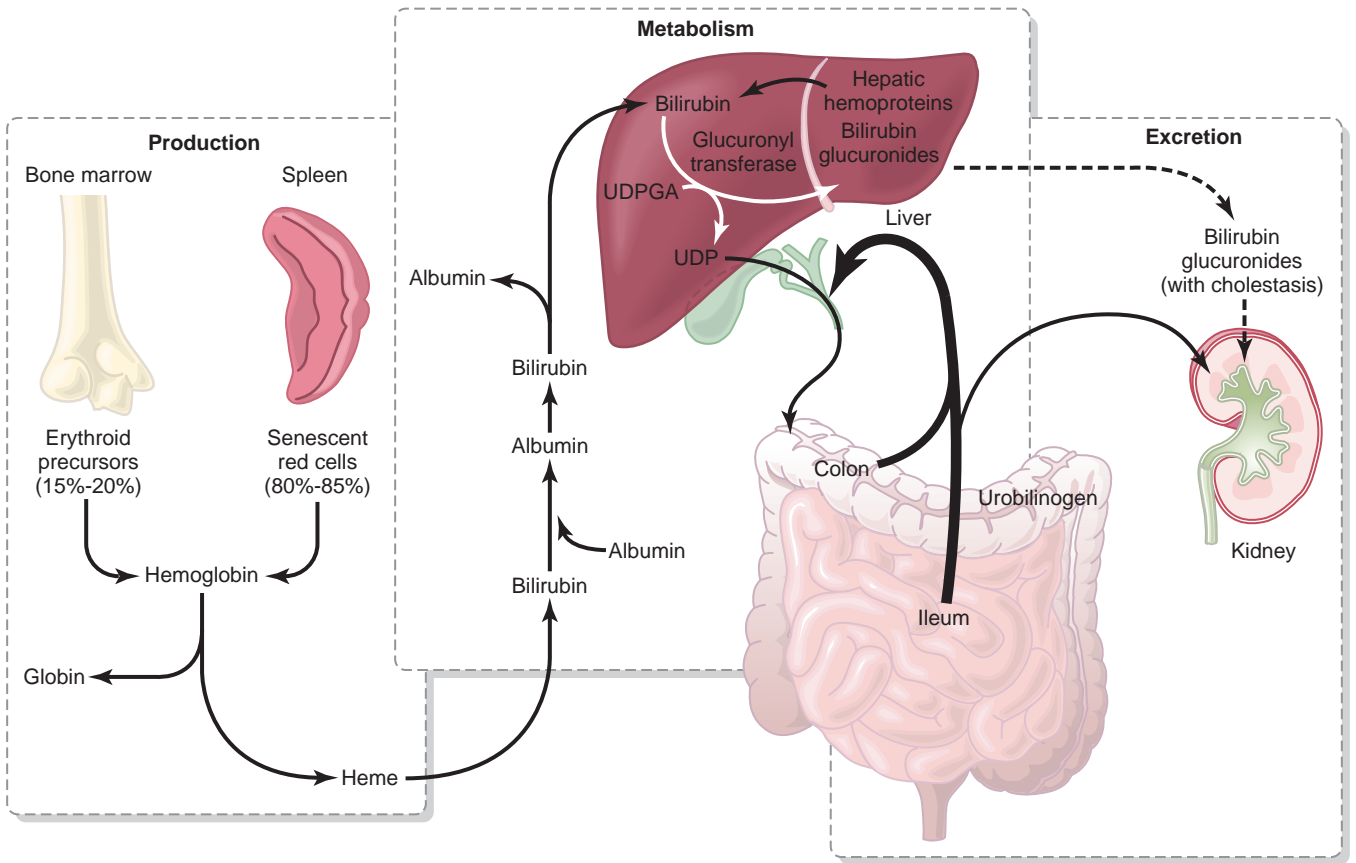

Decreased hepatic uptake
 Therapeutic drugs that interfere with bilirubin uptake (e.g., rifampin, metformin, methimazole, propylthiouracil, clopidogrel, sulfamethoxazole/trimethoprim)
 Herbal medicines (e.g., *Teucrium viscidum*, kava-kava, chaparral, greater celandine)
 Hyperthyroidism
 Diminished uptake and decreased cytosolic binding proteins (e.g., newborn or premature infants)
 Shunting of blood away from the liver (portal hypertension or surgical shunt)
 Decreased conjugation due to limited glucuronyltransferase activity
 Gilbert's syndrome
 Crigler-Najjar syndrome types I and II
 Neonatal jaundice
 Breast-milk jaundice
 Drug-induced inhibition (e.g., chloramphenicol)

Predominantly Conjugated Hyperbilirubinemia

Impaired hepatic excretion
 Familial cholestasis (Dubin-Johnson syndrome, Rotor's syndrome, benign recurrent cholestasis, cholestasis of pregnancy)
 Hepatocellular injury from infiltrative disorders, hemochromatosis, α_1 -antitrypsin deficiency, lymphoma, sarcoidosis, extensive metastases)
 Liver cirrhosis
 Hepatitis
 Drug-induced cholestasis (chlorpromazine, erythromycin estolate, isoniazid, halothane, and many others)
 Primary biliary cirrhosis
 Congestive heart failure
 Sepsis

POSTHEPATIC CAUSES

Extrahepatic biliary obstruction
 Common bile duct obstruction from gallstones
 Benign and malignant tumors of the pancreas
 Tumors of bile ducts (cholangiocarcinoma) and ampulla of Vater
 Biliary strictures (postsurgical, gallstone-related, primary sclerosing cholangitis)
 Congenital disorders (biliary atresia, cystic fibrosis)
 Infectious cholangiopathy
 Chronic pancreatitis (fibrosis of the head of the pancreas)

E-FIGURE 40-1 Bilirubin production, metabolism, and excretion. See text for details. UDP, Uridine diphosphate; UDPGA, uridine diphosphate glucuronic acid.

As erythrocytes are destroyed within the reticuloendothelial system, free hemoglobin is ingested by macrophages and then split into heme and globin moieties. The heme ring is cleaved by the enzyme microsomal heme oxygenase to form biliverdin (*verde* = “green”), which is then converted to the tetrapyrrol pigment bilirubin by the cytosolic enzyme biliverdin reductase. This unconjugated (or “indirect”) bilirubin is released into the plasma, where it is tightly bound to albumin. Because unconjugated bilirubin is insoluble in water, it cannot be excreted in urine or bile. However, it is permeable across lipid-rich environments and therefore can traverse the blood-brain barrier and the placenta.

The unconjugated bilirubin-albumin complex is transported to the liver. Once in the space of Disse, this complex dissociates; unconjugated bilirubin is transported across the basolateral plasma membrane of liver cells and attaches to intracellular binding proteins (ligandins). It is then conjugated with glucuronic acid by the enzyme uridine diphosphate–glucuronyltransferase (UDP-GT) to form bilirubin monoglucuronide and diglucuronide, making the molecule water soluble. This conjugated (or “direct”) bilirubin is excreted into bile via active transport across the canalicular membrane by means of a multispecific canalicular transport protein.

If biliary excretion of conjugated bilirubin is impaired, it can exit the basolateral membrane and reenter the circulation, causing an increase in plasma levels. Because conjugated bilirubin is water soluble and less tightly bound to albumin than its unconjugated form, it is readily filtered by the glomerulus and appears in the urine, giving it a dark color (choloria). Once in bile, bilirubin enters the intestine, where bacteria convert it to colorless tetrapyrroles (urobilinogens) that are excreted in feces. Up to 20% of urobilinogen is reabsorbed and undergoes enterohepatic circulation or excretion in urine.

LABORATORY MEASUREMENT OF BILIRUBIN

The *van den Bergh reaction*, which is the most commonly used test for detecting bilirubin in biologic fluids, combines bilirubin with diazotized sulfanilic acid to form a colored compound. The direct-reacting fraction is roughly equivalent to conjugated bilirubin and the indirect-reacting fraction (total minus direct fraction) to unconjugated bilirubin. This characteristic provides a

means for classifying jaundice into two categories: unconjugated hyperbilirubinemia and conjugated hyperbilirubinemia.

UNCONJUGATED HYPERBILIRUBINEMIA

Mechanisms that cause unconjugated hyperbilirubinemia include overproduction, impaired hepatic uptake, and decreased conjugation of bilirubin. These disorders are not usually associated with significant hepatic disease.

Etiology of Hyperbilirubinemia

There are many potential causes of hyperbilirubinemia, and the major categories are summarized in [Table 40-1](#). It is helpful to consider them mechanistically as conditions affecting the balance of bilirubin production, liver metabolism, and excretion. The classic cause of bilirubin overproduction is hemolysis, whereas the most common cause of impaired bilirubin uptake and metabolism is cirrhosis or other liver disease. Bile duct obstruction due to cancer, stones, or strictures is the most common cause of obstructive jaundice. Because multiple mechanisms are often involved in an individual patient, the evaluation of jaundice can be complex.

Prehepatic Jaundice

Prehepatic jaundice is associated with excessive bilirubin production ([Fig. 40-1](#)), which most often results from hemolysis (intravascular or extravascular), resolution of large hematomas, or mechanical injury to red cells, such as can occur with pulmonary emboli. Certain genetic diseases can lead to increased red cell lysis and therefore to hemolytic jaundice. Sickle cell anemia is the classic cause, but others include glucose 6-phosphate dehydrogenase deficiency and hereditary spherocytosis. Infectious diseases also can cause hemolysis, either directly (e.g., malaria) or indirectly (e.g., autoimmune injury). Jaundice resulting from hemolysis is characteristically mild in degree, and serum bilirubin levels rarely exceed 5 mg/dL in the absence of coexisting hepatic disease. Ineffective erythropoiesis, which may be significantly increased in megaloblastic anemias, also leads to mild jaundice.

Hemolysis should be considered in the evaluation of unconjugated hyperbilirubinemia and evaluated by examination of the peripheral blood smear (and, in some cases, the bone marrow

FIGURE 40-1 Hemolytic anemia associated with lymphoma. **A**, Blood smears show the destroyed red blood cells. **B**, Lymphoma.

smear) as well as measurements of the reticulocyte count, haptoglobin, lactate dehydrogenase (LDH), erythrocyte fragility, and Coombs' test as indicated.

Hepatic or Hepatocellular Jaundice

Typically, considerable reserve exists within the liver, so jaundice of hepatocellular origin can be indicative of significant injury or dysfunction. The differential diagnosis is broad because the liver is susceptible to many different forms of injury (Fig. 40-2). The most common categories are viral hepatitis, exposure to toxins (e.g., alcohol, carbon tetrachloride, amanita), prescription or nonprescription drugs, autoimmune disorders (e.g., autoimmune hepatitis, primary biliary cirrhosis [PBC], primary sclerosing cholangitis [PSC]), and liver tumors (mostly metastatic in origin). Impaired hepatic uptake of bilirubin can be a cause of unconjugated hyperbilirubinemia. When present, it is typically caused by competition for bilirubin uptake by drugs such as rifampin. Removal of the competing agent usually leads to resolution of the jaundice.

Impaired Conjugation

Another common cause of unconjugated hyperbilirubinemia is Gilbert's syndrome, a benign disorder that affects up to 7% of the population. This represents a normal variant that is not associated with intrinsic liver disease. Rather, it typically manifests during the second or third decade of life as mild unconjugated hyperbilirubinemia that is exacerbated by fasting or physical stress. Most of those affected have a total bilirubin level of less than 3 mg/dL, mostly of the unconjugated (indirect) fraction. The underlying genetic variant responsible is a homozygous abnormality in the TATAA element of the promoter region of the UDP-GT gene that results in lower enzymatic levels. The diagnosis is strongly suggested by unconjugated hyperbilirubinemia in the setting of normal hepatic enzyme levels, no known liver disease, and no evidence of hemolysis. Liver biopsy usually is not indicated, and therapy is not warranted. However, the bilirubin level does decrease significantly with phenobarbital administration. It is important to be aware of this common cause of unconjugated hyperbilirubinemia so that the patient can be reassured and more costly or invasive tests can be avoided.

Crigler-Najjar syndrome is another cause of unconjugated hyperbilirubinemia in which the bilirubin levels may be much

higher due to a genetically determined decrease or absence of UDP-GT activity. Conjugation may also be impaired by mild, acquired defects of UDP-GT induced by drugs such as chloramphenicol.

NEONATAL JAUNDICE

About 50% of term and 80% of preterm babies develop jaundice, which usually appears 2 to 4 days after birth and resolves spontaneously after 1 to 2 weeks. Most jaundice in newborn infants occurs for two main reasons. First, the enzymatic and transport pathways responsible for bilirubin metabolism are relatively immature and are unable to conjugate bilirubin as efficiently or as quickly as in adults. Second, bilirubin production is increased. Of those two mechanisms, the major defect is in bilirubin conjugation, which may cause mild to moderate unconjugated hyperbilirubinemia between the second and fifth days of life lasting until day 8 in normal births or about day 14 in premature births. This neonatal jaundice is usually harmless, and no specific therapy is required other than close observation.

More severe pathologic unconjugated hyperbilirubinemia can occur in neonates and usually is caused by a combination of hemolysis secondary to blood group incompatibility and defective conjugation. This neonatal jaundice is a serious condition that requires immediate attention because severe hyperbilirubinemia can lead to permanent neurologic damage (kernicterus). Phototherapy provided by conventional lighting or a fiberoptic light is the treatment of choice; it reduces neonatal jaundice (as assessed by serum bilirubin levels) compared with no treatment. Low-threshold compared with high-threshold phototherapy reduces neurodevelopmental impairment and hearing loss and reduces serum bilirubin on day 5 in infants with extremely low birth weight. However, it increases the duration of phototherapy, and it has no effect on mortality or on the rate of exchange transfusion. Close phototherapy, compared with distant light-source phototherapy, reduces the duration of phototherapy in infants with hyperbilirubinemia. If jaundice does not improve with phototherapy, other causes of neonatal jaundice should be assessed.

CONJUGATED HYPERBILIRUBINEMIA

Conjugated hyperbilirubinemia is associated with impaired formation or excretion of *all* components of bile, a situation termed *cholestasis*. The two major mechanisms of conjugated hyperbilirubinemia are defective excretion of bilirubin from hepatocytes into bile (intrahepatic cholestasis) and mechanical obstruction to the flow of bile through the bile ducts.

Impaired Hepatic Excretion (Intrahepatic Cholestasis)

Intrahepatic cholestasis can result from a wide range of conditions, including those that impair canalicular transport (e.g., certain drugs, circulating inflammatory cytokines during sepsis) and those that cause destruction of the small intrahepatic bile ducts. PBC, for example, is a chronic, progressive liver disease that occurs primarily in women and is characterized by the indolent destruction and subsequent disappearance over time of small lobular bile ducts. The gradual decrease in the number of bile ducts leads to progressive cholestasis, portal inflammation, fibrosis, and eventually cirrhosis. A similar loss of intrahepatic

FIGURE 40-2 Ultrasound image shows a cirrhotic liver with atrophy, irregular contours, and ascites.

ducts can occur as a result of chronic rejection after liver transplantation.

Drug-induced cholestasis is increasingly common, and immune-mediated or idiosyncratic mechanisms predominate. In some cases, there is associated hepatitis with significant cell injury. Representative drugs include, but are not limited to, nitrofurantoin, oral contraceptives, anabolic steroids, erythromycin, cimetidine, gold salts, chlorpromazine, prochlorperazine, imipramine, sulindac, tobutamide, ampicillin, and other penicillin-based antibiotics. Given the broad access to drugs in Western societies and the unpredictable nature of the adverse liver effects, a high index of suspicion for drug-induced cholestasis is required.

Intrahepatic cholestasis of pregnancy (ICP), also known as idiopathic jaundice of pregnancy, is a cholestatic disorder that is characterized by pruritus in the absence of a skin rash and elevation of aminotransferases (often up to 100 IU/L), alkaline phosphatase, 5-nucleotidase, and total and direct bilirubin concentrations. Total levels of bilirubin rarely exceed 6 mg/dL. The levels of γ -glutamyl transpeptidase are normal or only modestly elevated. ICP occurs in the second or third trimester of pregnancy and usually resolves spontaneously within 2 to 3 weeks after delivery. The diagnosis is suggested by the combination of pruritus and abnormal liver function tests with exclusion of other causes such as gallstones or intrinsic liver disease. ICP is associated with a higher risk for adverse perinatal outcome, including preterm birth, meconium passage, and fetal death.

The cause of ICP is not fully defined, but genetic, hormonal, and environmental factors are all likely to be involved. There is a high incidence of ICP in Chile and some other areas, and studies of potential genetic contributors are underway. Because adverse outcomes appear to occur predominantly after 37 weeks' gestation, management by an experienced obstetrics team and consideration of early delivery are warranted. Ursodeoxycholic acid may be effective in ameliorating maternal pruritus and improving liver function test results; however, no medication has yet been shown to reduce the risk to the fetus.

The hemophagocytic syndrome, also known as hemophagocytic lymphohistiocytosis (HLH), is an uncommon hyperinflammatory disorder caused by severe hypercytokinemia. It

manifests as fever, splenomegaly, and jaundice, with hemophagocytosis in the bone marrow and other tissues pathologically. Primary or familial HLH, also called familial erythrophagocytic lymphohistiocytosis, is a heterogeneous autosomal recessive disorder that has been found to be more prevalent with parental consanguinity. Secondary HLH is associated with malignancy, immunodeficiency, and infection, especially viral infection. In HLH, there is an inherent defect of natural killer cells and cytotoxic T cells, so they are unable to cope effectively with the infectious agent or antigen. Liver biopsies in HLH reveal sinusoidal dilation with hemophagocytic histiocytosis.

Postoperative jaundice typically occurs 1 to 10 days after surgery and has an incidence of approximately 15% after heart surgery and 1% after elective abdominal surgery. It is multifactorial in origin, with increased bilirubin load from bleeding and blood transfusions as well as impaired bilirubin conjugation and secretion caused by inflammatory cytokines. It typically resolves fully over time. In hepatocellular disease, all three steps of hepatic bilirubin metabolism are impaired. Excretion, the rate-limiting step, is usually most affected, leading to predominantly conjugated hyperbilirubinemia.

Jaundice can be profound in acute hepatitis (see Chapter 41) without adverse prognostic implications. In chronic liver disease, however, persistent jaundice usually implies irreversible decrease in hepatic function and a poor prognosis.

Posthepatic Jaundice

Posthepatic jaundice, also called obstructive jaundice, results from a complete or partial obstruction of intrahepatic or extrahepatic bile ducts (Fig. 40-3 and E-Fig. 40-2). The most common causes are gallstones in the common bile duct and tumors of the pancreatic head. Not infrequently, the first sign of pancreatic cancer is jaundice. Other causes include strictures of the common bile duct resulting from prior surgery or passage of gallstones. Less common causes include congenital biliary atresia, pancreatitis, pancreatic pseudocysts, and parasites such as liver flukes (e.g., *Clonorchis sinensis*, *Dicrocoelium dendriticum*, *Opisthorchis viverrini*).

Mirizzi syndrome is an uncommon cause of posthepatic jaundice observed in 0.7% to 1.4% of patients after cholecystectomy.

FIGURE 40-3 Hepatocellular carcinoma compressing the bile ducts. **A**, Sagittal view of computed abdominal tomography scan. **B**, Endoscopic retrograde cholangiopancreatography demonstrates multiple strictures of the bile ducts.

E-FIGURE 40-2 Various pathologies causing extrahepatic bile duct obstruction. **A**, Cholangiocellular carcinoma. **B**, Chronic pancreatitis. **C**, Pancreatic cancer. **D**, Klatskin tumor.

This syndrome is caused by extrinsic compression from an impacted stone in the cystic duct that impinges on and obstructs the common bile duct (see [Table 40-1](#)). Portal hypertensive biliopathy (or vascular biliopathy) is characterized by anatomic and functional abnormalities of the intrahepatic, extrahepatic, and pancreatic ducts in patients with portal hypertension associated with extrahepatic portal vein obstruction or, less frequently, cirrhosis. These morphologic changes, consisting of dilatation and stenosis of the biliary tree, are caused by extensive venous collaterals that develop in an attempt to decompress the portal venous blockage. The condition is usually asymptomatic until it has progressed to a more advanced stage such as biliary cirrhosis.

Immunoglobulin G4 (IgG4)-related sclerosing disease has recently been recognized as a distinct disease entity that can affect the bile ducts, gallbladder, pancreas, and other sites. Most cases of IgG4-related pancreatobiliary disease are associated with elevated serum IgG4 levels, extensive IgG4-positive plasma cells, and infiltration of lymphocytes into various organs, which leads to fibrosis. Several established systems are used to diagnose IgG4 disease; they rely on a combination of imaging findings of the pancreas, bile duct, and other organs; serologic findings; pancreatic histologic findings; and response to corticosteroid therapy.

CLINICAL APPROACH TO THE EVALUATION OF JAUNDICE

Because the differential diagnosis of jaundice is broad, a thorough history and physical examination and judicious use of laboratory and imaging studies are needed to define its cause. Jaundice appears as yellowing of the skin and sclera. Other conditions may mimic this presentation (e.g., carotinemia, Addison's disease, quinacrine ingestion), but scleral and mucosal discolorations are absent in these conditions. In hypercarotinemia, for example, the yellowish-orange coloration typically involves only the palms of the hands and soles of the feet.

An elevated serum bilirubin level, usually higher than 3 mg/dL, confirms the clinical impression of jaundice. The most important initial step is to define whether the jaundice is predominately caused by an elevation of unconjugated or of conjugated bilirubin. If jaundice is primarily the result of unconjugated bilirubin, evaluation for hemolysis and other conditions with shortened red blood cell survival is required. In patients with elevated conjugated bilirubin, the clinical challenge lies in determining whether biliary obstruction or impaired hepatic excretion is responsible (see [Chapter 39](#)).

In cholestatic jaundice caused by biliary obstruction the alkaline phosphatase level is typically increased to more than three times normal, whereas serum transaminases are usually elevated less than 5-fold to 10-fold ([E-Fig. 40-3](#); see [Chapter 39](#)). Patients with cholestasis also may develop pruritus and malabsorption of fat and fat-soluble vitamins (vitamins A, D, E, and K). More specific causes of biliary obstruction are suggested by recurrent abdominal pain and nausea (gallstones) or epigastric pain radiating to the back with weight loss and gallbladder distention

(carcinoma of the pancreatic head). In complete biliary obstruction, conjugated hyperbilirubinemia is prominent and usually peaks at about 30 mg/dL in the absence of renal failure. Eosinophilia may accompany drug-induced jaundice. Inquiry about the use of drugs known to cause cholestasis, serologic testing for antimitochondrial antibody in suspected PBC, and endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) to evaluate PSC may be helpful.

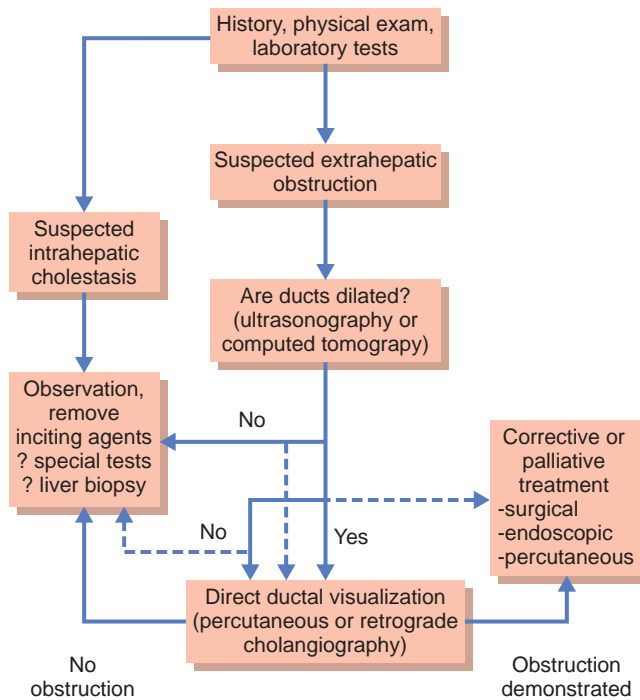

In jaundice produced by hepatocellular disease (see [Chapters 41 and 43](#)), serum transaminases are characteristically elevated more than 10-fold and alkaline phosphatase levels are less than three times normal. Evidence of hepatocellular damage is commonly associated and includes a prolonged prothrombin time, hypoalbuminemia, and clinical features of hepatic dysfunction (palmar erythema, spider angiomas, gynecomastia, and ascites). A careful evaluation includes inquiry about the use of drugs known to cause hepatocellular injury, alcohol, risk factors for viral hepatitis, and preexisting liver disease. More selected laboratory studies, such as serologic testing for hepatitis, are usually required (see [Chapter 41](#)).

A diagnostic approach to jaundice is outlined in [E-Figure 40-2](#). If extrahepatic obstruction is suspected, noninvasive studies such as ultrasound or computed tomography should be used to determine whether bile ducts are dilated. If dilated ducts are found on noninvasive imaging, then direct cholangiography (either endoscopic or radiologic) provides the most reliable approach to management and potential treatment of cholestatic jaundice. If intrahepatic cholestasis is suggested clinically and extrahepatic obstruction is excluded by noninvasive means or by direct cholangiography, then the emphasis is placed on further laboratory testing to define the specific cause. Liver biopsy is sometimes required to define a specific histologic diagnosis, rule out other causes of disease, and assess the degree of injury and fibrosis.

 For a deeper discussion on this topic, please see [Chapter 147, "Approach to the Patient with Jaundice or Abnormal Liver Tests,"](#) in *Goldman-Cecil Medicine, 25th Edition*.

Acute and Chronic Hepatitis

Jen-Jung Pan and Michael B. Fallon

INTRODUCTION

The term *hepatitis* denotes inflammation of the liver. It is applied to a broad category of clinicopathologic conditions that result from the damage produced by viral, toxic, metabolic, pharmacologic, or immune-mediated injury to the liver.

ACUTE HEPATITIS

Acute hepatitis implies a recent-onset inflammatory condition lasting less than 6 months. It can culminate either in complete resolution of the liver damage with return to normal function and structure or rapid progression of the acute injury toward extensive necrosis and a fatal outcome. The most common causes of acute hepatitis are viral hepatitis (hepatitis A through E) and nonviral causes such as drugs (prescription, nonprescription, and illicit), alcohol, toxins, autoimmune hepatitis, and Wilson's disease.

Acute Viral Hepatitis

Five hepatotropic viruses cause acute viral hepatitis (Table 41-1), but other viruses, including cytomegalovirus and herpesviruses, can also cause liver injury. All of the hepatotropic viruses are ribonucleic acid (RNA) viruses except hepatitis B virus (HBV), which has a deoxyribonucleic acid (DNA) genome.

Hepatitis A virus (HAV) is a nonenveloped, single-stranded RNA virus classified in the Picornaviridae family and in the *Hepatovirus* genus. It is stable at moderate temperature and low pH, allowing the virus to survive in the environment and be transmitted by the fecal-oral route. Hepatitis E virus (HEV) belongs to the genus *Hepevirus* in the Hepeviridae family and has four genotypes. HEV1 and HEV2 are restricted to human beings and are

transmitted via contaminated water in developing countries. HEV1 occurs mainly in Asia, whereas HEV2 occurs in Africa and Mexico. HEV3 and HEV4 infect human beings, pigs, and other mammalian species and are responsible for sporadic cases of autochthonous hepatitis E in both developing and developed countries. HEV3 has a worldwide distribution. HEV4 mostly occurs in Southeast Asia.

HBV is a small DNA virus that belongs to the Hepadnaviridae family. Approximately 350 million persons are carriers of HBV worldwide; of these, 75% reside in Asia and the Western Pacific. Hepatitis C virus (HCV) is a single-stranded positive-sense RNA virus that belongs to the Flaviviridae family and has been classified as the sole member of the genus *Hepacivirus*. More than 170 million people are infected with HCV worldwide. HBV has eight genotypes (labeled A through H), and HCV has six genotypes (1 through 6). Both HBV and HCV viruses are transmitted parenterally. HBV is present in virtually all body fluids and excreta of carriers. Transmission occurs most commonly through blood and blood products, contaminated needles, and sexual contact. Historically, HCV was the main cause of post-transfusion hepatitis before 1992. It is currently the most common cause of hepatitis among intravenous drug users. The Centers for Disease Control and Prevention now recommends one-time screening of persons born between 1945 and 1965 for hepatitis C because of the high prevalence of the disease in this birth cohort.

Hepatitis D virus (HDV) is classified in a separate genus of the Deltaviridae family. It is a small, defective RNA virus that can propagate only in an individual who has coexistent HBV infection, either after simultaneous transmission of the two viruses or via superinfection of an established HBV carrier. HDV has at

TABLE 41-1 CHARACTERISTICS OF ACUTE VIRAL HEPATITIDES

	HEPATITIS A	HEPATITIS B	HEPATITIS C	HEPATITIS D	HEPATITIS E

least eight genotypes, four of which (genotypes 5 through 8) seem to be of exclusively African origin. Of the 350 million chronic carriers of HBV worldwide, more than 15 million have serologic evidence of exposure to HDV. Like HBV, HDV is transmitted via the parenteral route through exposure to infected blood or body fluids. Because there is evidence for sexual transmission, people with high-risk sexual activity are at increased risk for infection.

Clinical and Laboratory Manifestations

Acute viral hepatitis typically begins with a prodromal phase lasting several days that is characterized by constitutional and gastrointestinal symptoms including malaise, fatigue, anorexia, nausea, vomiting, myalgia, and headache. A mild fever may be present. Clinical manifestations of hepatitis A depend on the age of the host: fewer than 30% of infected young children showed symptomatic hepatitis, whereas about 80% of infected adults had severe acute hepatitis with remarkably elevated serum aminotransferases. Arthritis and urticaria resembling serum sickness, attributed to immune complex deposition, are present in 5% to 10% of cases of acute hepatitis B and C. Taste and smell alterations may also occur. Jaundice soon appears, with bilirubinuria and acholic (pale) stools, which are often accompanied by an improvement in the patient's sense of well-being. The liver is usually tender and enlarged; splenomegaly is found in about one fifth of patients. Notably, many patients with acute viral hepatitis are asymptomatic or have symptoms without jaundice (anicteric hepatitis). In such instances, medical attention often is not sought.

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are released from acutely damaged hepatocytes, and serum levels can rise to 20-fold or more above normal. An elevated serum bilirubin level (>2.5 to 3 mg/dL) results in jaundice and is defined as icteric hepatitis. Values higher than 20 mg/dL are uncommon and correlate in a general way with the severity of disease. Elevations in serum alkaline phosphatase (ALP) are usually limited to 3 times normal levels except in cases of cholestatic hepatitis. A complete blood cell count most commonly

shows mild leukopenia with atypical lymphocytes. Anemia and thrombocytopenia may also be present. The icteric phase of acute viral hepatitis may last days to weeks and is followed by gradual resolution of symptoms and laboratory values.

Diagnosis

Acute viral hepatitis can be diagnosed either directly, by detecting the nucleic acids of the infecting virus, or indirectly, by demonstrating an immune response in the host (Tables 41-2 and 41-3). Epstein-Barr virus and cytomegalovirus hepatitis are part of the differential diagnosis and also may be diagnosed by the appearance of specific antibodies of the immunoglobulin M (IgM) class.

In acute hepatitis B, hepatitis B surface antigen (HBsAg) and e antigen (HBeAg) are present in serum. Both are usually cleared within 3 months in acute self-limited infection, but HBsAg may persist in some patients with uncomplicated disease for 6 months to 1 year. Clearance of HBsAg is followed after a variable period by the emergence of antibodies against hepatitis B surface antigen (anti-HBs), which confers long-term immunity. Antibodies against hepatitis B core antigen (anti-HBc) and e antigen (anti-HBe) appear in the acute phase of the illness, but neither provides immunity. Uncommonly, during the serologic window period, anti-HBc IgM, a marker of active viral replication suggesting recent infection, may be the only evidence of HBV infection.

Every patient who is HBsAg positive should be tested for antibodies against HDV (anti-HDV IgG), which persist even after the patient has cleared HDV infection. Active HDV infection is now confirmed by the detection of serum HDV RNA with sensitive real-time polymerase chain reaction (PCR) assays. However, because of the variability of the genome sequence, assays of HDV RNA can produce false-negative results. Testing of anti-HDV IgM antibodies still has a role in patients who test negative for HDV RNA but have clinical features of HDV-related liver disease.

Acute hepatitis C can be detected within 2 weeks after exposure with the use of a sensitive PCR assay for HCV RNA. Serum antibodies to HCV develop within 12 weeks after exposure or

TABLE 41-2 SEROLOGIC MARKERS OF VIRAL HEPATITIS

AGENT	MARKER	DEFINITION	SIGNIFICANCE
HAV	Anti-HAV IgM	IgM antibody to HAV	Marker of acute or recent infection
	Anti-HAV IgG	IgG antibody to HAV	Marker of acute or previous infection; post vaccination; confers protective immunity
HBV	HBsAg	Hepatitis B surface antigen	The presence of HBsAg indicates that the person is infectious.
	HBeAg	Hepatitis B e antigen	Transiently positive in acute infection; may persist in chronic infection; reflection of active viral replication and high infectivity
	Anti-HBs	Antibody to surface antigen	Marker of acute self-limited infection; post vaccination; confers protective immunity
	Anti-HBe	Antibody to e antigen	Transiently positive in convalescence; positive in chronic infection before seroconversion; usually a reflection of low infectivity
	Anti-HBc IgM Anti-HBc IgG	IgM antibody to core antigen IgG antibody to core antigen	Marker of acute or exacerbation of chronic infection Appears at the onset of symptoms in acute infection and persists for life; not seen in vaccinees without prior infection
HCV	Anti-HCV	Antibody to HCV	Marker of acute and chronic infection; does not provide immunity
HDV	Anti-HDV IgM	IgM antibody to HDV	Positive in acute infection, negative in past infection but persists in a large proportion of patients with chronic infection
	Anti-HDV IgG	IgG antibody to HDV	Positive in all individuals exposed to HDV, and persists long-term, even after viral clearance
HEV	Anti-HEV IgM	IgM antibody to HEV	Marker of acute or recent infection*
	Anti-HEV IgG	IgG antibody to HEV	Marker of chronic or previous infection*

HAV, Hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; IgG, immunoglobulin G; IgM, immunoglobulin M.

*Serologic testing is unreliable, and seroconversion might never occur in immunosuppressed persons.

TABLE 41-3 INTERPRETATION OF DIAGNOSTIC MARKERS IN HEPATITIS B

	HBsAg	HBeAg	ANTI-HBc IgM	ANTI-HBc IgG	ANTI-HBs	ANTI-HBe	BLOOD HBV DNA
Acute infection	+	+	+	+	–	+/-	High
Acute self-limited infection	–	–	+	+	+	+/-	–
Vaccinated	–	–	–	–	+	–	–
Chronic infection							
HBeAg positive	+	+	–	+	–	–	High
HBeAg negative	+	–	–	+	–	+	Low
Immune escape	+	–	–	+	–	+	High
Occult infection	–	–	–	+	–	+/-	Very low
Reactivation of chronic infection	+	+	+/-	+	–	+/-	High

anti-HBc IgG, Immunoglobulin G antibody against hepatitis B core antigen; anti-HBc IgM, immunoglobulin M antibody against hepatitis B core antigen; anti-HBe, antibody against hepatitis B e antigen; anti-HBs, antibody against hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV DNA, hepatitis B virus deoxyribonucleic acid.

within 4 to 5 weeks after biochemical abnormalities are discovered. Importantly, these are not neutralizing antibodies and do not indicate immunity. At onset of symptoms, 30% of patients will be missed if checked by serum enzyme immunoassay (EIA) for HCV antibody alone.

Commercial EIAs for hepatitis E to detect both IgM and IgG class antibodies are also available but may lack sensitivity and specificity. Diagnosis of HEV infection should be established by PCR assays in immunosuppressed patients, because serologic testing is unreliable and seroconversion might never occur.

Complications

Cholestatic Hepatitis

In some patients, most commonly during HAV infection, a prolonged but self-limited period of cholestasis occurs that is characterized by marked conjugated hyperbilirubinemia, elevation of ALP, and pruritus. Further investigation may be required to rule out biliary obstruction (see [Chapter 40](#)).

Fulminant Hepatitis

Massive hepatic necrosis occurs in fewer than 1% of patients with acute viral hepatitis; it leads to a devastating and often fatal condition called acute liver failure. This condition is discussed in detail in [Chapter 42](#).

Chronic Hepatitis

Hepatitis A does not progress to chronic liver disease, although occasionally it has a relapsing course. Persistence of elevated levels of ALT and AST, viral antigens, or nucleic acids beyond 6 months in patients with hepatitis B or C suggests evolution to chronic hepatitis, although slowly resolving acute hepatitis may occasionally exhibit such test abnormalities for up to 12 months with eventual complete resolution. About 60% of organ transplant recipients infected with HEV fail to clear the virus and go on to develop chronic hepatitis. Chronic hepatitis is considered in detail later in this chapter.

Rare Complications

Acute viral hepatitis may rarely be followed by aplastic anemia, which tends to affect mostly male patients and results in a mortality rate greater than 80%. Pancreatitis, myocarditis, pericarditis, pleural effusion, and neurologic complications including Guillain-Barré syndrome, aseptic meningitis, and encephalitis have also been reported. Cryoglobulinemia and glomerulonephritis

are associated with hepatitis B and C, and polyarteritis nodosa is associated with hepatitis B. These manifestations are more common in patients who fail to clear acute HBV or HCV and develop chronic hepatitis.

Management

Unless complicated by fulminant hepatitis, cases of acute hepatitis A, B, and E are usually self-limited and are managed by supportive care including rest, maintenance of adequate hydration and dietary intake, and avoidance of alcohol use. Hospitalization may be needed for patients who cannot tolerate oral intake and for those with evidence of deteriorated liver function, such as hepatic encephalopathy or coagulopathy.

In general, hepatitis A and E may be regarded as noninfectious after 3 weeks, whereas hepatitis B is potentially infectious to sexual contacts throughout its course, although the risk is low once HBsAg has been cleared. Studies of antiviral therapy in acute hepatitis B have not shown clear benefit, although some experts advocate the use of nucleos(t)ide analogues, specifically in the setting of acute liver failure due to hepatitis B. Treatment of acute hepatitis C is not fully defined because it is often asymptomatic, although early treatment within 12 weeks of diagnosis with pegylated interferon- α -based therapy induces high sustained virologic response rates (>90%) and in responders may prevent the development of chronic infection.

Prevention

In patients with hepatitis A or E, both feces and blood contain virus during the prodromal and early icteric phases. General hygiene measures should include handwashing by contacts and careful handling, disposal, and sterilization of excreta, contaminated clothing, and utensils. HAV vaccination is appropriate for children older than 12 months of age, travelers to endemic areas, individuals with immunodeficiency or chronic liver disease, and those with high-risk behaviors or occupations. Since 2007, HAV vaccination has been preferred over immunoglobulin for postexposure prophylaxis, based on results from randomized trials. With the availability of two candidate vaccines, one of which is already licensed for use in China, HEV prevention through vaccination is now a realistic possibility.

HBV is rarely transmitted by body fluids other than blood; however, it is highly infectious, and strict adherence to universal precautions is mandatory. Efforts at preventing hepatitis B have involved the use of hepatitis B immunoglobulin (HBIG) and

recombinant HBV vaccines. Prophylaxis with HBIG after blood or mucosal exposure should be given within 7 days along with HBV vaccine. Preventive vaccination is currently recommended for high-risk individuals—health care professionals, patients undergoing hemodialysis, patients with chronic liver disease, residents and staff of custodial care institutions, and sexually active homosexual men—and is advocated universally for children.

No accepted prevention strategies other than universal precautions are available for HCV, and serum immunoglobulin is not useful for postexposure prophylaxis. The advent of widespread blood product screening for hepatitis C has made such infection after transfusion a rarity.

Alcoholic Liver Disease

Alcohol abuse continues to be a major cause of liver disease in the Western world. The three major pathologic findings resulting from alcohol abuse are fatty liver, alcoholic hepatitis, and cirrhosis. These findings are not mutually exclusive and may all be present in the same patient. The first two conditions are potentially reversible. Alcoholic cirrhosis is discussed in [Chapter 43](#).

Mechanism of Injury

The mechanisms of liver injury caused by alcohol are complex. Ethanol and its metabolites, acetaldehyde and nicotinamide adenine dinucleotide phosphate, are directly hepatotoxic and cause a large number of metabolic derangements. Induction of cytochrome P-450 (i.e., CYP2E1) and cytokine pathways, particularly tumor necrosis factor- α (TNF- α), are also critical in initiating and perpetuating hepatic injury.

Hepatotoxic effects from alcohol vary considerably among individuals. Nevertheless, consumption by men of 40 to 80 g of alcohol per day for 10 to 15 years carries a substantial risk for the development of alcoholic liver disease. Women appear to have a lower threshold of injury than men. Malnutrition and other forms of chronic liver disease may potentiate the toxic effects of alcohol on the liver. Genetic factors contribute to individual susceptibility as well.

Clinical and Pathologic Features

Alcoholic fatty liver may manifest as incidentally discovered hepatomegaly or elevated aminotransferase levels on screening blood tests. Vague discomfort in the right upper quadrant of the abdomen may be the only symptom. Jaundice is rare, and aminotransferases are only mildly elevated (<5 times normal). Liver biopsy shows either diffuse or centrilobular fat occupying most of the hepatocytes.

Alcoholic hepatitis is much more severe and is characterized on liver biopsy by the histologic triad of Mallory bodies, infiltration by polymorphonuclear leukocytes, and a network of interlobular connective tissue surrounding hepatocytes and central veins (pericellular, perivenular, and perisinusoidal fibrosis). Patients with alcoholic hepatitis may be asymptomatic, or they may be extremely ill with hepatic failure. Other common symptoms are anorexia, nausea, vomiting, weight loss, and abdominal pain. For those with fever, infection needs to be ruled out. Jaundice is commonly present and may be pronounced, with cholestatic features that require differentiation from biliary tract disease (see [Chapters 40](#) and [44](#)). Physical examination may

reveal cutaneous signs of chronic liver disease, including spider angiomas and palmar erythema. In addition, gynecomastia, parotid enlargement, testicular atrophy, and loss of body hair may be found. The presence of ascites and hepatic encephalopathy suggests cirrhosis. Aminotransferases are only moderately increased (200-400 U/L) in alcoholic hepatitis compared with other forms of acute hepatitis. The ratio of AST to ALT almost always exceeds 2:1, in contrast to viral hepatitis, in which the aminotransferases are usually increased in parallel. The white blood cell count may be strikingly increased.

Diagnosis

A history of excessive and prolonged alcohol intake is frequently difficult to obtain from patients with alcoholic liver disease. However, historical, clinical, and biochemical features of alcoholic hepatitis are often sufficient to establish the diagnosis. Many patients suspected or found to imbibe alcohol excessively may have causes in addition to alcohol contributing to liver disease (e.g., chronic viral hepatitis). Therefore, when other causes of liver disease are suggested and alcohol intake is uncertain, appropriate serologic testing and a liver biopsy may be needed to establish a diagnosis.

Treatment

Complete abstinence from alcohol is the most important step. Meticulous supportive care, including tube feeding for those with severe anorexia, is the cornerstone of treatment for acute alcoholic hepatitis. In the absence of contraindications (i.e., infection, gastrointestinal bleeding, or renal failure), some patients with alcoholic hepatitis may benefit from treatment with corticosteroids. A calculated discriminant function (DF) value greater than 32 (where $DF = 4.6 \times [\text{prothrombin time (in seconds)} - \text{control (in seconds)}] + \text{total bilirubin [in mg/dL]}$) may identify a subgroup of patients who are more likely to benefit from the use of corticosteroids, but these patients have advanced liver disease and a high mortality rate. Pentoxifylline, an oral TNF- α antagonist, was shown to reduce the risk of renal failure but not mortality in a single randomized trial.

Complication and Prognosis

Alcoholic fatty liver disease completely resolves with cessation of alcohol intake. Alcoholic hepatitis can also resolve, but it commonly progresses either to cirrhosis, which may already be present at the time of initial diagnosis, or to hepatic failure and death. The development of encephalopathy, ascites, acute kidney injury, and gastrointestinal bleeding from varices often complicates alcoholic hepatitis (see [Chapter 43](#)). Patients with a DF greater than 32 have a high risk of death. The Lille model combines six reproducible variables (age, renal insufficiency, albumin, prothrombin time, bilirubin, and evolution of bilirubin at day 7) and is highly predictive of death at 6 months. A score greater than 0.45 predicts a 6-month survival rate of 25%, compared with 85% survival when the score is less than 0.45.

Drug-Induced Liver Injury

Drug-induced liver injury (DILI), also known as hepatotoxicity, refers to liver injury caused by drugs or other chemical agents and represents a special type of adverse drug reaction. More than

1000 medications and supplements are known to cause hepatotoxicity. Antibiotics remain the drugs most commonly responsible for DILI in the United States and Europe; the annual incidence of antibiotic-associated DILI is 1 in 10,000 to 100,000 individuals.

DILI may be classified by the pattern of liver injury observed. *Acute hepatocellular injury* is characterized by elevated levels of serum ALT and minimal elevations of serum ALP. *Cholestatic injury* is characterized by a disproportionately elevated level of ALP, which is synthesized and released by injured bile ducts. Liver injury that has both hepatocellular and cholestatic features is called *mixed liver injury*. DILI can also be classified into two broad categories, predictable and unpredictable, depending on the hepatotoxins involved. Predictable hepatotoxins, such as acetaminophen and carbon tetrachloride, cause dose-dependent liver injury. Acetaminophen is now the leading cause of life-threatening acute liver failure in the United States and Europe. Unpredictable hepatotoxins cause DILI in a so-called idiosyncratic fashion. Idiosyncratic reactions are difficult to predict and are not dose dependent; they occur relatively rarely in individuals with unique genetic and environmental characteristics.

Clinical and Laboratory Manifestations

DILI symptoms are similar to those associated with viral hepatitis and include malaise, anorexia, nausea and vomiting, right upper quadrant abdominal pain, jaundice, acholic stools, and dark (tea-colored) urine. Patients with cholestatic DILI may also have pruritus. Fever and rash, hallmarks of hypersensitivity, may be present with DILI caused by certain drugs such as anticonvulsants and sulfamethoxazole-trimethoprim. Cholestatic or mixed hepatitis related to amoxicillin-clavulanic acid (Augmentin) may develop shortly after the drug has been stopped, usually within 2 to 3 weeks. Nitrofurantoin (Macrobid) characteristically causes a chronic hepatitis after many weeks, months, or even years of therapy and is often associated with the presence of serum anti-nuclear antibodies (ANA).

Diagnosis

The diagnosis of DILI is challenging because of the lack of specific or uniform clinical features or laboratory tests in the majority of cases. A high level of suspicion for DILI is essential for diagnosis, as is the exclusion of other possible causes of liver injury. The Russel-Uclaf Causality Assessment Method (RUCAM) provides objective and consistent assessment but can be cumbersome for routine clinical use. Moreover, a recent study conducted by Grant and Rockey suggested that expert opinion outperforms RUCAM in making a diagnosis of DILI. There is definitely a need for a simple, accurate, and reproducible method for diagnosing DILI.

Hepatitis E appears to be a small but important alternative diagnosis for suspected DILI. Of 318 patients in the multicenter U.S. Drug-Induced Liver Injury Network (DILIN) with suspected drug hepatotoxicity, 9 (3%) were found to be positive for HEV IgM.

Treatment

The mainstay of management of DILI is withdrawal of the offending agent and supportive care, which is usually sufficient in cases of mild to moderate DILI. Reexposure to the implicated drug

should be avoided. Specific therapies are available for some types of DILI. Timely administration of *N*-acetylcysteine (NAC) for acetaminophen overdose can be lifesaving. NAC may also improve outcomes of patients with early acute liver failure from a variety of other causes. Corticosteroids are probably ineffective for DILI from most drugs; however, a short course of steroids is sometimes used for treatment of immune-mediated DILI with the manifestations of rash, fever, and eosinophilia. Ursodeoxycholic acid is safe and may possibly hasten the resolution of jaundice and pruritus.

Complication and Prognosis

With supportive care and discontinuation of the offending drug, mild to moderate DILI usually resolves rapidly. Cholestatic liver injury may take many weeks and even months to completely resolve. Occasionally, cholestatic DILI can evolve into permanent bile duct injury with so-called vanishing bile duct syndrome. Patients who develop acute liver failure manifesting with hyperbilirubinemia, coagulopathy, and hypoalbuminemia may need liver transplantation.

CHRONIC HEPATITIS

Chronic hepatitis is defined as a sustained inflammatory process in the liver lasting longer than 6 months. On initial presentation, chronic hepatitis can be difficult to differentiate from acute hepatitis on clinical or histologic criteria alone. Except for hepatitis A, acute viral hepatitis, especially that caused by HBV or HCV, can ultimately lead to chronic hepatitis. Nonalcoholic steatohepatitis (NASH) is now the most frequent cause of chronic hepatitis in the United States and Western Europe. Several drugs can cause chronic hepatitis, the best recognized being methyl dopa. In contrast to acute hepatitis, an etiologic agent is sometimes difficult to identify in cases of chronic hepatitis. The pathogenesis of these idiopathic forms may represent quiescent autoimmune disease, undetected past DILI or NASH, antibody-negative viral infection, or misdiagnosed cholestatic liver injury (e.g., primary biliary cirrhosis [PBC], primary sclerosing cholangitis [PSC]).

Chronic Viral Hepatitis

In Western countries, acute HBV infection usually occurs in adults; 5% to 10% of patients fail to clear the virus and develop chronic hepatitis. In other areas, childhood acquisition is common, and children who are infected within 2 years of birth have a much higher rate of chronic hepatitis B. HBV infection without evidence of any liver damage may persist, resulting in asymptomatic hepatitis B carriers. In Asia and Africa, many such carriers appear to have acquired the virus from infected mothers during infancy (vertical transmission).

Patients who are HBsAg and HBeAg positive and have high blood HBV DNA (>20,000 IU/mL), coupled with elevated serum aminotransferases, are in a high replicative phase (see Table 41-3). In contrast, patients in a low replicative phase are HBsAg and anti-HBe positive, have low blood HBV DNA (<20,000 IU/mL), and have near-normal or normal aminotransferase levels. Such patients can enter a high replicative phase and exhibit features of acute or chronic hepatitis B. A subgroup of patients with chronic hepatitis B who are HBeAg negative are still in a high replicative phase, as evidenced by high HBV DNA levels in blood. These patients likely have HBV with precore and/or

core promoter mutation. Patients infected with HBV in high replicative phase are at high risk for cirrhosis and hepatocellular carcinoma. Such patients and those who have already progressed to early cirrhosis are the primary candidates for antiviral therapy.

Currently, seven drugs are approved for the treatment of adults with chronic hepatitis B in the United States, including interferon- α and its pegylated form and five nucleos(t)ide analogues (lamivudine, telbivudine, adefovir dipivoxil, tenofovir disoproxil, and entecavir). The primary aim of therapy is to eliminate or permanently suppress HBV and thus reduce the activity of hepatitis and slow or limit the progression of liver disease. It is important to start therapy with a nucleos(t)ide analogue that has a high genetic barrier to resistance, such as entecavir or tenofovir, as first-line therapy. Long-term follow-up studies have shown interferon-based therapy increases HBsAg seroclearance over time. HBsAg seroclearance is less common in patients who are treated with nucleos(t)ide analogues rather than interferon-based therapy.

In patients with HBV and HDV coinfection, the fate of HDV is determined by the host response to HBV, which in more than 95% of adults results in viral clearance. By contrast, HDV superinfection of an individual with chronic hepatitis B usually results in chronic HDV infection. Treatment with nucleos(t)ide analogues is not effective in reducing HDV replication. The accepted practice for treatment of chronic HDV infection is weekly pegylated interferon for at least 48 weeks. In patients with a high concentration of HBV DNA, the addition of a potent nucleos(t)ide analogue to inhibit HBV replication is logical, but long-term effectiveness has yet to be defined.

Chronic hepatitis C develops in up to 75% of individuals who are acutely exposed to HCV. Approximately 1.6% of the United States population (4.1 million people) are positive for antibodies to HCV (anti-HCV), and 3.2 million of them have chronic infection. Up to 20% of HCV cases progress to cirrhosis, usually within 20 years after infection. HCV has six major genotypes, of which genotype 1 is the most common in the United States, followed by genotypes 2 and 3. The genotype determines the treatment regimen and duration of therapy. The goal of antiviral therapy is to achieve a sustained virologic response (SVR), defined as undetectable HCV RNA levels (aviremia) 6 months after treatment discontinuation. As many as 80% of patients with genotype 2 or 3 disease achieve SVR after receiving dual therapy consisting of weekly pegylated interferon- α and daily ribavirin for 24 weeks. In contrast, only about 50% of patients with genotype 1 disease can achieve SVR after receiving the dual therapy for 48 weeks. With the addition of direct-acting antivirals (DAA), especially the first generation NS3/4 protease inhibitors boceprevir and telaprevir (both approved in May 2011), to pegylated interferon and ribavirin, up to 70% of patients with genotype 1 hepatitis C can achieve SVR in 24 weeks. However, the addition of a first-generation DAA to interferon- and ribavirin-based treatment for hepatitis C results in increased potential for side effects, drug-drug interactions, and a high pill burden. With the addition of the once daily, second generation protease inhibitor simeprevir (approved in November 2013) and the NSSB polymerase inhibitor sofosbuvir (approved in December 2013) to pegylated interferon and ribavirin, up to 90% of patients with genotype 1 hepatitis C can achieve SVR in as little as 12 weeks. For the first

time, patients with genotype 2 and 3 hepatitis C can be treated with an interferon-free regimen consisting of sofosbuvir and ribavirin. Several new DAAs with novel mechanisms of action—such as NSSB polymerase inhibitors, NSSA inhibitors, and new NS3/4 protease inhibitors—are either under review for approval or under development.

Among organ transplant recipients, the consumption of game meat, pork products, or mussels may result in HEV infection, which is most commonly asymptomatic without jaundice. About 60% of such infections become chronic, and up to 10% of patients progress to cirrhosis. Treatment includes careful reduction in immunosuppression, which results in viral clearance in 30% of patients on ribavirin monotherapy.

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) has several clinical forms that share typical histologic findings including significant hepatic inflammation with a preponderance of plasma cells and fibrosis. Type 1, or classic, AIH is characterized by the presence of hypergammaglobulinemia as well as ANA or anti-smooth muscle antibodies (ASMA). Type 2 AIH is characterized by the presence of anti-liver/kidney microsomal antibodies (anti-LKM1) and the absence of ANA and ASMA. The type 1 variant can affect people of any age or gender, whereas the less common type 2 variant primarily affects girls and young women. A third type of AIH with antibodies to soluble liver antigen or liver-pancreas antigen (anti-SLA/LP) is no longer considered a unique entity because these antibodies may be found in type 1 and 2 variants as well. There are also uncommon overlap variants of AIH that have features of both AIH and other liver diseases such as PBC or PSC.

There are no pathognomonic features of AIH, and the diagnosis is made by a combination of factors. A simplified diagnostic algorithm that includes the presence of autoantibodies, hypergammaglobulinemia, typical liver histology, and absence of viral hepatitis has proved useful in identifying patients with AIH. Extrahepatic manifestations such as amenorrhea, rashes, acne, vasculitis, thyroiditis, and Sjögren's syndrome are common. Evidence of hepatic failure and the presence of chronic disease on liver biopsy are often discernable at the time of diagnosis. Indications for treatment include abnormal liver function tests and significant hepatic inflammation on biopsy.

Corticosteroids are the mainstay of treatment, typically in combination with azathioprine as a steroid-sparing agent. This regimen is efficacious in most patients (>80%) and in many instances prolongs survival.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) has a spectrum of presentations from simple steatosis, which usually does not progress to advanced liver disease, to NASH, which may exhibit or lead to cirrhosis. It is the most common cause of abnormal liver function tests among adults in the United States and western Europe. NAFLD is commonly seen in people with central obesity, hypertension, diabetes, and hyperlipidemia, although it can be observed in persons with normal weight as well. Insulin resistance plays a central role in the pathophysiology of NAFLD. Estimates indicate that about 30 million Americans have NAFLD; of these, 8.6 million have NASH and almost 20% have signs of

advanced disease (i.e., bridging fibrosis, cirrhosis) on histologic examination.

Liver biopsy is the “gold standard” for diagnosis of NASH. The procedure is invasive and costly and can cause complications including a small mortality risk (0.01% to 0.1%). Radiologic imaging studies are neither sensitive nor able to distinguish simple steatosis from steatohepatitis. Noninvasive biomarkers are currently under active investigation. The NAFLD Activity Score has been developed and represents the sum of scores for steatosis, lobular inflammation, and hepatocyte ballooning. It ranges from 0 to 8, with a score of 5 or higher considered diagnostic of NASH.

Currently, no generally accepted medical treatment is available for NASH. However, weight loss and regular exercise are associated with biochemical and histologic improvement and are important components of therapy. Vitamin E and pioglitazone have recently been shown to improve hepatic inflammation in nondiabetic patients with NASH, but they are not routinely recommended because of questions regarding long-term safety.

Genetic and Metabolic Hepatitis

Hemochromatosis is an autosomal recessive genetic disorder that causes defective sensing of iron stores and leads to excessive absorption of iron from the digestive tract. In the United States, about 5 of every 1000 white people have the condition. Elevated ferritin and transferrin saturation values are typically used to screen patients with evidence of chronic liver disease and guide the need for further genetic testing. Most patients with hemochromatosis are homozygous for the C282Y mutation in the *HFE* gene, and a subset of individuals who are heterozygous for both C282Y and the H63D mutation may also develop iron overload. Iron overload is very uncommon among those who are homozygous for the H63D mutation. Genetic mutations in a number of other proteins involving in iron sensing have also been associated with iron overload but are not routinely tested in clinical practice. Hemochromatosis is a systemic disease that can cause skin discoloration, liver cirrhosis and cancer, heart failure, diabetes mellitus, hypogonadism, and arthralgias due to iron deposition in various organs. A high index of suspicion is required to detect the disorder in early stages. The standard treatment for hemochromatosis is therapeutic phlebotomy. For patients who cannot undergo phlebotomy, chelation therapy may be offered.

Wilson's disease is an autosomal recessive genetic disorder that results from mutations in the *ATP7B* gene located on

chromosome 13. These mutations result in excessive accumulation of copper in a number of organs, most notably the liver, cornea, and brain. The prevalence of the disease is approximately 1 in 30,000 live births in most populations. Wilson's disease can occur at any age. Measurement of the 24-hour urine copper excretion, slit lamp examination of corneas for Kayser-Fleischer rings, and direct measurement of hepatic copper confirm the diagnosis. Patients should receive lifelong chelation treatment with either penicillamine or trientine. Zinc may be used to maintain stable copper levels in the body.

α_1 -Antitrypsin deficiency is an autosomal recessive genetic disorder of chromosome 14 that causes retention of α_1 -antitrypsin in the liver, resulting in liver damage. The normal gene product is designated as PiM, and the deficiency variants are PiS (50% to 60%) and PiZ (10% to 20%). The most common carrier phenotypes are PiMS and PiMZ, and the disease phenotypes are PiZZ, PiSS, and PiSZ. A low serum α_1 -antitrypsin level and diastase-positive staining of hepatocellular α_1 -antitrypsin inclusions on liver biopsy support the diagnosis. Phenotypic testing in the serum has been the traditional gold standard for the diagnosis. However, genotypic testing is now available and widely used. Lung disease results from a loss of protective effects in patients with low levels of circulating α_1 -antitrypsin. α_1 -Antitrypsin replacement therapy is an option for those with lung disease but is not useful for patients with liver disease.

 For a deeper discussion on this topic, please see Chapters 148, “Acute Viral Hepatitis,” and 149, “Chronic Viral and Autoimmune Hepatitis,” in *Goldman-Cecil Medicine, 25th Edition*.

Acute Liver Failure

Brendan M. McGuire and Michael B. Fallon

DEFINITIONS

Acute liver failure (ALF) is defined as the onset of encephalopathy within 6 months after the occurrence of jaundice in a patient with hepatic injury but no prior history of liver disease. ALF replaces the older term for the same patient population, *fulminant hepatic failure*. Hepatic injury is usually defined as an international normalized ratio (INR) greater than 1.5 times normal with elevations of serum aminotransferases and total bilirubin. Other parameters further define hepatic failure based on the length of time from onset of jaundice to hepatic encephalopathy: *hyper-acute hepatic failure* for periods shorter than 7 days, and *late-onset hepatic failure* for periods of 8 to 24 weeks.

PATHOGENESIS

ALF develops as a result of severe, unrelenting hepatocyte necrosis. It is uncommon clinically but represents a medical emergency. ALF may result from infection with hepatitis viruses A, B, C, D, or E (see [Chapter 41](#)). Additionally, exposure to hepatotoxins such as acetaminophen, isoniazid, halothane, valproic acid, or mushroom toxins (e.g., those of *Amanita phalloides*) can produce ALF. Reye's syndrome, a disease that predominantly affects children, and acute fatty liver of pregnancy often resemble ALF; they are characterized by microvesicular fatty infiltration and little hepatocellular necrosis. Other rare causes of ALF include Wilson's disease, hepatic ischemia, autoimmune hepatitis, and malignancy ([E-Figs. 42-1](#) and [42-2](#)).

CLINICAL PRESENTATION

The clinical presentation, by definition, includes jaundice and hepatic encephalopathy without clinical evidence of underlying chronic liver disease. Other common but nonspecific symptoms include nausea, vomiting, loss of appetite, right upper abdominal pain from hepatomegaly, fever, fatigue, dark urine, and clay-colored stools. Typically, the features of impaired hepatic synthetic and metabolic function predominate, with portal hypertension much less common than in patients with established cirrhosis.

DIAGNOSIS

The clinical presentation of ALF can be dramatic, with jaundice and advanced systemic manifestations as the first indication of a severe and potentially threatening illness. A complete medical history is essential and should focus on potential exposure to viruses and hepatotoxins, pregnancy, an event associated with hypotension, and clues to suggest autoimmune causes.

Early laboratory testing should focus on assessing the severity of hepatic dysfunction and on detection of possible acetaminophen exposure, for which specific treatment must be initiated in a timely manner. Further specialized laboratory testing is designed to identify particular viral causes—with tests for anti-hepatitis A immunoglobulin M (IgM), hepatitis B surface antigen (HBsAg), anti-hepatitis B core antigen (anti-HBc) IgM, hepatitis D antigen, anti-hepatitis C antibody and/or hepatitis C virus RNA, anti-hepatitis E IgM, anti-varicella IgM, and herpes simplex IgM—or other causes (e.g., pregnancy test in females of child-bearing age, ceruloplasmin level, autoimmune markers).

A negative serum acetaminophen level does not exclude acetaminophen overdose, because the drug is rapidly cleared in the blood. Importantly, acetaminophen overdose accounts for approximately 50% of all cases of ALF and 20% of all cases of presumed indeterminant causes in Western countries. Therefore, careful clinical assessment is essential to determine if an acetaminophen overdose may have occurred.

TREATMENT

Treatment of ALF is largely supportive, because specific treatment for the underlying cause of liver failure is often not available. However, many processes that result in widespread liver cell necrosis and ALF are transient events, and liver cell regeneration with recovery of liver function often occurs if patients survive the initial insult. Acetaminophen toxicity and hypotension with hepatic necrosis are representative. In contrast, ALF resulting from viral hepatitis or idiosyncratic reactions to medications typically has a longer time course and an uncertain prognosis. In either case, meticulous supportive treatment in an intensive care unit setting has been shown to improve survival. Patients with ALF should be treated in centers with experience with this disease and with a liver transplantation program. Numerous complications can result from ALF, and each must be thoroughly identified and treated ([Table 42-1](#)). As liver failure progresses, a syndrome of multiorgan failure can result; this can include encephalopathy, coagulopathy, infection, and renal failure in the worst cases.

Hepatic encephalopathy is often the first and most dramatic sign of liver failure. The pathogenesis of hepatic encephalopathy in ALF remains unclear, and it differs from that associated with chronic liver disease or portal hypertension in two important aspects. First, it often responds to therapy only when liver function improves, and second, it is frequently associated with hypoglycemia or cerebral edema, two other potentially treatable causes of coma. Therapy for hepatic encephalopathy in ALF

E-FIGURE 42-1 Etiology of acute liver failure (ALF) in the USA Adult Registry ($N = 2102$). APAP, Acetaminophen; Autoimmune, autoimmune hepatitis; Hep, hepatitis; Indeter, indeterminate cause. (Data from The Acute Liver Failure Study Group 1998-2013 [unpublished].)

E-FIGURE 42-2 Fulminant hepatic failure and normal liver. Relative to normal, the liver of a patient with fulminant hepatic failure shows a shrunken parenchyma, wrinkled capsule, and necrotic areas.

TABLE 42-1 MANAGEMENT OF SELECTED PROBLEMS IN FULMINANT HEPATIC FAILURE

COMPLICATION	PATHOGENESIS	MANAGEMENT
Hepatic encephalopathy	Liver failure	Search for treatable causes (e.g., hypoglycemia, drugs used for sedation, sepsis, gastrointestinal bleeding, electrolyte imbalance, decreased PO ₂ , increased PCO ₂); lactulose
Cerebral edema	Unknown	Elevate head of bed 20-30 degrees; hyperventilate (PCO ₂ , 25-30 mm Hg); mannitol, 0.5-1 g/kg IV bolus over 5 min; pentobarbital infusion; urgent liver transplantation
Coagulopathy and gastrointestinal hemorrhage	Decreased synthesis of clotting factors Gastric erosions	Vitamin K; fresh-frozen plasma if actively bleeding and for prevention of bleeding; gastric acid suppression
Hypoglycemia	Decreased gluconeogenesis Decreased insulin degradation	IV 10% dextrose, monitor every 2 hr; 30-50% dextrose may be needed
Agitation	May be caused by encephalopathy, intracranial pressure, hypoxemia	Search for treatable causes (e.g., PO ₂ , skin ulcers, lacerations, abscesses); soft restraints; if severely agitated and injury is a concern, consider sedation along with mechanical ventilation to protect airway
Infection	Liver failure and invasive monitoring	Surveillance cultures and low threshold for empiric antibiotics

PCO₂, Partial pressure of carbon dioxide; PO₂, partial pressure of oxygen.

differs slightly from the principles outlined in Chapter 43. Lactulose may be given orally, through a nasogastric tube, or rectally, but the oral route should not be used if the patient is at risk for aspiration. Lactulose should be discontinued if no improvement is observed after several doses have been administered. Intubation is often necessary to protect the airway from aspiration and to allow ventilation in patients with advanced encephalopathy.

Cerebral edema, the pathogenesis of which is unknown, is a leading cause of death in ALF. Differentiation between cerebral edema and hepatic encephalopathy can be difficult, and computed tomography of the head is often unreliable. Therefore, measurement of the intracranial pressure (ICP) is the standard monitoring tool, although it also can be associated with complications. The goal is to maintain an ICP of less than 20 mm Hg while maintaining a cerebral perfusion pressure (calculated as mean arterial pressure minus ICP) greater than 60 mm Hg. Management includes control of agitation, head elevation of 20 to 30 degrees, hyperventilation, administration of mannitol, barbiturate-induced coma, and urgent liver transplantation.

As hepatic synthetic function deteriorates, *hypoglycemia* can occur as a result of impaired hepatic gluconeogenesis and insulin degradation. All patients at risk should receive 10% glucose IV infusions with frequent monitoring of blood glucose levels. Other metabolic abnormalities commonly occur, including hyponatremia, hypokalemia, respiratory alkalosis, and metabolic acidosis. Therefore, frequent monitoring of blood electrolytes and pH is indicated.

Bleeding occurs frequently and is commonly caused by gastric erosions in the setting of impaired synthesis of clotting factors and prolonged prothrombin times. All patients should receive vitamin K and prophylactic gastric acid suppression. Fresh-frozen plasma should be used if clinically significant bleeding occurs or if major procedures, including ICP monitoring and central line placement, are performed.

Up to 80% of patients with ALF develop infection at some point in their illness; both bacterial (~80% of infections) and fungal (~20% of infections) have been implicated. Patients are at higher risk for infection as a result of impaired immunity resulting from liver failure and the need for invasive monitoring. Severe infection may occur without fever or leukocytosis. Therefore, frequent cultures are recommended, and there should be a low threshold for beginning antibiotic therapy.

Hepatic transplantation (see Chapter 43) has been performed with success in patients with ALF and is the treatment of choice for patients who appear unlikely to recover spontaneously. Because of the urgent need for transplantation, potential candidates should be transferred to transplantation centers before significant complications develop (e.g., coma, cerebral edema, hemorrhage, infection). Transplantation is usually indicated in patients with severe encephalopathy or coagulopathy.

PROGNOSIS

The cause of ALF and the degree of hepatic encephalopathy are important factors in determining prognosis. Patients with ALF resulting from acetaminophen overdose or viral hepatitis A or B have a better survival rate than do patients with Wilson's disease or those without a known cause. The short-term survival rate for patients with ALF in coma is 20% without liver transplantation. The 1-year survival rate of patients with ALF after liver transplantation is 80% to 90%. Patients who survive without transplantation also have an excellent prognosis, because liver tissue usually regenerates normally regardless of the cause of ALF.

Lee WM, Larson AM, Stravitz RT: AASLD position paper: the management of acute liver failure—update 2011. Available at: <http://www.aasld.org/practiceguidelines/Documents/AcuteLiverFailureUpdate2011.pdf>. Accessed June 23, 2014.

Cirrhosis of the Liver and Its Complications

Shaheryar A. Siddiqui and Michael B. Fallon

LIVER CIRRHOSIS

Definition

Cirrhosis is a slowly progressive disease that is characterized by formation in the liver of fibrous and scar tissue which eventually replaces normal hepatocytes and impairs portal blood flow. Fibrosis can be a self-perpetuating result of many initial processes, including infectious, inflammatory, toxic, metabolic, genetic, and vascular insults that lead to liver damage. Most of the clinical features of cirrhosis develop as a result of portal hypertension, hepatocellular dysfunction, or altered cellular differentiation.

Etiology

Nonalcoholic fatty liver disease (NAFLD), alcoholic liver disease, and hepatitis C virus infection are the most common causes of cirrhosis in industrialized nations; hepatitis B virus is the major cause in Asia and in most of Africa. There are many other significant causes of cirrhosis, including biliary cirrhosis (primary and secondary), autoimmune hepatitis, inherited diseases (e.g., α_1 -antitrypsin deficiency), and drug-induced injury, that require specific evaluation. However, a significant number of patients with cirrhosis at presentation have no readily identifiable cause. These cases are referred to as idiopathic or cryptogenic in origin, and it remains a diagnosis of exclusion. Common and uncommon conditions that may lead to cirrhosis are listed in [Table 43-1](#). Chronic active hepatitis, NAFLD, and α_1 -antitrypsin deficiency are discussed in [Chapter 41](#).

Pathology

The typical sequence of events that leads to development of cirrhosis involves significant hepatocyte injury followed by ineffective repair that results in hepatic fibrosis. The injury can be acute or chronic in nature, depending on the mechanism. The fibrotic response to injury leads to development of nodules surrounded by fibrous tissue that consist of foci of regenerating hepatocytes,

formation of fibrovascular membranes, rearrangement of blood vessels, and finally cirrhosis. This disruption of the normal hepatic lobular architecture distorts the vascular bed and contributes to development of portal hypertension and intrahepatic shunting. On gross morphology, cirrhosis can be referred to as macronodular (>3 mm), commonly seen as a result of chronic active hepatitis, or micronodular (<3 mm) a typical feature of alcoholic cirrhosis or cirrhosis of mixed origin.

Clinical Presentation

Symptoms of liver cirrhosis are often nonspecific in the early stages and include fatigue, malaise, weakness, weight change, anorexia, and nausea. With progression of portal hypertension or loss of hepatocytes, increased abdominal girth, sexual dysfunction, altered mental status, and gastrointestinal bleeding may be noted. Physical findings depend on the stage at presentation. [Table 43-2](#) highlights the pathogenetic mechanisms underlying these diverse signs and symptoms.

Diagnosis

Owing to significant reserves of liver function, patients with cirrhosis are often asymptomatic and the diagnosis is established incidentally at the time of physical examination or laboratory testing. Alternatively, patients abruptly experience specific life-threatening complications of cirrhosis, most notably variceal bleeding, ascites, spontaneous bacterial peritonitis, and hepatic encephalopathy (HE). If cirrhosis is suspected on clinical grounds, the diagnosis can be made reliably by a combination of clinical, laboratory, and radiologic findings in most cases. However, liver biopsy is still considered the “gold standard” for accurate diagnosis. With advances in imaging, biopsy is now done more often to assess the stage and severity of disease, assign prognosis, and monitor the response to treatment.

Laboratory Findings

Hepatocellular dysfunction leads to impaired protein synthesis (hypoalbuminemia), hyperbilirubinemia, low levels of blood urea nitrogen (BUN), and elevated serum ammonia levels. Portal hypertension causes hypersplenism, which results in anemia, thrombocytopenia, and leukopenia. Patients with ascites often develop dilutional hyponatremia as a result of avid renal retention of sodium (Na^+) and water. The liver enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are good markers of active hepatocyte necrosis, whereas elevations of alkaline phosphatase and bilirubin out of proportion to

TABLE 43-1 COMMON CAUSES OF CIRRHOSIS

Alcohol abuse	Drug-induced liver injury (DILI)
Nonalcoholic steatohepatitis	Autoimmune hepatitis
Viral hepatitis (chronic hepatitis B, C, and D)	Primary biliary cirrhosis
Cardiac cirrhosis	Hemochromatosis (primary and secondary)
Chronic right-sided heart failure	Wilson's disease
Constrictive pericarditis	α_1 -antitrypsin deficiency

TABLE 43-2 CLINICAL FEATURES AND PATHOGENESIS OF CIRRHOSIS

SIGNS AND SYMPTOMS	PATHOGENESIS
CONSTITUTIONAL	
Fatigue, anorexia, malaise, weakness, weight loss	Liver synthetic or metabolic dysfunction
CUTANEOUS	
Spider angiomas, palmar erythema	Altered estrogen and androgen metabolism
Jaundice	Decreased bilirubin excretion
Caput medusae	Porto systemic shunting due to portal hypertension
ENDOCRINE	
Gynecomastia, testicular atrophy, decreased body hair in men	Altered estrogen and androgen metabolism
Decreased libido, virilization, and menstrual irregularities in women	
GASTROINTESTINAL	
Abdominal pain	Hepatomegaly, hepatocellular carcinoma
Abdominal swelling	Ascites due to portal hypertension
Gastrointestinal bleeding	Variceal hemorrhage due to portal hypertension
HEMATOLOGIC	
Anemia, leukopenia, thrombocytopenia	Hypersplenism secondary to portal hypertension
Ecchymosis	Decreased synthesis of coagulation factors
NEUROLOGIC	
Altered sleep pattern, somnolence, confusion, asterixis	Hepatocellular dysfunction: inability to metabolize ammonia to urea

ALT and AST suggest intrahepatic or extrahepatic biliary obstruction.

Radiology

Various radiologic modalities including ultrasound (with and without Doppler imaging of the portal and hepatic venous vasculature), computed tomography, and magnetic resonance imaging have complementary profiles in the evaluation of suspected cirrhosis. Findings supportive of the diagnosis of cirrhosis include relative enlargement of the left hepatic and caudate lobes as a result of right lobe atrophy, surface nodularity, and features of portal hypertension such as ascites, intra-abdominal varices, and splenomegaly.

Transient elastography (Fibroscan) is a newer noninvasive modality that provides an indirect measure of liver fibrosis and cirrhosis by calculating liver stiffness. Abnormal liver stiffness suggests underlying fibrosis; in the presence of clinical and laboratory features of cirrhosis, this finding may obviate the need for diagnostic liver biopsy in some patients. Biopsy is more invasive and is usually reserved for situations in which the results of noninvasive studies are indeterminate or the cause of the liver disease is in doubt.

COMPLICATION OF CIRRHOSIS

The major sequelae of cirrhosis are illustrated diagrammatically in [Figure 43-1](#) and can be categorized broadly into features of hepatocellular dysfunction and portal hypertension. The

pathophysiologic interrelationships among these complications are described in the following sections.

Hepatocellular Dysfunction

The loss of hepatocyte mass that occurs in cirrhosis results in impaired synthesis of many important proteins, which in turn leads to hypoalbuminemia, deficient production of vitamin K–dependent coagulation factors, and diminished capacity for hepatic detoxification (see [Chapters 39](#) and [42](#) for details). In addition, there is a decline in the capacity for conjugation and excretion of bilirubin.

Portal Hypertension

Under normal circumstances, the portal circulation is a low-pressure system with only small changes in pressure as blood flows from the portal vein, through the liver, and into the inferior vena cava. The hepatic venous pressure gradient (HVPG), which reflects sinusoidal pressure, is the gradient between the wedged hepatic venous pressure and the free hepatic venous pressure measured by direct catheterization. Normal HVPG values range between 3 and 5 mm Hg. In cirrhosis, the distortion of hepatic architecture by fibrous tissue and regenerative nodules, along with an increased intrahepatic vascular tone, leads to increased resistance to portal venous flow and resultant portal hypertension. Portal hypertension is defined as an HPV greater than 5 mm Hg, and clinically significant complications typically develop at values greater than 10 mm Hg.

Although cirrhosis is the most important cause of portal hypertension, any process that increases resistance to portal blood flow through the presinusoidal, sinusoidal, or hepatic venous outflow tracts may result in portal hypertension ([Table 43-3](#)). In addition, cirrhosis is associated with increased cardiac output, which leads to greater splanchnic blood flow, further aggravating portal hypertension. It is important to recognize that the HVPG is reliably increased only in sinusoidal portal hypertension.

With sustained portal hypertension, portosystemic collaterals are formed which have the benefit of decreasing portal pressures at the expense of bypassing the liver. Major sites of collateral formation includes the gastroesophageal junction, retroperitoneum, rectum, and falciform ligament of liver (abdominal and periumbilical collaterals). Clinically, the most important collaterals are those connecting the portal to the azygos vein through the dilated and tortuous vessels (varices) in the submucosa of the gastric fundus and esophagus.

VARICEAL HEMORRHAGE

Definition and Pathology

Varices are abnormally large veins that are most commonly recognized near the gastroesophageal junction or the stomach wall. Gastroesophageal varices usually develop when the portal pressure gradient (HVPG) exceeds 10 mm Hg, and the risk for variceal rupture increases when the gradient is higher than 12 mm Hg. Bleeding occurs most commonly from large varices in the esophagus when high tension in the walls of these vessels leads to rupture. Among gastric varices, fundal varices have the highest

Cirrhosis (many causes) Alcoholic hepatitis	

rate of bleeding and may bleed with portal pressure gradients of less than 12 mm Hg.

Clinical Presentation

Variceal bleeding usually manifests as painless hematemesis, melena, or hematochezia, which typically leads to hemodynamic compromise due to higher portal pressures. Bleeding is further aggravated by impaired hepatic synthesis of coagulation factors and thrombocytopenia from hypersplenism.

Treatment

The management of gastroesophageal varices includes prevention of initial bleeding (primary prophylaxis), treatment of acute variceal hemorrhage, and prevention of rebleeding (secondary prophylaxis) (Fig. 43-2). If varices are large, primary prophylaxis is commonly undertaken with nonselective β -adrenergic receptor blocking (NSBB) agents such as propranolol and nadolol. Carvedilol is a newer NSBB that may improve prevention of initial variceal bleeding. Surveillance for varices using esophago-gastroduodenoscopy is advocated on an annual basis in patients with decompensated cirrhosis, every 1 to 2 years in those with compensated cirrhosis, and every 2 to 3 years for cirrhotic

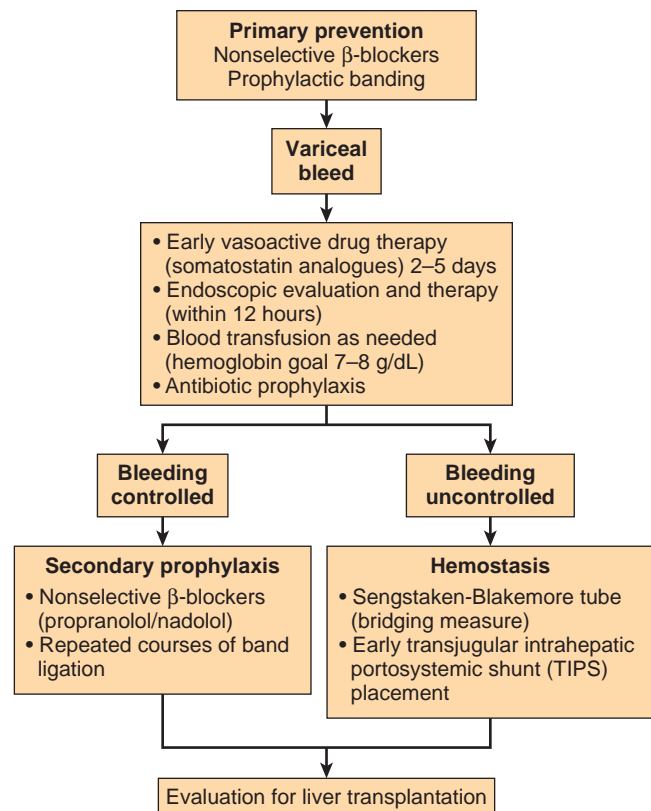

FIGURE 43-2 Prevention and treatment of variceal bleeding.

patients without varices. Periodic endoscopic band ligation (EBL) is also effective if the patient has contraindications or intolerance to β -blockers. Isosorbide mononitrate therapy should not be used for prophylaxis because it has been shown to increase adverse events.

When varices are present, 5% to 15% of patients experience an initial episode of bleeding annually, and this episode carries a significant mortality risk of 7% to 15% at 6 weeks. Management

includes stabilization (airway, breathing, and circulation) and blood transfusions to maintain a hemoglobin level of 7 to 8 g/dL. Combined pharmacologic and endoscopic therapy is the current standard for control of bleeding and is superior to either therapy alone. Prophylactic intravenous antibiotics should be administered early because they reduce the risk for infection, rebleeding, and death.

Current pharmacologic therapy consists of octreotide, a somatostatin analogue, which is widely used because of a good safety profile. This agent is best instituted before endoscopic examination. Endoscopic therapy includes EBL or sclerotherapy or both. EBL is the preferred modality given the lower incidence of adverse effects and complications. In patients with gastric variceal hemorrhage, endoscopic variceal ablation with cyanoacrylate glue is superior to EBL, although this therapy is not approved in the United States. Balloon tamponade (Sengstaken-Blakemore tube, Linton tube, or Minnesota tube) is a temporary measure reserved only for cases in which endoscopic therapy has failed in the setting of massive hemorrhage. In these patients, there is evidence that early placement of a transjugular intrahepatic portosystemic shunt (TIPS) for active variceal bleeding improves survival. The most common side effect of the TIPS is postprocedural encephalopathy.

Recommendations for secondary prophylaxis to prevent rebleeding include a combination of nonselective β -blockers (propranolol and nadolol) and variceal obliteration through repeated courses of EBL. In patients who undergo TIPS, the patency must be assessed using Doppler ultrasound on a regular basis.

Prognosis

Overall, the frequency and mortality rates from variceal bleeding appear to be decreasing in the United States over the past 2 decades. However, variceal hemorrhage is life-threatening, and after an initial episode the risk of rebleeding approaches 60% with a mortality rate of approximately 33% if secondary prophylaxis is not instituted.

ASCITES

Definition and Pathology

Ascites represents the accumulation of excess fluid in the peritoneal cavity. Although cirrhosis is the most common cause of ascites, there are also other important causes (Table 43-4). The precise sequence of events leading to the development of cirrhotic ascites remains debated. The *overflow* theory suggests that

portal hypertension and splanchnic vasodilation result in excess renal sodium and water retention and overflow of fluid into the peritoneum. The *underflow* theory suggests that decreased effective circulating blood volume resulting from systemic arterial vasodilation leads to activation of neurohumoral systems and results in sodium and water retention. In any case, avid renal Na^+ retention is characteristic and results in an increase in total body Na^+ and water.

Diagnosis

Physical examination is relatively insensitive for detection of small volumes of ascites, but bulging flanks, shifting dullness, and evidence of portal hypertension (e.g., distended veins over the abdominal wall and caput) become evident with increasing amounts of fluid. Abdominal ultrasound is both sensitive and specific and is widely used in screening. When fluid is present, abdominal paracentesis is the quickest and most direct approach for confirmation of the presence of fluid in the abdominal cavity and initial characterization of the cause. In addition to standard measures such as cell count, the serum-ascites albumin gradient (SAAG), which is proportional to the sinusoidal portal pressure, is calculated as follows:

$$\text{SAAG} = (\text{Serum albumin concentration}) \\ - (\text{Ascitic fluid albumin concentration}).$$

An elevated SAAG (>1.1 g/dL) correlates well with portal hypertension as the likely cause of fluid accumulation (see Table 43-4).

Clinical Presentation

Patients usually report increasing abdominal girth, fullness of the flanks, and weight gain with or without peripheral edema. Ascites becomes clinically detectable with fluid accumulation greater than about 500 mL. Shifting dullness to percussion is the most sensitive clinical sign of ascites, but about 1500 mL of fluid must be present for reliable detection.

Treatment

Management of cirrhotic ascites depends on the cause. Patients with high SAAG (>1.1 g/mL), which is used as a surrogate measure for elevated portal pressures, usually respond to salt restriction (<2 g/day) and diuretics to stimulate renal Na^+ loss. The administration of spironolactone, an aldosterone antagonist, supplemented with a loop diuretic (e.g., furosemide), is effective in about 90% of patients. Diuresis should be monitored closely because aggressive diuretic therapy may result in electrolyte disturbances (e.g., hyponatremia, hypokalemia) and hypovolemia, leading to impaired renal function and potentially precipitating HE. Water restriction is implemented when the serum sodium concentration is less than 120 to 125 mEq/L.

Prognosis

Refractory ascites occurs in up to 10% of patients with cirrhosis and is defined as the persistence of tense ascites despite maximal diuretic therapy (spironolactone, 400 mg/day, and furosemide, 160 mg/day) or the development of azotemia or electrolyte disturbances at submaximal doses of diuretics. Treatment includes repeated large-volume paracentesis and colloid volume

TABLE 43-4 CLASSIFICATION OF ASCITES

SAAG, Serum-ascites albumin gradient.

expansion with albumin (6 to 8 g/L of fluid removed), TIPS placement in appropriate candidates, and eventually liver transplantation (Fig. 43-3). Peritoneovenous shunts are not commonly used and are reserved for patients who are not candidates for paracentesis, TIPS, or transplantation.

SPONTANEOUS BACTERIAL PERITONITIS

Definition and Pathology

Cirrhotic patients may develop infection of ascitic fluid in the absence of an obvious source of contamination or surgically treatable source, a condition known as acute spontaneous bacterial peritonitis (SBP). The exact mechanism of contamination of the ascitic fluid is unclear. Factors such as bacterial overgrowth, altered motility, and increased intestinal permeability may contribute. The microbiology of SBP includes most commonly *Escherichia coli* and Enterobacteriaceae (*Klebsiella*). Gram-positive organisms such as *Streptococcus* (viridans), *Enterococcus*, and *Pneumococcus* species may also be found. Anaerobes are uncommon, and a single organism is isolated on culture in most cases; the presence of multiple organisms suggests bowel perforation or other causes of peritonitis.

Clinical Presentation

Clinical features include fever, abdominal pain, and signs of peritoneal irritation. Often, the infection is clinically silent or manifests with worsening of HE, diarrhea, ileus, or renal insufficiency.

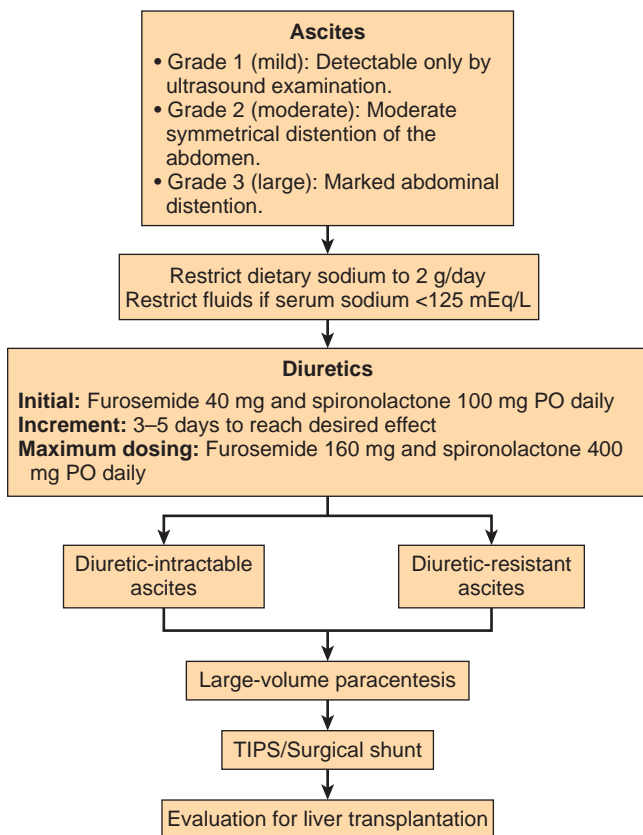

FIGURE 43-3 Management of ascites in cirrhosis. TIPS, Transjugular intrahepatic portosystemic shunt.

Diagnosis

Diagnostic paracentesis should be considered in any patient with cirrhotic ascites who deteriorates clinically. The diagnosis of SBP is highly likely if a high concentration (>250 cells/ mm^3) of polymorphonuclear leukocytes (PMNs) is present in the ascitic fluid, and this finding should prompt empiric therapy while blood and ascitic fluid culture results are pending. The use of rapid bedside diagnostic methods such as leukocyte esterase reagent strips is not routinely recommended in view of their low sensitivity.

Treatment

Patients are usually treated with intravenous third-generation cephalosporin (e.g., cefotaxime, 2 g every 8 hours); quinolones are also routinely used, provided that the patient does not have prior exposure and is not in overt shock. Response to treatment is usually seen within 72 hours; therapy is continued for a minimum of 5 days and can extend up to 14 days. Repeat peritoneal fluid analysis may be done if recovery is delayed or to ensure that the ascitic fluid is sterile after treatment. The administration of intravenous albumin on day 1 (1.5 g/kg) and day 3 (1g/kg) has been shown to decrease the incidence of renal dysfunction and to improve short-term survival in SBP.

Prognosis

There is a high rate of recurrence, up to 70% within 1 year, and the 1-year mortality rate with a prior episode of SBP is 50% to 70%. Long-term antibiotic prophylaxis is indicated to reduce the recurrence rate to approximately 20%. Short-term prophylaxis should be considered for patients with cirrhosis and ascites who are hospitalized with upper gastrointestinal bleeding. Common prophylactic regimens for SBP include fluoroquinolones (ciprofloxacin, 750 mg/week; norfloxacin, 400 mg/day) and trimethoprim-sulfamethoxazole (1 double-strength tablet daily). Long-term antibiotic prophylaxis can lead to infection with resistant extended-spectrum β -lactamase (ESBL)-producing organisms or methicillin-resistant *Staphylococcus aureus* (MRSA).

HEPATORENAL SYNDROME

Definition and Pathology

Hepatorenal syndrome (HRS) is a form of functional renal failure that occurs in the presence of significant hepatic synthetic dysfunction and ascites. Three mechanisms of kidney dysfunction have been proposed: splanchnic arterial vasodilation, renal arterial vasoconstriction, and cardiac dysfunction.

Clinical Presentation and Diagnosis

Patients with HRS typically have advanced ascites and other manifestations of cirrhosis but are not otherwise symptomatic. However, some patients may notice decreased urine output or signs of encephalopathy. There is no single laboratory or imaging study that can be used alone to diagnose HRS. However, the 5-year probability of developing HRS in patients with cirrhosis and ascites is 40%, and HRS develops in approximately 30% of cirrhotic patients who are admitted with SBP. Therefore, a high

clinical suspicion is warranted along with a systematic approach to diagnosis based on fulfillment of certain criteria.

The diagnostic criteria for HRS as defined by the International Ascites Club Consensus Workshop in 2007 include the following:

1. Cirrhosis with ascites
2. Serum creatinine level higher than 1.5 mg/dL (133 μ mol/L)
3. Lack of improvement in the serum creatinine level (to \leq 1.5 mg/dL or \leq 133 μ mol/L) after at least 2 days of diuretic withdrawal and volume expansion with albumin (1 g/kg of body weight per day, up to a maximum of 100 g/day)
4. Absence of shock
5. Lack of current or recent treatment with nephrotoxic drugs
6. Absence of parenchymal kidney disease as indicated by proteinuria of more than 500 mg/day, microhematuria ($>$ 50 red blood cells per high-power field), or abnormal renal ultrasonographic findings.

HRS has two types, type 1 and type 2. HRS type 1 is characterized by rapid deterioration of kidney function with doubling of the initial creatinine to greater than 2.5 mg/dL within 2 weeks or less. HRS type 2 produces a more moderate renal failure that is slowly progressive.

An Acute Kidney Injury Network criterion redefines acute renal failure and is generally recognized by criticare specialists and nephrologists. This criterion divides kidney injury into three stages. Stage I is defined as an increase in serum creatinine of more than or equal to 0.3 mg/dL (\geq 26.4 μ mol/L) or urine output of less than 0.5 mL/kg/hour for longer than 6 hours. Stage II is an increase in serum creatinine of more than 2 to 3 folds from baseline or urine output of less than 0.5 mL/kg/hour for longer than 12 hours. Finally stage III is a rise in serum creatinine of more than 3 fold from baseline or serum creatinine of more than or equal to 4.0 mg/dL. This can also be characterized by either oliguria (output $<$ 0.3 mL/kg/hour) for 24 hours or anuria for 12 hours. The key is to detect renal failure early and start appropriate therapy promptly in order to prevent progression.

Typically, the kidneys are histologically normal and can regain normal function in the event of recovery of liver function (e.g., after liver transplantation). Severe cortical vasoconstriction has been demonstrated angiographically, and such vasoconstriction reverses when these kidneys are transplanted into patients who do not have cirrhosis.

Treatment and Prognosis

The mortality rate is high in HRS, and so prevention is important. In all patients with cirrhosis, precipitating factors (e.g., diuretics, lactulose, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors) should be avoided if possible. Patients should be promptly diagnosed and treated for any signs of SBP, and colloid (albumin) should be administered if rising creatinine levels are observed. Prevention of variceal bleeding should also be optimized by primary and secondary prophylaxis.

Studies have shown an increased mortality rate with AKI among hospitalized cirrhotic patients. Several medical therapies are currently under review, including use of terlipressin, a vasopressin V_1 receptor analogue, in combination with albumin for type 1 HRS. Other studies have evaluated the combination of octreotide and midodrine (an α -adrenergic agonist) and intravenous albumin. Placement of TIPS has also been reported to stabilize or even improve renal function, mainly in patients with type 2 HRS. However, a significant limitation of TIPS is the possibility of worsening hepatic function in decompensated cirrhosis. Liver transplantation has become the accepted treatment for HRS because it is the only known therapeutic intervention that reverses the process. It is limited by rapid progression of HRS and lack of available organs.

HEPATIC ENCEPHALOPATHY

Definition

HE is a complex, reversible neuropsychiatric syndrome that occurs in patients with chronic liver disease, portal hypertension, or portosystemic shunting. HE is also seen in patients with acute liver failure. HE develops in about 30% to 45% of cirrhotic patients, and when it is present, the survival probability is approximately 23% at 3 years.

Pathophysiology

The pathogenesis of HE in the setting of cirrhosis is thought to be multifactorial and may differ in acute and chronic liver disease. Contributors include the inadequate hepatic removal of potential endogenous neurotoxins, altered permeability of the blood-brain barrier, and abnormal neurotransmission. Elevation of blood ammonia levels, derived from both amino acid deamination and bacterial hydrolysis of nitrogenous compounds in the gut, has been the best studied factor, but its specific role in the pathogenesis of HE remains uncertain. Many other potential contributors to HE have been investigated, including increased tone of the inhibitory GABAA/benzodiazepine neurotransmitter system, activation of the astrocytic 18-kDa translocator protein (PTBR), production of endogenous benzodiazepine-like compounds, altered cerebral metabolism, zinc deficiency, increase in serotonin levels, up regulation of H1 receptors, altered melatonin production, and deposition of manganese in the basal ganglia.

Clinical Presentation

The clinical features of HE include disturbances of higher neurologic function such as intellectual and personality disorders, dementia, inability to copy simple diagrams (constructional apraxia), disturbance of consciousness, disturbances of neuromuscular function (asterixis, hyperreflexia, myoclonus), and, rarely, a Parkinson-like syndrome and progressive paraplegia. One of the earliest manifestations of overt HE is alteration of the normal sleep-wake cycle

Diagnosis

There is no laboratory or imaging study that allows a specific diagnosis of HE. Rather, it is a clinical syndrome. Blood levels of ammonia are commonly measured, but elevated levels are neither sensitive nor specific for HE. Neuropsychometric and

neurocognitive tests such as the Portosystemic Encephalopathy Syndrome Test (PSET) and the earlier Stroop Color-Word Test evaluate the patient's attention, concentration, fine motor skills, and orientation and have been shown to be highly specific for the diagnosis of HE, but they are reasonably labor intensive. Imaging modalities such as magnetic resonance spectroscopy are being used experimentally to assess HE; however, their clinical utility has not been ascertained. It is imperative that reversible causes of neurologic dysfunction, such as hypoglycemia, subdural hematoma, meningitis, and drug overdose, be considered and excluded early in the differential diagnosis of altered mental status in patients with cirrhosis.

Classification of Hepatic Encephalopathy

There are three major types of HE: type A (Acute), which is associated with acute liver failure; type B (Bypass), which is associated with portosystemic shunts in the absence of liver disease; and type C (Cirrhosis), which is associated with liver cirrhosis and is subdivided into episodic, persistent, and minimal types.

HE has been further graded based on the West Haven Criteria from 0 to 4. A new nomenclature, termed the Spectrum of Neurocognitive Impairment in Cirrhosis (SONIC) classification, has been proposed to improve recognition of earlier forms of HE that require specialized testing for detection and to facilitate research studies. Patients are divided into those who are unimpaired, those with covert HE, and those with overt HE (Table 43-5).

Treatment

Treatment of HE starts with identifying and addressing any precipitating factors (Table 43-6), reducing and eliminating substrates for the generation of nitrogenous compounds, and preventing ammonia absorption from the bowel. Protein restriction was considered to be important in preventing excess ammonia production in the past; however, studies have demonstrated that

dietary restriction of protein is not of significant benefit. Short-term protein restriction may be considered for patients with severe encephalopathy, but long-term restriction is associated with worsening malnutrition. Treatment with formulas rich in branched-chain amino acids has shown no benefit in improving encephalopathy or mortality.

Nonabsorbable disaccharides (e.g., lactulose) are the mainstay treatment of HE. These agents are fermented to organic acids by colonic bacteria, processes that lower stool pH and trap NH_4^+ in the colon, thereby decreasing absorption. In addition, the cathartic effect of lactulose eliminates ammonia and other nitrogenous compounds. Patients are usually directed to achieve two to three soft stools per day as the goal of lactulose therapy. Reduction and elimination of nitrogenous compound substrates can also be achieved by administering enemas and using nonabsorbable antibiotics such as rifaximin in patients who do not tolerate or respond to lactulose. Rifaximin (Xifaxin), 550 mg PO twice daily, is approved by the U.S. Food and Drug Administration for the treatment of HE and has a favorable side effect profile; however, cost is the limiting factor. Other agents that affect intestinal motility and ammonia generation are being evaluated, including acarbose and probiotics.

TABLE 43-6 HEPATIC ENCEPHALOPATHY: PRECIPITATING FACTORS

Gastrointestinal bleeding
Increased dietary protein
Constipation
Infection
Central nervous system depressant drugs (benzodiazepines, opiates, tricyclic antidepressants)
Deterioration in hepatic function
Hypokalemia: most often induced by diuretics
Azotemia: most often induced by diuretics
Alkalosis: most often induced by diuretics
Hypovolemia: most often induced by diuretics

TABLE 43-5 CLINICAL STAGES OF HEPATIC ENCEPHALOPATHY AS DEFINED BY THE WEST HAVEN CRITERIA AND THE PROPOSED SONIC CLASSIFICATION

Grade	WEST HAVEN CRITERIA			SONIC		
	Intellectual Function	Neuromuscular Function	Classification	Mental Status	Special Tests	Asterixis
0	Normal	Normal	Unimpaired	Not impaired	Normal	Absent
Minimal	Normal examination findings. Subtle changes in work or driving	Minor abnormalities of visual perception or on psychometric or number tests	Covert HE	Not impaired	Abnormal	Absent
1	Personality changes, attention deficits, irritability, depressed state	Tremor and incoordination				
2	Changes in sleep-wake cycle, lethargy, mood and behavioral changes, cognitive dysfunction	Asterixis, ataxic gait, speech abnormalities (slow and slurred)	Overt HE	Impaired	Abnormal	Present (absent in coma)
3	Altered level of consciousness (somnolence), confusion, disorientation, and amnesia	Muscular rigidity, nystagmus, clonus, Babinski sign, hyporeflexia				
4	Stupor and coma	Oculocephalic reflex, unresponsiveness to noxious stimuli

SONIC, Spectrum of Neuro-Cognitive Impairment in Cirrhosis.

HEPATOPULMONARY SYNDROME AND PORTOPULMONARY HYPERTENSION

The effects of cirrhosis and portal hypertension on the pulmonary circulation manifest as two distinct disorders, hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PoPH).

Hepatopulmonary Syndrome

HPS occurs in 5% to 30% of patients with cirrhosis and is a progressive disease. It is characterized by gas exchange abnormalities (increased alveolar-arterial gradient and hypoxemia) resulting from intrapulmonary vascular dilation. The vascular dilation leads to vascular remodeling and angiogenesis, resulting in impaired oxygen transfer from the alveoli to the central stream of red blood cells within capillaries. Usually, this functional intrapulmonary right-to-left shunt significantly improves with the administration of 100% oxygen. HPS also has been reported in cases of hepatic venous outflow obstruction without cirrhosis.

Diagnosis

HPS is diagnosed based on high clinical suspicion and measurement of a widened alveolar-arterial oxygen gradient on room air in the presence or absence of hypoxemia. The gradient is calculated by analyzing arterial blood gases. HPS is graded from mild, in which the arterial partial pressure of oxygen (PaO_2) is greater than 80 mm Hg to very severe ($\text{PaO}_2 < 50$ mm Hg). Intrapulmonary shunting is demonstrated by contrast echocardiography, in which agitated saline is injected into a peripheral vein during the performance of two-dimensional echocardiography. Delayed appearance of microbubbles in the left cardiac chambers (more than three to six cardiac cycles after injection) indicates intrapulmonary vasodilation. Early visualization of microbubbles in the left cardiac chambers indicates intracardiac shunting. Other tests, including chest radiography, computed tomography, and pulmonary function tests, are performed to exclude intrinsic cardiopulmonary disorders.

Clinical Presentation

Clinical features range from subclinical abnormalities in gas exchange to profound hypoxemia causing significant dyspnea. Classically in HPS, the dyspnea is worse on standing and improves when the patient lies down (orthodeoxia and platypnea, respectively). Patients may also have marked nocturnal hypoxemia.

Screening and Treatment

Screening by pulse oximetry typically targets patients with values lower than 96% at rest on room air for further evaluation. However, no generally accepted guidelines exist. Currently, there is no established medical therapy for HPS. Liver transplantation remains the only option and reverses HPS in most patients. The use of TIPS to treat HPS is not established.

Prognosis

HPS carries a mortality rate of up to 40% in 2.5 years.

PORTOPULMONARY HYPERTENSION

PoPH is defined as the presence of pulmonary arterial hypertension in the setting of portal hypertension.

Diagnosis and Pathology

The diagnosis of PoPH is based entirely on results of right heart catheterization. The diagnostic values include a mean pulmonary arterial pressure greater than 25 mm Hg at rest or 30 mm Hg with exercise, a pulmonary capillary wedge pressure lower than 15 mm Hg, and a pulmonary vascular resistance greater than 240 dynes, all in the presence of portal hypertension or liver disease or both. PoPH is graded according to the mean pulmonary artery pressure, from mild (>25 to 35 mm Hg) to moderate (35 to 50 mm Hg) to severe (>50 mm Hg). Patients with mild PoPH do not appear to have increased operative risk. Moderate PoPH carries a high intraoperative risk and should be medically managed before transplantation. Severe PoPH is generally considered a contraindication to surgery. The exact mechanisms of PoPH are poorly understood. Histologically, it has characteristics similar to those of pulmonary hypertension.

Clinical Presentation

The most common symptom of PoPH is dyspnea on exertion, but many cirrhotic patients with PoPH are asymptomatic.

Treatment

In addition to symptomatic treatment (oxygen for dyspnea and diuretics for volume overload), the medical management of PoPH is similar to that for pulmonary arterial hypertension. Small studies have shown benefit for the use of intravenous vasodilator (prostacyclin) therapy, oral treatments including phosphodiesterase inhibitors, and endothelin receptor antagonist.

If moderate PoPH responds to therapy, liver transplantation may be considered. However, it has not been established whether successful liver transplantation reliably reverses PoPH. Liver transplantation is contraindicated in severe PoPH because of high transplant-related morbidity and mortality.

Prognosis

Untreated PoPH carries high rates of morbidity and mortality; the mean survival time from diagnosis is 15 months. A study on the U.S.-based Registry to Evaluate Early and Long-term Pulmonary Arterial Hypertension Disease Management (REVEAL) showed a 5-year survival rate of 40% from the time of diagnosis in patients with PoPH.

HEPATOCELLULAR CARCINOMA

Epidemiology

Liver cancer is the fifth most common cancer in men and the seventh most common in women worldwide; HCC is the most common type of liver cancer. In the United States, approximately 90% of liver cancers are HCC, and cholangiocarcinomas account for most of the rest. In other areas of the world, including sub-Saharan Africa, China, Japan, and Southeast Asia, HCC is one of the most frequent malignancies and is an important cause of mortality, particularly among middle-aged men.

Etiology

HCC often arises from a cirrhotic liver, and it is closely associated with chronic viral hepatitis. Hepatitis B virus DNA has been shown to integrate into the host cell genome, where it may

disrupt tumor suppressor genes and activate oncogenes. In areas of high prevalence, vaccination to prevent infection with hepatitis B virus has reduced the incidence of HCC. The exact pathophysiologic mechanisms leading to tumorigenesis in patients with other causes of cirrhosis (e.g., hemochromatosis, alcohol, hepatitis C viral infection) remain poorly understood. Risk factors for the development of HCC and its clinical manifestations are listed in (Table 43-7).

Diagnosis

Table 43-8 lists currently used imaging techniques for detection of HCC and the most common findings. A tissue specimen may be necessary to confirm the diagnosis in some cases, but it is not needed if characteristic clinical and radiologic features are present, especially if they are accompanied by a rise in serum α -fetoprotein levels. Diagnosis of small, treatable tumors is possible with intensive screening programs that employ imaging studies, although the long-term outcomes and cost-effectiveness of these strategies remain unclear.

Staging

Although many staging systems for HCC are in use, the Barcelona Clinic Liver Cancer (BCLC) system is most commonly used.

TABLE 43-7 HEPATOCELLULAR CARCINOMA

Arterial phase: tumor enhances quickly Venous phase: quick de-enhancement of tumor relative to parenchyma
MAGNETIC RESONANCE IMAGING
T1-weighted images: hypointense T2-weighted images: hyperintense After gadolinium administration, tumor increases in intensity

Treatment

Patients with well-compensated cirrhosis may undergo surgical resection or liver transplantation, with a 5-year survival rate of up to 70%. Nonsurgical options include percutaneous ethanol injection, transarterial chemoembolization (TACE), and radiofrequency ablation. Sorafenib (a receptor tyrosine kinase angiogenesis inhibitor) has been approved for use in patients with unresectable HCC and has been shown to prolong survival in such patients.

Prognosis

In patients with widespread, multifocal disease and in those with vascular invasion, the prognosis is poor, with a 5-year survival rate of 5% to 6%. Accordingly, emphasis is placed on prevention of viral hepatitis and other causes of liver disease and on screening by ultrasound of those who are at higher risk, including patients with known cirrhosis.

VASCULAR DISEASE OF THE LIVER

Disorders of the hepatic vasculature are uncommon and include portal vein thrombosis (PVT), hepatic vein thrombosis (Budd-Chiari syndrome), and veno-occlusive disease. Affected patients usually have portal hypertension with or without associated liver dysfunction, which may mimic the presentation of cirrhosis.

Portal Vein Thrombosis

Definition and Etiology

Thrombosis of the portal vein may develop after blunt abdominal trauma, umbilical vein infection, neonatal sepsis, intra-abdominal inflammatory diseases (e.g., pancreatitis), or hypercoagulable states, and in association with cirrhosis. Myeloproliferative diseases (including polycythemia vera, essential thrombocytosis, and myelofibrosis) are now being recognized as possible causes of PVT. One study observed that as many as 25% to 65% of patients with splanchnic vein thrombosis in the absence of cirrhosis had a myeloproliferative disease. The Janus kinase 2 (JAK2) mutation is a marker for myeloproliferative disease and is often checked in patients with PVT. The disease produces the manifestations of portal hypertension, but the liver histology is usually normal.

Diagnosis

The diagnosis is established by angiography, but noninvasive imaging modalities such as Doppler ultrasonography, computed tomography, and magnetic resonance imaging may reveal thrombus, collateral circulation near the porta hepatis, and splenomegaly. In long-standing PVT, tortuous venous channels develop within the organized clot, leading to cavernous transformation.

Treatment

In acute PVT, thrombolysis may be attempted, but anticoagulation with warfarin remains the mainstay of therapy. In most patients, recanalization of the thrombus occurs within 6 months after initiation of anticoagulation. Recommendations for duration of anticoagulation after an acute event vary and are usually

3 to 6 months. Long-term anticoagulation may be used in cases of chronic thrombosis, especially when associated with hypercoagulable states.

Concern exists that anticoagulation may precipitate hemorrhage from varices that arise as a consequence of portal hypertension; however, studies have not shown an increased risk for variceal bleeding in anticoagulated patients with chronic PVT. In fact, recent studies suggest a role for prophylactic anticoagulation (Enoxaparin) for prevention of PVT and hepatic decompensation in cirrhosis. If variceal hemorrhage occurs, it is best managed with endoscopic obliteration. Prophylaxis with β -blockers to prevent variceal bleeding may decrease the portal pressure, potentially propagating thrombus, and therefore is not usually recommended. If endoscopic treatment fails, surgical management with portosystemic shunting may be attempted, but this approach is often difficult because of the absence of suitable patent vessels.

Budd-Chiari Syndrome

Definition and Etiology

Occlusion of the major hepatic veins or the inferior vena cava, especially in the intrahepatic and suprahepatic segments, causes Budd-Chiari syndrome. Most cases are associated with hematologic disease (e.g., polycythemia vera, paroxysmal nocturnal hemoglobinuria, essential thrombocytosis, other myeloproliferative disorders), pregnancy, oral contraceptive use, tumors (especially HCC), or other causes of a hypercoagulable state (e.g., factor V Leiden mutation, protein C and S deficiency). Abdominal trauma and congenital webs of the vena cava are also related to Budd-Chiari syndrome. About 20% of cases are idiopathic, but many of these patients prove to have early, subclinical myeloproliferative disease or genetic mutations associated with a hypercoagulable state.

Clinical Presentation

Budd-Chiari syndrome can manifest acutely, possibly in association with acute liver failure, or it can manifest as a subacute or chronic illness. Acute disease produces right upper quadrant abdominal pain, hepatomegaly, ascites, and jaundice, whereas the subacute or chronic form produces primarily portal hypertension. Elevation of serum bilirubin and transaminase levels may be mild, but liver function is often poor, with profound hypoalbuminemia and coagulopathy.

Diagnosis

The diagnosis can be established noninvasively with Doppler ultrasonography, which shows decreased or absent hepatic vein blood flow, and computed tomography, which shows delayed or absent contrast filling of the hepatic veins and hypertrophy of the caudate lobe. Magnetic resonance angiography may also demonstrate these findings. Hepatic venography is especially useful if the results of noninvasive imaging are inconclusive. Venography often shows an inability to catheterize and visualize the hepatic veins; the characteristic spiderweb pattern of collateral vessels may also be demonstrated, and the inferior vena cava may appear compressed owing to hepatomegaly or an enlarged caudate lobe. On liver biopsy, centrilobular congestion, hemorrhage, and

necrosis (nutmeg liver) are seen, with cirrhosis developing in patients with chronic obstruction.

Treatment

Treatment should be individualized and is dependent on the mode and severity of presentation and the potential cause of the disease. Supportive therapy to relieve ascites and edema (e.g., dietary sodium restriction, diuretics) and chronic anticoagulation may be considered for patients with chronic Budd-Chiari syndrome in whom methods to decompress congestion are not feasible. Thrombolysis followed by anticoagulation is most useful in patients with acute forms of the disease. In selected patients (such as those with venous webs or strictures or single-vessel thrombosis), angioplasty with or without stent placement may be used. Decompressive modalities are most useful before the development of cirrhosis and include transjugular intrahepatic portacaval and side-to-side portacaval shunts. In patients with cirrhosis, liver transplantation followed by continued anticoagulation is often considered the best option.

Veno-Occlusive Disease

Definition and Etiology

Hepatic veno-occlusive disease, also called sinusoidal obstruction syndrome, often occurs after cytoreductive therapy and before bone marrow transplantation but may also follow exposure to other drugs or herbal preparations (e.g., azathioprine, pyrrolizidine alkaloids). Endothelial cell injury leads to obstruction at the level of the hepatic venules and the sinusoids.

Clinical Presentation

The disease is characterized by jaundice, painful hepatomegaly, and fluid retention. Clinical manifestations can be rapidly progressive and lead to multiorgan dysfunction and death in 20% to 25% of patients.

Diagnosis

The diagnosis is clinically suspected when weight gain, epigastric or right upper quadrant abdominal pain, and jaundice develop within the first 3 to 4 weeks after bone marrow transplantation. Laboratory abnormalities include hyperbilirubinemia, elevated transaminases, and, in severe cases, profound synthetic dysfunction. Doppler abdominal ultrasonography may reveal ascites, reversal of portal vein flow, and an elevated hepatic artery resistance index. Liver biopsy is diagnostic and is usually obtained with use of the transjugular approach. The advantages of this approach compared with the percutaneous route include the ability to measure the hepatic venous pressure gradient (which is typically elevated in veno-occlusive disease) and a lower incidence of bleeding.

Treatment

Mild forms of the disease may favorably respond to supportive therapy alone. In moderate to severe disease, treatment has been attempted with tissue plasminogen activator and heparin, anti-thrombin III, prostaglandin E₁, and glutamine plus vitamin E, although the efficacies of these treatments have not been clearly established. Recently, defibrotide (a mixture of porcine-derived

single-stranded phosphodiester oligonucleotides) has been evaluated as a potential treatment option for severe veno-occlusive disease. It is an attractive option because of the lack of severe adverse effects, although convincing evidence for efficacy has not been established.

LIVER TRANSPLANTATION

MELD Score

The Model for End-stage Liver Disease (MELD) score is calculated based on the serum creatinine concentration, prothrombin time (International Normalized Ratio), and bilirubin level and has been used to predict short-term mortality in cirrhosis and to prioritize patients awaiting liver transplantation. The MELD score ranges from 6 to 40. Higher scores are associated with more advanced disease and increased predicted mortality. Patients are typically considered for liver transplantation when the MELD score reaches 15. The average MELD score nationally at which patients undergo transplantation is 20.

Prognosis

Liver transplantation is a highly successful procedure in patients with progressive, advanced, and otherwise untreatable liver disease. Advances in surgical techniques and supportive care, the use of cyclosporine and tacrolimus for immunosuppression, and careful selection of patients have all contributed to the excellent results of liver transplantation. Between 70% and 80% of patients undergoing liver transplantation survive at least 5 years, usually with good quality of life. The most common indication for liver transplantation in the United States is chronic liver disease resulting from hepatitis C virus infection. Other liver diseases for which transplantation is commonly performed include cirrhosis from alcoholic liver disease, NAFLD, autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis. Patients with hepatitis B are candidates for liver transplantation

if they can be given hepatitis B immunoglobulin or nucleoside analogues to help prevent recurrence. Excellent results have also been obtained in selected patients with acute liver failure (see [Chapter 42](#)). Liver transplantation for malignant hepatobiliary disease has been less successful because of recurrent disease in the transplanted liver.

For a deeper discussion on this topic, please see Chapter 153, "Cirrhosis and Its Sequelae," in Goldman-Cecil Medicine, 25th Edition.

Disorders of the Gallbladder and Biliary Tract

Matthew P. Spinn and Michael B. Fallon

INTRODUCTION

The gallbladder and biliary tract transport bile from the liver into the intestines, a process central to digestion of fat and absorption of lipids and fat-soluble vitamins. Gallbladder and biliary tract diseases are among the most common and costly of all digestive disorders. This chapter examines the principal gallbladder and biliary tract disorders, focusing on cholelithiasis. The reader is referred to [Chapter 40](#) for a detailed discussion of bilirubin metabolism and the diagnostic approach to jaundice and to [Chapter 34](#) for a review of the various imaging techniques used to study the biliary tract.

NORMAL BILIARY ANATOMY AND PHYSIOLOGY

[Figure 44-1](#) outlines the basic anatomy of the liver and biliary tract. The liver produces 500 to 1500 mL of bile per day. The secretory product of individual hepatocytes contains bile acids, phospholipids, and cholesterol, which are transported across the apical membrane and into the canalicular space between cells. These canaliculi merge to form larger intrahepatic bile ducts and then the common hepatic duct. During fasting, tonic contractions of the sphincter of Oddi, located in the region of the ampulla of Vater, divert about one half of the bile through the cystic duct into the gallbladder, where it is stored and concentrated by water resorption. Cholecystokinin, which is released after food enters the small intestine, causes the sphincter of Oddi to relax, allowing delivery of a timed bolus of bile into the intestine. Bile acids are present in millimolar concentrations. They are detergent molecules that possess both fat-soluble and water-soluble moieties. Cholesterol is secreted by the liver to the intestine, where it undergoes fecal excretion (see [E-Fig. 40-1](#) in [Chapter 40](#)). In the intestinal lumen, bile acids solubilize dietary fat and promote its digestion and absorption. Bile acids are, for the most part, efficiently reabsorbed by the small intestinal mucosa, particularly in the terminal ileum. They are then recycled to the liver for re-excretion, a process termed *enterohepatic circulation*.

GALLBLADDER DISORDERS

Gallstones (Cholelithiasis)

Gallstone formation constitutes a significant health problem, affecting 10% to 15% of the adult population. Complications from gallstones are a leading cause for hospital admissions related to gastrointestinal problems. In the United States, gallstone disease leads to more than 750,000 cholecystectomies annually,

making this the most common elective abdominal surgery, with estimated costs of \$6.5 billion per year. Gallstones are of two types: 75% are made of cholesterol, and 25% are pigmented stones (black or brown). The latter are composed of calcium bilirubinate and other calcium salts. The risk factors for cholelithiasis are shown in [Table 44-1](#).

Pathogenesis of Cholelithiasis

The three main factors that lead to cholesterol gallstone formation are cholesterol supersaturation of bile, nucleation, and gallbladder hypomotility. The liver is the most important organ in regulating total-body cholesterol stores. Once it is secreted, cholesterol, which is insoluble in water, is solubilized in bile through the formation of mixed micelles with bile acids and phospholipids. In most individuals, there is more cholesterol in bile than can be maintained in stable solution. As bile becomes supersaturated, microscopic cholesterol molecules aggregate into coalescent vesicles that crystallize, a process referred to as *nucleation*. The gradual deposition of additional layers of cholesterol leads to the appearance of macroscopic stones. Factors that influence nucleation include bile transit time, gallbladder contraction, bile composition (concentrations of cholesterol, phospholipids, and bile salts), and presence of bacteria, mucin, and glycoproteins, which can act as a nidus to initiate cholesterol crystal formation. The interplay between *pronucleating* and *antinucleating* factors in the gallbladder may determine whether cholesterol gallstones will form from supersaturated bile. Gallbladder sludge is a superconcentrated mixture of bile acids, bilirubin, cholesterol, mucus, and proteins that exhibits various degrees of fluidity and is prone to precipitate into a semisolid or solid form.

The pathophysiologic factors leading to pigment stone formation are less well understood; however, increased production of bilirubin conjugates (hemolytic states), increased biliary calcium (Ca^{2+}) and bicarbonate (HCO_3^-) levels, cirrhosis, and bacterial deconjugation of bilirubin to a less soluble form are all associated with pigment stone formation. Black pigment stones, which are composed primarily of calcium bilirubinate, are formed in sterile bile in the gallbladder and are common in chronic hemolytic states, in cases of cirrhosis, and in patients with ileal resection. Their brown pigment counterparts, composed primarily of calcium salts, are formed in the bile ducts and are seen in the setting of infection of the biliary tract.

Many of the recognized predisposing factors for cholelithiasis and gallbladder sludge can be understood in terms of the pathophysiologic scheme outlined previously:

FIGURE 44-1 Normal anatomy and histology of the liver and biliary tract. Materials destined for metabolism or excretion by the liver (such as unconjugated bilirubin) enter the sinusoidal bed and cross the endothelial barrier and the space of Disse. Unconjugated bilirubin is taken up by the hepatocyte, conjugated with glucuronide to become water soluble, and excreted into bile across the canalicular membrane of the hepatocyte. The canaliculi empty into bile ductules (BD), which lead to the interlobular (small), septal (medium), and large intrahepatic bile ducts and finally to the main branches of the common bile duct. The portal areas, or portal triads, are composed mainly of portal vein (PV), hepatic artery (HA), and BD branches. During fasting, tonic contraction of the sphincter of Oddi, located in the region of the ampulla of Vater, diverts about one half of the bile through the cystic duct into the gallbladder, where it is stored and concentrated to be released later during meal times. Disease at any level of the biliary tree can lead to cholestasis and obstructive jaundice.

1. Biliary cholesterol saturation is increased by estrogens, multiparity, oral contraceptives, obesity, rapid weight loss, and terminal ileal disease, which decreases the bile acid pool.
2. Nucleation is enhanced by biliary parasites, recurrent bacterial infection of the biliary tract, and antibiotics such as ceftriaxone, which has a proclivity to concentrate and crystallize with calcium in the biliary tree. Total parenteral nutrition and blood transfusions also promote bile pigment accumulation and *gelfaction* of sludge.
3. Bile stasis is caused by gallbladder hypomotility (resulting from pregnancy, somatostatin, or fasting), bile duct stric-

tures, choledochal cysts, biliary parasites, and total parenteral nutrition.

Clinical Manifestations of Gallstones

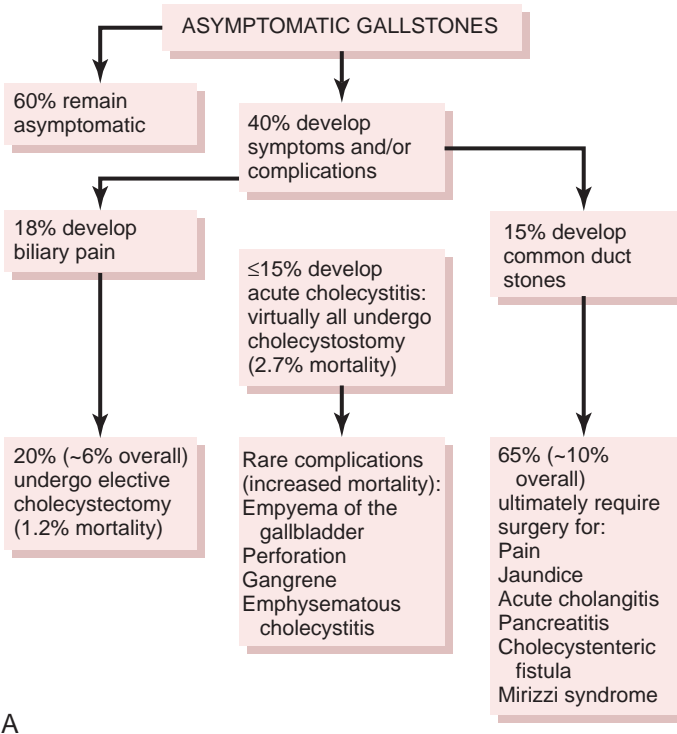

Gallstones develop at some point in 10% to 20% of Americans. Between 50% and 60% of these individuals remain asymptomatic, but about one third develop biliary colic or chronic cholecystitis, and 15% develop acute complications. The natural history of gallstone disease is outlined in [Figure 44-2](#). Obstruction of the biliary tract at any level by stones or sludge is the underlying cause of the clinical manifestations of gallstone disease. Obstruction by gallstones can occur at the level of the

TABLE 44-1 RISK FACTORS FOR CHOLELITHIASIS

PRIMARY	
Age	Pregnancy
Obesity	Diabetes mellitus
Female sex	Low socioeconomic status
Rapid weight loss	Sedentary lifestyle
Ethnic background (e.g., Native American)	Total parenteral nutrition
	Hemolysis
	Cirrhosis
	Crohn's disease
SECONDARY	Biliary parasites (e.g., <i>Clonorchis sinensis</i>)
Drugs: oral contraceptives, ceftriaxone, octreotide, thiazide diuretics	Terminal ileum resection

TABLE 44-2 DIFFERENTIAL DIAGNOSIS OF CHOLELITHIASIS

Peptic ulcer disease	Nephrolithiasis
Gastroesophageal reflux disease	Pyelonephritis

FIGURE 44-2 Natural history of asymptomatic gallstones. **A**, The clinical syndromes associated with gallstones are shown, and the numbers represent the approximate percentage of adults who develop one or more of these symptoms or complications over a 15- to 20-year period. Over this period, about 30% of individuals with gallstones undergo surgery. (The risk for developing complications of gallstones varies considerably among series. The figures shown represent those derived from more recent studies.) **B**, Clinical manifestations of symptomatic gallstones. Locations of blockages associated with various conditions are indicated.

cystic duct, common hepatic duct, common bile duct, or ampulla of Vater (see Figs. 44-1 and 44-2). Symptoms arise from contraction of the gallbladder during transient obstruction of the cystic duct by gallstones, and persistent obstruction of the cystic duct leads to superimposed inflammation or infection of the gallbladder (i.e., acute cholecystitis). Obstruction of the distal common bile duct may result in abdominal pain, cholangitis (infection of the biliary tract), or pancreatitis (resulting from pancreatic duct obstruction). The presence of a large stone in the cystic duct can cause common bile duct obstruction and is referred to as *Mirizzi syndrome*. Common conditions to consider in the differential diagnosis of gallstone disease are listed in Table 44-2.

Asymptomatic Gallstones

Most gallstones are clinically “silent,” and they are often uncovered as an incidental finding during abdominal ultrasound

performed for another reason. The risk of developing symptoms is low, averaging 2% to 3% per year, 10% at 5 years, and 1% to 2% per year with major complications. Expectant management is an appropriate choice for the general population. Prophylactic cholecystectomy should be considered in those groups who are at increased risk for the development of complications, including (1) patients with diabetes, who have a greater morbidity and mortality from acute cholecystitis; (2) patients with a calcified (porcelain) gallbladder, large gallbladder polyps, or large stones (>3 cm), which are associated with an increased risk for gallbladder carcinoma; (3) patients with sickle cell anemia, in whom hepatic crises may be difficult to differentiate from acute cholecystitis; (4) children with gallstones, because they frequently develop symptomatic disease; and (5) Native Americans, who are predisposed to gallbladder cancer in the setting of gallstones.

Symptomatic Gallstones and Biliary Colic

Symptomatic cholelithiasis is defined by gallbladder pain in the presence of gallstones. *Biliary colic* refers to the constellation of symptoms experienced when the gallbladder contracts against outlet obstruction. Classically, biliary colic starts as a steady ache in the epigastrium or right upper quadrant; it has a sudden onset, reaches a plateau of intensity over a few minutes, and then subsides gradually over 30 minutes to several hours. Referred pain may be felt at the tip of the scapula or right shoulder. Nausea and vomiting may occur, but fever and a palpable mass (signs of acute cholecystitis) are not evident. Other symptoms, such as dyspepsia, fatty food intolerance, bloating and flatulence, heartburn, and belching, may occur in patients with gallstones; however, these symptoms are nonspecific and frequently occur in individuals with normal gallbladders.

Gallstones are best demonstrated by transabdominal ultrasonography, which has become the initial test to evaluate cholelithiasis. The sensitivity and specificity of ultrasound are greater than 90%, but accuracy drops to 20% for visualization of stones within the common bile duct. This limitation has been overcome by endoscopic ultrasonography (EUS) (Video 44-1) and magnetic resonance cholangiopancreatography (MRCP), both of which have an accuracy of 90% to 95% for detecting cholelithiasis and common bile duct stones. Oral cholecystography is no longer used for the routine evaluation of gallstones.

If gallbladder removal is indicated, laparoscopic cholecystectomy has replaced open cholecystectomy as the treatment of choice for recurrent biliary pain. Open cholecystectomy is typically reserved for selected high-risk patients (e.g., prior abdominal surgery with adhesions, obesity, cirrhosis). Laparoscopic cholecystectomy may be accompanied by intraoperative endoscopic retrograde cholangiopancreatography (ERCP) (see Fig. 44-1 and Chapter 34) or transoperative radiologic examination of the common bile duct if concomitant choledocholithiasis is suspected. Factors that may predict the presence of choledocholithiasis include jaundice, pancreatitis, abnormal liver test results, and bile duct dilation.

Cholecystectomy relieves biliary pain in virtually all patients with gallstone disease and prevents the development of future complications. Dissolution of cholesterol gallstones by orally administered chenodeoxycholic acid or ursodeoxycholic acid is successful in highly selected patients but is slow and costly and requires lifelong administration. Alternative methods to eliminate gallstones, including contact dissolution and fragmentation of stones, are used rarely.

Acute Cholecystitis

Acute cholecystitis refers to distention, edema, ischemia, inflammation, and secondary infection of the gallbladder. This typically results from obstruction of the cystic duct by gallstones or, less commonly, from gallbladder cancer or sludge. The clinical hallmark of acute cholecystitis is the acute onset of upper abdominal pain that lasts for several hours. The pain gradually increases in severity and typically localizes to the epigastrium or right hypochondrium with radiation to the right lumbar, scapular, and shoulder area. Nausea and vomiting, anorexia, and low-grade fever are common. Unlike biliary pain, the pain of acute

cholecystitis does not subside spontaneously. The findings on physical examination in patients with acute cholecystitis may include inspiratory arrest on palpation of the right upper quadrant (Murphy's sign), fever, and, less commonly, mild jaundice or a palpable gallbladder.

Complications of acute cholecystitis include emphysematous cholecystitis (in people with diabetes, older adults, and individuals who are immunosuppressed), empyema, gangrene, and perforation of the gallbladder. Gallbladder perforation may occur directly into the peritoneum ("free") or through a cholecystenteric fistula with gallstone migration and bowel obstruction (gallstone ileus). Mirizzi syndrome is the occurrence of profound jaundice resulting from extrinsic compression of the bile duct by an impacted stone in the cystic duct at the gallbladder neck.

The diagnostic approach for suspected acute cholecystitis is similar to that for biliary pain. A transabdominal ultrasound study that demonstrates gallstones, along with pericholecystic fluid, gallbladder wall thickening, and localized tenderness over the gallbladder (ultrasonographic Murphy's sign), provides strong supportive evidence for acute cholecystitis. Ultrasound is safe and widely available and has emerged as the initial test of choice. Radionuclide scanning after intravenous administration of technetium-99m-labeled diisopropyl iminodiacetic acid (DISIDA) or hepatobiliary iminodiacetic acid (HIDA) is also accurate. If the gallbladder fills with the isotope, acute cholecystitis is highly unlikely; if contrast material enters the bile duct and duodenum without gallbladder visualization, acute cholecystitis is strongly supported.

Because of the high risk for recurrent acute cholecystitis, most patients need to undergo cholecystectomy, which is often performed within the first 24 to 48 hours after presentation or, less often, 4 to 8 weeks after an acute episode (Fig. 44-3).

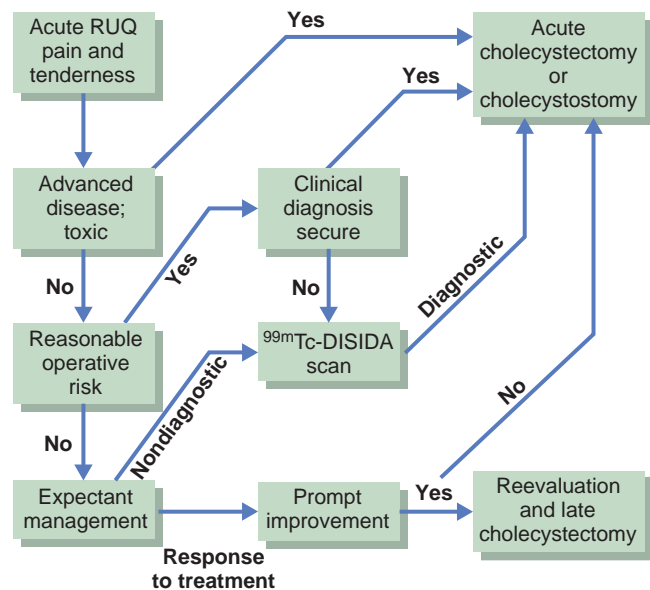

FIGURE 44-3 Algorithm for management of right upper quadrant (RUQ) pain and tenderness in patients with suspected acute cholecystitis. This scheme is based on a policy of early operation (conventional or laparoscopic) for appropriate patients and use of cholecystostomy (operative or percutaneous) for patients who are poor operative risks. ^{99m}Tc-DISIDA, Technetium-99m-labeled diisopropyl iminodiacetic acid.

Cholecystostomy may be performed for patients who have a high operative risk. Antibiotics are typically used when fever or leukocytosis is present. Expectant management is reserved for patients with uncomplicated disease who are not good operative candidates and those in whom the diagnosis is not clear.

Acalculous Cholecystitis

Acalculous cholecystitis is an acute inflammatory condition in patients without gallstones. It accounts for approximately 5% of all cases of acute cholecystitis and carries higher morbidity and mortality rates than acute calculous cholecystitis. Acalculous cholecystitis is classically associated with the triad of prolonged fasting, immobility, and hemodynamic instability; such as may occur in critically ill patients, especially if they have required total parenteral nutrition or blood transfusions. Gallbladder ischemia and stasis are considered important in the pathogenesis. It is also seen in patients with AIDS, often in association with cytomegalovirus or *Cryptosporidia* infection. Abdominal pain, fever, and leukocytosis in a patient with the classic triad along with ultrasonographic features of a thickened gallbladder wall and a positive Murphy's sign in the absence of gallstones raises suspicion for this entity. As in acute cholecystitis, the gallbladder is not visualized on HIDA scanning. Management includes administration of antibiotics and cholecystectomy. If the patient is seriously ill, the gallbladder can be drained percutaneously as a temporizing measure.

Chronic Cholecystitis

Chronic cholecystitis is a term used by pathologists to describe chronic inflammatory cell infiltration of the gallbladder on histopathology. Chronic cholecystitis is thought to be an evolving inflammatory process, caused by repeated episodes of low-grade gallbladder obstruction over a period of days to years resulting in recurrent mucosal trauma and inflammation. The symptoms are those of biliary colic without clinical features of acute cholecystitis. Gallstones are the causative agent in most patients. However, there is little correlation between the number of gallstones and the degree of gallbladder wall inflammation. In approximately 12% of patients with chronic cholecystitis, there are no demonstrable stones. The diagnosis is made in a patient with gallstones who has the clinical signs and symptoms with no other obvious cause. Transabdominal ultrasound is the best initial test, and EUS may be used to demonstrate microlithiasis (gallstones ≤ 3 mm) if gallstones are not seen on initial imaging. The treatment is laparoscopic cholecystectomy, but conversion to open cholecystectomy is required in up to 5% of cases.

Gallbladder Polyps

Gallbladder polyps are outgrowths of the gallbladder mucosal wall that are seen in up to 5% of normal subjects undergoing gallbladder ultrasonography. Most of these lesions are not neoplastic but are hyperplastic or represent lipid deposits (cholesterolosis). The differential diagnosis includes cholesterol polyps, adenomyomatosis, inflammatory polyps, adenomas, and gallbladder cancer. Factors associated with increased risk of malignancy include size greater than 1 cm, presence of gallstones, age greater than 60 years, and increased size on subsequent imaging. Cholecystectomy is indicated if one or more of these

risk factors are present or if the patient has biliary symptoms. Polyps that are smaller than 1 cm should be monitored with periodic ultrasound examination.

Gallbladder Carcinoma

Gallbladder carcinoma is relatively uncommon but has a high case fatality rate. The incidence and mortality are higher in Latin American countries (e.g., Chile) and in Southeast Asia. Carcinoma of the gallbladder often produces advanced disseminated disease with weight loss, jaundice, pruritus, and a large right upper quadrant mass. Symptoms may resemble those of acute or chronic cholecystitis, particularly if the tumor is small. Risk factors include gallbladder polyps, porcelain gallbladder, choledochal cysts, gallstones, and anomalous pancreaticobiliary junction. Although early-stage tumors can be treated surgically, most cases are diagnosed at an advanced stage and are incurable.

Gallbladder Dyskinesia

A disorder caused by abnormal motility or contraction of the gallbladder in the absence of gallstones resulting in symptoms of biliary colic. Laboratory studies and abdominal imaging findings are usually normal. HIDA scanning may show a decreased gallbladder ejection fraction, or there may be reproducible pain with administration of cholecystokinin (CCK). Cholecystectomy commonly shows acalculous cholecystitis.

BILIARY TRACT DISORDERS

Choledocholithiasis

In Western countries, most stones found in the common bile duct (choledocholithiasis) originate in the gallbladder. Up to 15% of individuals with cholelithiasis develop choledocholithiasis (Fig. 44-4). Less commonly, stones may form *de novo* in the biliary tree. Common bile duct stones may be asymptomatic (30% to 40%), or they may produce biliary colic and jaundice. Two major complications are acute cholangitis and acute

FIGURE 44-4 Cholangiogram obtained on endoscopic retrograde cholangiopancreatography demonstrates a common bile duct stone.

pancreatitis. The diagnosis is supported by the results of liver function tests and abdominal imaging. Transabdominal ultrasound is the initial imaging modality of choice; it has a sensitivity of 20% to 90% for detection of a stone and 55% to 90% for detection of dilation of the common bile duct. EUS and MRCP have replaced ERCP for diagnosis of bile duct stones; the sensitivity and specificity are 94% and 95%, respectively, for EUS and 93% and 94% for MRCP. ERCP is reserved for therapeutic interventions.

Acute Cholangitis

Acute (suppurative) cholangitis is a life-threatening infection of the biliary tract that occurs as a result of choledocholithiasis. The classic clinical manifestations are abdominal pain, jaundice, and fever (Charcot's triad). Clinical findings may be absent or atypical in elderly or immunosuppressed patients. Cholangitis is a medical-surgical emergency that can lead rapidly to sepsis, shock, and death. Diagnosis is based on a compatible clinical and laboratory picture (abnormal liver function test results and leukocytosis) together with radiologic or endoscopic evidence of common bile duct stones.

Treatment of acute cholangitis includes administration of broad-spectrum antibiotics and prompt removal of stones, typically with ERCP and sphincterotomy (Video 44-2). Cholecystectomy is subsequently performed after the patient has been stabilized.

Gallstone Pancreatitis

Biochemical evidence of pancreatic inflammation complicates choledocholithiasis and acute cholecystitis in up to 30% and 15% of patients, respectively. There are two proposed mechanisms by which gallstones may induce pancreatitis: reflux of bile into the pancreatic duct due to transient obstruction of the ampulla and obstruction at the ampulla secondary to stones or edema. Considering that gallstone pancreatitis recurs in 25% of patients, a cholecystectomy should be performed once the patient has recovered clinically from an attack of pancreatitis. If the patient remains jaundiced during an attack, suggesting the presence of a stone in the bile duct, an ERCP with sphincterotomy is performed to extract the stone.

Biliary Neoplasms

Cholangiocarcinoma and cancer of the ampulla of Vater are uncommon in the United States. Cholangiocarcinoma can arise at any level of the biliary system. It is more common in older men, occurring predominantly in men 50 to 70 years of age. Risk factors include primary sclerosing cholangitis (PSC), choledochal cysts, chronic ulcerative colitis, liver flukes, and recurrent pyogenic cholangitis (Oriental cholangiohepatitis). Patients with these cancers usually have unremitting painless jaundice, although necrosis and sloughing of the tumor can cause intermittent biliary obstruction and the appearance of occult fecal blood. Cholangiocarcinoma located at the bifurcation of the extrahepatic bile duct (50% of cases) is known as a *Klatskin tumor* (Fig. 44-5). Surgical cure is possible in only a small proportion of patients with cholangiocarcinoma. If the tumor is unresectable, palliative biliary drainage is undertaken.

FIGURE 44-5 Cholangiogram obtained on endoscopic retrograde cholangiopancreatography demonstrates a Klatskin tumor at the bile duct bifurcation.

Nonmalignant Causes of Biliary Obstruction

Biliary Strictures

Benign biliary strictures usually result from surgical injury or chronic pancreatitis. Biliary strictures resulting from surgical injury may cause symptoms even years after the initial injury. Early diagnosis is important because strictures that partially obstruct are clinically asymptomatic and can cause secondary biliary cirrhosis. Biliary stricture should be suspected in any patient with a history of surgery of the right upper quadrant or chronic pancreatitis who has persistently elevated levels of serum alkaline phosphatase and γ -glutamyl transpeptidase. Endoscopic balloon catheter dilatation with or without stenting or surgical repair is useful in selected patients.

Other Causes of Biliary Obstruction

Structural abnormalities such as choledochal cysts, Caroli's disease (congenital segmental intrahepatic bile duct dilation), and duodenal diverticula may cause bile duct obstruction, often with secondary choledocholithiasis resulting from bile stasis. Hemobilia, with intermittent bile duct obstruction by blood clots, may be caused by hepatic injury, neoplasms, or hepatic artery aneurysms. Biliary parasites should always be considered as a cause of biliary obstruction in the appropriate epidemiologic setting. *Ascaris lumbricoides* is a common cause of cholangitis and jaundice in South America, Africa, and the Indian subcontinent. *Clonorchis sinensis* is the etiologic agent of Oriental cholangiohepatitis in Korea and Southeast Asia and in immigrants to the United States. The liver fluke *Fasciola hepatica* is a leading cause of biliary strictures and cholangitis worldwide, most commonly in the Bolivian Andes.

Primary Sclerosing Cholangitis

PSC is an idiopathic condition of nonmalignant, nonbacterial, chronic inflammatory fibrosis and obliteration of the intrahepatic and extrahepatic bile ducts. It most commonly occurs in young

FIGURE 44-6 Cholangiogram obtained on endoscopic retrograde cholangiopancreatography demonstrates the characteristic beading of the intrahepatic and extrahepatic bile ducts in a patient with primary sclerosing cholangitis.

men (two thirds of patients are younger than 45 years of age), often in association with ulcerative colitis. Approximately 70% of patients with PSC have ulcerative colitis. The clinical spectrum of PSC is broad, ranging from asymptomatic patients with abnormal liver enzyme levels (typically an elevated alkaline phosphatase concentration) to patients with recurring episodes of fever, chills, abdominal pain, and jaundice. The diagnosis of PSC is made by MRCP or ERCP, which show characteristic changes (beading) of the intrahepatic and/or extrahepatic bile duct (Fig. 44-6).

No proven therapy exists for PSC, although ursodeoxycholic acid and methotrexate are being used in some centers. Other forms of therapy include prophylactic antibiotics for prevention of recurrent bacterial cholangitis, treatment of pruritus, and repletion of fat-soluble vitamins. Endoscopic dilatation of a dominant biliary stricture during ERCP is an effective treatment of

cholestasis in selected patients. Most patients with advanced PSC eventually progress to end-stage liver disease, and evaluation for liver transplantation is appropriate in advanced disease. One third of patients with PSC will develop cholangiocarcinoma; therefore, thorough clinical and laboratory studies (liver function tests and cancer markers such as CA 19-9) and radiologic follow-up are warranted.

Sphincter of Oddi Dysfunction

Sphincter of Oddi dysfunction is a benign motility disorder that leads to noncalculous obstruction of the flow of bile or pancreatic juice at the level of the pancreaticobiliary junction. Patients typically have unexplained biliary-type abdominal pain, with or without elevated results on liver function tests and with or without bile duct dilation. In a selected group of patients, endoscopic or surgical sphincterotomy is of value.

For a deeper discussion of this topic, please see Chapter 155, "Diseases of the Gallbladder and Bile Ducts," in Goldman-Cecil Medicine, 25th Edition.

HEMATOPOIESIS

Hematopoiesis is the process of formation and development of blood cells. The constituents of peripheral blood arise by a complex and carefully regulated process of ontogeny. The pluripotent hematopoietic stem cell (HSC) maintains itself by self-renewal and undergoes multilineage differentiation to generate the appropriate numbers and types of cells in the circulating blood compartment (Table 45-1). The hematopoietic system is unique in that it is constantly undergoing this full cycle of maturation by which a primitive cell develops into a variety of highly specialized end-stage cells, all of which have different lifespans and occur in different quantities.

The bone marrow must have the capacity to produce cells to compensate for the normal rapid turnover of hematopoietic cells resulting from senescence, normal use, and migration into tissue spaces. It must have a reserve capacity to produce additional cells in response to unusual demands that arise from bleeding, infection, or other stresses. Understanding the repeated cycle of cellular ontogeny and self-renewal that meets these challenges provides important insights into normal and pathologic mechanisms in hematology.

Hematopoietic Tissues

Hematopoiesis commences in the embryonic yolk sac, in which early erythroblasts in blood islands form the first hemoglobinized cells. After 6 weeks' gestation, the fetal liver begins

producing primitive lymphocytoid cells, megakaryocytes, and erythroblasts, and the spleen becomes a secondary site of erythropoiesis. Hematopoiesis then shifts to its definitive long-term site in the bone marrow, the principal site for lifelong hematopoiesis in the normal host.

Early in life, all fetal bones contain regenerative bone marrow, but the marrow becomes progressively replaced by fat with age. In adults, active marrow resides only in the axial skeleton (i.e., sternum, vertebrae, pelvis, and ribs) and in the proximal ends of the femur and humerus. Consequently, bone marrow samples, which are needed for many hematologic diagnoses, are usually obtained from the iliac crest or sternum. Under pathologic conditions that stress the capacity of the marrow space, as seen in diseases associated with marrow fibrosis (e.g., myeloproliferative diseases) or in severe inherited hemolytic anemia (e.g., thalassemia major), extramedullary hematopoiesis may be reestablished in sites of fetal hematopoiesis, especially the spleen.

Stem Cell Theory of Hematopoiesis

All mature hematopoietic cells are hypothesized to originate from a small population of pluripotent stem cells. Comprising less than 1% of all cells in the bone marrow, these cells bear no distinctive morphologic markings and are best defined by their unique functional properties.

Stem cells have two distinctive characteristics. First, they are highly resilient and productive, capable of continuously replenishing huge numbers of granulocytes, lymphocytes, and erythrocytes throughout life. The demand for a continuous, fluctuating supply of blood cells requires a hematopoietic system capable of producing large numbers of selected cells in a short time. For example, overwhelming infection by invading microorganisms triggers the release of neutrophils, whereas hypoxia or acute blood loss leads to increased red blood cell production. Second, HSCs represent a self-renewing cell population that is able to maintain its numbers while providing a continued supply of progenitor cells of many different lineages.

Despite their vast proliferative potential, under normal conditions, most HSCs are quiescent, and few cells undergo expansion or differentiation at any one time. However, their ability to proliferate is striking. Studies with lethally irradiated mice have demonstrated the ability of a few transplanted cells (i.e., spleen colony-forming unit [CFU-S] cells) to regenerate multilineage hematopoiesis.

The signals regulating the differentiation of pluripotent stem cells into committed progenitors are unknown. Data suggest that the first step in lineage commitment is a stochastic (chance)

TABLE 45-1 NORMAL VALUES FOR PERIPHERAL BLOOD CELLS

CELL TYPE AND SIZE	MEAN	RANGE
Hemoglobin	Women: 14 g/dL Men: 15.5 g/dL	Women: 12-16 g/dL Men: 13.5-17.5 g/dL
Hematocrit	Women: 41% Men: 47%	Women: 36-46% Men: 41-53%
Reticulocyte count	60,000/ μ L (1%)	35,000-85,000/ μ L (0.5-1.5%)
Mean corpuscular volume		80-100 fL
Platelet count	250,000/ μ L	150,000-400,000/ μ L
Total white blood cell count	7400/ μ L	4500-11,000/ μ L
Neutrophils	4400/ μ L (40-60%)	1800-7700/ μ L
Lymphocytes	2500/ μ L (20-40%)	1000-4800/ μ L
Monocytes	300/ μ L (<5%)	200-950 (4-11%)

event; subsequent stages of maturation are hypothesized to occur under the influence of growth factors, or cytokines (Table 45-2). Cytokines act on different cells through specific cytokine receptors. Receptor activation induces signal-transduction pathways that lead to changes in gene transcription and eventual cell proliferation and differentiation. These growth factors also act as survival factors for the developing hematopoietic cells by preventing *apoptosis* (i.e., programmed cell death). This process occurs in the cellular milieu of the bone marrow, where hematopoiesis depends in part on the nonhematopoietic cells (i.e., fibroblasts, endothelial cells, osteoblasts, and fat cells) that make up that microenvironment. Research in HSC biology has focused on how the cells are regulated by growth factors in the bone marrow microenvironment and by unique cell surface ligand interactions between stem cells and the surrounding stromal cells in well-defined sites called *stem cell niches*.

Hematopoietic Differentiation Pathway

Hematopoiesis has been hypothesized to proceed along a tightly regulated hierarchy (Fig. 45-1) governed by effects of intrinsic transcription factors and cytokines in the bone marrow microenvironment. As more primitive cells mature under the influence of specific regulatory cytokines, they undergo several cell divisions and become *progenitor cells* committed to one lineage. They also lose their self-renewal capacity. Morphologically, these cells are transformed from nonspecific blastlike cells into cells that can be identified by their color, shape, and granular and nuclear content. Functionally, they acquire distinguishing cell surface receptors and responses to specific signals.

Maturing granulocytes and erythroid cells undergo several more cell divisions in the bone marrow, whereas lymphocytes travel to the thymus and lymph nodes for further development. Megakaryocytes cease cellular division but continue with nuclear replication. Eventually, these cells are released from the marrow as fully functional erythrocytes, mast cells, granulocytes, monocytes, eosinophils, macrophages, and platelets.

Pluripotent Stem Cells

The pluripotent HSC is morphologically indistinguishable and is best identified by its expression of the cell differentiation antigen, CD34, and by its ability to form pluripotent colonies in vitro. Under the influence of interleukin-1 (IL-1), IL-3, IL-6, FMS-like tyrosine kinase 3 (FLT3), and a specific stem cell factor (KIT ligand [KITLG], or steel factor), this cell matures into a myeloid-lineage stem cell (i.e., granulocyte-erythrocyte-macrophage-megakaryocyte colony-forming unit [CFU-GEMM] cell)

FIGURE 45-1 Development of bone marrow cells. Ba, Basophil; BFU, blast-forming unit; CFU, colony-forming unit; E, erythroid; Eo, eosinophil; G, granulocyte; GEMM, granulocyte-erythrocyte-macrophage-megakaryocyte; GM, granulocyte-macrophage; Meg, megakaryocyte; NK, natural killer.

TABLE 45-2 CYTOKINES AND THEIR ACTIVITIES

ACRONYM	NAME	EFFECTS ON HEMATOPOIESIS
EPO	Erythropoietin	Stimulation of proliferation and maturation of erythroid progenitors; produced by the kidney in response to anemia and hypoxia; important clinically for treatment of anemia associated with low EPO levels (e.g., renal failure, anemia of chronic disease)
G-CSF	Granulocyte colony-stimulating factor	Stimulation of proliferation and maturation of granulocytes; more broad-based effect because also increases release of stem cells in peripheral blood; clinically important for treatment of neutropenia and mobilization of stem cells for transplantation
GM-CSF	Granulocyte-monocyte colony-stimulating factor	Proliferation of granulocyte and monocyte precursors; role unclear in steady-state hematopoiesis because knockout has no hematopoietic phenotype
TPO	Thrombopoietin	Proliferation of megakaryocytes; results disappointing in clinical studies
M-CSF	Monocyte colony-stimulating factor	Proliferation of monocytes
IL-2	Interleukin-2	Proliferation of T cells
IL-3	Interleukin-3 (multi-colony-stimulating factor)	Proliferation of granulocytes, monocytes; broad-based effects, appearing to increase the proliferation of stem cells; not in use clinically
IL-4	Interleukin-4	Proliferation of B cells
IL-5	Interleukin-5	Proliferation of T cells, B cells; proliferation and differentiation of eosinophils
IL-11	Interleukin-11	Proliferation of megakaryocytes; undergoing clinical testing
LIF	Leukemia inhibitory factor	Proliferation of stem cells and megakaryocytes
SCF	Stem cell factor (kit ligand)	Proliferation of progenitor cells; broad-based effects on multiple lineages

or a lymphoid-lineage stem cell. In the presence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3, the myeloid stem cell further differentiates into daughter cells of its named lineages (see Fig. 45-1). The lymphopoietic stem cell becomes a pre-B cell or a prothymocyte (pre-T cell) and leaves the marrow for further maturation.

Erythroid Lineage

Primitive erythroid precursors arising from the myeloid stem cell are called burst-forming unit–erythroid cells. These cells then differentiate into erythroid colony-forming unit (CFU-E) cells, which are the committed progenitor cells of erythrocytes. CFU-E cells express receptors for erythropoietin (EPO), an 18-kD molecule produced by renal interstitial cells in response to low oxygenation states or anemia. EPO upregulates proliferation of CFU-E cells and promotes their maturation into proerythroblasts and reticulocytes, which begin to synthesize hemoglobin (see Table 45-2).

Granulocyte and Monocyte Lineages

Human GM-CSF acts early in the hematopoietic pathway to regulate maturation of the CFU-GEMM stem cell. Differentiation of this myeloid precursor into specific committed progenitors occurs under the direction of granulocyte CSF (G-CSF) and monocyte CSF (see Table 45-2). Granulocyte CFU cells undergo sequential transformation into easily recognizable myeloblasts, myelocytes, and eventually early polymorphonuclear neutrophils with their characteristic polysegmented nuclei. Monocyte CFU cells, in contrast, retain a single nucleus as they mature from monoblasts to promonocytes to monocytes and sometimes to macrophages.

Other Lineages

Eosinophils and basophils develop from CFU-GEMM cells under the influence of IL-5 and IL-3 plus IL-4, respectively. The acquisition of their specific granular contents helps in distinguishing their precursors from those of early monocytes.

The development of platelets is morphologically distinct from the other lineages. CFU-GEMM cells differentiate into megakaryocyte CFU cells, so named because the cells cease cell division early but not nuclear replication. Megakaryocytes are the only cells in the body with the capacity to double their DNA content (i.e., endomitosis). Over the course of several cell cycles, the maturing megakaryocyte eventually acquires several times the nuclear content of other cells in preparation for its eventual dissolution into platelets with a fraction of the cytoplasm of other hematopoietic cells. Two growth factors, thrombopoietin (TPO) and IL-11, increase platelet counts by promoting megakaryocyte development (see Table 45-2).

Stem Cell Plasticity

Provocative data have challenged the conventional paradigm of hierarchical HSC differentiation. Experts have proposed that HSCs dedifferentiate into more immature progenitors and can cross lineages and transdifferentiate into nonlymphohematopoietic cells such as myocytes, hepatocytes, gastrointestinal epithelial cells, and neurons.

Whether this plasticity of HSCs is an intrinsic property of adult stem cells or is caused by contaminating cells of other

populations, fusion of hematopoietic cells with other tissue cells, or artifacts introduced by ex vivo stem cell isolation techniques remains controversial. Nevertheless, the suggestion that adult HSCs may be a dynamic, renewable resource for tissue repair and regeneration holds great promise.

PRIMARY HEMATOPOIETIC FAILURE SYNDROMES

Diseases of the HSC that disrupt the normal regulated pattern of stem cell development can result in underproduction of mature progeny (i.e., aplastic anemia), overproduction of mature progeny (i.e., myeloproliferative disease), or failed differentiation with the production of excess immature forms (i.e., myelodysplasia and acute leukemia). *Hematopoietic failure*, defined as the inability of HSCs to produce normal numbers of mature blood cells, manifests clinically as peripheral pancytopenia (i.e., decreased production of all blood cell lineages).

Although marrow dysfunction producing pancytopenia can result from several hematologic and nonhematologic causes (Table 45-3), primary bone marrow failure disorders are characterized by a profound impairment of the ability of the HSC to replenish the stem cell pool. Rarely, marrow failure syndromes result from intrinsic HSC defects. In most cases, these disorders are the result of extrinsic damage to normal HSCs. The most common treatment modalities for primary hematopoietic failure disorders are exogenous growth factor administration and stem cell transplantation.

Growth Factors in Clinical Use

Discovery of the factors that influence normal hematopoiesis led to important therapeutic applications for patients with defects in hematopoietic cell production. The finding that committed hematopoietic cells of each lineage can be stimulated to proliferate and differentiate by specific cytokines (see Table 45-2) has been clinically useful.

Advances in DNA technology led to the synthesis and purification of recombinant human (rh) proteins with similar biologic activity in vivo. Administration of these products to patients enabled successful manipulation of mature cells in the peripheral

TABLE 45-3 DIFFERENTIAL DIAGNOSIS OF PANCYTOPENIA

Primary bone marrow disorders

- Aplastic anemia
- Congenital aplastic anemia syndromes
- Fanconi's anemia
- Shwachman-Diamond syndrome
- Congenital dyskeratosis
- Acquired aplastic anemia
- Hypocellular myelodysplastic syndrome
- Myelofibrosis
- Paroxysmal nocturnal hemoglobinuria
- Acute leukemias: acute lymphocytic leukemia, acute myeloid leukemia
- Hairy cell leukemia

Systemic diseases with secondary bone marrow effects

- Metastatic solid tumor to marrow
- Autoimmune disorders: systemic lupus erythematosus, Sjögren's syndrome
- Nutritional deficiencies: vitamin B₁₂, folate, alcoholism
- Infections: overwhelming sepsis from any cause, viruses, brucellosis, ehrlichiosis (mycobacteria)
- Storage diseases: Gaucher's disease, Niemann-Pick disease
- Anatomic defects: hypersplenism

blood. For example, exogenous EPO has become a mainstay in the management of anemia caused by renal failure, chemotherapy, and marrow failure syndromes. The use of G-CSF or GM-CSF in patients with febrile neutropenia and documented infection or sepsis after chemotherapy or radiation therapy has reduced hospital stays and shortened the period of high infection risk. Administration of GM-CSF is thought to improve host immune responses to fungal infections. High-dose G-CSF also is routinely used to mobilize CD34+ marrow stem cells into the peripheral blood for collection before and after stem cell transplantation in patients with delayed stem cell engraftment (discussed later).

Early trials of TPO growth factors to stimulate platelet production were halted because of development of antihuman TPO antibodies in some patients, leading to severe thrombocytopenia. Second-generation thrombopoietic agents bearing no structural resemblance to TPO but designed to bind and activate the TPO receptor are in clinical use. Romiplostim, a recombinant Fc-peptide fusion protein (i.e., peptibody) given as a weekly subcutaneous injection, can increase platelet counts, decrease platelet transfusion requirements, and improve quality of life for patients with refractory chronic immune-mediated thrombocytopenia. Eltrombopag is an orally available, small, organic TPO agonist that increases platelet counts and decreases bleeding in similar patients. The application of TPO agonists for management of thrombocytopenia in other marrow failure syndromes is being investigated.

Hematopoietic Stem Cell Transplantation

Types of Transplantations

Improved understanding of HSC biology has fostered the development of techniques to manipulate these cells for therapeutic purposes. The antitumor effects of most chemotherapeutic drugs and radiation therapy are dose dependent, and both cause the major dose-limiting toxicity of myelosuppression.

Before HSC transplantation, intense myeloablative doses of chemotherapy and total body irradiation are administered to eradicate malignant cells. Stem cells from a donor or the same patient are then infused to replete the ablated marrow. Although historically used in the treatment of primary stem cell disorders such as leukemia, the therapeutic potential of transplantation is also employed for patients with nonmalignant hematologic malignancies (e.g., aplastic anemia, sickle cell anemia, congenital immunodeficiencies), solid tumors (e.g., renal cell carcinoma, melanoma), and nonmalignant autoimmune diseases (e.g., amyloidosis, systemic lupus). Younger patients (<50 years) are considered the best candidates for this intensive therapy, although this is changing in the setting of newer supportive modalities.

Several modes of stem cell transplantation have been developed. In *autologous transplantation*, the patient's bone marrow or peripheral blood stem cells (PBSCs) are collected during remission after high-dose chemotherapy or G-CSF administration. These cells are cryopreserved, thawed, and reinfused. This approach incurs a higher risk of relapse as a result of reinfusion of a stem cell product that may remain contaminated with tumor cells.

In *allogeneic stem cell transplantation*, abnormally functioning hematopoietic bone marrow is eradicated and is replaced with

normal bone marrow or stem cells from a compatible source (i.e., related or unrelated donor). High-dose chemotherapy with or without total body irradiation is used to destroy the patient's bone marrow, followed by infusion of new stem cells that engraft and restore normal hematopoiesis. Treatment-related morbidity is significant, and the procedure has a mortality rate of 10% to 30%. However, improvements in supportive care and immunomodulatory therapy designed to suppress graft-versus-host disease (GVHD), an autoimmune phenomenon in which intact lymphocytes in the transplanted marrow attack the host tissues, are continuing to improve outcome.

Donor and patient are tested for compatibility of human leukocyte antigen (HLA) and major histocompatibility complex (MHC) proteins expressed on all cells. Three major HLA class I antigens (i.e., A, B, and C) and three MHC class II antigens (i.e., DP, DQ, and DR) have been developed. The six HLA gene loci are tightly linked on chromosome 6 and are almost always inherited on a single cluster of genes, or *haplotype*. All children are a half-match (i.e., haploidentical) to each of their parents, and full siblings have a 25% probability of being HLA identical to one another. HLA-matched, nonrelated transplants have higher rates of GVHD than transplants from HLA-matched, related donors as a result of other minor HLA incompatibilities. Patients who receive an HLA-mismatched stem cell transplantation risk acute GVHD, marrow rejection, and fatal marrow aplasia. Morbidity and mortality rates associated with non-HLA-compatible transplants can be prohibitive.

Evidence indicates that the excellent response of some patients to HSC transplantation is partly related to the active suppression of the patient's original (residual) or relapsing disease by cells from the newly transplanted donor graft, referred to as the *graft-versus-leukemia effect*. Studies have documented that infusion of donor lymphocytes can restore remission in patients with evidence of relapse after allogeneic transplantation for chronic myelogenous leukemia. Conversely, procedures that minimize the reactivity between donor and host increase disease relapse. For example, there is an increased rate of relapse among patients who undergo syngeneic (identical twin) stem cell transplantation and patients who receive T-cell-depleted marrow in an attempt to reduce GVHD.

The observed effectiveness of donor lymphocyte infusions in controlling chronic myelogenous leukemia led to the conclusion that the immunologic effects of transplanted allogeneic cells might be as important as or more important than cytoreduction for the cure of some hematologic malignancies. To exploit these effects, nonmyeloablative stem cell transplantations are performed. Patients receive conditioning and immunosuppressive regimens in doses sufficient to permit donor stem cell engraftment without aggressive cytoreduction. These mini-transplantations result in chimeric marrows (i.e., part patient and part donor) without significant periods of cytopenias or hematopoietic compromise, although most responding patients convert to a fully donor-derived marrow over time. Although still experimental, these procedures are increasingly being used in patients who are otherwise ineligible for traditional myeloablative transplantation regimens (i.e., age greater than 50 to 55 years, other comorbidities) or in individuals with nonmalignant autoimmune or congenital disorders.

Hematopoietic Stem Cell Sources for Transplantation

Historically, stem cell transplantations have employed allogeneic bone marrow stem cells aspirated from the posterior iliac crest of the donor and intravenously infused into the patient after myeloablation and immunosuppressive therapy. The process of engraftment or reconstitution of normal hematopoietic function takes several weeks. Patients often require almost daily platelet and red blood cell transfusions, and they are hospitalized during this period of prolonged neutropenia to minimize life-threatening bacterial, viral, and fungal infections. Other complications include severe mucositis, hemorrhagic cystitis, GVHD, relapsed disease, and graft failure.

The discovery that high-dose G-CSF treatment mobilizes large numbers of CD34+ hematopoietic progenitor and stem cells from bone marrow sites into circulating blood (i.e., 10-fold to 15-fold increase over baseline levels) led to the use of PBSCs collected by apheresis procedures in place of bone marrow stem cells for allogeneic transplantation. Compared with marrow-derived stem cells, PBSCs engraft more rapidly after myeloablation. Patients receiving allogeneic PBSC transplants have decreased neutrophil recovery time, lower transfusion requirements, fewer inpatient hospital days, and similar rates of acute GVHD and long-term survival outcomes as traditional marrow-transplanted patients. Because PBSC collections often contain threefold to fourfold more CD34+ stem cells and 10-fold more lymphoid cells than harvested marrow grafts, higher rates of chronic GVHD may occur.

Umbilical cord blood (UCB) stem cells are a rich source of immature CD34+ HSCs. The less stringent HLA-compatibility requirements for UCB HSC matches prompted increasing use of these transplants as a therapy for patients lacking fully compatible HLA-matched PBSCs or bone marrow donors. Although still considered experimental, some transplantation centers have reported long-term outcomes after UCB HSC transplants similar to those for conventional marrow or peripheral PBSC transplants for primary hematologic diseases. However, the relatively limited numbers of CD34+ stem cells found in harvested UCB units accounts for a much slower hematopoietic recovery after the procedure and a statistically higher risk for nonengraftment compared with other stem cell sources. For this reason, UCB transplantation procedures have been limited to pediatric patients and smaller adults or to adult patients for whom there is more than one HLA-compatible UCB unit.

Aplastic Anemia

Definition and Epidemiology

Aplastic anemia (AA) is a rare disorder characterized by pancytopenia with a markedly hypocellular bone marrow. This disease was first described in 1888 by Paul Ehrlich, who observed that autopsy bone marrow specimens from a young woman who died of severe anemia and neutropenia were extremely hypoplastic. Later studies demonstrated that patients with severe AA possessed only a fraction of normal pluripotent stem cell numbers despite normal functional marrow stromal cells and normal or even elevated levels of stimulatory cytokines.

The incidence of AA ranges from 1 to 5 cases per million people in the general population. It occurs predominantly in young adults (20 to 25 years old) and older adults (60 to 65 years old). The incidence is threefold higher in developing countries (e.g., Thailand and China) compared with industrialized Western nations (e.g., Europe and Israel), a fact that is not explained by differences in drug or radiation exposure. A few AA cases occur in the context of a congenital bone marrow failure disorder, such as Fanconi's anemia, Shwachman-Diamond syndrome, and dyskeratosis congenita. The most common congenital AA, Fanconi's anemia, is an autosomal recessive disorder arising from mutations in genes encoding DNA repair proteins.

Pathology

The known causes of acquired AA are numerous (Table 45-4) and range from myeloablative radiation exposure to common viruses and medications. Prior bone marrow toxicity from drugs, chemicals (e.g., benzene, cyclic hydrocarbons found in petroleum products, rubber glue, insecticides, chemical dyes), or radiation predisposes to AA because these agents directly injure proliferating and differentiating HSCs by inducing DNA damage. In contrast, cytotoxic chemotherapy (especially with alkylating agents) and radiation therapy target all rapidly cycling cells and often induce reversible bone marrow aplasia. Despite the many causes of acquired AA, most cases are idiopathic.

Acquired and congenital AAs appear to be etiologically linked through abnormal telomere maintenance. Telomeres are repeated nucleotide sequences that cap and protect chromosome ends from degradation. Cell division leads to normal telomere erosion; when telomeres reach a critically short length, cells cease to proliferate, senesce, and undergo apoptosis, often with accompanying DNA damage and genomic instability. Telomerase enzyme in normal HSCs preserves long telomeres and promotes quiescence and a prolonged cellular lifespan. Patients with autosomal dominant dyskeratosis congenita have mutations in the genes for telomerase complexes, predisposing to premature aging and enhanced marrow failure in the setting of accelerated telomere shortening. One third of patients with acquired AA also have short telomeres, likely due to a combination of genetic, environmental, and epigenetic factors.

Autoreactive host lymphocytes can destroy normal hematopoiesis in AA. Bone marrow stromal cells and cytokine levels in patients with AA are normal. The fact that AA also occurs in diseases of immune dysregulation and after viral infections

TABLE 45-4 CAUSES OF ACQUIRED APLASTIC ANEMIA

Drugs (dose related): chemotherapeutic agents, antibiotics (chloramphenicol, trimethoprim-sulfamethoxazole)
Idiosyncratic causes (many unproved): chloramphenicol, quinacrine, nonsteroidal anti-inflammatory drugs, anticonvulsants, gold, sulfonamides, cimetidine, penicillamine
Toxins: benzene and other hydrocarbons, insecticides
Viral infection: hepatitis, Epstein-Barr virus, human immunodeficiency virus (HIV)
Immune disease: graft-versus-host disease in immunodeficiency, hypogammaglobulinemia
Paroxysmal nocturnal hemoglobinuria (PNH)
Radiation exposure
Pregnancy

further suggests an immune-mediated mechanism for the disease. One hypothesis is that drug or viral antigens presented to the immune system trigger cytotoxic T-cell responses that persist and destroy normal stem cells. Only 1 in 100,000 patients develops severe AA as an idiosyncratic drug reaction. Whether these individuals have a genetically predisposed sensitivity to common exposures (e.g., nonsteroidal anti-inflammatory drugs, sulfonamides, Epstein-Barr virus) is unknown.

Clinical Presentation

The clinical onset of AA can be insidious or abrupt. Patients often complain of symptoms related to their cytopenias: weakness, fatigue, dyspnea, or palpitations resulting from anemia; gingival bleeding, epistaxis, petechiae, or purpura caused by low platelet counts; or recurrent bacterial infections caused by low or non-functioning neutrophils. Results of the physical examination are often normal except in patients with congenital AA, who may have various abnormalities.

Diagnosis and Differential Diagnosis

Diagnostic confirmation of AA requires bone marrow biopsy to confirm hypocellularity and to rule out other marrow processes. Normal bone marrow cellularity ranges from 30% to 50% up to age 70 years and is less than 20% after 70 years of age (E-Fig. 45-1A). In contrast, bone marrow cellularity in patients with AA usually ranges from 5% to 15%, with increased fat accumulation and few or no hematopoietic cells (primarily plasma cells and lymphocytes) (see E-Fig. 45-1B).

In AA, hematopoietic progenitor and precursor cells are morphologically normal but number less than 1% of normal levels, and they are markedly dysfunctional, with a decreased ability to form differentiated progenitor cell colonies in vitro. Evidence of increased blasts, dysplastic hematopoietic cells (e.g., pseudo-Pelger-Huët abnormalities, micromegakaryocytes) (E-Fig. 45-2), and clonal cytogenetically abnormal cells in the peripheral blood or marrow are diagnostic of acute leukemia or myelodysplasia but not AA, even in the setting of a hypocellular marrow.

In young patients, a diagnosis of Fanconi's anemia is made by demonstrating enhanced sensitivity of cultured cells to mitomycin or diepoxybutane-induced chromosomal damage. Although patients with AA typically have a low reticulocyte count from low red blood cell production and a paucity of blood cells (E-Fig. 45-3A) and macrocytic red cells (see E-Fig. 45-3B) on the peripheral smear, patients with other primary marrow disorders may exhibit similar findings.

Treatment and Prognosis

Treatment of AA is based on the severity of disease. Patients with mild cytopenias can be monitored expectantly. However, patients with severe AA based on peripheral blood cells counts (i.e., neutrophil count $<500/\mu\text{L}$, platelet count $<20,000/\mu\text{L}$, anemia with corrected reticulocyte count $<1\%$, and marrow cellularity of 5% to 10%) have a poor median survival of 2 to 6 months without treatment. Because most of these patients die of overwhelming infections, supportive care with broad-spectrum antibiotics, antifungal agents, and antiviral agents is warranted for those with advanced neutropenia. Red blood cell and platelet transfusions can help patients who are profoundly

symptomatic, along with care given to patients eligible for transplantation.

Current therapeutic approaches to AA focus on replacing the defective HSCs by stem cell transplantation or controlling an overactive immune response. All young patients with severe AA and an HLA-compatible bone marrow donor should be considered for allogeneic bone marrow transplantation, which offers the best chance for definitive cure. Although long-term survival is excellent for patients younger than 30 years transplanted from a sibling donor (75% to 90%), morbidity due to the transplant itself and the management of long-term complications are continuing problems. Outcomes for patients older than 40 years or patients without an HLA-matched related donor are poor.

The presumed immune mechanisms for drug-induced aplasia have encouraged immunosuppressive approaches to the treatment of AA in older patients, in patients who are unable to find a compatible HSC donor, and in those who are otherwise ineligible for stem cell transplantation. Treatment with a combination of antithymocyte globulin (ATG) and cyclosporine (a specific T-cell inhibitor) restores marrow function (i.e., independence from red blood cell or platelet transfusions) in 70% to 80% of patients, and responders have a 5-year survival rate of 90%. Side effects of ATG include anaphylaxis and serum sickness as a result of foreign antigens in the antisera, but these adverse effects usually are self-limited.

Patients often relapse, and recurrence of disease may warrant retreatment with ATG, androgens, and newer immunosuppressive agents. Alemtuzumab, a humanized monoclonal antibody directed against the CD52 protein found on lymphocytes and which has efficacy in other autoimmune diseases, has been as effective as rabbit ATG and cyclosporine in relapsed and refractory severe AA. Eltrombopag, an oral TPO mimetic drug that stimulates platelet production by binding to MPL receptors on megakaryocytes, is an exciting agent for the treatment of severe AA patients. Almost one half of patients treated with eltrombopag exhibited clinically significant responses in all three hematopoietic lineages, with normalization of bone marrow cellularity and trilineage hematopoiesis.

Treatment of AA with traditional chemotherapy such as high-dose cyclophosphamide usually has proved too toxic. Because endogenous cytokine production is usually high in patients with AA, the routine use of growth factors such as G-CSF, EPO, or stem cell factor typically is ineffective. However, in patients with refractory disease, long-term administration of combination cytokines may have some effect in sustaining blood cell counts. Patients who survive initial treatment of AA remain at increased risk for the emergence of other primary hematologic disorders, such as myelodysplasia, leukemia, and paroxysmal nocturnal hemoglobinuria (PNH) for unknown reasons.

Paroxysmal Nocturnal Hemoglobinuria

Definition, Epidemiology, and Pathology

PNH is an uncommon disease characterized by intravascular hemolysis, venous thrombosis, and bone marrow failure. The disease arises from expansion of pluripotent HSCs containing a somatic mutation in the phosphatidylinositol glycan complementation class A (*PIGA*) gene. Loss of *PIGA*, which codes for

E-FIGURE 45-1 Comparison of normal bone marrow (**A**) with empty bone marrow characteristic of aplastic anemia (**B**). Notice the differences in overall marrow cellularity. **A**, In the normal marrow biopsy, the fat-to-cell ratio is 50:50. Myeloid cells and megakaryocytes are positive for periodic acid–Schiff (PAS) stain, whereas hemoglobin-containing erythroid precursors are negative. The myeloid-to-erythroid ratio is 2:1. An iron-laden phagocyte (*upper right*) stains rust-brown. A small fragment of bone trabecular is seen (PAS stain, $\times 100$). **B**, In the aplastic marrow biopsy (i.e., aplastic anemia), the fat-to-cell ratio is 95:5. Trilineage hematopoiesis is virtually absent, but rare lymphocytes remain. An osteocyte is embedded in normally calcified bone trabecular (PAS stain, $\times 100$). (Courtesy Maurice Barcos, MD, PhD, Chief of Hematopathology, Roswell Park Cancer Institute, Buffalo, N.Y.)

E-FIGURE 45-3 Peripheral blood findings in aplastic anemia. **A**, In pancytopenia, the peripheral blood smear shows marked leukopenia. A single lymphocyte with azurophilic cytoplasmic granules is seen. The large granular lymphocytes may cause granulocytopenia through the FAS–FAS ligand apoptotic system (Wright-Giemsa stain, $\times 100$). **B**, In macrocytosis, the peripheral blood smear shows normochromic red cell anisopoikilocytosis and macrocytes (Wright-Giemsa stain, $\times 100$). (Courtesy Maurice Barcos, MD, PhD, Chief of Hematopathology, Roswell Park Cancer Institute, Buffalo, N.Y.)

E-FIGURE 45-2 Pseudo-Pelger-Huët abnormalities.

a membrane lipid moiety (i.e., glycosyl phosphatidylinositol [GPI]), produces abnormal hematopoietic cells deficient in dozens of proteins that are normally attached to the cell surface by the GPI anchor. Disease manifestations of PNH result from lack of the GPI-linked proteins (CD55 and CD59) that usually protect red blood cells and platelets from complement-mediated attack. Loss of CD55 or CD59 leads to increased immune destruction of blood cells.

Blood cells arising from abnormal PNH clones can have complete (type III cells) or partial (type II cells) GPI deficiency. The degree of GPI deficiency is associated with the severity of the clinical symptoms. GPI-deficient cells typically coexist in the marrow with various populations of normal GPI-expressing cells (type I cells). Small numbers of abnormal PNH clones in patients with AA or myelodysplastic syndrome (MDS) suggest significant overlap in the causes of these three diseases. This led to reclassification of PNH as classic PNH disease and PNH in the setting of another specified bone marrow disorder. Suppression of normal hematopoiesis by the host immune system directly or indirectly by a preceding or coexistent disorder appears to provide a marrow environment favoring selective expansion of PNH stem cell clones and their deficient blood cell progeny over normal hematopoiesis.

Clinical Presentation

Patients are typically younger individuals with chronic complaints of abdominal pain, dysphagia, erectile dysfunction, and intense lethargy due to smooth muscle dystonia resulting from depletion of circulating nitric oxide levels by free hemoglobin. Acute exacerbations may occur intermittently or frequently and are difficult to manage.

Diagnosis and Differential Diagnosis

The diagnosis of PNH is made by identification of complete or partial GPI protein deficiency on red cells and granulocytes, which usually is determined by the loss of CD59, CD55, CD16, or CD24 expression in a clonal population. Laboratory tests reveal ongoing, low-grade intravascular hemolysis with increased lactate dehydrogenase levels correlating with severity of hemolysis and symptoms. Cytopenias, particularly anemia, often render patients transfusion dependent with ongoing hemoglobinuria due to the release of free plasma hemoglobin from intracellular compartments. About 15% of PNH patients have spontaneous resolution of disease without long-term sequelae, suggesting that *PIGA* mutations may appear transiently and disappear spontaneously in normal hematopoietic cell populations for unknown reasons.

Treatment

Treatment of PNH ranges from supportive care with transfusions and iron and folic acid supplementation to allogeneic stem cell transplantation in selected patients for curative intent. Documented venous thrombosis is treated with lifelong full anticoagulation.

Eculizumab is a humanized monoclonal antibody that binds with high affinity to the complement protein C5, preventing terminal complement-mediated intravascular hemolysis in PNH patients. Eculizumab therapy decreases hemolysis and

hemoglobinuria, reduces requirements for red blood cell transfusions, improves chronic renal failure, and is associated with significant improvement in quality of life and survival for PNH patients. The incidence of life-threatening thrombotic events is decreased by more than 80%, likely contributing to the significant improvement in overall survival. Although this agent is associated with a theoretical increased risk for meningococcal infections due to complement-mediated blockade, the long-term safety and efficacy of sustained eculizumab therapy administered for more than 5 years appear to outweigh the potential risks of prolonged treatment.

Prognosis

Despite advances in treatment and adequate anticoagulation, PNH remains a life-threatening disease. Venous thrombosis involving the cerebral and intra-abdominal veins occurs in about one half of patients and is the cause of death for up to one third, although the cause of the increased thrombotic risk is not entirely understood. Other causes of morbidity and mortality are side effects of progressive AA and a 5% long-term risk for leukemic transformation. Historically, the median survival from diagnosis is 10 to 15 years, with one third of patients dying within 5 years of the diagnosis. Whether long-term eculizumab therapy can change the natural history of disease is unknown and is the goal of an international registry of PNH patients.

Myelodysplastic Syndrome

Definition and Epidemiology

MDS is a heterogeneous group of blood disorders characterized by ineffective and disordered hematopoiesis in one or more of the major myeloid cell lines: erythroid cells, neutrophils and their precursors, and megakaryocytes. Patients have one or more cytopenias despite normal or increased numbers of hematopoietic cells in the bone marrow. Disordered maturation is accompanied by increased intramedullary apoptosis, which contributes to the decreased release of mature cells into the periphery.

Primary MDS is predominantly a disease of elderly persons and occurs in about 1 of 500 patients between the ages of 60 and 75 years. Most cases are idiopathic. Although often considered a preleukemic disease, the overall risk of MDS transformation to acute myeloid leukemia (AML) is only 25% to 30%. However, identification of characteristic gene deletions (5q-) and translocations diagnostic of MDS and AML subtypes (see [Chapter 46](#)) underlines the likelihood of similar mechanisms of clonal myeloid stem cell injury in both disorders.

Pathology

Persons with prior exposure to radiation therapy, chemotherapy, and organic chemicals (e.g., benzene) are at increased risk for secondary MDS. This disorder may occur at any age and comprises 10% to 15% of all diagnosed MDS cases. MDS arising months to years after prior chemotherapy (involving any cytotoxic agent but particularly alkylating agents and anthracyclines), ionizing radiation, radiolabeled antibody therapy, or stem cell transplantation for cancer is called *therapy-related MDS*. Because therapy-related MDS typically evolves swiftly to more

aggressive disease, these cases have been reclassified with therapy-related AML and treated accordingly (see Chapter 46).

Clinical Presentation

Most patients with MDS are referred for evaluation of an incidental finding of peripheral cytopenias. Symptomatic patients usually exhibit findings related to the secondary effects of cytopenias: bleeding and bruising caused by thrombocytopenia, infection caused by leukopenia, or fatigue and dyspnea related to anemia. Physical examination is usually unremarkable, although 25% or more of patients may have splenomegaly. In some patients with MDS, development of skin lesions with fever (i.e., acute febrile neutrophilic dermatosis [Sweet's syndrome]) may herald the transformation of MDS into acute leukemia.

The disease course of MDS varies widely. Some patients may live normal lifespans, but most die prematurely of cytopenia-related complications, marrow failure, or evolution to AML. Median survival is usually less than 2 years.

Diagnosis and Differential Diagnosis

Dysplasia of myeloid hematopoietic cells is evident in the blood and marrow of MDS patients. Review of the peripheral blood smear may show characteristic morphologic abnormalities in addition to cytopenias. Erythroid cells are usually macrocytic, often with basophilic stippling. Neutrophils are often hypogranular and hypolobulated, with a characteristic bilobed nuclear morphology called *pseudo-Pelger-Huët abnormality*. This anomaly should be anticipated when automated differential cell counts report unusually large numbers of bands.

The bone marrow in MDS is usually normocellular or hypercellular, although 10% of patients may have a hypocellular marrow. Dysplastic changes usually occur in all three cell lines. Erythroid cells appear megaloblastic, with multinucleated cells or asynchronous nuclear-cytoplasmic development. Extremely small micromegakaryocytes and agranular megakaryocytes also may be seen. The myeloid series shows poor maturation with a left shift to earlier hypogranulated myeloid forms. Although elevated numbers of myeloid blasts are common, increasing blast numbers indicate progression to acute leukemia. Electron microscopy of the marrow shows cellular changes (i.e., prominent nuclear chromatin, cytoplasmic vacuoles, and blebs) characteristic of increased apoptosis (see E-Fig. 45-4).

The natural history and treatment of some MDS subtypes correlate with specific cytogenetic abnormalities, and careful molecular studies of the marrow should be performed during the initial evaluation. For example, MDS cases associated with deletion of the short arm of chromosome 7 (7p-) or complex cytogenetic abnormalities such as monosomy 7 or trisomy 8 often have poor clinical outcomes. MDS with an isolated deletion in the long arm of chromosome 5 (i.e., 5q- syndrome) can have a well-characterized clinical course. Patients are predominantly older women with a refractory macrocytic anemia, normal or elevated platelet counts, and an overall better clinical prognosis. These patients often live for several years with intermittent red blood cell transfusions and have a low risk of leukemic transformation. Multiple or complex cytogenetic aberrations carry a worse prognosis.

Although one third to one half of patients with cytopenia and myeloid dysplasia have diagnostic clonal cytogenetic abnormalities in marrow cells, the marrow karyotype is normal in many cases. For these patients, the diagnosis of MDS should be one of exclusion after other potential causes of marrow failure and pancytopenia have been evaluated (see Table 45-3). MDS should never be diagnosed in acute disease states, during chronic hospitalization, or within 6 months of known myelotoxic therapy (e.g., irradiation, chemotherapy). Causes such as vitamin B₁₂ or folate deficiency, alcohol use, and human immunodeficiency virus (HIV) infection should be considered. A patient with possible MDS and hypocellular bone marrow must be evaluated for AA. Consistent cytopenia in one or more myeloid lineages, no other obvious causes, and dysplasia of at least 10% of myeloid marrow cells or 5% to 19% of blast cells should be considered MDS.

In the past, MDS was classified based on dysplastic marrow morphology and percentage of blasts as one of five subtypes: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEBT), and chronic myelomonocytic leukemia (CMML). Later, these five subtypes were expanded to eight subtypes, with recognition of multilineage dysplasia as an important feature (e.g., refractory cytopenia with multilineage dysplasia, refractory cytopenia with multilineage dysplasia and ringed sideroblasts) and the reclassification of CMML as myeloproliferative-myelodysplastic syndrome (Table 45-5). MDS with an isolated 5q- cytogenetic abnormality was established as a distinct clinical syndrome. Evidence of marrow dysplasia after prior chemotherapy, radiation therapy, or other myeloablative therapy is considered therapy-related AML. Although MDS patients with refractory anemia and excess blasts or refractory cytopenias with multilineage dysplasia usually fare poorly, morphologic classification of MDS correlates only approximately with overall survival.

Treatment

Insights into the pathophysiology of ineffective hematopoiesis characterizing MDS has led to several therapeutic options for this disease. Individualized therapy is based on the patient's preference, performance status, disease biology, and prognostic risk category.

Transfusions and Growth Factors

Most patients with MDS are elderly individuals who may not tolerate or desire aggressive intervention without hope of cure. Asymptomatic individuals who have disease at low risk for disease transformation or progression and are transfusion independent are typically observed expectantly. Those with symptomatic anemia and thrombocytopenia can often be treated supportively with chronic red blood cell and platelet transfusions to maintain quality of life.

One complication of chronic transfusion therapy is iron overload caused by the delivery of between 200 and 250 mg of iron with each unit of transfused red blood cells. Excess iron is stored in macrophages and eventually accumulates in the hepatic parenchyma, myocardium, skin, and the pancreas, leading to secondary hemochromatosis or transfusional iron overload. Clinical symptoms include liver dysfunction, heart failure, hyperpigmentation,

E-FIGURE 45-4 **A**, Marrow biopsy section for del(5q)-associated myelodysplastic syndrome (MDS) shows numerous hypolobulated and dysplastic megakaryocytes, moderate granulopoiesis and erythropoiesis, and hemosiderin-laden macrophages (periodic acid–Schiff stain, $\times 100$). **B**, Corresponding marrow smear shows trilineage dysplasia, including hypogranular myelocytes and band granulocytes, disorderly erythropoiesis with an increase in megablastoid pronormoblasts with a binucleate form, and a hypolobated megakaryocyte with an immature nucleus showing semidispersed chromatin and ample cytoplasm with deficient platelet formation (Wright-Giemsa stain, $\times 250$). **C**, Marrow smear from another case of MDS. Dysplastic granulopoiesis with hypogranular myelocytes shows immature nuclei with visible nucleoli, giant metamyelocytes, pseudo-Pelger-Huët neutrophils with typical pince-nez bi-segmented nuclei, and a neutrophil with quadri-segmented, jagged-edge nuclei. An early lobated megakaryocyte with dense chromatin and scant cytoplasm with early giant platelet formation is also seen (Wright-Giemsa stain, $\times 250$). (Courtesy Maurice Barcos, MD, PhD, Chief of Hematopathology, Roswell Park Cancer Institute, Buffalo, N.Y.)

and diabetes mellitus. To prevent these symptoms, patients who develop marked elevations in transferrin saturation or serum ferritin levels should undergo iron chelation therapy with deferoxamine or an oral agent (e.g., deferiprone).

Chronic administration of recombinant EPO reduces the transfusion needs of some MDS patients, particularly those with low endogenous serum EPO levels and few transfusion requirements. Individuals with recurrent or refractory neutropenic infections often receive G-CSF and GM-CSF treatment alone or

in addition to EPO and antibiotic regimens. These treatments are supportive and do not affect overall survival.

Immunosuppressive Therapy

Certain MDS disease subgroups appear to have hematopoietic failure mediated in part by autoimmune cells selectively targeting the destruction of normal HSCs. These disease subsets exhibit significant overlap with AA and PNH. For instance, some young patients with low-risk MDS disease and an HLA-DR15 haplotype have demonstrated a 30% to 50% improvement in counts after T-cell immunosuppressive therapy with ATG or cyclosporine. MDS patients with isolated trisomy 8 or demonstrated PNH clones, or both, have responded to treatment with immunosuppressive agents.

Stem Cell Transplantation

As in other hematologic stem cell disorders, the only curative therapy for MDS patients remains allogeneic stem cell transplantation, ideally performed at complete remission. All MDS patients younger than 40 years with an available HLA-matched sibling donor should be offered transplantation at diagnosis. Long-term, disease-free survival rates for patients with low-risk disease are greater than 50%. However, the high transplantation-related mortality, morbidity, and relapse rates associated with mismatched or unrelated donor transplants or with transplantation in older MDS patients have limited the use of these forms of transplantation to patients with high-risk disease.

Patients with intermediate-2 or high-risk MDS (i.e., MDS with cytogenetic abnormalities predisposing to leukemic transformation or high levels of circulating blasts with International Prognostic Scoring System [IPSS] scores of intermediate-2 or higher) (Table 45-6) may be offered acute leukemia-based chemotherapy regimens (see Chapter 46) designed to eradicate rapidly proliferating blast cells, not dysfunctional MDS cells. These therapies for MDS patients are associated with a high relapse rate within 12 to 18 months and no significant prolongation of overall survival, even for patients who achieve remission.

Targeted Therapeutic Agents

Although not curative, a panoply of novel therapeutic agents targeting the unique biologic features of MDS have improved outcomes for many MDS patients ineligible for or unwilling to pursue stem cell transplantation or supportive care. Administered largely in the outpatient setting, these agents have induced disease remissions, retarded leukemia evolution, and for the first time, prolonged overall survival of MDS patients.

TABLE 45-5 WORLD HEALTH ORGANIZATION CLASSIFICATION OF MYELODYSPLASTIC SYNDROMES

CLASS	DEFINITION
Refractory anemia	Blood: anemia, no or rare blasts BM: erythroid dysplasia only, <5% blasts, and <15% ringed sideroblasts
Refractory anemia with ringed sideroblasts (RARS)	Blood: anemia, no blasts BM: ≥15% ringed sideroblasts, erythroid dysplasia only, <5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Blood: cytopenias (bicytopenia or pancytopenia), no or rare blasts, <1 × 10 ⁹ /L monocytes BM: dysplasia in ≥10% of the cells of two or more myeloid cell lines, <5% blasts, no Auer rods, <15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Blood: cytopenias (two or more), no or rare blasts, no Auer rods, and <1 × 10 ⁹ /L monocytes BM: dysplasia in ≥10% of the cells of two or more myeloid cell lines, <5% blasts, ≥15% ringed sideroblasts, no Auer rods
Refractory anemia with excess blasts type 1 (RAEB-1)	Blood: cytopenias, <5% blasts, no Auer rods, <1 × 10 ⁹ /L monocytes BM: unilineage or multilineage dysplasia, 5-9% blasts, no Auer rods
Refractory anemia with excess blasts type 2 (RAEB-2)	Blood: cytopenias, 5-19% blasts, Auer rods ± <1 × 10 ⁹ /L monocytes BM: unilineage or multilineage dysplasia, 10-19% blasts, ± Auer rods
Myelodysplastic syndrome—unclassified (MDS-U)	Blood: cytopenias, no or rare blasts, no Auer rods BM: unilineage dysplasia in one myeloid line, <5% blasts, no Auer rods
MDS associated with isolated del(5q)	Blood: anemia, usually normal or increased platelet count, <5% blasts BM: normal to increased megakaryocytes with hypolobulated nuclei, <5% blasts, isolated cytogenetic abnormality of deletion 5q, no Auer rods

BM, Bone marrow.

TABLE 45-6 WORLD HEALTH ORGANIZATION CLASSIFICATION-BASED PROGNOSTIC SCORING SYSTEM (WPSS) FOR MYELODYSPLASTIC DISORDERS

FACTOR	SCORING*			
	0	1	2	3
WHO category	RA, RARS, 5q-	RCMD, RCMD-RS	RAEB-1	RAEB-2
Karyotype [†]	Good	Intermediate	Poor	—
Transfusion requirement [‡]	No	Regular	—	—

MDS, Myelodysplastic syndrome; RA, refractory anemia; RARS, refractory anemia with ringed sideroblasts; RCMD, refractory cytopenia with multilineage dysplasia; RCMD-RS, refractory cytopenia with multilineage dysplasia and ringed sideroblasts; RAEB-1, refractory anemia with excess of blasts type 1; RAEB-2, refractory anemia with excess of blasts type 2; 5q-, myelodysplastic syndrome with isolated del(5q) and marrow blasts less than 5%; WHO, World Health Organization.

*Risk groups were determined as follows: very low (total score = 0), low (1), intermediate (2), high (3 to 4), and very high (5 to 6).

[†]Karyotype was as follows: good: normal, -Y, del(5q), del(20q); poor: complex (≥3 abnormalities), chromosome 7 anomalies; and intermediate: other abnormalities.

[‡]Red blood cell (RBC) transfusion dependency was defined as having at least one RBC transfusion every 8 weeks over a period of 4 months.

The recognition that epigenetic modifications of the abnormal HSC clones in MDS affect cell growth and apoptosis and are central to disease pathogenesis led to the therapeutic application of two DNA methyltransferase inhibitors (i.e., 5-azacytidine and decitabine) to the disease. These agents are hypothesized to reverse the abnormal hypermethylation and gene silencing in abnormal HSCs.

5-Azacytidine delays the time to leukemic transformation in two thirds of patients with transfusion-dependent MDS, decreases transfusion requirements, and improves quality of life compared with transfusion support alone. This agent is the only drug shown to significantly prolong overall survival of MDS patients, largely by delaying (but not preventing) the time of onset of acute leukemic transformation in a phase III clinical trial comparing 5-azacytidine with conventional care regimens for higher-risk MDS patients. These results are the first to demonstrate that any therapy can alter the natural history of this disease and renders 5-azacytidine the standard of care for transfusion-dependent MDS patients.

Decitabine is a compound related to 5-azacytidine and represents an alternative treatment option for patients with high-risk MDS. Decitabine therapy induces remission and reduces transfusion needs compared with supportive care and historical controls; however, the survival benefit of decitabine use in MDS has not been demonstrated.

A unique feature of DNA methyltransferase inhibitor therapy with either hypomethylating agent is that most therapeutic responses occur 4 to 6 months after treatment initiation. Moreover, MDS patients treated with 5-azacytidine who did not achieve a defined complete remission in the marrow still survived significantly longer than patients treated with supportive care alone. These data suggest that (unlike AML) the best treatment for MDS is not cytotoxic-mediated eradication of abnormal HSC clones but chronic (epigenetic) modification of cells resulting in restoration of normal hematopoiesis. It remains to be seen whether achievement of remission after hypomethylation modulation in MDS equates with long-term disease control.

Lenalidomide

Patients with lower-risk MDS characterized by deletions in the long arm of chromosome 5 (5q- aberration) typically have anemia with preserved platelet counts. Many have a disease subtype that is extraordinarily sensitive to therapy with lenalidomide, an immunomodulatory agent that exerts antigrowth effects on MDS cells and their surrounding marrow microenvironment. Complete and durable responses after lenalidomide therapy occur in up to 66% of 5q- syndrome MDS patients and are accompanied by disappearance of the abnormal cytogenetic

clone in the marrow in some patients. Defects in ribosomal protein function, specifically the ribosomal subunit protein RPS14, have been identified as the cause of 5q- syndrome MDS, paralleling findings implicating a different ribosomal subunit (RPS19) in the congenital bone marrow syndrome Diamond-Blackfan anemia.

Studies have suggested that lenalidomide targets aberrant signaling pathways caused by haplosufficiency of specific genes in a commonly deleted region on chromosome 5 (i.e., *SPARC*, *RPS14*, *CDC25C*, and *PPP2CA*). The agent specifically targets del(5q) clones while also promoting erythropoiesis and repopulation of the bone marrow in normal cells. Lenalidomide induces responses in up to one third of non-5q- MDS patients, demonstrating a specific defect in erythroid differentiation on gene expression profiling.

Prognosis

Formulation of MDS prognostic categories remains a work in progress. In 1998, the IPSS was developed by an international working group to better predict clinical outcomes in MDS. The IPSS divides patients with MDS into three prognostic categories based on cytogenetic abnormalities, cytopenias, advanced age, and percentage of bone marrow blasts, and it provides median survival and time to leukemic transformation for each IPSS stage (Table 45-7).

Based on criticism that the IPSS relies only on characteristics of patients at disease onset and includes cases now considered to be AML by the World Health Organization (WHO) criteria, a new WHO classification-based prognostic scoring system (WPSS) was devised emphasizing WHO morphology, karyotype, and transfusion dependence at any time during the MDS disease course. Division of MDS patients into five new risk categories was validated to predict for overall survival and leukemic evolution for MDS at any follow-up time (see Table 45-6).

Combined data from multiple international databases, including 7012 MDS patients, were statistically analyzed and used to generate a new prognostic classification system for untreated MDS patients, the Revised International Prognostic Scoring System (R-IPSS). This model retained marrow cytogenetics (including several novel karyotypic abnormalities), marrow blast percentage, and cytopenias as clinically prognostic markers but divided patients into five, rather than three, prognostic categories (Table 45-8). Despite the advances made in predicting outcomes for MDS patients, all of these prognostic models are limited by their exclusion of molecular features, specifically gene mutations.

Modern genomic sequencing technologies have revolutionized biomedical investigation by allowing parallel assessment of

TABLE 45-7 INTERNATIONAL PROGNOSTIC SCORING SYSTEM FOR MYELODYSPLASTIC DISORDERS

SCORE	BLASTS	KARYOTYPE	CYTOPENIAS*	OVERALL SCORE	MEDIAN SURVIVAL (YR)

[‡]N = 2754; Data from Schanz J, Tüchler H, Solé F, et al: New comprehensive cytogenetic scoring system for primary myelodysplastic syndromes and oligoblastic AML following MDS derived from an international database merge, *J Clin Oncol* 30:820–829, 2012.

hundreds of thousands of genes, pathways, and biologic processes in cancer samples. Whole-genome sequencing of untreated MDS samples has revealed that at least 78% of patients carry one or more oncogenic mutations. Although more than 40 genes are recurrently mutated in MDS, most are altered in less than 5% of MDS patients, reflecting the enormous biologic heterogeneity of this disorder. Genes implicated in MDS are involved in cell signaling, DNA methylation, chromatin regulation, and most importantly, RNA splicing. Several studies have shown that several individual gene mutations, including *EZH2*, *DNMT3A*, *SF3B1*, *TET2*, *NRAS*, *TP53*, *RUNX1*, and *ASXL1*, predict MDS outcomes independent of IPSS classification and can improve on prognostication based on clinical features alone.

Comprehensive genomic screening of diagnostic MDS samples occurs largely in academic centers. However, as technology advances, it is likely that novel prognostic models incorporating these mutational signatures will be adopted into the clinical care of patients.

PROSPECTUS FOR THE FUTURE

The field of stem cell biology is rapidly changing. The study of HSC function in marrow failure syndromes provides hints of specific molecular pathways disturbed in many diseases of hematopoietic and nonhematopoietic stem cells. These observations are furthering our knowledge about the complex interplay among AA, PNH, and MDS. Understanding stem cells' plasticity and regulatory roles promises new therapeutic avenues for a wide array of diseases.

UCB stem cells represent a potential source of donor cells for allogeneic stem cell transplantation in patients with primary hematologic diseases lacking other HLA-matched marrow donors. Nonmyeloablative stem cell transplantations (i.e., mini-transplantations) employing low-dose conditioning and immunosuppressive regimens represent another emerging treatment option for older patients with primary marrow failure syndromes.

The TPO agonist eltrombopag and the anti-CD52 antibody alemtuzumab show promise in restoring normal hematopoiesis

in refractory AA patients. Novel agents targeting the unique biologic features of ineffective hematopoiesis in marrow failure syndromes have improved outcomes for many patients over the past few years: eculizumab in PNH; 5-azacytidine in transfusion-dependent MDS; immunosuppressive drugs in AA and MDS subsets; lenalidomide in 5q- MDS.

Discoveries elucidating the complex genomic landscape of MDS have revealed that almost 80% of cases are characterized by at least one oncogenic mutation, and more than 40 unique genes are recurrently mutated in this disorder. Much research remains to be done to determine how best to incorporate this vast amount of information into the clinical care of MDS patients and to tailor therapeutic options for these unique biologic signatures.

For a deeper discussion of these topics, please see Chapter 156, "Hematopoiesis and Hematopoietic Growth Factors," in Goldman-Cecil Medicine, 25th Edition.

Clonal Disorders of the Hematopoietic Stem Cell

Eunice S. Wang and Nancy Berliner

INTRODUCTION

Malignant transformation involves combined defects in cellular maturation and differentiation. The multistep theory of oncogenesis suggests that these defects are often separable and contribute to a stepwise progression from a normal to a fully transformed cell. The continuous cycling of hematopoietic cells provides a milieu for the development of clonal genetic abnormalities that supports the multistep model. Clonal defects of the hematopoietic stem cell give rise to an array of preleukemic and leukemic disorders. Primary defects of maturation give rise to the myelodysplastic disorders (see [Chapter 45](#)), whereas loss of normal control of proliferation results in myeloproliferative disease. All of these disorders are preleukemic, with a variable but definite rate of transformation to acute leukemia.

MYELOPROLIFERATIVE NEOPLASMS

Definition and Pathology

Myeloproliferative neoplasms (MPNs), also known as chronic myeloproliferative diseases (MPDs), are clonal stem cell disorders characterized by leukocytosis, thrombocytosis, erythrocytosis, splenomegaly, and bone marrow hypercellularity. The hallmark of MPNs is the failure of a transformed multipotent stem cell to respond to normal feedback mechanisms regulating hematopoietic cell mass. Stem cells from patients with MPNs demonstrate clonal colony growth *in vitro* when they are grown in serum without the addition of exogenous cytokines, and this technique has been used as a diagnostic test for MPNs.

MPNs have traditionally been divided into four classic disorders based on the predominant hyperproliferative cell type: polycythemia vera (PV), essential thrombocytosis (ET), primary myelofibrosis (PMF; *i.e.*, idiopathic myelofibrosis or agnogenic myeloid metaplasia), and chronic myelogenous leukemia (CML). Hypereosinophilic syndrome (HES), mast cell disease, and other less common diseases are also included ([Table 46-1](#)).

Complications of MPNs arise from the overproduction of one or more lineages in the blood. All can be associated with clonal evolution and blastic transformation to acute leukemia, although with the exception of CML, this is an infrequent and late complication. In most patients with MPNs, the pathogenesis of disease is attributed to dysfunctional kinases.

In CML, a reciprocal translocation between chromosomes 9 and 22 (*i.e.*, Philadelphia chromosome or translocation) results in an Abelson (ABL) leukemia virus–breakpoint cluster region

(BCR) fusion protein (BCR/ABL) with constitutive kinase activity. In PV, PMF, and ET, a mutation involving the substitution of a valine for phenylalanine at position 617 (V617F) in the Janus kinase 2 (JAK2) has been identified in most patients and may account for the abnormal growth properties that characterize these stem cell disorders.

Identification of somatic JAK2 mutations in all MPNs has led to clinical development and testing of orally bioavailable small-molecule inhibitors that selectively target dysfunctional JAK2 for the treatment of MPNs. Results from these trials are eagerly awaited.

POLYCYTHEMIA VERA

Definition and Epidemiology

PV, a term meaning increased numbers of red blood cells in the blood, is a syndrome of increased red blood cell mass in the peripheral blood resulting from a clonal multipotent hematopoietic stem cell defect. PV occurs in 1 to 3 of 100,000 people, with a median age at diagnosis of 65 years.

Clinical Presentation

PV is a primary clonal stem cell disorder of unknown origin that is characterized by predominant erythrocytosis associated with other hematopoietic abnormalities. Although one half of patients

have concurrent leukocytosis or thrombocytosis, erythrocytosis is the hallmark and the cause of the most serious clinical complications of this disease. Typically, patients complain of headache, visual problems, mental clouding, and pruritus after bathing. Occlusive vascular events such as stroke, transient ischemic attacks, myocardial ischemia, and digital pain, paresthesias, or gangrene are common. Pulmonary, deep vein, hepatic, and portal vein thromboses may occur. Paradoxically, patients are also predisposed to hemorrhagic events, which are presumably caused by abnormal platelet function, and they may exhibit gastrointestinal bleeding. Physical examination often shows retinal vein occlusion, ruddy cyanosis, and splenomegaly.

Diagnosis and Differential Diagnosis

When patients are first diagnosed with an elevated hemoglobin concentration per unit volume (i.e., erythrocytosis), the initial evaluation should focus on whether this increase reflects an enhanced red cell mass (i.e., absolute erythrocytosis or polycythemia) or a normal red cell mass in the setting of a decreased plasma volume (i.e., relative erythrocytosis caused by dehydration or other causes). The latter condition is not true polycythemia (Table 46-2). Polycythemia or absolute erythrocytosis is an absolute increase in red cell mass caused by increased red blood cell production.

Under normal conditions, the body's ability to increase red blood cell production in states of hypoxemia, anemia, hemolysis, and acute blood loss ensures continuous oxygen delivery to tissues. In response to physiologic stimuli, pluripotent stem cell precursors are activated by erythropoietin (EPO) to differentiate into erythroid progenitor cells and eventually into hemoglobin-carrying erythrocytes. When numbers of mature red blood cells are adequate, a negative feedback mechanism suppresses further EPO production, and the serum hemoglobin level remains normal.

TABLE 46-2 CAUSES OF ERYTHROCYTOSIS

- I. Relative or spurious erythrocytosis (normal red cell mass)
 - A. Hemoconcentration due to dehydration (e.g., diarrhea, diaphoresis, diuretics, water deprivation, emesis, ethanol, hypertension, preeclampsia, pheochromocytoma, carbon monoxide intoxication)
- II. True or absolute erythrocytosis
 - A. Polycythemia vera
 - B. Primary congenital polycythemia
 - C. Secondary erythrocytosis due to
 1. Congenital causes (e.g., activating mutation of erythropoietin receptor)
 2. Hypoxia caused by carbon monoxide poisoning, high oxygen affinity hemoglobin, high-altitude residence, chronic pulmonary disease, hypoventilation syndromes such as sleep apnea, right-to-left cardiac shunt, neurologic defects involving the respiratory center
 3. Nonhypoxic causes with pathologic erythropoietin production
 - a. Renal disease (e.g., cysts, hydronephrosis, renal artery stenosis, focal glomerulonephritis, renal transplantation)
 - b. Tumors (e.g., renal cell cancer, hepatocellular carcinoma, cerebellar hemangioblastoma, uterine fibromyoma, adrenal tumors, meningioma, pheochromocytoma)
 4. Drug-associated causes
 - a. Androgen therapy
 - b. Exogenous erythropoietin growth factor therapy

Modified from Hoffman R, Benz EJ, Shattil SJ, et al, editors: Hematology: basic principles and practice, ed 2, New York, 1995, Churchill Livingstone.

Diagnosis of PV was formerly one of exclusion based on an elevated red cell mass, splenomegaly, thrombocytosis, leukocytosis, lack of hypoxemia and other secondary causes of polycythemia, and elevated levels of leukocyte alkaline phosphatase and serum vitamin B₁₂-binding protein levels. More information about the disease pathophysiology led to new diagnostic criteria (Table 46-3) based on the discovery of JAK2 gene mutations in 97% of patients with PV. A suspected diagnosis of PV can now be confirmed by testing for a JAK2 mutation, and identification of low serum EPO levels and EPO-independent erythroid colony growth have become secondary diagnostic criteria.

Peripheral blood often appears microcytic, with or without iron deficiency. Bone marrow examination shows a hypercellular marrow with pronounced hyperplasia of erythroid lineage cells. Cytogenetic features at the time of diagnosis are usually normal. The development of clonal cytogenetic abnormalities heralds transformation in the later stages of disease.

Treatment and Prognosis

Early recognition and treatment of PV are important because untreated patients with PV suffer significant morbidity and mortality from thromboembolic complications involving the cerebral, coronary, and mesenteric circulations. Twenty percent of patients show symptoms of arterial and venous thrombosis, and thrombosis remains the most common cause of death. Without treatment, one half of patients with PV die of thrombotic complications within 18 months of diagnosis. With therapy, PV is a chronic, progressive disease. The risk of transformation to acute myeloid leukemia (AML) is 2.3% at 10 years and 5.5% at 15 years. Patients with advanced age (>60 years), prior history of thrombosis, leukocytosis, and high hematocrit values are at high risk for subsequent vascular events. The JAK2 V617F mutation and clinical cardiovascular factors are also associated with an increased risk of thrombosis.

Intermittent phlebotomy is the mainstay of treatment and usually results in iron deficiency anemia, which further reduces the rate of red blood cell production. Cyto-reductive therapy is indicated for patients who cannot tolerate or fail phlebotomy, those with a history of or risk factors for thrombosis, and those with symptomatic splenomegaly. Cyto-reductive therapies include hydroxyurea (i.e., low-dose cytotoxic agent that does not appear to increase leukemic risk), interferon- α (i.e., for young

TABLE 46-3 WORLD HEALTH ORGANIZATION 2008 DIAGNOSTIC CRITERIA FOR POLYCYTHEMIA VERA

Major criteria*

1. Hemoglobin (Hgb) >18.5 g/dL (men), >16.5 (women); or Hgb or hematocrit (Hct) >99% reference range for age, sex, or altitude of residence; or Hgb >17 g/dL (men), >15 g/dL (women) if associated with a sustained increase of ≥ 2 g/dL from baseline that cannot be attributed to correction of iron deficiency; or elevated red cell mass (>25% above mean normal predicted value)
 2. Presence of JAK2 V617F or similar mutation
- Minor criteria
1. Bone marrow trilineage myeloproliferation
 2. Subnormal serum erythropoietin level
 3. Endogenous erythroid colony formation in vitro

*Both major criteria and one minor criterion or the first major criterion and two minor criteria must be met for the diagnosis of polycythemia vera.

patients and women during pregnancy), and anagrelide (i.e., megakaryotoxic agent for treating refractory thrombocytosis).

The typical goal of therapy is maintenance of hematocrit values less than 45% in men and less than 42% in women. In a multicenter, prospective clinical trial, adult PV patients randomized to a therapeutic hematocrit target of less than 45% using hydroxyurea, phlebotomy, or both modalities had a significantly lower rate of cardiovascular death (2.7% vs. 9.8%) and major thrombosis than those with a hematocrit target between 45% and 50%.

Low-dose chemotherapeutic agents (e.g., chlorambucil, busulfan) may be used to treat leukocytosis and thrombocytosis not responding to hydroxyurea, but they are associated with increased toxicity and risk of secondary AML. As with all myeloproliferative disorders, initiation of cytoreductive therapy may precipitate hyperuricemia that results in secondary gout and uric acid stones, warranting treatment with allopurinol.

Low-dose aspirin and treatment of asymptomatic thrombocytosis decrease thromboembolic events in low- and high-risk PV patients and are especially important in older patients with significant cardiovascular risk factors. In younger patients, nonsteroidal anti-inflammatory drugs and antiplatelet agents should be used judiciously because of the risk of gastrointestinal hemorrhage.

With effective therapy, the long-term survival of PV patients is excellent. Clinical trials of novel agents targeting constitutively active JAK2 signaling pathways are being conducted (primarily in patients failing prior hydroxyurea therapy), and it remains to be seen whether this class of drugs will improve outcomes and/or quality of life for PV patients.

ESSENTIAL THROMBOCYTHEMIA

Definition and Epidemiology

ET (i.e., primary thrombocythemia) is a pluripotent stem cell disorder resulting in elevated levels of platelets and white blood cells. Platelet function and length of survival remain normal. ET is an uncommon disorder, with an increasing number of cases found among patients who are asymptomatic on routine laboratory testing. Although the median age at diagnosis is 60 to 65 years, 10% to 25% of patients are younger than 40 years.

Clinical Presentation

Up to two thirds of patients are symptomatic. Vasomotor symptoms include headache, dizziness, visual changes, and erythromelalgia (i.e., burning pain and erythema of feet and hands). Serious arterial thrombotic complications such as transient ischemic attacks, strokes, seizures, angina, and myocardial infarctions may occur. Patients may rarely have purpuric skin lesions or hematomas. The risk for gastrointestinal bleeding is less than 5%.

Diagnosis and Differential Diagnosis

Elevated platelet counts (i.e., thrombocytosis) can result from other causes (e.g., bacterial infections, sepsis, iron deficiency, autoimmune diseases, malignant diseases), which must be excluded before a diagnosis of ET is considered. The diagnosis requires a platelet count exceeding $450,000 \times 10^9/L$ with a JAK2 V617F mutation or no evidence of reactive thrombocytosis.

Bone marrow histology displays predominant proliferation involving the megakaryocytic lineage with increased mature megakaryocytes and little or no granulocytic or erythroid proliferation. Marrow immunohistochemical and cytogenetic studies are essential to exclude myelodysplasia, myelofibrosis, or the Philadelphia chromosome, which are diagnostic of CML (Table 46-4).

Although no genetic or biologic marker is 100% specific for ET, the JAK2 V617F mutation is found in more than one half of samples from patients with ET. Unlike other MPNs, bone marrow cells from patients with ET frequently do not show factor-independent colony growth, and the precise cause of this disease and its relation to JAK2 mutational status are under intense investigation.

Treatment and Prognosis

Patients with ET typically have long-term survival rates similar to those of age-matched control patients. Similar to PV, shortened overall survival is associated with increased age (>60 years), a history of thrombosis, and leukocytosis. The risk of leukemic transformation is extremely low (3% to 4%) compared with other MPNs. However, morbidity from recurrent hemorrhagic and thrombotic complications is high and cannot be reliably predicted from the platelet count or platelet function abnormalities.

Because treatment requires lifelong administration for disease control, assessment of risk factors and a history of clinical signs and symptoms dictate therapeutic choices. All patients benefit from aggressive management of cardiovascular risk factors (e.g., smoking, hypertension, obesity, hypercholesterolemia). Although low-dose enteric aspirin may be used in all patients to relieve neurologic symptoms and carries a minimal risk for bleeding, excessive thrombocytosis (platelet count $>1000 \times 10^9/L$) can be associated with excessive bleeding due to acquired von Willebrand syndrome. Although young and pregnant patients are often not treated until they become symptomatic, older patients (>60 years) and those with a history of thrombosis, long disease duration, or significant cardiovascular risk factors are likely to benefit from the addition of platelet-lowering agents.

Hydroxyurea, an oral cytotoxic, myelosuppressive agent, is the most common first-line agent, and it usually is well tolerated and has low long-term leukemogenic risks. Anagrelide, an oral antiplatelet agent that inhibits platelet aggregation and megakaryocyte maturation, is also used, primarily as a second-line agent

TABLE 46-4 WORLD HEALTH ORGANIZATION 2008 DIAGNOSTIC CRITERIA FOR ESSENTIAL THROMBOCYTHEMIA

Major criteria*

1. Platelet count $\geq 450 \times 10^9/L$
2. Megakaryocyte proliferation with large and mature morphology; no or little granulocytic or erythroid proliferation
3. Not meeting WHO criteria for CML, PV, PMF, MDS, or other myeloid neoplasm
4. Demonstration of JAK2 V617F mutation or other clonal marker or no evidence of reactive thrombocytosis

CML, Chronic myelogenous leukemia; MDS, myelodysplastic syndrome; PMF, primary myelofibrosis; PV, polycythemia vera; WHO, World Health Organization.

*Diagnosis of essential thrombocytopenia requires meeting all four major criteria.

after hydroxyurea failure. This agent is associated with acute side effects (e.g., fluid retention, palpitations), hemorrhage (i.e., with concomitant aspirin use), and an increased risk of transformation to myelofibrosis. Both agents are known teratogens and therefore cannot be used in the significant fraction of patients with ET who are young women of childbearing age. Because patients with ET have a high incidence of fetal wastage, interferon- α (i.e., cytokine that alters the biologic mechanisms of the malignant clone but does not cross the placenta) with heparin or aspirin has been recommended to improve pregnancy outcomes in these patients.

PRIMARY MYELOFIBROSIS

Definition and Epidemiology

PMF (i.e., idiopathic myelofibrosis or agnogenic myeloid metaplasia) is a clonal stem cell disorder characterized by abnormal excessive marrow fibrosis leading to marrow failure. PMF is a rare chronic disease that usually is seen in elderly persons. The annual incidence of PMF is 0.5 cases per 100,000 people.

Pathology

An abnormal myeloid precursor is thought to give rise to dysplastic megakaryocytes that produce increased levels of angiogenic and fibroblast growth factors. These cytokines act on normal fibroblasts and other stromal cells, a process that stimulates excessive proliferation and collagen deposition. Over time, increasing fibrosis of the bone marrow leads to premature release of multipotent hematopoietic precursors into the periphery. These cells then migrate and reestablish themselves in other sites, thereby shifting hematopoiesis out of the bone marrow and into other tissues, especially the spleen and liver. This process is called *extramedullary hematopoiesis*.

Diagnosis and Differential Diagnosis

Early in the disease, patients may be asymptomatic, with incidental findings of abnormal blood counts on routine laboratory tests. Although low blood counts may occur, overall platelet and red blood cell numbers at diagnosis may be increased or normal depending on the degree of compensatory extramedullary hematopoiesis. Review of the peripheral blood profile commonly reveals leukoerythroblastic changes characterized by teardrop-shaped erythrocytes, giant platelets, and nonleukemic immature myeloid, erythroid, and leukocyte cells.

Diagnosis of PMF is made by demonstration of bone marrow fibrosis with markedly increased reticulin or collagen fibers (see E-Fig. 46-1) or increased marrow cellularity. Other underlying causes of neoplastic and non-neoplastic bone marrow fibrosis (Table 46-5) should be ruled out. Testing for *JAK2*, *BCR/ABL*, or other diagnostic mutations and cytogenetic markers should be performed before a diagnosis of PMF is made (Table 46-6).

Clinical Presentation

Although many patients are asymptomatic at diagnosis, most complain over time of progressive fatigue and dyspnea related to anemia or early satiety and left upper quadrant pain associated with splenomegaly and splenic infarction. More than one half of these patients develop massive hepatosplenomegaly due to extramedullary hematopoiesis. Patients with more advanced disease

TABLE 46-5 CAUSES OF BONE MARROW FIBROSIS

- I. Neoplastic causes

 - e. Acute lymphoblastic leukemia
 - f. Multiple myeloma
 - g. Metastatic carcinoma
 - h. Systemic mastocytosis
- II. Non-neoplastic causes
 - a. Granulomatous diseases: mycobacterial infections, fungal infections, sarcoidosis
 - b. Paget's disease of bone
 - c. Hypoparathyroidism or hyperparathyroidism
 - d. Renal osteodystrophy
 - e. Osteoporosis
 - f. Vitamin D deficiency
 - g. Autoimmune diseases: systemic lupus erythematosus, systemic sclerosis

FAB M7, French-American-British acute myeloid leukemia classification subtype 7.

TABLE 46-6 WORLD HEALTH ORGANIZATION 2008 DIAGNOSTIC CRITERIA FOR PRIMARY MYELOFIBROSIS MAJOR CRITERIA

Major criteria*

1. Megakaryocyte proliferation and atypia accompanied by reticulin and/or collagen fibrosis, or in the absence of reticulin fibrosis, the megakaryocytic changes must be accompanied by increased marrow cellularity, granulocytic proliferation, and often decreased erythropoiesis (i.e., prefibrotic primary myelofibrosis)
2. Not meeting World Health Organization criteria for chronic myelogenous leukemia, polycythemia vera, myelodysplastic syndrome, or other myeloid neoplasm
3. Demonstration of *JAK2* V617F mutation or other clonal marker or no evidence of reactive marrow fibrosis

Minor criteria

1. Leukoerythroblastosis
2. Increased serum lactate dehydrogenase level
3. Anemia
4. Palpable splenomegaly

*Diagnosis of primary myelofibrosis requires meeting all three major criteria and two minor criteria.

may have constitutional symptoms such as fever, weight loss, night sweats, cachexia, pruritis, and bone pain.

As bone marrow failure evolves, complications of neutropenia, thrombocytopenia, and anemia develop as a result of ineffective hematopoiesis. Bleeding from occult disseminated intravascular coagulation is a risk. Extramedullary hematopoiesis in the peritoneal and pleural cavities and in the central nervous system (CNS) may also cause symptoms.

Treatment and Prognosis

Median survival of patients with PMF is poor, ranging from 2 to 5 years after diagnosis. The most commonly accepted adverse prognostic factors at onset include age greater than 65 years, hemoglobin concentration of less than 10 g/dL, leukocyte count of more than $25 \times 10^9/L$, a high percentage of circulating blasts ($\geq 1\%$), and constitutional symptoms. Other important clinical factors are leukopenia, thrombocytopenia (platelets $<100 \times 10^9/L$), massive hepatosplenomegaly, red cell transfusion needs, and unfavorable cytogenetic abnormalities.

E-FIGURE 46-1 **A**, Marrow biopsy with disorganized hematopoiesis due to unsuspected myelofibrosis (*bottom*) is compared with a crush artifact (*top*) (periodic acid–Schiff stain, $\times 50$). **B**, Corresponding reticulin stain shows a diffuse increase in fine (*black*) reticulin fibers ($\times 100$). **C**, Corresponding collagen stain shows an increase in coarse (*blue*) collagen fibers ($\times 100$). Diffuse deep blue and red staining is seen in the bone trabeculae (*left*). Disorganized and disorderly granulopoiesis with an increase in immature forms and two large dysplastic hypolobulated megakaryocytes can be seen ($\times 100$). **D**, Leukoerythroblastosis in peripheral blood smear shows a myeloblast, two hypogranular band neutrophils, a monocyte, and a nucleated erythrocyte (Wright-Giemsa stain, $\times 250$). **E**, Teardrop-shaped, anucleate red cells and a normoblast can be seen in the peripheral blood smear (Wright-Giemsa stain, $\times 250$). (Courtesy Maurice Barcos, MD, PhD, Chief of Hematopathology, Roswell Park Cancer Institute, Buffalo, N.Y.)

Over time, the disease may progress from a chronic phase to an accelerated phase, with acute leukemic transformation in 8% to 20% of patients. Treatment of PMF-related AML is usually ineffective. Other causes of nonleukemic death include heart failure, infection, intracranial hemorrhage, and pulmonary embolism.

Medical therapy for PMF is predicated on the risk category of patients. Low-risk, asymptomatic patients may be treated expectantly. All patients with symptomatic anemia benefit from palliative transfusions and administration of recombinant EPO, androgens (e.g., danazol), or low-dose thalidomide to maintain red blood cell levels. Symptoms caused by excess thrombocytosis and leukocytosis or progressive extramedullary hematopoiesis may be managed with hydroxyurea as a first-line agent or interferon- α in younger or pregnant patients. Symptomatic splenomegaly is best managed with hydroxyurea because open splenectomy is associated with significant operative morbidity and mortality and splenic irradiation is poorly tolerated except as a palliative approach. Young patients with intermediate- to high-risk PMF and possible HLA-matched donors should be considered for potentially curative allogeneic stem cell transplantation (SCT) at academic medical centers.

Although not all patients with PMF have the JAK2 V617F mutation, almost all have constitutive activation of the JAK1 and JAK2 signaling pathways, rendering them potentially responsive to treatment with novel JAK1/2 inhibitors. Ruxolitinib is an oral JAK inhibitor approved for the treatment of patients with intermediate- or high-risk myelofibrosis, including PMF, and myelofibrosis arising from prior PV or ET independent of JAK2 mutational status.

In two prospective, randomized, phase III clinical trials, ruxolitinib therapy for myelofibrosis patients was compared with placebo (COMFORT-I trial) and with best available therapy (COMFORT-II trial). Patients receiving ruxolitinib had significantly greater spleen volume reduction and symptom improvement (e.g., abdominal pain, early satiety, night sweats, muscle pain), which correlated with overall improvement in quality of life. Updates from both trials have demonstrated significantly prolonged overall survival and improvements in bone marrow fibrosis in the ruxolitinib-treated patients compared with control arms.

Many other JAK2 inhibitors are in active clinical development as single agents and in combination with ruxolitinib. Preliminary results of these trials suggest that even more effective therapies for PMF are on the horizon.

CHRONIC MYELOGENOUS LEUKEMIA

Definition, Epidemiology, and Pathology

CML is the most common MPN, accounting for 15% to 20% of all leukemias and occurring in 1 of 100,000 people. The median age at diagnosis is 53 years, but patients of any age may be affected. CML is characterized by a predominant increase in the granulocytic cell line associated with concurrent erythroid and platelet hyperplasia. It is unique among the MPNs in its natural history, including an inevitable transformation to acute leukemia.

CML was the first malignant hematologic disease shown to be associated with a specific chromosomal abnormality. More than 95% of patients with CML have a clonal expansion of a stem cell that has acquired the Philadelphia chromosome, which is a balanced translocation between chromosomes 9 and 22 that is designated t(9;22)(q34;q11). The translocation juxtaposes the *ABL* gene from chromosome 9 (region q34) to the *BCR* gene on chromosome 22 (region q11) and generates the oncogenic *BCR/ABL* fusion gene. The gene product, the *BCR/ABL* protein, is a deregulated, constitutively active cytoplasmic tyrosine kinase that induces a leukemic phenotype in hematopoietic stem cells. Expression of the *BCR/ABL* fusion protein activates multiple downstream signal transduction pathways that permits proliferation independent of cytokine and stromal regulation and renders cells resistant to chemotherapy and normal programmed cell death (i.e., apoptosis).

Diagnosis and Differential Diagnosis

Laboratory tests for CML patients typically demonstrate a markedly elevated white blood cell count (median, $170 \times 10^9/L$), with low leukocyte alkaline phosphatase levels, high uric acid and lactate dehydrogenase levels, and thrombocytosis. Review of the peripheral smear in chronic phase CML demonstrates a full complement of myeloid cells in all stages of granulocytic development, including immature myeloblasts (usually <5%), myelocytes, metamyelocytes, basophils, eosinophils, bands, and neutrophils. In contrast, the peripheral blood smear in reactive granulocytic hyperplastic states (i.e., leukemoid reaction) caused by acute infection or sepsis consists predominantly of mature neutrophils and bands with few myelocytes, basophils, or eosinophils.

The bone marrow in CML is densely hypercellular, with an overwhelming predominance of myeloid cells at all developmental stages and reticulin fibrosis (see E-Fig. 46-2). The differential diagnosis of CML includes reactive leukocytosis (e.g., in active infection or sepsis with a profound neutrophilic response) and other MPNs (e.g., myelofibrosis).

Detection of the Philadelphia chromosome on standard cytogenetic studies and abnormal *BCR/ABL* transcripts using reverse transcriptase–polymerase chain reaction (RT-PCR) or fluorescent in situ hybridization (FISH) analysis is required for the diagnosis of CML. Assessment of the *BCR/ABL* fusion gene by the same methods is used to monitor disease and response to therapy. Exquisitely sensitive and quantitative RT-PCR procedures allow detection of up to a single *BCR/ABL*-positive cell in 10^5 to 10^6 peripheral cells and permit measurement of disease status in peripheral blood and marrow samples.

A subset of patients with CML lacking a detectable Philadelphia chromosome was found to possess detectable *BCR/ABL* fusion products by RT-PCR, indicating a subchromosomal translocation resulting in the same pathologic gene product. Responses to treatment regimens for CML are defined as hematologic (i.e. restoration of normal peripheral blood cell counts), cytogenetic (i.e., loss of the Philadelphia chromosome determined by normal karyotypic or FISH analysis), and molecular (i.e., a three log or greater reduction of detectable *BCR/ABL* transcripts below a standard baseline by RT-PCR) remissions.

Clinical Presentation

Up to 40% of newly diagnosed CML patients are initially asymptomatic. Other patients exhibit fatigue, lethargy, shortness of breath, weight loss, easy bruising, and early satiety. Physical examination usually detects splenomegaly.

The natural history of CML is characterized by chronic, accelerated, and blastic phases. Patients are typically diagnosed during the chronic phase of CML, an indolent stage lasting 3 to 5 years. Peripheral white blood cell counts are elevated, with eosinophilia and basophilia (>20%) but few blasts (<5%). With control of peripheral blood cell counts, patients are essentially asymptomatic during this period.

Eventually, the disease enters the accelerated phase, which is characterized by fever, weight loss, worsening splenomegaly, and bone pain related to rapid marrow cell turnover. Despite therapy, the white blood cell count rises with increased numbers of circulating blasts (between 10% and 19%). The increased percentage of peripheral blood basophils (>20%) results in histamine production, with symptoms of pruritus, diarrhea, and flushing. During the accelerated phase of CML, patients may develop increasing splenomegaly, persistent thrombocytopenia, or thrombocytosis and leukocytosis, with new clonal cytogenetic abnormalities found in marrow cells.

The CML blast crisis phase marks the evolution to acute leukemia, in which marrow is replaced by 20% or more blasts, with accompanying loss of normal mature cellular elements in the marrow and periphery and extramedullary blast proliferation. Death occurs in a few weeks to months. Two thirds of patients develop AML, whereas the others develop acute lymphocytic (lymphoblastic) leukemia (ALL), a finding confirming that the initial neoplastic cell is an early stem cell capable of multilineage differentiation.

Treatment

Historically, oral chemotherapeutic agents such as hydroxyurea and busulfan were used to reduce myeloid cell numbers in patients during the chronic phase of CML. Although these drugs decreased the rate of acute disease complications, they did not alter the long-term prognosis or prevent progression to blast crises.

Treatment with interferon resulted in hematologic remissions in 60% to 80% of patients with chronic phase CML and was the first agent to induce cytogenetic responses in 20% to 30% of these patients. Achievement of cytogenetic remissions using interferon- α was associated with prolonged survival, and higher response rates were obtained by combining chemotherapy with interferon. Although most patients treated with interferon still possessed cells with a detectable *BCR/ABL* translocation by PCR and remained at risk for disease relapse, many remained in hematologic and cytogenetic remission for several years. Unfortunately, patients with accelerated or blast crisis CML did poorly with interferon, and high-dose chemotherapy regimens induced only transient responses, with durations of less than 6 months.

Imatinib mesylate (Gleevec, formerly known as STI-571) for the treatment of CML was heralded as the first successful targeted therapy for cancer. Imatinib is a rationally designed competitive inhibitor of multiple tyrosine kinases, including ABL,

BCR/ABL, platelet-derived growth factor receptor (PDGFR), and KIT. Inhibition of phosphorylation of BCR/ABL results in blockade of downstream signaling and growth pathways and induces apoptosis of BCR/ABL-positive cells. Preclinical studies demonstrated that imatinib potently inhibited the growth of BCR/ABL-expressing CML cell lines and progenitor cells in vitro and prolonged survival in animal tumor models.

Initial clinical trials of this orally active drug were begun in 1998 in CML patients who had failed interferon- α . Imatinib was well tolerated and had manageable side effects. In the treatment arm, 96% of patients receiving a dose greater than 300 mg per day for 4 weeks achieved hematologic remissions, and 33% obtained cytogenetic remissions after 8 weeks. Imatinib was subsequently shown to be superior to interferon- α and cytarabine in untreated patients with newly diagnosed chronic phase CML and to induce complete cytogenetic responses in almost 90% of patients with chronic phase CML, with an estimated overall survival rate of 89%. Based on this study, imatinib was the first rationally designed biologically targeted drug approved for the treatment of cancer.

Despite these results, imatinib has not cured chronic phase CML. Similar to interferon- α treatment, most patients achieving cytogenetic responses on imatinib demonstrate persistence of BCR/ABL-positive leukemic CML stem cells by sensitive molecular testing. Lifelong imatinib therapy may be required to control disease, and even patients with excellent control of chronic phase CML on imatinib therapy remain at risk for eventual disease progression and therapy failure. It is estimated that up to one third of chronic phase CML patients initiated on imatinib therapy will eventually discontinue drug due to long-term intolerance of drug-induced side effects (e.g., nausea, vomiting, gastrointestinal issues, peripheral and periorbital edema) or development of imatinib resistance.

To address these issues, four newer tyrosine kinase inhibitors (TKIs) of BCR/ABL have been developed for the treatment of chronic phase CML: dasatinib (Sprycel), nilotinib (Tasigna), bosutinib (Bosulif), and ponatinib (Iclusig). All display increased in vitro potency against the BCR/ABL kinase compared with imatinib.

Imatinib, dasatinib, and nilotinib are approved for the initial therapy of chronic phase CML. After the diagnosis, patients are typically started on one of these three TKIs along with careful interim monitoring for toxicities and clinical response. Standardized RT-PCR assays for BCR/ABL are used to measure disease response on a molecular level at 3, 6, and 12 months after therapy initiation. In two randomized clinical trials comparing dasatinib with imatinib or nilotinib with imatinib in newly diagnosed CML patients, both second-generation TKIs outperformed imatinib, as reflected by significantly higher numbers of patients treated with these agents achieving complete cytogenetic and molecular responses at the specific time points compared with imatinib-treated individuals. However, whether these results translate into long-term overall survival benefit for either agent over imatinib remains to be seen.

CML patients resistant to or intolerant of first-line TKI therapy are usually switched to another agent. Up to one half of CML patients who develop resistance to imatinib have cancer cells carrying single-nucleotide mutations in the *BCR/ABL* gene. These mutations result in conformational changes of the BCR/ABL

kinase, altering drug binding and inhibitory effects. For this reason, it is recommended that patients requiring second-line therapy or beyond undergo testing for identification of mutations as a potential guide to therapy. CML patients with disease associated with a mutation at T315I are known to be resistant to imatinib, nilotinib, dasatinib, and bosutinib, but not to ponatinib, a third-generation BCR/ABL inhibitor.

Omacetaxine mepesuccinate is a natural alkaloid product with proven antitumor activity and efficacy in CML patients failing multiple TKIs or carrying the T315I mutation, or both. Its mechanisms of action are distinct from the TKIs and involve inhibition of protein synthesis and induction of apoptosis in tumor cells. Several clinical trials have confirmed the activity of this agent in this patient population. A major drawback is the need for subcutaneous injections administered twice daily for 7 to 14 days of every 28 days per month.

Unfortunately, although treatment with the newer BCR/ABL inhibitors can induce transient hematologic and cytogenetic responses in patients with accelerated or blast phase CML, these responses are short lived. The treatment modality known to result in eradication of all detectable BCR/ABL-expressing cells remains allogeneic SCT. Before the advent of targeted BCR/ABL kinase inhibitor therapy, young patients with an HLA-matched donor were routinely offered potentially curative allogeneic bone marrow transplantation at the time of diagnosis of chronic phase CML. Evidence indicated that the excellent response (50% to 75%) of CML patients to SCT was partly related to the active suppression of the disease by the newly transplanted graft, called the *graft-versus-leukemia effect*.

In the face of the excellent control and low overall toxicity of long-term BCR/ABL inhibitors for chronic phase CML, together with the known 20% to 30% mortality and morbidity rates after SCT, transplantation is viewed as an option only for patients with accelerated or blast phase disease or chronic phase CML failing multiple lines of prior therapy. Transplantation remains the only known curative therapy for these patients. Blast phase CML patients often undergo induction chemotherapy with acute leukemia regimens followed by BCR/ABL inhibition and allogeneic SCT.

Prognosis

Overall, the transformation of CML from a progressively fatal cancer to one in which almost 90% of patients are alive with stable disease on oral kinase therapy after 5 years remains one of the crowning achievements in cancer therapy in the past decade. The median overall survival for chronic phase CML patients has risen dramatically from a few months to a few years in the first half of the 20th century to 6 years for interferon-treated patients. In the era of BCR/ABL inhibition therapy, it is expected to be almost normal for most patients on long-term TKI therapy.

The standard of care for CML patients who are responding optimally to treatment is to continue TKI therapy indefinitely. However, ongoing studies are examining the impact of discontinuing TKI in selected individuals whose disease has responded particularly well to therapy based on molecular criteria. Despite many therapeutic advances, a true cure for CML disease remains elusive and presents a therapeutic challenge for the years ahead.

ACUTE LEUKEMIAS

Definition and Epidemiology

The acute leukemias are clonal hematopoietic diseases that arise from the malignant transformation of an early hematopoietic stem cell. Leukemias occur in 8 to 10 of 100,000 people (compared with 42 of 100,000 for prostate cancer and 62 of 100,000 for breast cancer). Acute leukemias are classified by cell lineage as AML or ALL based on morphology, cytogenetics, cell surface and cytoplasmic markers, and molecular studies. Between 80% and 90% of adult leukemia diagnoses are AML (others are ALL), whereas most childhood leukemias are ALL (10% are AML).

Pathology

The pathogenesis of acute leukemia is under intense investigation. Many patients with acute leukemia have detectable characteristic clonal chromosomal abnormalities, but the role of all but a few of these aberrations in malignant transformation is unknown. Unregulated proliferation of immature cells incapable of further differentiation (i.e., blasts) results in marrow replacement and hematopoietic failure.

Known risk factors for leukemia are high-dose radiation exposure and occupational exposure to benzene. Patients with secondary AML after prior chemotherapy have usually received alkylating agents (e.g., chlorambucil, melphalan, nitrogen mustard) or topoisomerase II inhibitors (e.g., epipodophyllotoxins). Patients with chromosomal instability disorders such as Bloom's syndrome, Fanconi's anemia, Down syndrome, and ataxia telangiectasia also have an increased incidence of leukemia.

Diagnosis and Differential Diagnosis

The distinction between AML and ALL is crucial diagnostically, therapeutically, and prognostically. AML can be distinguished from ALL by cell morphology and the finding of Auer rods, which are formed by the aggregation of myeloid granules (E-Fig. 46-2). Further immunophenotyping of blast cells using cell surface antigens, cytochemistry, and immunohistochemistry confirms cells as having a myeloid or lymphoid origin (Table 46-7). Morphologic subgroups of ALL and AML were originally defined by the French-American-British (FAB) classification and then by the World Health Organization (WHO) classification, which incorporated newer biologic information (Table 46-8).

Clinical Presentation

Patients exhibit clinical evidence of bone marrow failure similar to other hematopoietic disorders. Complications of disease include anemia, infection, and bleeding from peripheral cytopenias. Proliferating blasts infiltrating the bone marrow may cause bone pain. Blasts also invade other organs and lead to peripheral, mediastinal, and abdominal lymphadenopathy, hepatosplenomegaly, skin infiltration, and meningeal involvement.

Treatment

Therapy for acute leukemias is divided into several stages. *Induction therapy* is directed at reducing the number of leukemic blasts to an undetectable level and restoring normal hematopoiesis (i.e.,

E-FIGURE 46-2 **A**, Marrow biopsy with a leukemoid reaction shows marked advanced granulocytic hyperplasia with a predominance of band and segmented neutrophils (Wright-Giemsa stain, $\times 100$). **B**, Leukemoid reaction in the peripheral blood smear shows two myelocytes and numerous segmented granulocytes. An erythrocyte rouleaux formation is also seen (Wright-Giemsa stain, $\times 100$). **C**, Marrow biopsy (fat-to-cell ratio of 0:100) in chronic myelogenous leukemia (CML) shows a preponderance of periodic acid–Schiff (PAS)–positive myelocytes. A small cluster of PAS-negative erythroid precursors, a megakaryocyte, and several phagocytes are also seen (PAS stain, $\times 100$). **D**, Marrow smear in CML shows disorderly granulopoiesis with increased myelocytes relative to metamyelocytes (i.e., hiatus leukemicus) and frequent mature forms (Wright-Giemsa stain, $\times 250$). **E**, Peripheral blood smear in CML shows two myeloblasts, one myelocyte, one metamyelocyte, one segmented neutrophil, one eosinophil, and marked thrombocytosis (Wright-Giemsa stain, $\times 100$). **F**, Another field in the blood smear of the same patient shows increased numbers of basophils (Wright-Giemsa stain, $\times 250$). **G**, The peripheral thrombocytosis in the same case includes medium-sized and giant platelets (the latter are the same size as the erythrocytes) (Wright-Giemsa stain, $\times 250$). (Courtesy Maurice Barcos, MD, PhD, Chief of Hematopathology, Roswell Park Cancer Institute, Buffalo, N.Y.)

TABLE 46-7 LABORATORY AIDS TO DIFFERENTIATE AML FROM ALL

*Auer rods are a linear coalescence of cytoplasmic granules that stain pink with Wright's stain.

complete remission). At complete remission, however, significant subclinical disease persists, requiring further therapy.

Subsequent *consolidation therapy* involves continuing chemotherapy with the same agents to induce elimination of additional leukemic cells. With development of a wider range of effective agents, *intensification therapy* has been introduced. It involves the use of high-dose therapy with different non-cross-reactive drugs to eliminate cells with potential primary resistance to the induction regimen.

Maintenance therapy employs low-dose, intermittent chemotherapy given over a prolonged period to prevent subsequent disease relapse. The goal of therapy is to induce remission (>5% blasts in the bone marrow and recovery of normal peripheral blood counts).

Prognosis

Adverse clinical prognostic factors for AML and ALL are similar despite widely different treatment approaches. In both leukemias, cytogenetic abnormalities represent the best independent predictor of overall survival (Tables 46-9 and 46-10). Clinical factors that predict a poor outcome include age exceeding 35 years for ALL or 60 years for AML, secondary or therapy-related disease, antecedent hematologic disorder, high initial leukocyte count (50 to 100 × 10⁹/L), and prolonged time (>4 weeks) to achieve a response to initial treatment.

ACUTE MYELOID LEUKEMIA

Definition and Epidemiology

AML represents a biologically heterogeneous group of neoplasms with widely divergent clinical outcomes. Long-term cure rates (survival >5 years) range from 5% to 60% after chemotherapy alone, with an overall cure rate of 20% to 30%. AML occurs primarily in older adults, with a median age at diagnosis of 65 years.

TABLE 46-8 FRENCH-AMERICAN-BRITISH AND WORLD HEALTH ORGANIZATION CLASSIFICATIONS OF ACUTE LEUKEMIA

FAB CLASSIFICATION OF ACUTE MYELOID LEUKEMIA (AML)

M0: Acute myelocytic leukemia with minimal differentiation
M1: Acute myelocytic leukemia without maturation
M2: Acute myelocytic leukemia with maturation (predominantly myeloblasts and promyelocytes)
M3: Acute promyelocytic leukemia
M4: Acute myelomonocytic leukemia
M5: Acute monocytic leukemia
M6: Erythroleukemia
M7: Megakaryocytic leukemia

FAB CLASSIFICATION OF ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)

L1: Predominantly small cells (twice the size of normal lymphocyte), homogeneous population; childhood variant
L2: Larger than L1, more heterogeneous population; adult variant
L3: Burkitt-like large cells, vacuolated abundant cytoplasm

WHO 2001 CLASSIFICATION OF ACUTE LEUKEMIA

I. AML

- A. AML with recurrent genetic abnormalities
 1. AML with t(8;21)(q22;q22)
 2. AML with abnormal bone marrow eosinophils, inv(16)(p13;q22) or t(16;16)(p13;q22); (CBFB/*MYH11*)
 3. Acute promyelocytic leukemia (AML with t[15;17][q22;q12] [*PML/RARA*]) and variants
 4. AML with 11q23 (*MLL*) abnormalities
 - B. AML with multilineage dysplasia
 - C. AML and MDS, therapy related, alkylating agent related, topoisomerase II inhibitor related
 - D. AML not otherwise defined
 1. AML minimally differentiated
 2. AML without maturation
 3. AML with maturation
 4. Acute myelomonocytic leukemia
 5. Acute monoblastic and monocytic leukemia
 6. Acute erythroid leukemia
 7. Acute megakaryoblastic leukemia
 8. Acute basophilic leukemia
 9. Acute panmyelosis with myelofibrosis
 10. Myeloid sarcoma
 - E. Acute leukemia of ambiguous lineage
 1. Undifferentiated acute leukemia
 2. Bilineal acute leukemia
 3. Biphenotypic acute leukemia
- #### II. Acute lymphocytic leukemia
- A. Precursor B-lymphoblastic leukemia/lymphoblastic lymphoma
 - B. Precursor T-lymphoblastic leukemia/lymphoblastic lymphoma

CBF, Core binding factor; ETO, eight twenty-one; FAB, French-American-British; MDS, primary myelodysplastic syndrome; *MLL*, mixed-lineage leukemia; *MYH11*, myosin heavy chain gene; *PML*, promyelocytic leukemia; *RARA*, retinoic acid receptor- α ; WHO, World Health Organization.

TABLE 46-9 POOR PROGNOSTIC CLINICAL FACTORS IN ACUTE MYELOID LEUKEMIA

Age >60 yr (median age for acute myeloid leukemia, 65 yr)
Therapy related or with antecedent hematologic disorder (e.g., myelodysplastic syndrome, myeloproliferative neoplasm, aplastic anemia)
Poor performance status
White blood cell count >20,000-30,000/mm³
Extramedullary disease sites

Clinical Presentation

Patients most often have complications related to progressively severe cytopenia, such as infection due to leukopenia, shortness of breath or fatigue due to anemia, or bleeding due to thrombocytopenia. AML patients may also have unique acute clinical emergencies requiring immediate stabilization.

TABLE 46-10 PROGNOSTIC FACTORS IN ACUTE LYMPHOBLASTIC LEUKEMIA

FACTOR	FAVORABLE	UNFAVORABLE
Age	2-10 yr	<2 yr or >10 yr
White blood cell count at diagnosis	<30,000/ μ L	>50,000/ μ L
Phenotype	Precursor B	Precursor T
Chromosome number	Hyperdiploidy	Pseudo/hypodiploidy, near tetraploidy
Chromosome abnormality	t(12;21)	<i>MYC</i> alterations: t(8;14), t(2;8), t(8;22) mixed-lineage leukemia alterations (11q23) Philadelphia chromosome: t(9;22), creating <i>BCR-ABL</i>
Central nervous system disease at diagnosis	No	Yes
Sex	Women	Men
Ethnicity	White	African American, Hispanic
Time to remission	Short (7-14 days)	Prolonged time to remission or failure to achieve remission

Leukostasis (i.e., hyperleukocytosis syndrome) caused by high levels of circulating blasts (>80,000 to 100,000) leads to diffuse pulmonary infiltrates and acute respiratory distress. Blast cells may also injure surrounding vasculature, causing life-threatening CNS bleeding and thromboses. High blast cell numbers result in the release of cellular breakdown products (i.e., tumor lysis syndrome), leading to hypokalemia, acidosis, and hyperuricemia with resultant renal failure.

Treatment of leukostasis should be instituted as soon as possible for all patients with white blood cell counts in excess of 100 to 200 $\times 10^9$ /L. Treatment consists of leukapheresis, hydroxyurea, and initiation of induction chemotherapy to inhibit further production of circulating tumor cells. Hydration, urine alkalinization to reduce urine crystallization, allopurinol, or rasburicase, or a combination, should be initiated as indicated. Red blood cell transfusions are often contraindicated in patients with high numbers of circulating blast cells because of the risk of further increases in blood viscosity. CNS complications such as intracranial bleeding, cranial nerve invasion, and leukemic meningitis are treated with emergency whole brain irradiation or radiation directed to affected sites.

Laboratory evaluation of patients with AML typically shows white blood cell counts ranging from neutropenic levels (<1 $\times 10^9$ /L) to extreme leukocytosis (>100,000 $\times 10^9$ /L). Severe thrombocytopenia, normocytic anemia, and circulating peripheral blasts are common. Bone marrow aspirate and biopsy typically show a profusion of myeloblasts (20% to 100%) and depressed production of normal mature cells.

Diagnosis

Diagnostic marrow aspirates are typically evaluated using morphology, flow cytometry, cytogenetic, and molecular analyses to distinguish between AML and ALL and to determine AML

disease subsets for therapeutic purposes. In the past, AML subsets were classified based largely on morphologic criteria and immunohistochemical staining as FAB subtypes M0 through M7, which are defined by the stage of cellular differentiation of the abnormal cells (see Table 46-8 and E-Fig. 46-3).

Some FAB subsets correlate with specific clinical syndromes, which helps to determine treatment approaches and prognosis. The most common FAB subtype of adult AML is M2. Patients with AML M3 (i.e., acute promyelocytic leukemia) often exhibit spontaneous bleeding from disseminated intravascular coagulation (discussed later). Patients with AML M4 or M5 disease (i.e., acute monocytic-myelomonocytic leukemias) have high levels of circulating white blood cells and may have swollen gums resulting from tissue infiltration with leukemic blasts. Patients with megakaryoblastic leukemia (AML M7) have significant marrow fibrosis and usually exhibit organomegaly and pancytopenia similar to those seen in patients with myelofibrosis and myeloid metaplasia.

In 2008, AML was reclassified as new subtypes defined primarily by unique karyotypic abnormalities—specifically t(8;21), inv(16), and t(15;17)—and gene mutations in a dysplastic bone marrow, independent of the number of marrow blasts. Because finding these specific cytogenetic abnormalities is crucial for the diagnosis, therapy, and prognosis for AML patients, karyotypic analysis is considered essential for any suspected AML diagnosis. Evidence of marrow dysplasia after prior chemotherapy, irradiation, or other myeloablative therapy is considered therapy-related AML rather than myelodysplastic syndrome (MDS), independent of the blast count (see Table 46-8).

Treatment and Prognosis

Chemotherapy for AML involves induction chemotherapy (administered in the inpatient setting) followed by two to four cycles of consolidation chemotherapy administered over 4 to 6 months. Standard induction regimens employing cytosine arabinoside (i.e., cytarabine) with high-dose anthracycline (i.e., daunorubicin or idarubicin) lead to complete remission in 60% to 80% of younger adults with de novo AML. Lower remission rates are achieved for older adults (>60 years) and in patients with antecedent hematologic diseases evolving into AML.

After achieving complete remission after induction, patients may be offered additional consolidation chemotherapy or treatment with allogeneic or autologous SCT (see Chapter 45). Patients whose AML fails to respond to initial induction therapy have a grim overall prognosis and may be retreated with experimental agents or with non-cross-reactive chemotherapy drugs such as epipodophyllotoxins, or both, to obtain remission.

Given the biologic heterogeneity of this disease, the AML risk category constitutes the most crucial determinant of an appropriate therapeutic strategy for individual patients. In the past, AML outcome could be predicted to some degree by clinical factors such as patient age, disease manifestation (i.e., white blood cell count), and history of antecedent hematologic or therapy-related disease (see Table 46-9). In the current era, AML risk is defined by diagnostic AML cytogenetics and molecular abnormalities and is typically divided into three categories: favorable, intermediate, and poor risk.

AML characterized by t(8;21), inv(16) or del(16q), or t(15;17) aberrations is unusually responsive to induction chemotherapy followed by two to four cycles of high-dose cytosine arabinoside consolidation. Long-term 5-year survival rates of 55% to 60% can be obtained.

AML subtypes associated with a poor prognosis include those with known deletions in chromosome 5 or 7, 11q23 aberrations other than t(9;11), inv(3q), t(3;3), t(6;9), t(9;22) (i.e., Philadelphia chromosome), monosomal karyotype, or three or more karyotypic abnormalities (i.e., complex karyotype). Remission rates for these AML subtypes are low; if remission is achieved, patients remain at high risk for AML relapse with chemotherapy-refractory disease. Overall survival rates for poor-prognosis AML are 5% to 15%.

The remaining AML patients have intermediate-risk cytogenetics, which is defined as a normal karyotype, trisomy 8, t(9;11), or other cytogenetic abnormalities not included in the other groups. These patients have a 30% to 45% long-term survival rate with standard chemotherapy (see Table 46-10).

Large-scale genomic analyses of AML samples have revealed the vast molecular complexity of this disease and identified myriad gene mutations capable of further refining AML prognosis in conjunction with karyotype. For instance, up to one third of patients with normal-karyotype AML have constitutive activation of the FMS-like tyrosine kinase 3 (FLT3) receptor as a result of point mutations or internal tandem duplications (ITDs) not seen on routine karyotypic testing) in FLT3 kinase. FLT3 ITDs in AML patients predict low remission rates, high relapse rates, and shorter overall survival compared with FLT3-negative AML patients. Mutations that predict improved overall survival after chemotherapy include biallelic mutations in the transcription factor CCAAT/enhancer binding protein- α (CEBPA) and nucleophosmin 1 (NPM1) in the absence of FLT3 ITDs (Table 46-11).

After remission is achieved after induction, AML patients are offered additional therapy in the form of consolidation chemotherapy and autologous or allogeneic SCT. Decisions about the best time to perform SCT in patients are most often guided by clinical risk factors and prognostic risk category (see Tables 46-9 and 46-10). Although clinical outcomes are improved when

patients undergo SCT after initial induction chemotherapy (i.e., during the first complete remission) rather than after disease relapse, chemotherapeutic regimens are also more effective in the first remission than they are after transplantation, and they may be better tolerated than SCT, which carries an overall mortality rate of 25% to 30%.

Allogeneic SCT is recommended for and represents the best chance for long-term cure of patients with poor-risk AML such as disease associated with unfavorable cytogenetic and molecular features, antecedent hematologic disease, or therapy-related or primary refractory disease. Poor-risk AML patients younger than 60 years undergoing allogeneic bone marrow transplantation from a matched donor have long-term overall survival rates of 40% to 60%, compared with cure rates after conventional chemotherapy of only 5% to 20%. AML patients with favorable disease features potentially responsive to high-dose cytarabine chemotherapy are encouraged to delay SCT until the time of relapse.

Intermediate- to high-risk AML patients (based on clinical or cytogenetic data) who are ineligible for allogeneic transplantation because of advanced age, other medical issues, or lack of HLA-compatible donors may be offered chemotherapy or autologous SCT instead. Whether autologous transplantation improves AML outcomes compared with chemotherapy alone is a matter of debate. However, the long-term survival rates after autologous transplantation range from 20% to 40% and are at least equivalent to consolidation chemotherapy regimens for these patients.

Because the median age at diagnosis of AML is 65 years, a sizable proportion of AML patients are elderly individuals with major comorbidities or antecedent hematologic or malignant diseases, rendering them poor candidates for standard induction chemotherapeutic regimens or myeloablative SCT. Infectious complications remain the major cause of morbidity and mortality during intensive inpatient chemotherapy despite advances in prophylactic growth factor support, antibiotics, and antifungal agents. The low expected remission rates (30% to 50%) and high mortality and morbidity rates associated with induction are additional reasons for many patients to decline aggressive therapy. For these patients, therapeutic options include supportive therapy with hydroxyurea, transfusion support alone, and hospice.

Patients unfit for and those who choose not to receive intensive therapy are increasingly being treated with low-dose chemotherapy regimens. Low-dose subcutaneous cytarabine is associated with remission rates of about 18%. Alternatively, hypomethylating agents (e.g., 5-azacytidine, decitabine) have been well tolerated in older AML patients and result in complete remission rates ranging from 20% to 47% in some studies. Individuals treated with these drugs also experience hematologic improvement and disease stabilization associated with prolonged overall survival, even in absence of complete remissions.

AML patients with relapsed or refractory disease after standard therapy should be considered for allogeneic SCT and clinical trials. Experimental therapies for AML, particularly nonmyeloablative SCT (see Chapter 45), have resulted in durable long-term remissions in a proportion of older AML patients and should be pursued based on patient preference, overall health status, and availability of an appropriate HLA-matched donor.

TABLE 46-11 PROGNOSIS OF ACUTE MYELOID LEUKEMIA BASED ON CYTOGENETIC AND MOLECULAR ABNORMALITIES

RISK STATUS	CYTOGENETICS	MOLECULAR ABNORMALITIES
Favorable	inv(16) or t(16;16) t(8;21), t(15;17)	Normal cytogenetics: <i>NPM1</i> mutation in the absence of <i>FLT3</i> ITDs or isolated biallelic <i>CEBPA</i> mutation
Intermediate	Normal cytogenetics +8 alone, t(9;11) Other undefined	t(8;21), inv(16), or t(16;16) in the presence of <i>KIT</i> mutation
Poor	Complex (≥ 3 aberrations) Monosomal karyotype -5, 5q-, -7, 7q- 11q23: non-t(9;11) inv(3), t(3;3), t(6;9), t(9;22)	Normal karyotype with <i>FLT3</i> ITDs

ITDs, Internal tandem duplications.

There has been much interest in the clinical development of TKIs blocking mutant FLT3 signaling pathways for the treatment of FLT3 mutant AML, similar to BCR/ABL inhibitors in CML. The most effective FLT3 inhibitor, AC220 (quizartinib), resulted in a composite complete remission rate of approximately 50% in relapsed or refractory FLT3 ITD mutant AML in the phase II setting. However, multiple signaling pathways in AML cells and rapid proliferation of AML clones likely contribute to the rapid development of drug resistance. The results of additional studies examining the efficacy of FLT3 inhibitors combined with chemotherapy for relapsed and newly diagnosed FLT3-positive AML patients are eagerly awaited.

ACUTE PROMYELOCYTIC LEUKEMIA

Definition, Epidemiology, and Pathology

Acute promyelocytic leukemia (APL), formerly known as the FAB M3 subtype of AML (see Table 46-8), is a rare malignancy that represents 10% to 15% of adult AML. The incidence is increased among younger patients (median age, 40 years). The annual incidence in the United States ranges from 600 to 800 cases.

APL is different from other acute leukemias because of its unique disease biology. Morphologically, APL blasts are distinctive immature promyelocytic cells containing large granules and typically high numbers of Auer rods diagnostic of AML. APL is characterized by a chromosomal translocation— $t(15;17)(q22;q12)$ —involving the promyelocytic leukemia gene (*PML*) on chromosome 15 and the retinoic acid receptor- α gene (*RARA*) on chromosome 17. Sequestration of the resulting PML/RARA fusion protein with other proteins produces a complex that represses the gene transcription essential for granulocytic differentiation, effectively arresting differentiation of leukemia cells at the promyelocytic stage.

Clinical Presentation

Clinically, patients with APL often exhibit life-threatening bleeding caused by disseminated intravascular coagulation related to high levels of procoagulant factors released from APL granules. Bleeding complications in the CNS and other sites can be rapidly fatal if the disease is not recognized and treated as a medical emergency. All patients suspected of having APL should be started empirically with all-*trans*-retinoic acid (ATRA) therapy (discussed later) and treated aggressively with transfusions of fresh-frozen plasma, fibrinogen, and platelets until resolution of coagulopathy and disease confirmation.

Unlike patients with other AML subsets, APL patients typically have cytopenias rather than leukocytosis. High-risk APL patients are defined as those with white blood cell counts greater than $10 \times 10^9/L$.

Treatment and Prognosis

Treated appropriately, APL is the most curable acute leukemia in adults. The centerpiece of APL treatment is the use of agents that induce the terminal differentiation of leukemic promyelocytes followed by senescence and spontaneous apoptosis. ATRA is an oral derivative of vitamin A shown to overcome growth arrest and permit differentiation of immature APL blast cells into

neutrophils by altering the configuration of PML/RARA to allow normal gene transcription.

Patients initiated on ATRA must be closely observed for development of retinoic acid or APL differentiation syndrome, which is life-threatening acute cardiopulmonary distress characterized by bilateral pulmonary effusions and infiltrates. This serositis-like disorder is attributed to adhesion of differentiating neoplastic cells to the pulmonary vasculature and carries a 5% to 10% mortality rate. Treatment consists of early initiation of corticosteroids and aggressive diuresis. In severe cases, ATRA should be temporarily withheld.

Although ATRA alone induces clinical remissions in up to 90% of patients with APL, high relapse rates observed after monotherapy led to the practice of combining ATRA with anthracycline with or without cytarabine chemotherapy in initial induction regimens. Using this approach, complete remission rates for APL rose to between 90% and 95%, and more than two thirds of patients with APL treated with standard ATRA-containing induction, consolidation, and maintenance chemotherapy regimens achieved long-term remission.

Relapsed APL patients were treated with arsenic trioxide, a naturally occurring compound used both as a poison and a drug in many countries. Low-dose arsenic therapy promotes APL cell differentiation and apoptosis and induces remission rates in up to 90% of relapsed APL cases. APL differentiation syndrome and prolongation of the QT interval are common side effects of arsenic therapy. Based on its tolerability and non-overlapping cytotoxicities with conventional cytotoxic drugs, arsenic was successfully used for consolidation therapy in APL patients and improved clinical outcomes.

Although highly effective, combination ATRA and chemotherapy regimens for newly diagnosed APL patients were associated with an overall mortality rate of 10% to 20% during the first month of treatment. Most deaths resulted from uncontrolled hemorrhage, differentiation syndrome, and complications of prolonged myelosuppression after cytotoxic therapy, particularly in older individuals. To address these concerns, a phase III trial randomized lower-risk APL patients to dual-differentiation therapy with ATRA and arsenic only (without cytotoxic chemotherapy) or to standard ATRA and chemotherapy during induction and consolidation. The trial results demonstrated that ATRA plus arsenic treatment was not inferior to ATRA plus chemotherapy and was not associated with increased toxicity.

The trial results led to establishment of differentiation therapy alone as the standard of care for lower-risk APL patients. Patients with residual PML/RARA-positive cells after standard induction and consolidation therapy containing ATRA and arsenic should be considered for autologous or allogeneic SCT.

ACUTE LYMPHOBLASTIC LEUKEMIA

Definition, Epidemiology, and Pathology

ALL is a neoplasm of immature lymphoblasts expressing markers of B-cell or T-cell lineage. ALL is predominantly a pediatric malignancy, with most cases occurring in children younger than 6 years. The prior FAB classification system divided ALL into three subtypes (i.e., L1, L2, and L3) based on the morphology of malignant cells (E-Fig. 46-3). The WHO system reclassified the

(Courtesy Maurice Barcos, MD, PhD, Chief of Hematopathology, Roswell Park Cancer Institute, Buffalo, N.Y.)

disease as precursor B-cell or T-cell ALL based on the lineage of specific cell surface antigens found on these cells during normal maturation (see Table 46-7). T-cell ALL represents 15% to 25% of ALL diagnoses. More than 50% of T-cell ALL cases have activating mutations in NOTCH1, a key regulator of T-cell fate. One third of adult and 20% of pediatric B-cell ALL cases are associated with detection of the Philadelphia chromosome, t(9;22).

Clinical Presentation

Clinical and biologic features, particularly cytogenetics, at diagnosis have been identified as important prognostic factors (see Table 46-10).

Treatment

Treatment of ALL is lengthy and involves multiple chemotherapeutic agents given over 2 to 3 years. Induction chemotherapy typically includes vincristine, corticosteroids, and L-asparaginase with the addition of an anthracycline, cytarabine, or cyclophosphamide (or a combination) for adult patients. Given the propensity of ALL cells to reside in the CNS and testes (so-called sanctuaries for leukemia cells because standard systemic chemotherapy does not penetrate into these sites), most ALL patients undergo lumbar puncture at the time of diagnosis, followed by routine administration of intrathecal methotrexate or whole brain irradiation, or both, as a necessary adjunct to systemic induction and consolidation chemotherapy. Complete remission rates are 97% to 99% for children and 75% to 90% for adults.

After normal hematopoiesis returns, patients undergo consolidation and intensification therapy with multiple drugs to eradicate disease. For unknown reasons, ALL tends to relapse several months to years after initial remission. Studies have shown that the frequency of relapse is reduced by maintenance chemotherapy given for 2 to 3 years after initial remission achievement. Prolonged treatment may eliminate slow-growing leukemic clones, prevent further transformation, or destroy occult disease in other sites, particularly the CNS.

Progress in the understanding and treatment of this disease in the 1990s led to cure rates of up to 90% for children with ALL. Despite this success, only 20% to 40% of adult patients with ALL achieve cure. The poorer outcomes for adults are attributed to differences in the biologic mechanisms of disease in the different age groups and the inability of older patients to tolerate the intensive chemotherapy or transplantation procedures required to achieve long-term responses. Moreover, Philadelphia chromosome-expressing ALL, which is much more common in older individuals, is notoriously chemoresistant, has an increased risk of CNS involvement, and has an overall 5-year survival rate of less than 10%. Patients with Philadelphia chromosome-positive ALL routinely receive therapy with the oral BCR/ABL TKIs (i.e., imatinib and dasatinib) used in CML in addition to conventional chemotherapy. High-risk young patients with B-cell ALL may benefit from anti-CD20 antibodies (i.e., rituximab) directed against B-cell antigens on abnormal lymphoblasts.

In ALL, as in AML, the worse the prognosis, the earlier transplantation should be offered. Studies have shown that high-risk ALL patients (i.e., as older patients, Philadelphia chromosome-positive disease, high white blood cell count at presentation, or prolonged time to first remission) clearly benefit from SCT,

preferably from an HLA-matched sibling, during the first remission. Early transplantation in adults has achieved 5-year survival rates of 40% to 44%, compared with 20% with other therapies.

Unfortunately, outcomes for high-risk ALL patients without an available HLA-matched donor are poor, and these individuals should pursue HLA-matched unrelated donor allogeneic SCT or experimental therapies. No significant benefit has been seen with autologous transplantation over standard chemotherapy for these patients. Standard-risk ALL patients, particularly pediatric patients, with high long-term remission rates after conventional chemotherapy and maintenance need not undergo allogeneic SCT unless disease recurs.

Most ALL relapses arise within 2 years of the initial diagnosis, with recurrence of leukemic cells in the bone marrow, CNS, or testes. Although relapsed disease may respond to further chemotherapy and local irradiation, the duration of second remissions is usually less than 6 months. All patients with relapsed ALL should be considered for allogeneic SCT (which represents the only known cure for disease) or experimental treatment. Autologous SCT for refractory or relapsed ALL is not routinely recommended because ALL blasts appear to be more chemoresistant, and failure rates after treatment are higher.

For relapsed ALL patients not eligible for SCT, several novel therapeutic approaches are available. The newest BCR/ABL inhibitor, ponatinib, is being investigated in combination with chemotherapy for Philadelphia chromosome-positive ALL. Toxin-containing antibodies targeting the B-cell markers CD19 and CD52 in relapsed ALL patients are also being explored. Marqibo, a liposomal formulation of vincristine and a standard chemotherapy drug used in initial ALL therapy, has induced clinical responses in 35% of refractory or relapsed ALL patients as a single agent with tolerable toxicities.

Perhaps the most exciting strategies for ALL therapy involve technologies specifically exploiting patient host immune responses to affect long-term cure. Blinatumomab (BiTE) is a bispecific single-chain antibody that binds the T-cell receptor CD3 on T cells and the B-cell antigen CD19 expressed by malignant lymphoblasts. Dual binding of CD3 and CD19 by BiTE brings reactive T cells close to tumor cells, redirects T cell lysis, and eliminates disease. Administration of BiTE to ALL patients in clinical remission but with evidence of minimal residual disease after standard chemotherapy resulted in eradication of detectable persistent disease in 76% of patients. Ongoing trials evaluating BiTE in relapsed or refractory ALL patients with much higher tumor burdens and in combination with chemotherapy regimens are ongoing.

An alternative approach has been to genetically modify autologous T cells from ALL patients with CD19-expressing chimeric antigen receptors, effectively reprogramming them to recognize and destroy CD19-expressing tumor cells. Reinfusion of these cells after lymphodepleting chemotherapy resulted in the complete eradication of ALL disease in 80% to 90% of individuals and some long-term disease control alone and when followed by SCT. Whether these engineered T-cell strategies will be broadly applicable for most patients with ALL outside of clinical trials at major academic centers remains to be determined.

PROSPECTUS FOR THE FUTURE

Molecular understanding of the pathogenesis of MPNs and acute leukemia is progressing rapidly. It is already promoting development of novel therapeutic approaches that promise to transform the clinical approach to these diseases in the coming years.

Myeloproliferative Disease

The importance of the spectacular success of imatinib as targeted therapy for CML cannot be overstated. As the first successful therapy based on an understanding of pathogenesis, imatinib has become emblematic of the translation of an understanding of disease pathogenesis into tangible innovations in clinical care. Because second- and third-generation TKIs with activity against imatinib-resistant CML are available, SCT is now only rarely offered to patients with CML.

Similarly, the discovery of JAK2 mutations in non-CML myeloproliferative diseases opened new avenues for targeted intervention in diseases for which previous therapy was largely supportive. Treatment with the JAK2 inhibitor, ruxolitinib, has decreased splenomegaly and improved constitutional symptoms in higher-risk myelofibrosis patients independent of JAK2 mutation status. Moreover, provocative results demonstrating that ruxolitinib potentially prolongs overall survival and reduces marrow fibrosis in myelofibrosis patients offer hope that JAK2 inhibitors, like BCR/ABL inhibitors in CML, may eventually alter the natural history of disease.

Acute Leukemia

An understanding of the molecular pathogenesis of acute leukemia has led to important therapeutic advances in the treatment of disease. The discovery of the link between the retinoic acid receptor and the origins of APL provided important insights into the unique sensitivity of this disease to ATRA therapy and paved the road for successful implementation of dual differentiation therapy with ATRA and arsenic. This regimen marks the first time that any acute leukemia can be cured without cytotoxic chemotherapy or SCT.

Oral BCR/ABL kinase inhibitors have become a routine part of the treatment of Philadelphia chromosome–positive ALL. Advances in novel immunotherapeutic approaches that effectively reprogram host T cells to seek out and destroy ALL cells in patients have begun to prove their worth in the clinic and await further clinical validation.

In AML, identification of FLT3 kinase mutations in normal-karyotype AML has led to ongoing clinical trials of targeted inhibitors of this pathway in newly diagnosed and relapsed patients and offer hope for this subset of patients, who historically respond poorly to standard chemotherapy. Similar approaches may soon provide therapeutic entry points into the treatment of other acute leukemias associated with pathognomonic chromosomal translocations and genetic and molecular aberrations. Development of low-dose chemotherapy and reduced intensity SCT strategies has allowed older AML patients the opportunity to live longer and, in some cases, to be cured of their disease.

Disorders of Red Blood Cells

Michal G. Rose and Nancy Berliner

NORMAL RED BLOOD CELL STRUCTURE AND FUNCTION

The red blood cells (RBCs), or erythrocytes, deliver oxygen to all the tissues in the body and carry carbon dioxide back to the lungs for excretion. The erythrocyte is uniquely adapted to these functions. It has a biconcave disk shape that maximizes the membrane surface area for gas exchange, and it has a cytoskeleton and membrane structure that allow it to deform sufficiently to pass through the microvasculature. Passage through capillaries whose diameter may be one fourth the resting diameter of the erythrocyte is made possible by interactions between proteins in the membrane (band 3 and glycophorin) and underlying cytoplasmic proteins that make up the erythrocyte cytoskeleton (spectrin, ankyrin, and protein 4.1).

The mature RBC contains no nucleus and is dependent throughout its life span on proteins synthesized before extrusion of the nucleus and release of the cell from the bone marrow into the peripheral circulation. About 98% of the cytoplasmic protein of the mature erythrocyte is hemoglobin. The remainder is mainly enzymatic proteins, such as those required for anaerobic metabolism and the hexose monophosphate shunt.

Defects in any of the intrinsic structural features of the erythrocyte can result in hemolytic anemia. Abnormalities of the membrane or cytoskeletal proteins are the causes of alterations in erythrocyte shape and flexibility. Inborn defects in the enzymatic pathways for glucose metabolism decrease the resistance to oxidant stress, and inherited abnormalities of hemoglobin structure and synthesis lead to polymerization of abnormal hemoglobin (sickle cell disease) or to the precipitation of unbalanced hemoglobin chains (thalassemia). All of these changes result in decreased erythrocyte survival.

Oxygen is transported by hemoglobin, a tetramer composed of two α chains, two β -like (β , γ , or δ) chains, and four heme molecules, each of which is composed of a protoporphyrin molecule complexed with iron. In fetal life, the main hemoglobin is fetal hemoglobin (HbF: $\alpha_2\gamma_2$); the switch from HbF to adult hemoglobin (HbA: $\alpha_2\beta_2$) occurs in the perinatal period. By 4 to 6 months of age, the level of HbF has fallen to about 1% of total hemoglobin. HbA₂ ($\alpha_2\delta_2$) is a minor adult hemoglobin, representing about 1% of adult hemoglobin (Table 47-1).

CLINICAL PRESENTATION

Anemia, defined as a reduction in RBC mass, is an important sign of disease. It may reflect decreased production of erythrocytes that reflects nutritional deficiencies, primary hematologic disease, or a response to systemic illness. Alternatively, anemia may reflect

increased blood loss or cellular destruction from hemolysis. Hemolysis may occur as a result of intrinsic abnormalities of the RBC, immune-mediated RBC destruction, or a systemic vascular process. The investigation of anemia is a critical component of the evaluation of the patient and commonly provides valuable insight into systemic illness. Figure 47-1 provides an overview of the differential diagnosis of anemia.

The symptoms of anemia reflect both the severity and the rapidity with which the reduction in erythrocyte mass has occurred. Patients with acute hemorrhage or massive hemolysis may exhibit symptoms of hypovolemic shock. However, most patients develop anemia more slowly and have few symptoms. Usual complaints are fatigue, decreased exercise tolerance, dyspnea, and palpitations. In patients with coronary artery disease, anemia may precipitate angina. On physical examination, the major sign of anemia is pallor. Patients may be tachycardic and often have audible flow murmurs. Patients with hemolysis often exhibit jaundice and splenomegaly.

LABORATORY EVALUATION

The key components of the laboratory evaluation of anemia are the reticulocyte count, the peripheral blood smear, erythrocyte indices, nutritional studies, and the bone marrow aspirate and biopsy.

The *reticulocyte count* allows the critical distinction between anemia arising from a primary failure of RBC production and anemia resulting from increased RBC destruction or bleeding. Erythrocytes newly released from the marrow still contain small amounts of RNA; these cells, termed *reticulocytes*, can be detected with the use of automated counters and fluorescent nucleic acid-binding dyes or manually by staining of the peripheral blood smear with methylene blue or other supravital stains. In response to the stress of anemia, erythropoietin (EPO) production increases, promoting the production and release of increased numbers of reticulocytes. The number of reticulocytes in the

peripheral blood therefore reflects the response of the bone marrow to anemia.

The reticulocyte count can be expressed either as a percentage of the total number of RBCs or as an absolute number. In patients without anemia, the normal reticulocyte count is 0.5% to 1.5% of RBCs or 20,000 to 75,000/ μL . When the anemia is caused by decreased RBC survival, the appropriate marrow response results in a reticulocyte count greater than 2%, with an absolute count of more than 100,000/ μL . If the reticulocyte count is not elevated, a cause of failure of RBC production should be sought. Reticulocyte counts that are expressed as a percentage of total RBCs must be corrected for anemia because decreasing the number of circulating cells increases the reticulocyte percentage without any increase in release from the marrow. The *corrected reticulocyte count* is calculated by multiplying the reticulocyte count by the ratio of the patient's hematocrit to a normal hematocrit. The advantage of using the absolute reticulocyte count is that this correction is not necessary.

Evaluation of the *peripheral blood smear* may provide important clues to the cause of anemia. Erythrocyte morphologic examination is especially critical in the evaluation of anemia associated with reticulocytosis, wherein an examination of the smear is essential to distinguish between immune hemolysis (which results in spherocytes) and microangiopathic hemolysis (which causes schistocytes or erythrocyte fragmentation). Changes associated with other causes of anemia include sickle and target cells that are characteristic of hemoglobinopathies, teardrop cells

and nucleated RBCs associated with myelofibrosis and marrow infiltration, intracorpuscular parasites in malaria and babesiosis, and pencil-shaped deformities associated with severe iron deficiency. Examination of myeloid cells and platelets may also be helpful. Hypersegmented neutrophils and large platelets support the diagnosis of megaloblastic anemia, and the presence of immature blast forms may be diagnostic of leukemia. [Figure 47-2](#) presents some common peripheral blood smear findings in patients with anemia.

In patients with anemia and an elevated reticulocyte count, the vigorous production of new erythroid cells suggests that marrow function is normal and is responding appropriately to the stress of the anemia. Bone marrow examination in this situation is rarely indicated because the marrow will simply show erythroid hyperplasia, usually without revealing any primary pathologic anomaly of the marrow. Evaluation in these cases should be focused on determining whether the cause of RBC consumption is bleeding or hemolysis. In contrast, bone marrow examination is often required for the evaluation of hypoproliferative anemia. After common abnormalities such as iron deficiency and other nutritional deficiencies have been ruled out, marrow aspiration and biopsy are indicated to search for abnormalities such as marrow infiltration, marrow involvement with granulomatous disease, marrow aplasia, or myelodysplasia.

The *mean corpuscular volume* (MCV) is an extremely helpful tool in the diagnosis of anemia with a low reticulocyte count (hypoproliferative anemia). The size of the RBCs (measured in femtoliters per cell) is used to characterize the anemia as

FIGURE 47-2 Peripheral blood smears in patients with anemia. **A**, Normal red blood cells. **B**, Iron deficiency anemia. **C**, Sickle cell anemia. **D**, Microangiopathic hemolytic anemia. **E**, Spherocytosis (*black arrow*) and reticulocytosis (*white arrow*) in autoimmune hemolytic anemia. **F**, Teardrops in myelofibrosis. **G**, Target cells. **H**, Pseudo-Pelger-Huet anomaly in myelodysplasia.

microcytic (MCV <80), normocytic (MCV 80 to 100), or macrocytic (MCV >100).

EVALUATION OF HYPOPROLIFERATIVE ANEMIAS

Microcytic Anemias

The differential diagnosis of microcytic anemia is outlined in [Table 47-2](#). Microcytosis and hypochromia are the hallmarks of anemias caused by defects in hemoglobin synthesis, which can reflect either failure of heme synthesis or abnormalities in globin production. The leading cause of microcytic anemia is iron deficiency, in which lack of heme synthesis results from the absence of iron to incorporate into the porphyrin ring (see later discussion). Up to 30% of patients with anemia of chronic inflammation have microcytosis. Lead poisoning blocks the incorporation of iron into heme, also resulting in a microcytic anemia.

Sideroblastic anemias arise from failure to synthesize the porphyrin ring, usually as a result of inhibition of the heme synthetic pathway enzymes. Congenital sideroblastic anemia may respond to pyridoxine, a cofactor for several of the heme synthetic pathway enzymes. A more common cause of acquired sideroblastic anemia is alcohol abuse; ethanol inhibits most of the enzymes in the heme synthetic pathway. Failure of globin synthesis occurs in thalassemic syndromes (see Hemoglobinopathies). All these disorders lead to decreased mean corpuscular hemoglobin concentration, resulting in hypochromia and a decrease in RBC size (i.e., low MCV).

Iron Deficiency Anemia

Iron deficiency is the leading cause of anemia worldwide. Although the presentation of classic iron deficiency anemia is linked with a microcytic anemia, early iron deficiency is associated with a normocytic anemia. Consequently, iron deficiency should be considered in all patients with anemia, and iron indices should be a part of the evaluation of any patient with hypoproliferative anemia, regardless of the MCV.

Iron is acquired in the diet from heme sources (i.e., meat) and from nonheme sources (e.g., vegetables such as spinach). Iron

TABLE 47-2 DIFFERENTIAL DIAGNOSIS OF ANEMIA WITH LOW RETICULOCYTE COUNT

MICROCYTIC ANEMIA (MCV <80 fL/cell)	Nonmegaloblastic Macrocytosis
Iron deficiency	Liver disease
Thalassemia minor	Hypothyroidism
Anemia of chronic inflammation	Reticulocytosis
Sideroblastic anemia	NORMOCYTIC ANEMIA (MCV 80-100 fL/cell)
Lead poisoning	Early iron deficiency
MACROCYTIC ANEMIA (MCV >100 fL/cell)	Aplastic anemia
Megaloblastic Anemias	Myelophthitic disorders
Folate deficiency	Endocrinopathies
Vitamin B ₁₂ deficiency	Anemia of chronic inflammation
Drug-induced megaloblastic anemia	Anemia of renal failure
Myelodysplasia	Mixed nutritional deficiency

MCV, Mean corpuscular volume.

from heme is better absorbed than nonheme iron. Iron absorption is increased in iron deficiency, hypoxia, ineffective erythropoiesis, and hereditary hemochromatosis (most commonly caused by mutations in the *HFE* gene). Iron is absorbed from the proximal small intestine; it is transported in the cell bound to ferroportin and through the plasma bound to transferrin. Its uptake into the RBC precursors is mediated through the transferrin receptor. Iron absorption from the intestine is further regulated by hepcidin (see [Anemia of Chronic Inflammation](#)). Iron outside hemoglobin-producing cells is stored in ferritin. Men and women have total-body iron concentrations of 50 mg/kg and 40 mg/kg, respectively. Between 60% and 75% of the iron is found in hemoglobin. A small amount (2 mg/kg) is found in heme and nonheme enzymes, and 5 mg/kg is found in myoglobin. The remainder is stored in ferritin, which resides primarily in liver, bone marrow, spleen, and muscle. The capacity for excreting iron is limited, and iron overload occurs in patients with excessive absorption from the gastrointestinal tract (as a result of ineffective erythropoiesis or congenital hemochromatosis) and in those with chronic transfusions. Iron overload leads to increased iron deposition in these tissues and secondary

deposition in endocrine organs, resulting in liver dysfunction, diabetes, and other endocrine abnormalities.

The most frequent cause of iron deficiency is occult blood loss. All men and postmenopausal women who are found to be iron deficient should have an evaluation for a source of gastrointestinal blood loss, regardless of the detection of occult blood. In premenopausal women, iron deficiency is most frequently related to loss of iron with menstruation (about 15 mg per month) and during pregnancy (about 900 mg per pregnancy). *Helicobacter pylori* infection can cause iron deficiency even in the absence of intestinal bleeding. Dietary deficiency of iron is most commonly seen in multiparous women of childbearing age, in young children whose growth outstrips their intake of iron, and in babies who drink mostly milk at the expense of an intake of iron-containing foods.

Laboratory Evaluation

As previously stated, early iron deficiency does not exhibit the hallmark microcytosis and hypochromia that characterize classic iron deficiency. Evaluation of the blood smear in advanced iron deficiency often demonstrates hypochromic RBCs, target cells, and pencil-shaped elongated cells. Iron deficiency is frequently associated with reactive thrombocytosis.

The mainstay of the diagnosis of iron deficiency is the peripheral blood iron indices. These include iron concentration, total iron-binding capacity (TIBC), transferrin saturation, and ferritin concentration. The transferrin saturation is the ratio of serum iron to transferrin concentration; it is normally at least 20%. Iron deficiency results in a decrease in serum iron and an increase in iron-binding capacity, decreasing this ratio to less than 10%. Chronic inflammatory conditions (e.g., infection, inflammation, malignancy) often decrease both iron and TIBC, but the transferrin saturation usually remains above 20%. The ferritin level is a reflection of total-body iron stores. The liver synthesizes ferritin in proportion to total-body iron, and a level of less than 12 ng/mL strongly supports a diagnosis of iron deficiency. Unfortunately, ferritin is an acute phase reactant, and levels rise in the setting of fever, inflammatory disease, infection, or other stresses. However, ferritin levels in response to stress do not often rise above 100 ng/mL, and levels higher than 100 ng/mL usually rule out iron deficiency.

If the indirect measurement of iron indices does not definitively confirm or refute a diagnosis of iron deficiency, a therapeutic trial of iron supplementation may be considered. Alternatively, a bone marrow examination can be performed to provide a direct assessment of marrow iron stores. Presence of iron in the marrow excludes iron deficiency anemia because marrow iron stores will be depleted before there is any fall in RBC production resulting from iron deficiency; conversely, complete absence of marrow iron confirms the diagnosis of iron deficiency.

Treatment

Oral iron supplementation, with administration of ferrous sulfate or ferrous gluconate two or three times daily, is the treatment for iron deficiency. Patients should be educated about the potential gastrointestinal side effects, including diarrhea or constipation, and some may benefit from a gradual increase in the dose based on tolerance. Iron should be administered for several months

after resolution of anemia to allow for the reconstitution of iron stores.

In patients with malabsorption, a complete inability to tolerate oral iron, or iron demands that outstrip replacement with oral supplements, parenteral iron may be administered. The parenteral administration of iron, especially iron dextran, has been associated with anaphylaxis. However, newer preparations such as sodium ferric gluconate, iron sucrose, ferumoxytol, and ferric carboxymaltose are significantly safer. As previously stated, all male patients and postmenopausal women with iron deficiency require evaluation for a source of gastrointestinal bleeding.

Macrocytic Anemias

Two categories of hypoproliferative macrocytic anemias exist: megaloblastic anemias and nonmegaloblastic macrocytic anemias. Megaloblastic anemias arise from a failure of DNA synthesis and result in lack of synchrony between the maturation of the nucleus and the cytoplasm of hematopoietic cells. Nonmegaloblastic macrocytic anemias usually reflect membrane abnormalities resulting from defects in cholesterol metabolism and are most commonly found in patients with advanced liver disease or severe hypothyroidism. Reticulocytosis greater than 10% causes an elevated MCV on automated blood counts because reticulocytes are larger than mature RBCs.

Megaloblastic Anemias

Megaloblastic anemias result from a block in the synthesis of critical nucleotide precursors of DNA, which leads to a cell cycle arrest in S phase. Cytoplasmic maturation occurs, but maturation of the nucleus is arrested. Cells take on a bizarre appearance, with large immature nuclei surrounded by more mature-appearing cytoplasm. Interference with DNA synthesis affects all rapidly dividing cells, so patients with megaloblastic syndromes often have pancytopenia and gastrointestinal symptoms such as diarrhea and malabsorption. In women, megaloblastic changes of the cervical mucosa occur and may cause abnormal results on Papanicolaou smears. The most common causes of megaloblastic anemia are deficiencies of vitamin B₁₂ or folate, medications that inhibit DNA synthesis or that block folate metabolism, and myelodysplasia.

Cobalamin Deficiency

Cobalamin (vitamin B₁₂) is absorbed from animal protein in the diet. The process of cobalamin absorption and metabolism is complex because cobalamin is always bound to other proteins. In the stomach, protein-bound vitamins are released by digestion with pepsin and are bound to haptocorrin (transcobalamin I). Within the proximal duodenum, pancreatic proteases digest cobalamin away from haptocorrin, and cobalamin binds to intrinsic factor (IF), also known as transcobalamin III. IF is secreted by the parietal cells of the stomach and mediates absorption of cobalamin through the cubam receptor in the distal ileum. Within the ileal mucosal cell, the IF-cobalamin complex is again digested, and cobalamin is released into the plasma bound to haptocorrin and transcobalamin II.

Within the cell, cobalamin is a cofactor for two intracellular enzymes, L-methylmalonyl-coenzyme A (CoA) mutase and homocysteine-methionine methyltransferase (Fig. 47-3).

Mitochondria

FIGURE 47-3 Metabolic pathways of folic acid and cobalamin. CoA, Coenzyme A; THF, tetrahydrofolate.

Methylmalonyl-CoA mutase is a mitochondrial enzyme that functions in the citric acid cycle to convert methylmalonyl-CoA to succinyl-CoA. The cytoplasmic enzyme homocysteine-methionine methyltransferase is necessary for the transfer of methyl groups from *N*-methyltetrahydrofolate to homocysteine to form methionine. Demethylated tetrahydrofolate is necessary as a carbon donor in the conversion of deoxyuridine to deoxythymidine. Absence of cobalamin results in a *trapping* of tetrahydrofolate in its methylated form, which blocks the synthesis of thymidine 5'-triphosphate for incorporation into DNA. The megaloblastic changes induced by cobalamin deficiency are mediated through this functional folate deficiency, which explains the similarity in the hematologic abnormalities induced by cobalamin and folate deficiency.

Causes of Cobalamin Deficiency

The most common cause of cobalamin deficiency is pernicious anemia, an autoimmune disease associated with gastric parietal cell atrophy, defective gastric acid secretion, and absence of IF. Antiparietal cell and anti-IF antibodies are frequently found in patients with pernicious anemia and other autoimmune conditions such as type 1 diabetes, vitiligo, Graves' disease, Addison's disease, and hypoparathyroidism. Many other lesions in the gastrointestinal tract can interfere with absorption of cobalamin (Table 47-3). Gastrectomy causes loss of parietal cell function and IF secretion. Pancreatic insufficiency interferes with digestion of the haptocorrin-cobalamin complex, thus hindering the binding of cobalamin to IF and ileal absorption. Resection of the terminal ileum prevents vitamin B₁₂ absorption, as do diseases that affect ileal mucosal function, such as Crohn's disease, sprue, intestinal tuberculosis, and lymphoma. Because the body stores of cobalamin are large and daily loss of cobalamin is low, the stores of cobalamin are adequate for 3 to 4 years if intake stops abruptly; signs of cobalamin deficiency do not develop until defective absorption has occurred for several years. Nutritional

TABLE 47-3 CAUSES OF COBALAMIN DEFICIENCY

Malabsorption of Vitamin B ₁₂	Tapeworm infection
Pernicious anemia	Nutritional (vegans)
Partial or total gastrectomy	Congenital deficiency of intrinsic factor or haptocorrin

Diseases of the terminal ileum	

TABLE 47-4 CAUSES OF FOLATE DEFICIENCY

DIETARY INSUFFICIENCY	MALABSORPTION
INCREASED FOLATE REQUIREMENTS	Sprue
Pregnancy	Crohn's disease
Lactation	Short bowel syndrome
Hemolysis	ANTIFOLATE MEDICATIONS
Exfoliative dermatitis	Chemotherapy agents (e.g., methotrexate, pemetrexed)
Malignancy	Sulfa drugs

cobalamin deficiency is rare and is seen only in individuals who have been on strict vegan diets that exclude all animal products for many years. Infants born to vegan mothers who are breastfed are also at risk for development of cobalamin deficiency.

Folate Deficiency

Folate is widely present in foods such as leafy vegetables, fruits, and animal protein. However, because it is destroyed by prolonged cooking, fresh fruits and vegetables are the most reliable sources of folate. Consequently, nutritional folate deficiency is common in malnourished individuals who eat very little fresh fruits and vegetables. Folate deficiency can also be caused by increased demand, as occurs with pregnancy, hemolysis, or exfoliative dermatitis, and by increased losses, which occur with dialysis (Table 47-4). Folate is absorbed in the proximal small intestine, and malabsorption of folate can also lead to folate deficiency.

Other Causes of Megaloblastic Anemia

Drugs and toxins are common causes of megaloblastic anemia. Some drugs, such as methotrexate and sulfa drugs, act as direct folate antagonists and mimic folate deficiency. Purine and pyrimidine analogue chemotherapeutic agents (e.g., azathioprine, 5-fluorouracil) are direct DNA-synthesis inhibitors. Antiviral agents cause megaloblastic changes by unclear mechanisms. Alcohol interferes with folate metabolism, increasing the effect of frequent concomitant nutritional folate deficiency. Myelodysplasia commonly appears as a macrocytic anemia, with megaloblastic changes primarily in the erythroid series.

Clinical Manifestations of Megaloblastic Anemia

The development of megaloblastic anemia is usually gradual, allowing adequate time for concomitant plasma expansion to prevent hypovolemia. Consequently, patients are frequently severely anemic at presentation. They may have yellowish skin as the result of a combination of pallor and jaundice. Some patients have glossitis and cheilosis. With severe anemia, patients usually have an MCV greater than 110 fL/cell, although concomitant iron deficiency, caused by malabsorption secondary to

megaloblastic changes in the intestinal tract, may decrease the macrocytosis. Patients frequently have pancytopenia.

A peripheral smear demonstrates large, oval cells (macroovalocytes), hypersegmented neutrophils, and large platelets. The bone marrow is hypercellular, with megaloblastic changes and abnormally large precursors. In addition, intramedullary destruction of erythrocytes (ineffective hematopoiesis) causes elevated concentrations of bilirubin and lactate dehydrogenase.

Cobalamin deficiency is associated with neurologic abnormalities that are not seen with other causes of megaloblastic anemia. The neurologic signs may range widely, from a subtle loss of vibratory sensation and position sense caused by demyelination of the dorsal columns to frank dementia and neuropsychiatric disease. The neurologic changes may be present without anemia, especially if a patient with cobalamin deficiency is treated with folate, which may correct the hematologic manifestations of megaloblastic anemia but does not treat the neurologic abnormalities. The neurologic manifestations of cobalamin deficiency are thought to be secondary to loss of function of the mitochondrial enzyme methylmalonyl-CoA mutase. One proposed explanation is that the failure to metabolize odd-chain fatty acids, which results in their improper incorporation into myelin, causes the neurologic dysfunction. This explains why these findings are uniquely seen in patients with cobalamin deficiency and are not seen in those with the megaloblastic anemias caused by abnormalities in the folate pathway.

Serum levels of both cobalamin and folate should be measured in patients with megaloblastic anemia because megaloblastic changes in the gut mucosa can cause concomitant malabsorption of folate in the presence of cobalamin deficiency and vice versa. RBC folate levels better reflect the body folate stores and should be measured if a deficiency is clinically suggested but the serum folate levels are normal. Recent studies have shown, however, that many patients with pernicious anemia may have normal serum cobalamin levels. Homocysteine levels are elevated in cobalamin and folate deficiency, and methylmalonic acid levels are elevated in cobalamin deficiency. These levels should be measured if cobalamin deficiency is suggested but serum cobalamin levels are in the normal range. Anti-IF and anti-parietal cell antibodies may help determine the cause of cobalamin deficiency.

Treatment of Megaloblastic Anemia

For patients with cobalamin deficiency, both high-dose oral and parenteral cobalamin administration have been shown to be effective. The oral dose should be at least 1000 µg daily. Patients with neurologic abnormalities or medication noncompliance and those who have not responded to oral therapy should receive parenteral therapy with 1000 µg subcutaneously or intramuscularly several times per week for four to eight doses. Maintenance therapy should then be instituted with 1000 µg parenterally monthly. Therapy with cobalamin should be accompanied by folate therapy because concomitant secondary folate deficiency may develop when RBC production increases with the availability of cobalamin. Treatment of pernicious anemia should be continued for life.

Patients with folate deficiency should receive replacement with 1 to 5 mg per day of oral folate. As previously stated, it is

critical to be certain that patients are not cobalamin deficient: Replacement of folate may correct the hematologic parameters in patients with cobalamin deficiency, but it will not improve the neurologic sequelae.

After treatment of megaloblastic anemia, a rapid response usually occurs. Reticulocytosis is seen as early as 2 days after therapy and peaks within 7 to 10 days. Despite rapid resolution of neutropenia, hypersegmentation of neutrophils may persist for several days. During this period, rapid cellular proliferation and turnover occur, which may precipitate hypokalemia, hyperuricemia, or hypophosphatemia. Patients should also be monitored for the development of iron deficiency, which may occur in the face of increased hematopoiesis. Anemia and other cytopenias should respond completely within 1 to 2 months, but the neurologic manifestations of cobalamin deficiency improve slowly and may be irreversible.

Normocytic Anemias

The differential diagnosis of a normocytic hypoproliferative anemia is extensive. Most nutritional anemias that cause microcytosis or macrocytosis begin as a normocytic anemia. Patients with combined nutritional deficiencies may also have a normal MCV. The measurement of EPO levels may be helpful in the diagnosis of anemia resulting from renal failure, and many of the anemias associated with chronic inflammation and endocrinopathies exhibit a depressed EPO level. However, interpretation of EPO levels can be difficult in patients with mild anemia because the levels do not usually rise above the normal range until the hematocrit is depressed below 30%. Even with a hematocrit level of 30%, the EPO level is often in the normal range, but such levels are inappropriately low in the setting of anemia. An elevated EPO level suggests an inadequate marrow response to anemia and increases the likelihood of myelophthisis or primary bone marrow failure. In patients for whom the diagnosis is not clear after routine nutritional and endocrine studies, a bone marrow examination is indicated to rule out primary pathologic conditions of the marrow.

Anemia of Chronic Inflammation

The anemia of chronic inflammation (previously called anemia of chronic disease) occurs in patients with chronic inflammatory, infectious, malignant, or autoimmune disorders. Patients have low-serum iron levels, but in contrast to the iron indices in iron deficiency anemia, the iron-binding capacity is also reduced, and the transferrin saturation is usually greater than 10%. Ferritin levels are often elevated, both as an acute phase reactant and as a reflection of decreased iron incorporation. These patients have inappropriately high levels of hepcidin, an acute phase reactant that facilitates the metabolism of ferroportin and reduces both intestinal iron absorption and iron mobilization from macrophages. Cytokines, including tumor necrosis factor, the interleukins, and interferon, also play a role in the anemia of chronic inflammation, both by inducing hepcidin and by directly increasing EPO resistance in erythroid progenitors. Patients have an absolute or relative EPO deficiency, poor iron incorporation into developing erythrocytes, and shortened erythrocyte survival time. The prevalence of anemia of inflammation increases with age; most likely, this is related to age-related comorbidities and

mediated through an increase in inflammatory cytokines and a relative EPO resistance.

Treatment of Normocytic Anemias

The mainstay of therapy for the anemia of chronic inflammation is treatment of the underlying condition and correction of nutritional deficiencies. Iron supplementation should be offered to all patients with a ferritin level lower than 100 ng/mL. Erythroid-stimulating agents (ESAs) have been shown to reduce transfusion needs in many of these patients. However, randomized studies and meta-analyses have shown that their use is associated with an increased incidence of arterial and venous thromboembolic events, an increased risk of mortality from cancer, and a reduced survival time. ESA should be avoided in cancer patients if they are being treated with curative intent, and in all other patients with cancer they should be offered only after a careful discussion of the risks and benefits (grade 1B recommendation).

Anemia of Chronic Kidney Disease

Most patients who have a glomerular filtration rate of less than 30 mL/min have anemia related primarily to low EPO levels. ESAs can help prevent transfusions in this population; however, their use has been associated with an increased risk of stroke, access thrombosis, hypertension, and even mortality in some studies, especially when the hemoglobin levels were normalized. Therefore, most guidelines recommend a target hemoglobin concentration of 10 to 11.5 g/dL when using ESA in patients with chronic kidney disease (grade 1B). As in the management of anemia of chronic inflammation, nutritional deficiencies should be corrected before the use of ESAs. The evaluation and treatment of primary marrow failure syndromes and hematologic malignancies are discussed in [Chapters 45](#) and [46](#), respectively.

EVALUATION OF ANEMIA WITH RETICULOCYTOSIS

An elevated reticulocyte count in the setting of anemia signals a compensatory response by a normal marrow to premature loss of erythrocytes. Hemolysis is the premature destruction of RBCs in the reticuloendothelial system (extrinsic hemolysis) or in blood vessels (intrinsic hemolysis). The only other condition that causes anemia with reticulocytosis is acute bleeding. The differential diagnosis of hemolytic anemia is outlined in [Table 47-5](#).

Whereas examination of the peripheral blood smear is helpful in characterizing any anemia, it is absolutely critical in the evaluation of hemolytic anemia. Morphologic examination of the erythrocytes is helpful in distinguishing immune hemolysis from microangiopathic hemolytic anemia. In addition, other RBC morphologic abnormalities are characteristic for specific diseases such as sickle cell disease (sickled cells), enzyme defects (*bite* cells), and erythrocyte membrane abnormalities (spherocytes and elliptocytes).

Immune Hemolytic Anemia

Immune-mediated hemolysis results from coating of the erythrocyte membrane with antibodies or complement, or both. It may be mediated by immunoglobulin G (IgG) antibodies (*warm* antibody) or by IgM antibodies (*cold* antibody). The designations *warm* and *cold* denote the temperature at which maximal

TABLE 47-5 DIFFERENTIAL DIAGNOSIS OF HEMOLYTIC ANEMIA

Other sickle syndromes
Thalassemia

HELLP, Hemolysis, elevated liver enzymes, and low-platelet count in association with preeclampsia.

antibody binding takes place, and the clinical syndromes caused by the two types of antibodies are distinct.

The diagnosis of hemolytic anemia is based on the direct and indirect antiglobulin (Coombs) tests. To perform a direct Coombs test, the patient's erythrocytes are mixed with antisera or monoclonal antibodies directed against human immunoglobulins and human complement. The cells are then monitored for agglutination, the presence of which confirms the presence of antibody or complement on the patient's RBCs. The indirect Coombs test is performed by mixing the patient's serum with ABO-compatible erythrocytes and then combining this mixture with antisera against IgG; the indirect Coombs tests allows for the evaluation of antibody in the patient's serum.

IgG-Mediated (Warm) Hemolytic Anemia

Classic autoimmune hemolytic anemia (AIHA) is caused by IgG antibody directed against erythrocyte antigens. Warm type hemolysis may be primary (idiopathic) or associated with autoimmune disease, lymphoproliferative disorders, or drugs. Patients exhibit acute anemia, jaundice, and an elevated reticulocyte count. Some patients have splenomegaly. The peripheral blood smear demonstrates spherocytes (see [Fig. 47-2E](#)). Laboratory analysis confirms the presence of IgG on the erythrocyte membrane, as demonstrated by a positive Coombs test; in some patients, the erythrocytes are also coated with complement.

Some patients do not have reticulocytosis; in them, the antibody may be destroying both reticulocytes and mature erythrocytes.

The mainstay of therapy for AIHA is corticosteroids. Patients are usually treated with 1 to 2 mg/kg of prednisone, and in responding patients, doses are tapered slowly over several months. Patients who fail to respond to prednisone or cannot be tapered off the prednisone can be treated with other immunosuppressive agents, such as cyclophosphamide, azathioprine, chlorambucil, or rituximab. Some patients respond to intravenous immunoglobulin. Splenectomy is effective in many patients who are steroid refractory or steroid resistant, and it is associated with greater sustained response rates than other immunosuppressive therapies in steroid-resistant patients. However, patients who do not respond and who have ongoing hemolysis after splenectomy are at high risk for secondary thromboembolic events.

Warm antibodies mediate *drug-induced hemolysis*. Several mechanisms exist through which drugs may induce AIHA (Table 47-6). Penicillin produces hemolysis by binding to erythrocytes and acting as a hapten; the antibody is directed against the drug, and hemolysis occurs only in the presence of the drug. Type 2 hemolysis is caused by the formation of an antibody-drug complex that binds to the erythrocyte membrane and activates complement. Drugs associated with this type of hemolysis include quinidine, quinine, and rifampin. Still other drugs, including methyl dopa and procainamide, cause hemolysis by inducing the production of *true* antierythrocyte antibodies directed against Rh and other RBC antigens. Antibody may persist in the absence of the drug, but not all patients with a positive Coombs test have evidence of hemolysis.

IgM-Mediated (Cold) Hemolytic Anemia

Cold-type immune hemolysis is usually postinfectious. The most common associated infectious agents are *Mycoplasma pneumoniae* and Epstein-Barr virus (EBV). IgM antibodies are produced that are directed against the RBC antigen I (*Mycoplasma*) or i (EBV). The antibodies bind at lower temperatures, present in fingers and toes, and bind complement. During the return to the central circulation, the IgM falls off the RBC, leaving complement bound. The Coombs test is negative for IgG and IgM but

positive for complement. Hemolysis is self-limited, is rarely severe, and resolves with supportive therapy. In cases of severe hemolysis requiring transfusion, the patient should be kept warm, and blood should be administered through a blood warmer to minimize further hemolysis.

Cold agglutinin disease is a chronic IgM antibody-mediated hemolysis that is usually seen in association with lymphoproliferative disease. Hemolysis is usually low grade; if severe, it responds poorly to steroids and splenectomy. Acute severe IgM-mediated hemolysis may respond to plasmapheresis. Supportive therapy includes avoidance of exposure to the cold. In the setting of lymphoproliferative disease, patients may respond to immunotherapy with rituximab.

Hemolysis from Causes Extrinsic to the Erythrocyte

Microangiopathic Hemolysis

Microangiopathic hemolytic anemia (MAHA) is caused by traumatic destruction of RBCs as they pass through small vessels. The leading causes of MAHA include thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome (TTP/HUS) (see Table 47-5 and Fig. 47-1). Other causes include pregnancy-related syndromes such as preeclampsia, eclampsia, and the HELLP syndrome (*hemolysis, elevated liver enzyme levels, and low platelet count*); drugs; and metastatic cancers. A similar hemolytic picture can be seen in traumatic hemolysis on a damaged cardiac valve.

The finding of schistocytes (fragmented erythrocytes) on the peripheral blood smear confirms the diagnosis of MAHA (see Fig. 47-2D). The presence of normal prothrombin and partial thromboplastin times supports a diagnosis of TTP/HUS over that of disseminated intravascular coagulation. Diagnosis and management are described further in Chapter 51.

Infection

Hemolysis can be caused by direct infection of RBCs by parasites, as seen in malaria, babesiosis, and bartonellosis. Severe, overwhelming hemolysis can be seen in clostridial sepsis, in which bacterial toxins directly damage the membrane.

TABLE 47-6 DRUG-INDUCED AUTOIMMUNE HEMOLYTIC ANEMIA

IgG, Immunoglobulin G; RBC, red blood cell.

Hemolytic Anemias Caused by Disorders of the Erythrocyte Membrane

Inherited Membrane Abnormalities

Hereditary spherocytosis (HS) is caused by heterogeneous congenital abnormalities in proteins of the erythrocyte cytoskeleton (Table 47-7). Most patients with HS have dominantly inherited mutations in spectrin or ankyrin. HS is characterized by hemolytic anemia, splenomegaly, and the presence of prominent spherocytes in the peripheral blood. Spherocytes are the result of *conditioning* of the erythrocytes in the spleen, during which reticuloendothelial cells remove portions of the abnormal membrane that are caused by the disordered cytoskeleton. Spherocytes reflect membrane loss that decreases the membrane-to-cytoplasm ratio. Because a high membrane-to-cytoplasm ratio is responsible for the flexible, biconcave shape of the normal erythrocyte, the erythrocyte loses its biconcave morphologic characteristics and assumes a spherocytic shape with loss of membrane. Spherocytes are less flexible and may be destroyed in the microvasculature. The laboratory finding characteristic of HS is increased osmotic fragility, which is caused by the loss of distensibility associated with a decrease in surface membrane. HS is usually a mild disorder with well-compensated hemolysis. Patients typically have exacerbations during infections or when given marrow-suppressing medication. Patients with significant hemolysis should receive folate supplementation. Many patients require cholecystectomy for pigment stones. Severe, symptomatic anemia is treated with splenectomy.

Hereditary elliptocytosis (HE) is caused by dominantly inherited mutations affecting the interactions between membrane proteins and underlying cytoplasmic proteins. The most common abnormalities affect the interactions with spectrin and protein 4.1, which causes the RBCs to assume an elliptical shape. As in HS, patients usually have mild hemolysis and splenomegaly.

Hereditary pyropoikilocytosis (HPP) is a rare recessive disorder that is frequently caused by the inheritance of two different membrane disorders (e.g., one allele for HS and one for HE). Patients have severe hemolysis with microspherocytes and elliptocytes on the smear. As with HS, treatment for symptomatic anemia in HE and HPP is splenectomy.

 *More information on hemolytic anemias caused by inherited membrane disorders can be found in Chapter 161, "Hemolytic Anemias: Red Cell Membrane and Metabolic Defects," in Goldman-Cecil Medicine, 25th Edition.*

TABLE 47-7 CONGENITAL RED BLOOD CELL MEMBRANE ABNORMALITIES

CONDITION	ABNORMAL MEMBRANE PROTEINS	INHERITANCE
Spherocytosis	Spectrin, ankyrin, band 3, protein 4.2	Autosomal dominant Recessive (rare)
Elliptocytosis	Spectrin, protein 4.1	Autosomal dominant Recessive (rare)
Pyropoikilocytosis	Spectrin	Recessive
Stomatocytosis	Sodium channel permeability defect	Autosomal dominant

Acquired Membrane Abnormalities

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal disease that is associated with an abnormality of complement regulation. Normal erythrocytes are protected from complement-mediated cell lysis by the presence of membrane proteins, including delay-accelerating factor (DAF or CD55) and membrane inhibitor of reactive lysis (MIRL or CD59). Both these proteins are members of a family of proteins that are anchored to the membrane by a glycosyl phosphatidylinositol (GPI) anchor. Patients with PNH have clonal mutations in phosphatidylinositolglycan A (PIG-A), the enzyme required for synthesis of GPI. These mutations arise in the hematopoietic stem cell, and all hematopoietic cells lack GPI-anchored proteins. Absence of GPI-anchored proteins from erythrocytes renders them susceptible to complement-mediated lysis. The diagnosis can be made by flow cytometric documentation of the absence of CD55 or CD59 on the surface of RBCs or leukocytes.

PNH is a clonal stem cell disorder with several characteristics. Patients suffer from episodic acute intravascular hemolysis with a release of free hemoglobin that results in the hemoglobinuria for which the disease is named. Patients are also susceptible to venous thrombotic complications, including Budd-Chiari syndrome, portal vein thrombosis, cerebrovascular thrombosis, and peripheral veins. The disease is associated with a risk for development of myelodysplasia, myelofibrosis, acute leukemia, or aplastic anemia. Furthermore, patients with aplastic anemia who respond to immunosuppressive therapy frequently develop PNH-like clones. In the past, treatment has been largely supportive. However, treatment with eculizumab, a monoclonal antibody that binds to the C5 component of complement, has been shown to reduce hemolysis, transfusion requirements, and thromboembolic events in this disease. Young patients should be considered for allogeneic stem cell transplantation.

Spur Cell Anemia

Spur cells (acanthocytes) are cells with abnormal membrane morphology found in patients with advanced liver disease, severe malnutrition, malabsorption, or asplenia. The membrane acquires protrusions as a result of the presence of abnormal lipids. The changes may be associated with mild hemolysis, although in patients with advanced liver disease, it is difficult to distinguish hemolysis from hypersplenism. Similar changes may be observed in patients with abetalipoproteinemia.

Hemolytic Anemias Caused by Disorders of Erythrocyte Enzymes

Glucose-6 Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) is a critical enzyme in the hexose monophosphate shunt pathway. By maintaining intracellular stores of reduced glutathione, it protects erythrocytes from membrane and hemoglobin oxidation (Fig. 47-4). The gene for G6PD resides on the X chromosome, and therefore almost all patients with G6PD deficiency are male. Most G6PD mutations are found in African and Mediterranean populations, most likely because they confer resistance to malaria.

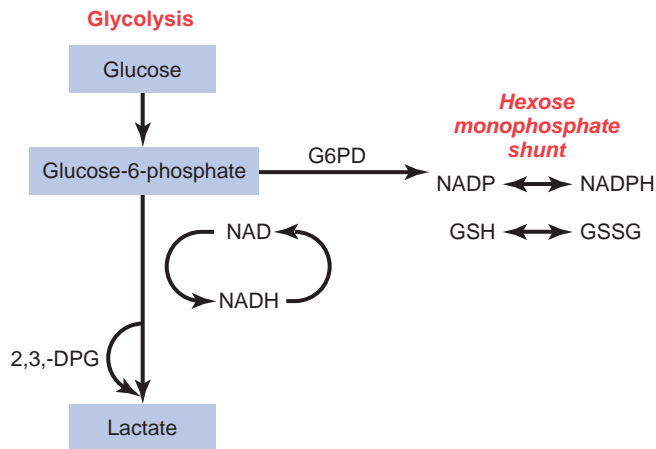

FIGURE 47-4 Metabolism of the red blood cell. 2,3-DPG, 2,3-Diphosphoglycerate; G6PD, glucose-6-phosphate dehydrogenase; GSH, reduced glutathione; GSSG, reduced and oxidized glutathione; NAD, nicotinamide adenine dinucleotide; NADH, reduced form of NAD; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of NADP.

The African form of G6PD deficiency is relatively mild, whereas the Mediterranean form is severe.

Absence of G6PD renders erythrocytes sensitive to oxidative stress. In the setting of infection, acidosis, or oxidant drugs, hemoglobin may precipitate within the cells, causing hemolysis. Many drugs are associated with hemolysis in the setting of G6PD deficiency, including sulfonamides, antimalarials, dapson, aspirin, and phenacetin. The diagnosis should be considered in male patients of African American or Mediterranean extraction who have evidence of hemolysis in the setting of acute infection or recent exposure to oxidant drugs. Patients with the Mediterranean variant of G6PD deficiency may develop hemolysis on exposure to fava beans (favism). Cells with precipitated hemoglobin contain Heinz bodies that can be visualized with crystal violet staining of the peripheral blood smear. These inclusions are removed in the spleen, resulting in the additional finding of bite cells in the blood smear. The diagnosis can be confirmed with measurement of G6PD levels in the peripheral blood. However, reticulocytes and young RBCs in patients with G6PD deficiency have a higher enzyme level; consequently, if the diagnosis is probable, the patients with a normal G6PD level should be retested at a time removed from the acute episode, when the percentage of young RBCs is high. The mainstay of preventing hemolysis in these patients is avoidance of oxidative stress, especially drugs implicated in causing hemolysis. Splenectomy is recommended only for patients with severe episodic or chronic hemolysis.

Other Enzyme Deficiencies

Enzyme deficiencies as rare causes of hemolytic anemia have been reported involving almost all of the enzymes of the glycolytic pathway. The most common of these is pyruvate kinase deficiency. Autosomal genes encode these enzymes, and the pattern of inheritance is therefore autosomal recessive.

 More information on hemolytic anemias caused by inherited enzyme deficiencies can be found in Chapter 161,

TABLE 47-8 CLINICAL MANIFESTATIONS OF SICKLE CELL DISEASE

ACUTE MANIFESTATIONS	CHRONIC MANIFESTATIONS
Vaso-occlusive crisis	Chronic renal disease
Painful crisis	Isosthenuria
Acute chest syndrome	Chronic renal failure
Priapism	Chronic pulmonary disease
Cerebrovascular events	Sickle hepatopathy
Thrombotic stroke	Proliferative retinopathy
Hemorrhagic stroke	Avascular necrosis
Aplastic crisis	Skin ulcers
Splenic sequestration	
Osteomyelitis	

"Hemolytic Anemias: Red Cell Membrane and Metabolic Defects," in Goldman-Cecil Medicine, 25th Edition.

Hemoglobinopathies

Hemoglobinopathies are disorders caused by mutations that result in the synthesis of quantitatively or qualitatively abnormal hemoglobins. The most common of these are the sickle syndromes and the thalassemias, which, like G6PD deficiency, arose in areas of the world with endemic malaria.

Sickle Cell Disease

Sickle cell disease, the most common of the sickle syndromes, arises from a point mutation that causes a substitution of valine for glutamic acid in the sixth amino acid of the β -globin gene. It has arisen as an independent mutation in diverse populations in Africa, India, the Mediterranean, and the Middle East. The substitution of a hydrophobic for a hydrophilic residue renders the deoxygenated sickle hemoglobin (HbS) less soluble and therefore susceptible to polymerization and precipitation. The rate of precipitation of HbS is exquisitely sensitive to the intracorporeal concentration of deoxygenated hemoglobin. Sickling is therefore increased in settings in which that concentration is increased, either by changes in cellular hydration (dehydration) or by changes in the oxygen dissociation curve (e.g., hypoxia, acidosis, high altitude).

Acute Manifestations

Most of the acute complications of sickle cell disease are related to vaso-occlusion (Table 47-8). Painful crises, secondary to occlusions of the microvasculature and ischemia of organs and tissues, can occur anywhere, with pain most commonly experienced in the extremities, chest, abdomen, and back. Painful crises are commonly precipitated by infections, dehydration, rapid changes in temperature, and pregnancy. Often, however, no obvious precipitating cause is found for an acute painful crisis.

Vaso-occlusion in the pulmonary circulation can be a particularly ominous complication of sickle cell disease. It results in the *acute chest syndrome*, which is characterized by chest pain, hypoxemia, and pulmonary infiltrates. The roles of infection, infarction, and in situ thrombosis in the acute chest syndrome are indistinguishable, but all patients should receive antibiotics for presumed pneumonia. Because hypoxemia predisposes to further sickling and increasing respiratory compromise, the acute chest syndrome is life-threatening and is an indication for emergent exchange transfusion.

Neurologic events are a major cause of morbidity in patients with sickle cell disease. Acute large-vessel occlusions occur in children, with a recurrence rate of 70% if untreated; such strokes are an indication for long-term exchange transfusion, which has been shown to decrease the rate of repeated occlusions. For reasons that are poorly understood, such large-vessel occlusions rarely occur in adults. Adults may suffer hemorrhagic strokes as a result of aneurysmal dilation of proliferative vessels that form in response to repeated micro-occlusions in the cerebral vessels.

Any toxic or infectious insult that transiently suppresses bone marrow activity can cause an *aplastic crisis*. The shortened survival time of the RBC in sickle cell disease renders patients highly dependent on vigorous ongoing marrow activity, and short intervals of decreased reticulocyte formation can cause profound anemia. Most dramatic are infections associated with parvovirus B19, which directly infects erythroid precursors. Supportive care is usually all that is required. However, some patients go on to develop bone marrow necrosis, with a leukoerythroblastic picture; this development may be further complicated by bone marrow embolization to the lungs.

Certain vascular beds are especially prone to complications of sickle cell disease. The renal medulla is highly susceptible to damage by vaso-occlusion because its high tonicity and low oxygen tension both significantly increase the concentration of HbS. All patients with sickle cell disease develop defects in the ability to concentrate urine, and by adulthood, they are uniformly isosthenuric. Acute episodes of hematuria secondary to papillary necrosis are common.

The spleen is another site in which recurrent sickling uniformly occurs. By adulthood, all patients have become functionally asplenic from repeated infarctions of the microvasculature. This contributing factor increases the susceptibility of patients with sickle cell disease to infections with encapsulated organisms. Acute infection remains a significant cause of death. For unclear reasons, patients with sickle cell disease are particularly prone to osteomyelitis, and there is an unusually high incidence of *Salmonella* as the responsible organism.

Chronic Manifestations

Sickle cell disease used to be a disease of childhood. As more patients survive to adulthood, it has become clear that repeated episodes of vaso-occlusion lead to damage to almost every end organ (see Table 47-8). Renal failure and pulmonary failure are leading causes of death in adult patients with sickle cell disease. Other long-term complications include chronic skin ulcers, retinopathy, and liver dysfunction. In addition, most patients require cholecystectomy for pigment stones.

Treatment

Treatment of sickle cell disease remains largely supportive. Painful crises are treated with fluid, oxygen supplementation, and analgesics. Patients with any indication of infection should receive antibiotics. Patients with symptomatic anemia should be transfused. Exchange transfusion is indicated for chest syndrome, stroke, bone marrow necrosis, and priapism. More controversial indications for exchange transfusion include intractable pain and slow response to other supportive measures. The goal of exchange transfusion is to achieve a level of 30% to 40% HbS. As previously

mentioned, patients who have sustained a thrombotic large-vessel stroke should undergo chronic exchange transfusion.

Treatment with hydroxyurea, an agent that increases the concentration of HbF in patients with sickle cell disease, reduces the incidence of vaso-occlusive crises. The efficacy of hydroxyurea in patients with recurrent crises has been demonstrated in a randomized study, and follow-up studies have revealed a survival advantage for patients treated with hydroxyurea.

Other Sickle Syndromes

Hemoglobin C

Hemoglobin C (HbC) is caused by another substitution, glutamic acid to lysine, in the sixth position of the β -globin chain. Homozygous HbC causes very mild symptoms of anemia and is usually clinically silent. Patients with hemoglobin S-C (HbSC) are compound heterozygotes for HbS and HbC. These patients are symptomatic, although the clinical manifestations are milder than in patients with homozygous HbS (HbSS). They have a higher hematocrit, and the higher viscosity increases the degree of retinopathy. They do not sustain splenic infarctions; unlike patients with HbSS, they usually have splenomegaly. Consequently, they occasionally have episodes of acute splenomegaly associated with profound decreases in hemoglobin concentration and hematocrit (splenic sequestration crisis). Although such crises also occur in children with HbSS, functional asplenia prevents this complication in adults with HbSS.

Sickle Cell β -Thalassemia

Patients who are double heterozygotes for HbS and β -thalassemia have a spectrum of disease dependent on the level of β -globin that they produce. Sickle cell β^+ -thalassemia is a milder disease than HbSS, probably because of the decreased intracorporeal concentration of HbS. Patients with sickle cell β^0 -thalassemia (see discussion that follows) produce no normal β chains and have essentially the same phenotype as patients with HbSS.

Thalassemia

The thalassemic syndromes (Table 47-9) are a heterogeneous group of disorders associated with decreased or absent synthesis of either α - or β -globin chains. Severe thalassemic syndromes are associated with severe hemolytic anemia and are diagnosed in early childhood. However, mild forms of thalassemia minor frequently cause mild microcytic anemia with little or no evidence of hemolysis. These syndromes are often confused with iron deficiency because of the decreased MCV.

β -Thalassemia

Over 100 mutations have been described that lead to β -thalassemia, causing a decrease or absence of expression from the β -globin locus. The decreased expression of β -globin can be caused by structural mutations in the coding region of the gene, which result in nonsense mutations, truncated messenger RNA (mRNA), and no expression of intact globin from the affected allele (β^0 -thalassemia). However, a large number of mutations that result in decreased transcription or translation or altered splicing of the β -globin mRNA result in reduction but not elimination of globin-chain expression from the affected allele (β^+ -thalassemia).

TABLE 47-9 THALASSEMIC SYNDROMES

DISORDER	GENOTYPIC ABNORMALITY	CLINICAL PHENOTYPE
β-THALASSEMIA		
Thalassemia major (Cooley's anemia)	Homozygous β ⁰ -thalassemia	Severe hemolysis, ineffective erythropoiesis, transfusion dependency, iron overload
Thalassemia intermedia	Compound heterozygous β ⁰ - and β ⁺ -thalassemia	Moderate hemolysis, severe anemia, but not transfusion dependent; iron overload
Thalassemia minor	Heterozygous β ⁰ - or β ⁺ -thalassemia	Microcytosis, mild anemia
α-THALASSEMIA		
Silent carrier	α- / αα	Normal complete blood count
α-thalassemia trait	αα / — (α-thalassemia 1) or α- / α- (α-thalassemia 2)	Mild microcytic anemia
Hemoglobin H	α- / —	Microcytic anemia and mild hemolysis; not transfusion dependent
Hydrops fetalis	— / —	Severe anemia, intrauterine anasarca from congestive heart failure; death in utero or at birth

Defective globin-chain synthesis in β-thalassemia causes both decreased normal hemoglobin production and the production of a relative excess of α chains. The decrease in normal hemoglobin synthesis results in a hypochromic anemia, and the excess α chains form insoluble α-chain complexes and cause hemolysis. In mild thalassemic syndromes, the excess α chains are insufficient to cause significant hemolysis, and the primary finding is a microcytic anemia. In severe forms of thalassemia, hemolysis occurs both in the periphery and in the marrow, with intense secondary expansion of the marrow production of RBCs. The expansion of the marrow space causes severe skeletal abnormalities, and the ineffective erythropoiesis also provides a powerful stimulus to absorb iron from the intestine.

The clinical spectrum of β-thalassemia reflects the heterogeneity of the molecular lesions causing the disease (see Table 47-9). β-Thalassemia major results from homozygous β⁰-thalassemia, leading to severe hemolytic anemia; such patients are diagnosed in infancy and are transfusion dependent from birth. Patients with β-thalassemia intermedia also have two β-thalassemia alleles, but at least one of them is a mild β⁺ mutation. These patients have severe chronic hemolytic anemia but do not require transfusions. Because of ineffective erythropoiesis, they patients chronically hyperabsorb iron and may develop iron overload in the absence of transfusions. β-Thalassemia minor is usually caused by heterozygous β-thalassemia, although it may reflect the inheritance of two mild thalassemic mutations. These are the patients in whom iron deficiency is often misdiagnosed. Iron studies show normal to increased iron with normal iron saturation. Documentation of a compensatory increase in HbA₂ and HbF on hemoglobin electrophoresis confirms the diagnosis.

α-Thalassemia

α-Thalassemia is almost always caused by mutations that delete one or more of the α-chain loci on chromosome 16. Four α-chain loci exist with two, almost identical, copies of the α-globin gene on each chromosome. The spectrum of α-thalassemia therefore reflects the lack of one, two, three, or all four α-globin genes (see Table 47-9). In general, the clinical manifestations of α-thalassemia are milder than those of β-thalassemia for two reasons. First, the presence of four α-chain genes allows for adequate α-chain synthesis unless three or four loci are deleted. Second, β-chain tetramers are more soluble than their α-chain counterparts and do not cause hemolysis. Patients with the loss of a single α-chain gene are silent carriers and have a normal hematocrit and MCV. Patients with deletion of two α chains, either on the same chromosome (— / αα, called α-thal 1) or on different chromosomes (α- / α-; α-thal 2), are microcytic and mildly anemic. Patients who inherit one α-thal 1 allele and one α-thal 2 allele (— / α-) have hemoglobin H disease. Hemoglobin H is the product of excess β-chain production, specifically β₄; it causes mild hemolytic anemia and minimal or no intramedullary erythrocyte destruction. Inheritance of the homozygous α-thal 2 allele results in no functional α-chain loci and is incompatible with life. The fetus is unable to make any functional hemoglobin beyond embryonic development because HbF also requires α chains. Free γ chains form tetramers, termed *hemoglobin Barts*. Hemoglobin Barts have an extremely high oxygen affinity, and failure to release oxygen in peripheral tissues results in severe congestive heart failure and anasarca, a clinical picture termed *hydrops fetalis*. Affected fetuses are stillborn or die soon after birth.

 More information on the thalassemias, sickle cell disease, and other hemoglobinopathies can be found in Chapter 162, "The Thalassemias," and Chapter 163, "Sickle Cell Disease and Other Hemoglobinopathies," in Goldman-Cecil Medicine, 25th Edition.

PROSPECTUS FOR THE FUTURE

Anemia is increasingly recognized as a marker of increased morbidity and mortality in adults with a wide range of medical conditions, including renal failure, malignancy, cardiac disease, inflammatory conditions, and other chronic diseases. Advances in understanding the pathophysiology of anemia of chronic inflammation are contributing to knowledge of iron metabolism and the roles cytokines play in hematopoiesis. These developments are paving the way for the development of new therapies for patients with anemia and iron overload. Ongoing progress in stem cell transplantation will contribute to the ability to treat the thalassemic syndromes and other hemoglobinopathies.

Clinical Disorders of Neutrophils

Michal G. Rose and Nancy Berliner

INTRODUCTION

Leukocytes provide the main defense against bacterial infection. Monocytes and granulocytes are phagocytic cells that can kill ingested bacteria through the generation of reactive intermediates. Monocytes also release inflammatory mediators that increase the activity of lymphocytes. Lymphocyte function is discussed in [Chapter 49](#).

NORMAL GRANULOCYTE DEVELOPMENT, STRUCTURE, AND FUNCTION

Neutrophils

Neutrophils (i.e., polymorphonuclear leukocytes) are the predominant white blood cell in the peripheral blood. They are morphologically recognizable by their characteristic segmented nucleus. Neutrophils also contain cytoplasmic granules that give them a characteristic appearance and are functionally important ([Fig. 48-1](#)).

Neutrophils achieve intracellular killing of bacteria through chemotaxis, adhesion, and phagocytosis ([Fig. 48-2](#)). *Chemotaxis* is the ordered movement of the cell toward an attracting stimulus, such as bacterial formyl peptides or complement fragments (i.e.,

C3b and C5a). Neutrophils adhere to endothelial cells by interaction of neutrophil surface glycoproteins (i.e., CD11b/CD18) with endothelial adhesion molecules (i.e., intracellular adhesion molecule 1 and endothelial leukocyte adhesion molecule 1), a process called *margination*. In response to a chemotactic stimulus, the adherent neutrophils move toward the target along the endothelial surface.

The syndrome of leukocyte adhesion deficiency underscores the importance of neutrophil adhesion as the first step in bacterial killing. This rare congenital disease is caused by the absence of surface expression of the CD11b/CD18 complex on neutrophils. Neutrophils fail to adhere to endothelium, are unable to undergo chemotaxis, and do not phagocytose or kill bacteria. Patients have severe, life-threatening bacterial infections despite high levels of circulating neutrophils.

Phagocytosis requires recognition of target bacteria or debris by the neutrophil. Targets are opsonized by the surface binding of immunoglobulin or complement factor C3b. The neutrophil has surface receptors for C3b and the Fc portion of immunoglobulin G, which allows recognition and binding to the opsonized target. The target then becomes engulfed in a phagocytic vacuole, which fuses with neutrophil granules inside the cell.

FIGURE 48-1 Normal granulocytes and monocytes in peripheral blood. **A** to **C**, Neutrophils (i.e., polymorphonuclear cells). **D**, Eosinophils. **E**, Basophils. **F**, Monocytes. (Courtesy Robert J. Homer, MD, PhD, Yale School of Medicine, New Haven, Conn.)

FIGURE 48-2 Sequence of neutrophil activation shows the process of rolling, engagement with the vessel wall, attachment, diapedesis, and phagocytosis. Mac 1, Macrophage antigen 1 (CD11b/CD18); RBC, red blood cell.

Intracellular killing occurs by oxygen-dependent and oxygen-independent mechanisms. Contents of the primary granules, including cathepsin G, defensins, and lysozyme, break down the bacterial cell wall and kill the target organism. However, the major mechanism of bacterial killing is the *respiratory burst*. Stimulation of the neutrophil activates a membrane-bound oxidase complex, which generates superoxide through the transfer of an electron from reduced nicotinamide-adenine dinucleotide phosphate (NADPH). The interaction of superoxide with water generates hydroxyl ions. Myeloperoxidase catalyzes the formation of hypochlorite ion from hydrogen peroxide and chloride. The NADPH oxidase is a multisubunit enzyme. Absence or decreased activity of any one subunit impairs bacterial killing and results in chronic granulomatous disease, a congenital illness in which patients are predisposed to life-threatening bacterial infections.

Neutrophil granules give neutrophils their characteristic appearance and have important functions in neutrophil-mediated activation and killing. *Primary granules* arise early in myeloid differentiation and are found in neutrophils and monocytes. They contain a large number of proteins, including myeloperoxidase, acid hydrolases, and neutral proteases. These granules fuse with the phagocytic vacuole and aid in the digestion of ingested bacteria. *Secondary granules* arise later in the differentiation pathway and give the neutrophil its characteristic granular (electron-dense) appearance. These granules contain lactoferrin, transcobalamin, and the matrix-modifying enzymes collagenase and gelatinase. On neutrophil stimulation, the granules are released into the extracellular space. Lactoferrin and transcobalamin act as antibacterial proteins by sequestering iron and vitamin B₁₂ away from bacteria, and collagenase and gelatinase break down connective tissues at the site of inflammation.

Abnormalities in neutrophil granules have been described in rare clinical syndromes. Absence of myeloperoxidase produces surprisingly mild symptoms and may be associated with defects in control of fungal infections. Secondary granule deficiency is rare and is associated with a slight increase in the risk of bacterial infections.

For a deeper discussion of these topics, please see Chapter 169, "Disorders of Phagocyte Function," in Goldman-Cecil Medicine, 25th Edition.

Eosinophils and Basophils

Eosinophils and basophils arise from myeloid precursors in the bone marrow. They transit rapidly from the marrow to the blood and into the peripheral tissues, where they play a role in allergic and inflammatory reactions. Like neutrophils, they have secondary granules that give them a characteristic appearance and are functionally important. Both cell types occur in small numbers under normal conditions.

Although eosinophils are capable of phagocytosis, most of the activity of these cells is mediated through the release of granule contents. The eosinophil numbers are elevated in parasitic and helminthic infections, in which these cells are thought to play a role in the allergic response to those organisms. Cell numbers are also elevated in allergic reactions and in collagen vascular diseases, linking their function to immunomodulation. Hypereosinophilic syndromes, in which extremely high levels of eosinophils can be seen, are rare, and hypereosinophilia can be associated with damage to the lung, peripheral nervous system, and endocardial tissues. The differential diagnosis of eosinophilia is outlined in [Table 48-1](#).

TABLE 48-1 DIFFERENTIAL DIAGNOSIS OF EOSINOPHILIA

CAUSES	COMMENTS
Infection*	Especially parasites; less commonly mycobacteria
Allergic diseases*	Drugs, asthma, allergic rhinitis, atopy, urticaria
Pulmonary diseases*	Churg-Strauss disease, Löffler's pneumonia, pulmonary infiltrates with eosinophilia
Drug reactions*	Usually disappears when drug discontinued
Malignancy*	Paraneoplastic, angioimmunoblastic T-cell lymphoma, Hodgkin's and non-Hodgkin's lymphoma
Connective tissue diseases*	Rheumatoid arthritis, eosinophilic fasciitis, vasculitis
Primary hypereosinophilic syndrome	More than 6 months of >1500 eosinophils/ μ L with no other apparent cause

*Reactive forms.

Basophils appear to play a role in immediate hypersensitivity reactions and chronic inflammatory conditions. Their levels are increased in chronic myeloid leukemias.

Monocytes

Monocytes arise from a common myeloid precursor along with granulocytes under the influence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage colony-stimulating factor (M-CSF). Most circulating monocytes are marginated along the walls of blood vessels. They migrate from the vessels into tissues, where they develop into macrophages.

The monocyte-macrophage lineage has many diverse functions. These phagocytic cells perform chemotaxis, phagocytosis, and intracellular killing in much the same manner as neutrophils. They are especially important in killing infectious mycobacterial, fungal, and protozoal species.

Monocytes interact with other components of the immune system. They are antigen-presenting cells for T lymphocytes, they are capable of cellular cytotoxicity, and they secrete certain cytokines. The macrophages (i.e., differentiated monocytes) that process antigens and present them to T lymphocytes take on different forms in different tissues: Langerhans cells in the skin, interdigitating cells in the thymus, and dendritic cells in the lymph nodes. Antigen-presenting cells are nonphagocytic, and the process by which they internalize antigen is not fully understood. Protein antigens are partially digested and expressed on the cell surface in association with major histocompatibility complex class II (Ia) antigens. This feature permits interaction with and activation of helper T cells. Other macrophages, such as Kupffer cells of the liver and alveolar macrophages of the lung, play an important role in removing particulate and cellular debris and senescent erythrocytes from the circulation.

Monocytes are capable of antibody-dependent and antibody-independent cytotoxicity against tumor cells. Cytotoxicity is increased by tumor necrosis factor, interleukin-1, and interferon, which are secreted by monocytes. Monocytes secrete large numbers of immunomodulatory proteins (e.g., tumor necrosis factor, interleukin-1, interferon), cytokines (e.g., granulocyte

colony-stimulating factor [G-CSF], GM-CSF), coagulation proteins, cell adhesion proteins, and proteases.

DETERMINANTS OF PERIPHERAL NEUTROPHIL NUMBERS

Most granulocyte precursors are in the bone marrow, where maturation occurs over 6 to 10 days. Marrow precursors represent 20% of the granulocyte mass, and the storage pool represents 75% of the granulocyte mass. Peripheral neutrophils represent only 5% of the total granulocyte mass.

Neutrophils circulate in transit between the marrow and peripheral tissues. More than one half of the circulating neutrophils adhere to the vascular endothelium (margination). The half-life of a neutrophil in the circulation was thought to be 6 to 12 hours, but in vivo studies suggest it may be as long as 3 to 4 days. After neutrophils migrate into tissues, they survive another 1 to 4 days. The peripheral neutrophil count therefore represents a sampling of less than 5% of the total granulocyte pool and is taken during a very short interval of the total neutrophil lifespan.

The peripheral white cell count is a poor reflection of granulocyte kinetics. Abnormalities in neutrophil number can occur rapidly and may reflect a change in marrow granulocyte production or a shift among various cellular compartments. An elevated peripheral white cell count may result from increased marrow production, or it may reflect mobilization of neutrophils from the marginated pool or release from the marrow storage pool. Similarly, a low granulocyte count may reflect decreased marrow production, increased margination or sequestration in the spleen, or increased destruction of peripheral cells.

The *total peripheral white cell count* represents the sum of lymphocytes and granulocytes. The significance of an elevated or depressed leukocyte count depends on the nature of the cellular elements that are increased or decreased. *Leukocytosis* is a non-specific term that may denote an increase in lymphocytes (i.e., lymphocytosis) or neutrophils (i.e., granulocytosis). In rare cases, increases may reflect excessive numbers of monocytes or eosinophils. Leukocytosis related to an elevation in the neutrophil count is called *neutrophil leukocytosis* or *neutrophilia*.

Extreme elevation of the white blood cell count to more than 50,000 cells/ μ L of blood with the premature release of early myeloid precursors is called a *leukemoid reaction*, which may be associated with inflammation and infection. It requires consideration of a diagnosis of myeloproliferative disease, especially chronic myelogenous leukemia (CML). Evaluation of the peripheral blood smear may reveal characteristic changes that provide clues to the underlying disorder. A leukoerythroblastic smear shows immature granulocytes, teardrop-shaped erythrocytes, nucleated erythrocytes, and increased platelets. These changes reflect marrow infiltration (i.e., myelophthisis) by fibrous tissue, granulomas, or neoplasm. As with leukocytosis, leukopenia may reflect lymphopenia or neutropenia. Neutropenia is defined by an absolute neutrophil count of less than 1500 cells/ μ L.

NEUTROPHILIA

Neutrophilia (i.e., leukocytosis) usually results from other processes, and it rarely indicates a primary hematologic disorder

(Table 48-2). However, patients with a persistently elevated neutrophil count, especially associated with an elevated hematocrit or platelet count, should be evaluated to rule out a primary myeloproliferative disorder. Peripheral blood evaluation for the BCR/ABL fusion product can be performed to rule out CML, and assays for JAK2 and calreticulin mutations can help to rule out non-CML myeloproliferative neoplasms. A leukocyte alkaline phosphatase assay was formerly used to rule out CML because the result was 0 in chronic phase CML, but with the advent of BCR/ABL testing, it has become obsolete.

Neutrophilia related to acute infection, stress, or acute steroid administration primarily reflects demargination and is usually transient. Persistent neutrophilia usually reflects chronic bone marrow stimulation. Nevertheless, a bone marrow aspirate and biopsy are rarely indicated in the work-up of neutrophilia. The exception is for patients who demonstrate leukoerythroblastic changes, for which a bone marrow examination and culture may be indicated to rule out tuberculosis or fungal infection, marrow infiltration with tumor, or marrow fibrosis. Cytogenetic and molecular studies should be performed to help eliminate the diagnosis of marrow malignancies, and the marrow should be cultured for mycobacteria and fungi.

NEUTROPENIA

Differential Diagnosis

Neutropenia (i.e., leukopenia) may reflect decreased production, increased sequestration, or peripheral destruction of neutrophils (Table 48-3). Patients should first be evaluated for splenomegaly to rule out the possibility of sequestration.

For patients who are completely asymptomatic and for whom previous studies are unavailable, the possibility of constitutional or cyclic neutropenia should be entertained and can be evaluated by serial peripheral blood counts. The normal neutrophil count varies among ethnic groups and is lower in American blacks (i.e., constitutional neutropenia) than it is in whites. Cyclic neutropenia is a relatively benign disorder, in which cyclical changes occur in all hematopoietic cell lines but are most dramatic in the neutrophil lineage. At the nadir of the neutrophil counts, patients may have infections, but the disease is often clinically silent. In contrast, patients with congenital agranulocytosis or severe congenital neutropenia (SCN) exhibit profound neutropenia and infections in the perinatal period. Kostmann's syndrome is a subset of SCN that was described 50 years ago as an autosomal

recessive disorder; later studies demonstrated that SCN might be autosomal dominant, autosomal recessive, X-linked, or sporadic and that the causes were also heterogeneous.

About 50% of autosomal dominant SCN and almost 100% of cyclic neutropenia cases are associated with inherited mutations in the neutrophil elastase gene. The mutations are thought to produce a misfolded neutrophil elastase protein, which accumulates in the endoplasmic reticulum and activates the unfolded protein response. This complex cellular stress response coordinates the degradation of misfolded protein in the endoplasmic reticulum and can trigger cellular apoptosis if the stress is severe. Later studies have established that autosomal recessive SCN (i.e. Kostmann's syndrome) is caused by mutations in the *HAX1* gene, which encodes a mitochondrial protein that is required for stabilization of the mitochondrial membrane. Absence of *HAX1* results in loss of the mitochondrial membrane potential and induction of apoptosis.

Until G-CSF became available, most patients with SCN died in early childhood, but the availability of cytokine therapy has prolonged survival. However, SCN is also associated with a significantly increased incidence of acute leukemia, a complication that has become apparent as patients survive longer. Up to 30% of patients with SCN develop acute myelogenous leukemia over 10 years. Acute myelogenous leukemia in these patients is often associated with truncation mutations in the G-CSF receptor. These acquired somatic mutations may contribute to the pathogenesis of leukemia but do not contribute to the congenital neutropenia. The role of the G-CSF receptor mutations in the pathogenesis of leukemic transformation is controversial, as is the relationship between G-CSF therapy and the acquisition of these mutations.

Neutropenia may occur during or after viral, bacterial, or mycobacterial infections. Postviral neutropenia is especially common in children and probably reflects increased neutrophil consumption and a viral suppression of marrow neutrophil production. Neutropenia may be seen as a complication of overwhelming sepsis and is associated with a poor prognosis.

Drug-induced neutropenia may reflect dose-dependent marrow suppression or an idiosyncratic immune response. The former is one of the most common complications of chemotherapeutic drugs and is also common with antibiotics such as sulfamethoxazole-trimethoprim. Chloramphenicol causes

TABLE 48-2 DIFFERENTIAL DIAGNOSIS OF NEUTROPHILIA

PRIMARY HEMATOLOGIC DISEASE	
Congenital neutrophilia	Cytokine stimulation (e.g., granulocyte colony-stimulating factor)
Leukocyte adhesion deficiency	Chronic inflammation
Myeloproliferative disorders	Malignancy
	Myelophthisis
DUE TO OTHER DISEASE PROCESSES	Marrow hyperstimulation
Infection (acute or chronic)	Chronic hemolysis, immune thrombocytopenia
Acute stress	Recovery from marrow suppression
Drugs (e.g., steroids, lithium)	After splenectomy
	Smoking

TABLE 48-3 DIFFERENTIAL DIAGNOSIS OF NEUTROPENIA

DECREASED PRODUCTION OF NEUTROPHILS	INCREASED PERIPHERAL DESTRUCTION
Congenital and/or constitutional cause	Overwhelming infection
Constitutional neutropenia	Immune destruction
Benign chronic neutropenia	Drug related
Kostmann's syndrome	Associated with collagen vascular disease
Benign cyclic neutropenia	Isoimmune (in newborns)
Postinfectious cause	Large granular lymphocyte leukemia
Nutritional deficiency (B ₁₂ , folate)	Hypersplenism and/or sequestration
Drug-induced cause	
Primary marrow failure	
Aplastic anemia	
Myelodysplasia	
Acute leukemia	

dose-dependent marrow suppression, although its more ominous complication is the rare idiosyncratic reaction that gives rise to marrow aplasia. Drugs that are most commonly associated with neutropenia include clozapine, sulfasalazine, ticlopidine, and the thionamide antithyroid agents. Most drug-induced neutropenias respond rapidly to discontinuation of the offending agent. The administration of G-CSF speeds recovery.

Autoimmune neutropenia may be seen as a primary disease or as a secondary manifestation of systemic autoimmune disease or lymphoproliferative disease. Primary autoimmune neutropenia is a disorder of infants and young children that resolves spontaneously in more than 90% of patients within 2 years. Secondary autoimmune neutropenia is a common accompaniment to systemic lupus erythematosus. Although not usually clinically severe, neutropenia is often a marker of disease activity.

Neutropenia in rheumatoid arthritis is associated with splenomegaly (i.e., Felty's syndrome) and is part of the spectrum of large granular lymphocyte (LGL) leukemia. LGL leukemia is a clonal expansion of suppressor T cells. Patients who develop LGL in association with rheumatoid arthritis share a common HLA-DR4 haplotype with patients with Felty's syndrome, suggesting that they are in a common spectrum of disease. LGL is also a relatively common cause of acquired neutropenia in elderly patients in the absence of rheumatoid arthritis. Recent data have linked LGL to mutations in the *STAT3* gene.

Laboratory Evaluation

Unless the diagnosis of benign or cyclic neutropenia is likely, the evaluation of the patient with neutropenia should include stopping all potentially offending drugs and performing serologic studies to rule out collagen vascular disease. Unlike the evaluation of patients with leukocytosis, bone marrow examination is indicated early for those with neutropenia and is frequently diagnostic. Neutropenia often reflects primary hematologic disease, and bone marrow examination enables the physician to diagnose marrow failure syndromes, leukemia, and myelodysplasia. In the absence of bone marrow failure, other causes of neutropenia may give a characteristic bone marrow picture. All patients undergoing bone marrow examination should have cytogenetic studies performed to aid in the diagnosis of myelodysplasia.

Sudden onset of agranulocytosis that does not affect platelets or erythrocytes typically is attributable to drug or toxin exposure. Bone marrow examination is rarely necessary. If performed, drug-induced neutropenia produces a characteristic maturation arrest of myeloid cells. Rather than actual inhibition of neutrophil maturation, this feature reflects the immune destruction of myeloid precursors that leaves only the earliest cells behind.

Treatment

The therapeutic approach to patients with neutropenia depends on the degree of depression of the neutrophil count. Neutrophil counts between 1000 and 1500 cells/ μL are not usually associated with significant impairment of the host response to bacterial infection and require no intervention beyond that demanded for diagnosis and treatment of the underlying cause. Patients with neutrophil counts between 500 and 1000 cells/ μL should be

alerted to their slightly increased risk of infection, although serious problems are rarely encountered in patients with functional neutrophils and counts higher than 500 cells/ μL .

Patients with neutrophil counts lower than 500 cells/ μL are at significant risk for infection. They should be instructed to notify the physician at the first sign of infection or fever, and they must be managed aggressively with intravenous antibiotics regardless of the documentation of a source or infecting organism. Patients with a significantly depressed neutrophil count may exhibit few signs of infection because much of the inflammatory response at the site of infection is generated by the neutrophils themselves.

In patients with severe immune-mediated neutropenia, steroids and intravenous immunoglobulin may be helpful in elevating the neutrophil count and in preventing infectious complications. G-CSF may increase the peripheral white cell count and may help resolve infections in neutropenia induced by drugs, including chemotherapy. It has been efficacious for some patients with immune-mediated neutropenia and those with myelodysplasia.

 For a deeper discussion of these topics, please see Chapter 167, "Leukocytosis and Leukopenia" in Goldman-Cecil Medicine, 25th Edition.

PROSPECTUS FOR THE FUTURE

Significant progress has been made in elucidating the molecular pathogenesis of severe congenital neutropenia and cyclic neutropenia. Compounds that modulate the unfolded protein response may play a role in the treatment of these disorders. Other studies of the molecular basis of myeloid differentiation are establishing the importance of transcription factor function in neutrophil maturation and are providing insights into the pathogenesis of leukemia and myelodysplasia. Their findings may delineate pathways with entry points for therapeutic intervention in myeloid malignancies.

Disorders of Lymphocytes

Jill Lacy and Stuart Seropian

INTRODUCTION

The central cell of the immune system is the lymphocyte. Lymphocytes mediate the adaptive immune response, providing specificity to the immune system by responding to specific pathogens and conferring long-lasting immunity to reinfection. Lymphocytes are derived from pluripotent hematopoietic stem cells that reside in the bone marrow and give rise to all of the cellular elements of the blood. The two major functional classes of lymphocytes—B lymphocytes (B cells) and T lymphocytes (T cells)—are distinguished by their site of development, antigenic receptors, and function.

The major disorders of lymphocytes include neoplastic transformations of specific subsets of lymphocytes that result in an array of lymphomas or leukemias, congenital or acquired defects in lymphocyte development or function with resultant immunodeficiency syndromes, and physiologic responses to infection or

antigenic stimulation that may lead to lymphadenopathy, lymphocytosis, or lymphocytopenia.

LYMPHOCYTE DEVELOPMENT, FUNCTION, AND LOCALIZATION

B Cells

B cells are characterized by cell surface immunoglobulins (i.e., antibodies). Their major function is to mount a humoral immune response to antigens by producing antigen-specific antibodies.

B cells develop in the bone marrow in a series of highly coordinated steps that involve sequential rearrangement of the heavy- and light-chain immunoglobulin genes and expression of B-cell-specific cell surface proteins (Fig. 49-1). Rearrangement of the immunoglobulin genes results in generation of a large repertoire of B cells that are each characterized by an immunoglobulin molecule with unique antigenic specificity. Mature B cells

FIGURE 49-1 The maturation of B lymphocytes. *Top*, The changes in immunoglobulin production and maturation. *Bottom*, The appearance and disappearance of surface markers. TdT, Terminal deoxynucleotidyl transferase. (Modified from Ferrarini M, Grossi CE, Cooper MD: Cellular and molecular biology of lymphoid cells. In Handin RI, Lux SE, Stossel TP, editors: Blood principles and practice of hematology, Philadelphia, 1995, JB Lippincott, p 643.)

migrate from the bone marrow to lymphoid tissue throughout the body and are readily identified by cell surface immunoglobulin and antigens that are B cell specific, including CD19, CD20, and CD21.

In response to antigen binding to cell surface immunoglobulin, mature B cells are activated to proliferate and undergo differentiation to end-stage plasma cells, which lose most of their B-cell surface markers and produce large quantities of soluble antibodies. Neoplastic disorders of B cells arise from B cells at different stages of development, and B-cell lymphomas can have highly varied morphology and cell surface expression of B-cell antigens (i.e., immunophenotype).

T Cells

T cells perform an array of functions in the immune response, including those that are regarded as classic cellular immune responses. T-cell precursors migrate from the bone marrow to the thymus, where they differentiate into mature T-cell subsets and undergo selection to eliminate autoreactive T cells that respond to self-peptides. In the thymus, T-cell precursors undergo a coordinated process of differentiation that involves rearrangement and expression of the T-cell receptor (TCR) genes and acquisition of cell surface proteins that are unique to T cells, including CD3, CD4, and CD8.

As T cells mature in the thymus, they ultimately lose the CD4 or CD8 protein. Mature T cells are composed of two major groups: CD4⁺ and CD8⁺ cells. After T-cell maturation and selection in the thymus, mature CD4⁺ and CD8⁺ T cells migrate to lymph nodes, spleen, and other sites in the peripheral immune system. Mature T cells constitute about 80% of peripheral blood lymphocytes, 40% of lymph node cells, and 25% of splenic lymphoid cells.

Mature CD4⁺ and CD8⁺ T-cell subsets mediate distinct immune functions. CD8⁺ cells kill virus-infected or foreign cells and suppress immune functions; CD8⁺ cells are called *cytotoxic T cells*. CD4⁺ cells activate other immune response cells such as B cells and macrophages by producing cytokines and through direct cell contact; CD4⁺ cells are called *helper T cells*.

Similar to B cells, T cells express unique TCR molecules that recognize specific peptide antigens. In contrast to B cells, T cells respond only to peptides that are processed intracellularly and bound to (or presented by) specialized cell surface antigen-presenting proteins, designated major histocompatibility complex (MHC) molecules. CD4⁺ and CD8⁺ T cells are MHC class restricted in their response to peptide-MHC complexes. CD4⁺ cells recognize antigenic peptide fragments only when they are presented by MHC class II molecules, and CD8⁺ cells recognize antigenic peptide fragments only when they are presented by MHC class I molecules. Binding of the TCR by a specific peptide-MHC complex triggers activation signals that lead to the expression of gene products that mediate the wide diversity of helper functions of CD4⁺ cells or cytotoxic effector functions of CD8⁺ cells. A detailed discussion is provided in Chapter 45.

Lymphoid System

Lymphocytes localize to the peripheral lymphoid tissue, which is the site of antigen-lymphocyte interaction and lymphocyte

activation. The peripheral lymphoid tissue is composed of lymph nodes, the spleen, and mucosal lymphoid tissue. Lymphocytes circulate continuously through these tissues through the vascular and lymphatic systems.

The lymph nodes are highly organized lymphoid tissues that are sites of convergence of the lymphatic drainage system, which carries antigens from draining lymph to the nodes, where they are trapped. A lymph node consists of an outer cortex and an inner medulla (Fig. 49-2). The cortex is organized into lymphoid follicles composed predominantly of B cells. Some of the follicles contain central areas or germinal centers, where activated B cells undergo proliferation after encountering a specific antigen, that are surrounded by a mantle zone. The T cells are distributed more diffusely in paracortical areas surrounding the follicles.

The spleen traps antigens from blood rather than from the lymphatic system and is the site of disposal of senescent red cells. The lymphocytes in the spleen reside in the areas described as the white pulp, which surround the arterioles entering the organ. As in lymph nodes, the B and T cells are segregated into a periarteriolar lymphoid sheath that is composed of T cells and flanking follicles composed of B cells. The mucosa-associated lymphoid tissues (MALTs) collect antigen from epithelial surfaces and include the gut-associated lymphoid tissue (i.e., tonsils, adenoids, appendix, and Peyer's patches of the small intestine) and more diffusely organized aggregates of lymphocytes at other mucosal sites.

Lymphocytes circulate in the peripheral blood and represent 20% to 40% of peripheral blood leukocytes in adults; the proportion is higher in newborns and children. Between 80% and 90% of peripheral blood lymphocytes are T cells, and the remaining lymphocytes are largely B cells. A small percentage of peripheral blood lymphoid cells represents a third category of lymphoid cells that are referred to as natural killer (NK) cells. These cells

FIGURE 49-2 Structure of the normal lymph node. The cortical area contains the follicles, which consist of a germinal center and a mantle zone. The medulla contains a complex of channels that lead to the efferent lymphatics.

do not bear the characteristic cell surface molecules of B or T cells, and their immunoglobulin or TCR genes have not undergone rearrangement. Morphologically, the cells are large, with abundant cytoplasm containing azurophilic granules, and they are often called *large granular lymphocytes*. Functionally, they are part of the innate immune system, responding nonspecifically to a wide range of pathogens without requiring prior antigenic exposure.

NEOPLASIA OF LYMPHOID ORIGIN

Malignant transformation of lymphocytes leads to a diverse array of neoplasms of lymphoid origin, including tumors that arise from T cells, B cells, or NK cells. Lymphoid malignancies usually involve lymphoid tissues, but they can arise in or spread to any site. The major clinical groupings of lymphoid malignancies include non-Hodgkin's lymphomas (NHLs), Hodgkin's lymphoma, lymphoid leukemias, and plasma cell dyscrasias.

Non-Hodgkin's Lymphomas

Definition and Epidemiology

The NHLs comprise a heterogeneous group of lymphoid malignancies that have different histologic appearances, cells of origin and immunophenotypes, molecular biologic factors, clinical features, prognoses, and outcomes with therapy. According to the Surveillance, Epidemiology, and End Results (SEER) database, the NHLs are the seventh most common cancer type, with 70,000 cases occurring in 2013 and 19,000 patients succumbing to these diseases. The NHLs occur at a median age of 66 and are more common in men and in whites. The rate of NHLs increased slowly between 2000 and 2010 by 0.5% per year, but the annual death rate declined during the same time period.

Pathology

In view of the heterogeneity of NHLs, classification systems have been devised to identify specific pathologic subtypes that correlate with distinct clinical entities. These systems have evolved steadily over the past 50 years as correlations between histopathologic and biologic behavior have emerged. Pathologic classification schemes have attempted to correlate malignant NHL subtypes with normal cellular counterparts. The World Health Organization (WHO) classification (Table 49-1) is the most current and incorporates morphologic features, immunophenotype, and cytogenetic characteristics to describe NHL subtypes. The most common NHLs encountered in the United States are diffuse large B-cell lymphoma (DLBCL), follicular lymphoma, small lymphocytic lymphoma or leukemia (i.e., chronic lymphocytic leukemia [CLL]), and mantle cell lymphoma.

The cause of most NHLs is unknown. In most patients with NHL, no apparent genetic predisposition or epidemiologic or environmental factor can be identified. Many of the NHL subtypes carry pathognomonic chromosomal translocations that often involve an immunoglobulin locus (or TCR locus in T-cell-derived NHLs) and an oncogene or growth regulatory gene. The cause of these aberrant chromosomal rearrangements is unknown.

Patients with congenital immunodeficiency syndromes or autoimmune disorders are at increased risk for NHL. Oncogenic human viruses play a causal role in some of the less common

TABLE 49-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF LYMPHOID NEOPLASMS*

B-CELL NEOPLASMS

Precursor B-cell neoplasm

Precursor B-lymphoblastic leukemia/lymphoma (precursor B-cell acute lymphoblastic leukemia)

Mature (peripheral) B-cell neoplasms

B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma

B-cell prolymphocytic leukemia

Lymphoplasmacytic lymphoma

Splenic marginal zone B-cell lymphoma (\pm villous lymphocytes)

Splenic B-cell lymphoma/leukemia, unclassifiable

Hairy cell leukemia

Plasma cell myeloma/plasmacytoma

Extranodal marginal zone B-cell lymphoma of MALT type

Nodal marginal zone B-cell lymphoma of MALT type

Primary cutaneous follicle center lymphoma

Follicular lymphoma

Mantle cell lymphoma

Diffuse large B-cell lymphoma

Mediastinal large B-cell lymphoma

Primary effusion lymphoma

Burkitt's lymphoma/Burkitt cell leukemia

T-CELL AND NK-CELL NEOPLASMS

Precursor T-cell neoplasm

Precursor T-lymphoblastic lymphoma/leukemia (precursor T-cell acute lymphoblastic leukemia)

Mature (peripheral) T-cell neoplasms

T-cell prolymphocytic leukemia

T-cell granular lymphocytic leukemia

Aggressive NK-cell leukemia

Adult T-cell lymphoma/leukemia (HTLV-1 positive)

Extranodal NK-cell or T-cell lymphoma, nasal type

Enteropathy-type T-cell lymphoma

Hepatosplenic gamma-delta T-cell lymphoma

Subcutaneous panniculitis-like T-cell lymphoma

Mycosis fungoides/Sézary syndrome

Anaplastic large cell lymphoma, T-cell/null cell, primary cutaneous type

Peripheral T-cell lymphoma, not otherwise characterized

Angioimmunoblastic T-cell lymphoma

Anaplastic large cell lymphoma, T-cell/null cell, primary systemic type

HTLV-1, Human T-cell leukemia virus type 1; MALT, mucosa-associated lymphoid tissue; NK, natural killer.

*Only major categories are included, and common entities are shown in bold type. B-cell and T-cell/NK-cell neoplasms are grouped according to major clinical presentations: predominantly disseminated or leukemic, primary extranodal, and predominantly nodal.

NHL variants. Epstein-Barr virus (EBV) is associated with several biologically aggressive NHLs, including acquired immunodeficiency syndrome (AIDS)-related diffuse, aggressive lymphomas, the lymphoproliferative disorders that arise in patients who are immunosuppressed after organ transplantation, and the form of Burkitt's lymphoma that is endemic in Africa. Human T-cell lymphotropic virus type 1 (HTLV-1) is causally linked with adult T-cell leukemia/lymphoma, which is endemic in areas of Japan and the Caribbean basin. The human herpesvirus 8 (HHV-8) of Kaposi's sarcoma has been implicated in a variant of diffuse, aggressive NHL that arises in serosal cavities and is encountered almost exclusively in patients infected with human immunodeficiency virus (HIV).

Several indolent lymphomas have been linked to infectious agents that appear to indirectly promote lymphomagenesis through chronic antigen stimulation, resulting in B-lymphocyte proliferation. *Helicobacter pylori* infection is linked to gastric MALT lymphomas in this manner, and eradication of infection

with antibiotics is often associated with regression of the lymphoma.

Clinical Presentation

Although numerous subtypes of NHL are recognized, most disease entities may be viewed conceptually as clinically indolent (i.e., low grade) or aggressive (i.e., high grade). Indolent lymphomas typically grow slowly, do not always require therapy, and have a long natural history. A clinical history of recurring and regressing adenopathy may be elicited. Aggressive lymphomas are more likely to manifest with symptoms and are associated with limited survival in the absence of therapy.

Most patients with NHL exhibit painless lymphadenopathy involving one or more of the peripheral nodal sites. NHL can involve extranodal sites, and patients can exhibit a variety of symptoms that reflect the site of involvement. Common sites of extranodal disease include the gastrointestinal tract, bone marrow or focal bone lesions, liver, skin, and Waldeyer's ring in the nasopharynx and oropharynx, although virtually any site can be involved. Aggressive subtypes of NHL are more likely than indolent lymphomas to involve extranodal sites.

Central nervous system involvement, including leptomeningeal spread, rarely occurs with the indolent subtypes but does occur with the aggressive variants. The most aggressive NHLs (i.e., Burkitt's and lymphoblastic lymphomas) have a particular propensity to spread to the leptomeninges.

Constitutional symptoms such as fever, weight loss, or night sweats occur in about 20% of patients with NHL at the time of onset. These symptoms are more common in patients with aggressive subtypes of NHL.

Diagnosis and Differential Diagnosis

Many causes of lymphadenopathy exist in addition to lymphoid malignancies (Table 49-2). A thorough history and careful physical examination are important before performing a lymph node biopsy. The investigation of lymphadenopathy can be organized according to the location of the enlarged nodes (i.e., localized or generalized) and clinical symptoms.

Cervical lymphadenopathy is most often caused by infections of the upper respiratory tract, including infectious mononucleosis syndromes, viral syndromes, and bacterial pharyngitis. Unilateral axillary, inguinal, or femoral adenopathy may be caused by skin infections involving the extremity, including cat-scratch fever. Generalized lymphadenopathy may be caused by systemic infections (e.g., HIV, cytomegalovirus), drug reactions, autoimmune diseases, or one of the systemic lymphadenopathy syndromes. If the cause of persistent lymphadenopathy is not apparent after a thorough evaluation, an excisional lymph node biopsy should be undertaken. An enlarged supraclavicular lymph node strongly suggests malignancy and should always be sampled.

The accurate diagnosis of lymphoma requires excisional biopsy of a lymph node or generous biopsy of involved lymph tissue. Fine-needle aspiration or needle biopsy is rarely sufficient. Analysis of the pathologic specimen should include routine histologic examination and immunophenotyping. Immunophenotyping can determine the cell of origin (i.e., B cell, T cell, NK cell, or nonlymphoid cell), and the pattern of cell surface antigens aids subclassification of lymphomas. In the case of B-cell NHLs,

TABLE 49-2 CAUSES OF LYMPHADENOPATHY

INFECTIOUS DISEASES

Viral: infectious mononucleosis syndromes (cytomegalovirus, Epstein-Barr virus), acquired immunodeficiency syndrome, rubella, herpes simplex, infectious hepatitis
 Bacterial: localized infection with regional adenopathy (streptococci, staphylococci), cat-scratch disease (*Bartonella henselae*), brucellosis, tularemia, listeriosis, bubonic plague (*Yersinia pestis*), chancroid (*Haemophilus ducreyi*)
 Fungal: coccidioidomycosis, histoplasmosis
 Chlamydial: lymphogranuloma venereum, trachoma
 Mycobacterial: scrofula, tuberculosis, leprosy
 Protozoan: toxoplasmosis, trypanosomiasis
 Spirochetal: Lyme disease, syphilis, leptospirosis

IMMUNOLOGIC DISEASES

Rheumatoid arthritis
 Systemic lupus erythematosus
 Mixed connective tissue disease
 Sjögren syndrome
 Dermatomyositis
 Serum sickness
 Drug reactions: phenytoin, hydralazine, allopurinol

MALIGNANT DISEASES

Lymphomas
 Solid tumors metastatic to lymph nodes: melanoma, lung, breast, head and neck, gastrointestinal tract, Kaposi's sarcoma, unknown primary tumor, renal, prostate

ATYPICAL LYMPHOID PROLIFERATIONS

Giant follicular lymph node hyperplasia
 Transformation of germinal centers
 Castleman's disease

MISCELLANEOUS DISEASES AND DISEASES OF UNKNOWN CAUSE

Dermatopathic lymphadenitis
 Sarcoidosis
 Immunoglobulin G4 (IgG4) Lymphadenopathy
 Amyloidosis
 Mucocutaneous lymph node syndrome (Kawasaki disease)
 Sinus histiocytosis (Rosai-Dorfman syndrome)
 Multifocal Langerhans cell (eosinophilic) granulomatosis
 Lipid storage diseases: Gaucher's and Niemann-Pick diseases

immunophenotyping can also reveal whether the process is monoclonal in origin (i.e., neoplastic) by determining whether the surface immunoglobulin is restricted to the κ or λ light chain. In some cases, cytogenetic analysis or molecular studies of immunoglobulin or TCR gene rearrangement may be required to determine the pathologic subtype of lymphoma or to establish a monoclonal (i.e., malignant) process. If a lymph node biopsy is nondiagnostic and unexplained lymph node enlargement persists, the biopsy should be repeated.

For patients with bone marrow and peripheral blood involvement, such as in small lymphocytic lymphoma or CLL, the diagnosis may be made based on immunophenotyping of peripheral blood lymphocytes by flow cytometry. Care must be taken to exclude the possibility of aggressive lymphoma manifesting with involved lymph nodes or extranodal sites in a patient harboring a low-grade or chronic indolent lymphoma such as small lymphocytic lymphoma that is confined to the blood or bone marrow.

Treatment

After a lymphoma has been diagnosed, patients should undergo a complete staging evaluation (Table 49-3). Staging determines

TABLE 49-3 STAGING EVALUATION FOR LYMPHOMAS**REQUIRED EVALUATION PROCEDURES**

Biopsy of lesion with review by an experienced hematopathologist
 History with attention to the presence or absence of B symptoms
 Physical examination with attention to node-bearing areas (including Waldeyer's ring) and size of liver and spleen
 Standard blood work:
 Complete blood count
 Lactate dehydrogenase and β_2 -microglobulin
 Evaluation of renal function
 Liver function tests
 Calcium, uric acid
 Bone marrow aspirate and biopsy
 Radiologic studies, including:
 Chest radiograph (posteroanterior and lateral)
 Chest, abdomen, and pelvic CT scans
 PET scan (in Hodgkin's and intermediate- and high-grade lymphomas)

PROCEDURES REQUIRED UNDER CERTAIN CIRCUMSTANCES

Plain bone radiographs of symptomatic sites or abnormal areas on bone scan
 Brain or spinal CT or MRI if neurologic signs or symptoms
 Serum and urine protein electrophoresis
 Lumbar puncture with cerebrospinal fluid cytology (Burkitt's and lymphoblastic lymphoma)

B symptoms, Fever, sweats, and weight loss >10% of body weight; CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

TABLE 49-4 LYMPHOMA STAGING SYSTEM

STAGE*	DESCRIPTION
I	Involvement of a single lymph node region or structure (I) or a single extralymphatic site (IE)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of a contiguous extralymphatic site and lymph node region (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may be accompanied by localized involvement of one extralymphatic site (IIIE) or spleen (IIIS) or both (IIISE)
IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement

*Presence or absence of symptoms should be documented with each stage designation: A (asymptomatic) or B (fever, sweats, and weight loss >10% of body weight).

the extent of involvement, provides prognostic information, and may influence the choice of therapy. The modified Ann Arbor staging classification is used to stage patients with NHL and Hodgkin's disease (Table 49-4).

A variety of ancillary tests may be performed in specific situations. For example, a test for HTLV-1 or HIV should be performed if adult T-cell leukemia/lymphoma is suspected. Patients with a clinical history suggesting immunodeficiency or behavioral risk factors should be tested for HIV infection. A gastrointestinal series or endoscopic evaluation may be warranted for patients with gastrointestinal symptoms or patients at risk for gastrointestinal tract involvement (i.e., mantle cell lymphoma and other lymphomas involving Waldeyer's ring). The choice of therapy for NHLs is guided by stage, specific subtype, and clinical considerations such as age and the general medical condition of the patient.

Lymphoma Subtypes**Indolent Non-Hodgkin's Lymphomas**

The common low-grade or indolent histologic conditions include follicular lymphoma, small lymphocytic lymphoma (which is identical to CLL and discussed later), and marginal zone lymphomas.

Follicular lymphoma accounts for one third of all lymphomas and is the most common indolent lymphoma. It is a mature clonal B-cell neoplasm that histologically retains nodular architecture in the lymph node, which is infiltrated by small, mature-appearing lymphocytes. The immunophenotype is positive for surface markers (CD10, CD19, CD20, CD21) and negative for CD5. Follicular lymphomas are characterized cytogenetically by the t(14;18) translocation that juxtaposes the immunoglobulin heavy chain (*IGH*) locus with the antiapoptotic B-cell CLL/lymphoma 2 gene (*BCL2*); the *BCL2* protein is uniformly overexpressed in follicular lymphomas, immortalizing affected cells.

Follicular lymphoma is a low-grade, indolent neoplasm with a long natural history (median survival approaches 10 years), but 80% to 90% of patients have advanced-stage (III/IV) disease at diagnosis, often with bone marrow involvement, and they cannot be cured with standard treatment modalities. For up to one half of patients with follicular NHL, the disease eventually transforms to a more aggressive lymphoma, characterized pathologically by a diffuse large cell infiltrate and clinically by rapidly expanding nodes or other tumor masses, rising lactate dehydrogenase (LDH) levels, and the onset of disease-related symptoms.

Management of follicular lymphomas is influenced by the stage. For the few patients with early-stage (I/some nonbulky II) disease after clinical staging, the appropriate treatment is radiation therapy. With the use of subtotal or total lymphoid irradiation, more than one half of patients with early-stage disease achieve a durable remission or cure.

For patients with advanced-stage disease, the management is more controversial. Although advanced-stage indolent NHL is responsive to a variety of treatment modalities, the incurability and the long natural history have led to the practice of deferring treatment until the patient develops symptoms. This strategy is referred to as the *watch and wait approach*. Indications for treatment include cosmetic or mechanical problems caused by enlarging lymph nodes, high tumor burden, constitutional symptoms, and evidence of marrow compromise.

Available treatment options include monoclonal antibody therapies, chemotherapeutic agents, and radiolabelled antibodies. For most patients, the appropriate treatment typically includes the chimeric anti-B-cell monoclonal antibody rituximab with or without systemic chemotherapy. The addition of rituximab to chemotherapy regimens has increased response rates, duration of remission, and in some studies, overall survival (level I evidence).

The choice of chemotherapy to employ in combination with rituximab may be influenced by the patient's age and medical condition. Multiple options are available, and no regimen has proved superior with regard to overall survival. The combination of bendamustine, a unique agent with properties similar to alkylating agents and purine analogues, plus rituximab appeared advantageous compared with the CHOP regimen

(i.e., cyclophosphamide, hydroxydaunorubicin [doxorubicin], Oncovin [vincristine], and prednisone) plus rituximab in a randomized trial with regard to toxicity, response rate, and progression-free survival (level 1 evidence).

Most patients respond to treatment, and at least one third achieve a clinical complete remission that may last 1 to 3 years. Treatment with cytotoxic agents is typically discontinued when the maximum response has been achieved, but rituximab may be continued on an intermittent schedule to maintain remission. It has been shown to prolong remission times in randomized studies (level 1 evidence). Risk of recurrence and cost considerations may influence the use of this therapy because rituximab may also be used at the time of recurrence with similar outcomes.

After a patient relapses, subsequent remissions may be achieved but are often less durable compared with the first remission. Therapeutic options for patients who relapse include retreatment with chemotherapy, often with a different drug or combination than that used initially. Patients in relapse can also be treated with rituximab as a single agent. Two radioactively labeled anti-CD20 antibodies, ibritumomab tiuxetan (yttrium labeled) and tositumomab (iodine 131 labeled), are also used for patients with relapsed or refractory follicular lymphoma, and they have been associated with a high response rate. For patients who have clinical or pathologic evidence of transformation to a higher grade of lymphoma, treatment that is appropriate for a diffuse, aggressive histology should be offered (discussed later).

High-dose chemotherapy with autologous or allogeneic stem cell transplantation for follicular NHLs may be appropriate for selected patients with recurrent or refractory disease. Long-term follow-up of patients undergoing allogeneic transplantation suggests that some patients are cured with this modality, but the morbidity associated with allogeneic transplantation has limited its widespread use for refractory indolent lymphomas.

In addition to the follicular NHLs, the MALT lymphomas and closely related marginal zone lymphomas are considered low-grade, indolent subtypes. Given the excellent prognosis, localized nature, and long natural history of the MALT lymphomas, they usually are managed conservatively with local treatment modalities (i.e., irradiation or surgery) and avoidance of systemic chemotherapy. The monoclonal antibody rituximab has activity against MALT lymphomas and may be used when systemic therapy is desired. The gastric MALT lymphomas are highly associated with *H. pylori* infection, and remissions can often be achieved with eradication of this infection. Antibiotic therapy is the first-line treatment for early *H. pylori*-positive gastric MALT lymphoma.

Aggressive Non-Hodgkin's Lymphomas

Aggressive NHLs include DLBCL, anaplastic large cell lymphoma, peripheral T-cell lymphomas, and the high-grade lymphomas, Burkitt's lymphoma and lymphoblastic lymphoma (see High-Grade Non-Hodgkin's Lymphomas). Most of the diffuse, aggressive large cell lymphomas are B cell in origin; aggressive T-cell lymphomas are managed similarly but have an overall worse prognosis compared with their B-cell counterparts.

DLBCL accounts for up to 40% of all NHL subtypes. In contrast to patients with low-grade follicular NHLs, all patients with

diffuse, aggressive histology should be offered immediate therapy because these lymphomas are life-threatening but potentially curable. The standard initial therapy for all patients with diffuse, aggressive NHL, regardless of stage, is a multidrug chemotherapy regimen that includes an anthracycline in combination with the anti-CD20 monoclonal antibody rituximab.

For DLBCL, CHOP is the most widely used chemotherapy regimen. Patients with early-stage disease (I/nonbulky II) may be treated with local radiation therapy after a minimum of three cycles of CHOP plus rituximab if there is a need to limit exposure to chemotherapy. Patients with advanced-stage disease require six cycles of CHOP plus rituximab; the role of local radiation to sites of bulky disease in the setting of advanced-stage disease is not established. Complete remissions can be achieved with CHOP plus rituximab or similar regimens, and more than 50% of patients are cured.

Patients who experience relapse after achieving a remission may be cured with high-dose chemotherapy with autologous peripheral blood stem cell transplantation, particularly if their relapsed disease remains responsive to standard doses of chemotherapy. High-dose chemotherapy with autologous stem cell transplantation is superior to standard doses of salvage chemotherapy and is considered standard therapy for patients with chemosensitive diffuse, aggressive NHL that has relapsed.

Mantle Cell Lymphoma

Mantle cell lymphoma accounts for 5% to 8% of all NHLs and is most common in older male patients. Mantle cell lymphomas are mature B-cell neoplasms that appear to arise in the mantle zone of the lymphoid follicle and display a highly characteristic immunophenotype, expressing the CD5 antigen and other B-cell markers, but CD23 expression is absent, in contrast to CLL. Mantle cell lymphomas are also characterized by a pathognomonic t(11;14) chromosomal translocation that juxtaposes the immunoglobulin heavy chain gene (14q32 locus) with the *BCL1* gene, which encodes the growth-promoting protein cyclin D1. Demonstration of the translocation or expression of cyclin D1 protein by immunohistochemistry allows a definitive diagnosis in most cases. Pathologic classification as a blastoid or pleomorphic subtype and a high proliferation rate are features associated with more aggressive behavior and a poor outcome.

Mantle cell lymphomas are in many ways similar to indolent lymphomas in that patients usually have advanced-stage disease with frequent bone marrow involvement. These lymphomas have a peculiar propensity to involve the Waldeyer ring and gastrointestinal tract. As with the low-grade follicular lymphomas, mantle cell lymphomas are treatable but not typically curable. However, in contrast to the indolent lymphomas, these neoplasms may be biologically aggressive, with a median survival of only 3 years.

Patients are usually treated with systemic chemotherapy combined with rituximab at diagnosis, but durable remissions are difficult to achieve. High-dose chemotherapy and autologous stem cell transplantation are often applied during first remission for younger patients and have been associated with more durable remissions (level II-1 evidence). Multiple agents and regimens are available for those who are not candidates for transplantation and patients with recurrent disease.

The proteasome inhibitor bortezomib is a novel nonchemotherapeutic agent with activity against mantle cell NHL. The Bruton tyrosine kinase inhibitor ibrutinib is a novel compound for the treatment of recurrent mantle cell lymphoma, and it represents a new class of targeted agents available for NHL treatment.

High-Grade Non-Hodgkin's Lymphomas

The two high-grade subtypes, Burkitt's lymphoma and lymphoblastic lymphoma, are rare in the adult population. Nonetheless, these subtypes are important because they are potentially curable with appropriate therapy and often require urgent, inpatient treatment at the time of diagnosis due to their highly aggressive nature, rapid growth, and tendency to develop tumor lysis on initiation of therapy.

Lymphoblastic lymphoma in adults is an aggressive lymphoma that is usually considered the lymphomatous counterpart of acute T-cell lymphocytic leukemia. B-cell lymphoblastic lymphoma is less common. Lymphoblastic lymphoma usually afflicts young adult men and involves the mediastinum and bone marrow, with a propensity to relapse in the leptomeninges.

Burkitt's lymphoma is a rare B-cell lymphoma in adults that is highly aggressive, with a propensity to involve the bone marrow and central nervous system. Burkitt's lymphoma is characterized cytogenetically by the pathognomonic t(8;14) translocation that moves the *MYC* oncogene from chromosome 8 to a location close to the enhancers of the antibody heavy-chain genes (*IGH* locus) on chromosome 14. In central Africa, where Burkitt's lymphoma is endemic in children, it is usually associated with EBV. However, in the United States, it is uncommon for sporadic Burkitt's lymphoma to be EBV positive.

Burkitt's lymphoma and lymphoblastic lymphomas require treatment with intensive multiagent chemotherapy, including intrathecal chemotherapy to prevent leptomeningeal relapse. These lymphomas undergo rapid tumor lysis on initiation of chemotherapy, and all patients must receive prophylaxis against tumor lysis syndrome before and during their first course of chemotherapy. Prophylaxis includes hydration, alkalization of the urine, allopurinol, and consideration of rasburicase therapy for rapid lowering of elevated uric acid levels.

Prognosis

A variety of prognostic variables have been identified for NHL, and specific prognostic schemes have been devised for common diseases, including DLBCL, follicular NHL, and mantle cell lymphomas. The predictors for poor survival for most subtypes of NHL include advanced stage (III/IV) at onset, involvement of multiple extranodal sites of disease, elevated LDH levels, B symptoms (e.g., fever, night sweats, weight loss), and poor performance status.

The International Prognostic Index (IPI) stratifies patients based on age, performance status, stage, and number of extranodal sites. The likelihood of cure and long-term, disease-free survival ranges from more than 75% for patients with one or no adverse factors to less than 50% for patients with four or more adverse factors.

Factors associated with shortened survival in follicular NHL include older age, advanced stage, anemia, multiple lymph node

sites (more than four), and elevated LDH levels. Patients with three or more of these factors have a median survival of 5 years, roughly one half of that of patients with zero or one risk factor. Aggressive T-cell lymphomas usually fare more poorly than B-cell NHL, and patients are typically considered candidates for investigational studies and transplantation therapies.

 For a deeper discussion of these topics, please see Chapter 185, "Non-Hodgkin's Lymphomas," in Goldman-Cecil Medicine, 25th Edition.

Hodgkin's Lymphoma

Hodgkin's lymphoma is a node-based lymphoid malignancy characterized by the neoplastic Reed-Sternberg (RS) cell in an inflammatory background. Hodgkin's lymphoma accounts for 10% of lymphomas, with about 9000 new cases diagnosed in the United States annually, and it is the most common lymphoma among young adults. The age distribution in industrialized countries is bimodal, with the larger peak occurring between the ages of 15 and 35 and a smaller peak seen in patients older than 50 years.

The cause of Hodgkin's lymphoma remains enigmatic. Risk factors include a history of infectious mononucleosis, high socioeconomic status, immunosuppression (e.g., HIV infection, allograft transplantation, immunosuppressive drugs), and autoimmune disorders. Although EBV is frequently detected in patients, a direct casual role has not been established.

Pathology

Hodgkin's lymphoma is diagnosed by identifying the RS cell in involved lymphoid tissue. The classic RS cell is large and binucleate, with each nucleus containing a prominent nucleolus, suggesting the appearance of owl eyes. Although the cellular origin of the RS cell was debated for decades, molecular studies have confirmed that RS cells are B cells with clonal rearrangement of the germline *IG* locus. Unlike NHL, the bulk of the infiltrate in lymph nodes involved with Hodgkin's lymphoma is usually composed of benign reactive inflammatory cells, and the RS cells often can be difficult to find. Immunophenotyping of classic RS cells reveals that they are CD30 (Ki-1) and CD15 positive and are negative for CD20, CD45, and cytoplasmic or surface immunoglobulin. EBV is identified in the RS cells in about 50% of cases.

The pathologic subtypes of classic Hodgkin's lymphoma include four variants—nodular sclerosing (NS), mixed cellularity (MC), lymphocyte depleted (LD), and lymphocyte rich (LR)—and the nonclassic variant, nodular lymphocyte-predominant (NLP). The NS form is the most common variant (60% to 80%) and is characterized by fibrous bands separating the node into nodules and by the lacunar type of RS cells. It is the predominant type encountered in adolescents and young adults and typically involves the mediastinum and supradiaphragmatic nodal sites. In the MC type (15%), band-forming sclerosis is absent, and RS cells are easily identified in a diffuse inflammatory infiltrate that is more heterogeneous than that seen in the NS variant. The LR variant (5%) is characterized by classic RS cells in a background composed predominantly of small lymphocytes. LD is a rare variant (<1%) that is associated with

advanced age, HIV infection, and low socioeconomic status. The pathologic hallmarks of LD Hodgkin's lymphoma include a notable paucity of inflammatory cells and sheets of RS cells.

The NLP variant has emerged as a distinct entity that is more closely related to indolent NHL than to classic Hodgkin's lymphoma. The NLP form is characterized by a nodular growth pattern with variants of RS cells that have polylobated nuclei (i.e., popcorn cells); classic RS cells are usually absent. The immunophenotype of these variant cells is distinct from classic RS cells, with expression of B-cell antigens (CD19 and CD20) and CD45 and absence of CD15 and CD30. The existence of CD20 allows the therapeutic use of rituximab, an agent not typically employed in classic Hodgkin's lymphoma. The NLP variant accounts for 5% of Hodgkin's lymphoma cases, has a strong male preponderance, and tends to involve peripheral nodes but spare the mediastinum. The prognosis is excellent, although late relapses are more common than they are in classic Hodgkin's lymphoma.

Clinical Presentation

Hodgkin's lymphoma arises in lymph nodes, most commonly in the mediastinum or neck, and spreads to adjacent contiguous or noncontiguous nodal sites, including retroperitoneal nodes and the spleen. As the disease progresses, it spreads hematogenously to involve extranodal sites, including bone marrow, liver, and lung. Unlike NHL, Hodgkin's lymphoma rarely arises in extranodal sites, although it can involve extranodal sites by contiguous spread from an adjacent lymph node (e.g., vertebrae from retroperitoneal lymph nodes, pulmonary parenchyma from hilar nodes).

Hodgkin's lymphoma usually produces painless enlargement of lymph nodes, most often in the neck. Mediastinal adenopathy may be found incidentally in an asymptomatic patient on routine chest radiography. Massive mediastinal or hilar adenopathy, with or without adjacent pulmonary involvement, may cause respiratory symptoms such as cough, shortness of breath, wheezing, or stridor. At clinical presentation, about one third of patients have constitutional symptoms of fever, night sweats, or weight loss (i.e., B symptoms). Generalized pruritus is associated with the NS subtype, and patients may give a history of troubling pruritus for months to years before the diagnosis.

If left untreated, the natural history is one of inexorable, albeit often slow, progression to involve multiple nodal sites, followed by hematogenous spread to the bone marrow, liver, and other viscera. As the disease advances, patients experience B symptoms, malaise, cachexia, and infectious complications. Patients with progressive disease ultimately die of complications of bone marrow failure or infection.

Accurate staging of patients with newly diagnosed Hodgkin's lymphoma is important for treatment planning, prognosis, and assessing response to therapy. A modification of the Ann Arbor classification is used (see [Table 49-4](#)), and the suffix A or B is appended to denote the absence or presence, respectively, of B symptoms. The staging work-up of a newly diagnosed patient is similar to that for patients with NHL (see [Table 49-3](#)) and includes a history and physical examination; complete blood work, including erythrocyte sedimentation rate (ESR) and HIV serology; computed tomography (CT) scan of the chest, abdomen, and pelvis; positron emission tomography (PET)

scan; and in selected cases, a bone marrow aspirate and biopsy. Additional radiographic tests (e.g., bone films, spinal magnetic resonance imaging [MRI]) should be obtained only if symptoms suggest involvement of these structures. Patients also require evaluation of cardiac and pulmonary function before administration of chemotherapy and testing for hepatitis B due to the risk of reactivation during chemotherapy. The information derived from this noninvasive work-up defines the clinical stage of a patient with Hodgkin's lymphoma.

Diagnosis and Differential Diagnosis

The diagnosis requires an adequate biopsy of the involved nodal tissue. Immunophenotyping is routinely performed to confirm the diagnosis made on routine light microscopy and to differentiate Hodgkin's lymphoma from morphologically similar NHLs (e.g., T-cell-rich large B-cell lymphoma, anaplastic large cell lymphoma).

Treatment

Hodgkin's lymphoma is highly curable; the cure rate exceeds 80% with the use of current treatment modalities. The optimal treatment, including the duration of chemotherapy and the use and dose of radiation therapy, is determined by the stage (i.e., early stage [I/II] vs. advanced stage [III/IV]), and additional prognostic features. Because most patients are young adults and experience long-term, disease-free survival, the emphasis during the past 3 decades has shifted to using therapies that minimize treatment-related morbidity and mortality without sacrificing curative potential. Primary radiation therapy is rarely used because of its delayed toxicities, which include a substantial risk of secondary solid tumors within the radiation field a decade or more after treatment, including a particularly high risk of breast cancer. Additional long-term sequelae of standard doses of chest irradiation include thyroid dysfunction (usually hypothyroidism) and accelerated coronary artery disease.

Most patients with early-stage (I/II) Hodgkin's lymphoma are treated with the ABVD chemotherapy regimen (i.e., doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) followed by a course of low-dose radiation (<30 Gy) to involved lymph node sites, which has not been associated with an increased risk of secondary solid tumors. The duration of chemotherapy and the dose of radiation depend on whether the patient has favorable or unfavorable early-stage disease. The definition of favorable disease usually incorporates the absence of a large mediastinal mass, a limited number of involved nodal sites, absence of B symptoms, younger age, and a low ESR. Patients with favorable early-stage disease typically receive two to four cycles (months) of ABVD followed by 20 Gy of radiation, whereas four to six cycles of ABVD and 30 Gy of radiation are required for patients with unfavorable disease (level I evidence).

Patients with advanced-stage (III/IV) Hodgkin's lymphoma are treated primarily with chemotherapy. The ABVD regimen is the most widely used initial treatment in the United States. ABVD is more effective and less toxic than the older MOPP regimen (i.e., nitrogen mustard, vincristine [Oncovin], procarbazine, and prednisone), and it does not cause the long-term sequelae of sterility, infertility, or treatment-induced leukemias

associated with MOPP (level I evidence). Roughly 60% of patients with stage III or IV disease are cured with six cycles (months) of ABVD.

The intensive regimen of BEACOPP (i.e., bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, prednisolone, and procarbazine) has been associated with higher rates of complete response and freedom from treatment failure compared with ABVD-based regimens used for patients with advanced disease, although overall survival has not been increased in all studies (level I evidence). BEACOPP is used increasingly in selected patients with high-risk features. Gonadal toxicity with permanent infertility is common after BEACOPP, and an increased risk of secondary leukemia has been reported. Late sequelae and acute toxicities must be considered when choosing this regimen.

Radiation therapy in combination with chemotherapy is typically not used to treat advanced-stage disease. However, in patients with bulky mediastinal disease, consolidative irradiation to the mediastinum after completion of chemotherapy has decreased the rate of relapse.

Evaluating the response to therapy involves repetition of the staging evaluation (i.e., physical examination, CT, and PET) during and at the completion of treatment. A mid-treatment PET scan after two cycles of ABVD for advanced disease is prognostically informative because persistent metabolic activity seen on PET highly correlates with resistance or subsequent relapse of disease. Conversely, patients may be cured despite the finding of a residual abnormality on CT (e.g., enlarged nodes, residual mediastinal mass) when residual disease is not found on PET imaging. A persistently positive PET scan after treatment of patients with residual radiographic abnormalities is associated with a high rate of subsequent relapse, and these patients should be monitored closely or considered for immediate repeat biopsy or salvage therapy. Most patients destined to relapse do so within 2 years; relapses after 5 years are rare except for patients with the NLP variant.

Patients who relapse or fail to respond after initial therapy should be offered salvage therapy because many can be cured if treated with high-dose chemotherapy and autologous hematopoietic cell transplantation (level I evidence). Patients who relapse after autologous transplantation usually are incurable, although a subset of young and medically fit patients can be considered for potentially curative allogeneic transplantation.

Palliation of refractory Hodgkin's lymphoma can be achieved with radiation therapy, salvage chemotherapy regimens, or with brentuximab vedotin, an immunotoxin composed of a CD30-directed antibody linked to an antitubulin agent. The latter agent is associated with high response rates, including complete responses in more than 30% of patients with relapsed disease after autologous transplantation (level II-1 evidence).

Prognosis

Approximately 80% of patients with Hodgkin's lymphoma are cured. Prognostic factors that influence risk of relapse or survival include MC or LD histology, male sex, large numbers of involved nodal sites, age older than 40 years, B symptoms, high ESR, and bulky disease (i.e., mediastinum widening by more than one third or a mass larger than 10 cm). The International Prognostic Score,

based on seven variables at diagnosis, is a validated predictor of outcome in advanced disease.

Lymphoid Leukemias

Acute Lymphocytic Leukemias

The acute lymphocytic leukemias that arise from precursor B or T cells are described in detail in [Chapter 48](#).

Chronic Lymphocytic Leukemia and Small Lymphocytic Lymphoma

Definition and Epidemiology

B-cell CLL is a malignant disorder of lymphocytes characterized by expansion and accumulation of small lymphocytes of B-cell origin. CLL is essentially identical to B-cell small lymphocytic lymphoma but represents the leukemic form of the disease. CLL is the most common form of leukemia in the United States and affects twice as many men as women. Although it can occur at any stage of life, the incidence increases with age, and more than 90% of cases are diagnosed in adults older than 50 years of age.

The cause of CLL is unknown. Familial clustering of CLL suggests a genetic basis in some cases. Radiation and common carcinogen exposures have not been associated with an increased risk of CLL.

Pathology

The common form of CLL is a clonal proliferation of mature B cells expressing characteristic mature B-cell markers and low levels of surface immunoglobulin M (IgM) that is light chain restricted, reflecting the clonal origin of this malignancy. Smears of the bone marrow or peripheral blood reveal a predominance of small lymphocytes with inconspicuous nucleoli; ruptured cells (i.e., smudge cells) are often observed. Examination of involved lymph nodes reveals a diffuse infiltrate of small lymphocytes ablating the normal architecture.

The diagnostic immunophenotype of CLL is unique, with expression of CD5 and CD23 along with the mature B-cell markers CD19, CD20 (dim expression), and CD21. Although a pathognomonic chromosomal abnormality has not been identified in CLL, 30% to 50% of patients have cytogenetic abnormalities, more so if sensitive assays such as fluorescence in situ hybridization (FISH) are employed. The most frequent abnormalities involve chromosome 12 (often trisomy 12), 13, and 14. Cytogenetic abnormalities of chromosomes 17 and 11 are associated with a very poor prognosis.

Diagnosis and Differential Diagnosis

The diagnosis of CLL is often made incidentally on a routine blood cell count that shows a leukocytosis with a predominance of small lymphocytes. Flow cytometric analysis of peripheral blood or a bone marrow aspirate reveals the characteristic clonal B-cell population that is CD5 and CD23 positive.

CLL must be distinguished from reactive causes of lymphocytosis and other forms of lymphoma or leukemia. Mantle cell lymphoma may appear similar morphologically and with a similar immunophenotype, although CD23 is typically absent and cyclin D1 expression is detected. An absolute lymphocytosis of more than 5000 cells/ μ L is required for the diagnosis of CLL.

Patients with characteristic clonal CLL cells in the blood to a lesser degree as an isolated abnormality are thought to have monoclonal B-cell lymphocytosis and may be observed.

Clinical Presentation

CLL cells accumulate in bone marrow, peripheral blood, lymph nodes, and spleen, resulting in lymphocytosis, lymphadenopathy, splenomegaly, and ultimately decreased bone marrow function. CLL is also frequently associated with immune dysregulation, exhibited as hypogammaglobulinemia with an increased risk of bacterial infections and autoimmune phenomena such as Coombs-positive hemolytic anemia or immune thrombocytopenia. Some patients exhibit lymphadenopathy, symptoms related to cytopenias, or occasionally, recurrent infections. As the disease progresses, patients develop generalized lymphadenopathy, hepatosplenomegaly, and bone marrow failure. Death often results from infectious complications or bone marrow failure after patients have become refractory to treatment. In about 5% of cases, CLL transforms to a highly malignant diffuse large cell lymphoma, which is usually rapidly fatal. This transformation is commonly referred to as Richter's syndrome.

Treatment

CLL is a low-grade leukemia or lymphoma that is typically characterized by a long natural history with slow progression over years or decades. Median survival is in excess of 6 years. The extent of disease (stage) at onset is the best predictor of survival. In the absence of immune phenomena, anemia and thrombocytopenia are signs of advanced-stage disease associated with poor survival.

Because standard therapy is not curative and CLL may have an asymptomatic phase lasting years, specific treatment is often withheld until signs of disease progression or development of symptoms (e.g., bulky lymphadenopathy, constitutional symptoms such as fevers, cytopenias caused by bone marrow infiltration). The rate of rise of the white blood cell count may also be used to predict development of symptoms and the need for therapy.

When treatment is required, multiple options for therapy are available. The patient's age, medical condition, and cytogenetic abnormalities may influence the choice of therapy. Active chemotherapeutic agents include several alkylating agents (e.g., chlorambucil, cyclophosphamide), the nucleoside analogue fludarabine, or the novel agent bendamustine. The monoclonal anti-CD20 antibody rituximab has activity against CLL, but it is most effectively employed in combination with chemotherapeutic agents.

Most patients respond to therapy with significant reductions in tumor burden. Fludarabine-based therapies are typically associated with a higher rate of complete remissions compared with other therapies, but they may carry higher risks of infections or marrow stem cell injury. Patients with recurrent or refractory disease may respond to a growing list of monoclonal antibodies. Alemtuzumab, a humanized monoclonal antibody to the CD52 molecule, which occurs on most lymphocytes, is efficacious, including in patients with a 17p deletion, a group for whom conventional chemotherapy works poorly. Additional agents include the anti-CD20 antibodies ofatumumab and obinutuzumab,

which was shown to improve remission duration in previously untreated patients when administered in combination with chlorambucil (level I evidence).

Patients with poor-risk cytogenetic abnormalities are more likely to demonstrate resistance to standard therapies and have shortened survival. These patients may be candidates for allogeneic transplantation, which appears to exert a therapeutic effect through a strong immune or graft-versus-leukemia phenomenon. Patients who develop autoimmune phenomena require treatment with corticosteroids, and intravenous gamma globulin may be used to reduce the frequency of infections in patients who have developed hypogammaglobulinemia. The development of a rapidly enlarging mediastinal mass, constitutional symptoms, and high serum LDH level suggests transformation of the disease to a diffuse large cell lymphoma (i.e., Richter's syndrome), which is associated with a poor prognosis.

Plasma Cell Disorders

The plasma cell disorders, or dyscrasias, are a group of clonal B-cell diseases that are related to each other by virtue of their production and secretion of monoclonal immunoglobulin (or part of an immunoglobulin molecule), called the *M protein*. The laboratory hallmark of plasma cell dyscrasias is a homogeneous immunoglobulin molecule (whole or part) that can be detected in the serum or urine by protein electrophoresis. Clinically, these disorders may be characterized by the systemic effects of the M protein and by the direct effects of bone and bone marrow infiltration. Primary amyloidosis, for instance, results in tissue injury through deposition of light chains produced by a clonal population of plasma cells in the absence of an observable proliferation of the plasma cell clone. Waldenström's macroglobulinemia is a disorder with features of NHL and plasma cell disorders. It is discussed in this section because of the distinct clinical effects of the IgM paraprotein produced in this disease.

The most common plasma cell dyscrasia is *monoclonal gammopathy of uncertain significance* (MGUS), followed by multiple myeloma and the closely related plasmacytoma, which is a solitary myeloma of bone or extramedullary soft tissue. Less common plasma cell dyscrasias include osteosclerotic myeloma (i.e., polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin abnormalities [POEMS syndrome]), heavy-chain disease, and primary amyloidosis.

When an M protein found on serum protein electrophoresis is from individuals with no apparent associated disease and in the absence of any other laboratory or clinical evidence of a plasma cell disorder, it is designated as a MGUS. MGUS is defined by low serum levels of M protein (<3 g/dL), no urinary Bence Jones protein, less than 10% clonal bone marrow plasma cells, and absence of anemia, hypercalcemia, renal failure, and lytic bone lesions. MGUS is more common than myeloma and increases in frequency with aging, occurring in 3% of the population older than 50 years. MGUS is considered a premalignant condition, and patients are at increased risk (sevenfold) for overt myeloma or related malignant plasma cell dyscrasias compared with the general population. Nonetheless, progression of MGUS to a frank plasma cell neoplasm occurs only in about 1% of patients per year.

Distinguishing patients with stable, nonprogressive MGUS from patients in whom multiple myeloma will eventually develop is difficult. The risk of progression is greater among patients with IgA- or IgM-type M proteins, in patients with initial concentrations of M protein in excess of 1.5 g/dL, and in patients with an abnormal free κ -to- λ light-chain ratio. Although no definitive evidence has been found that monitoring patients with the diagnosis of MGUS improves survival, it is recommended that patients undergo annual evaluation, including serum electrophoresis, to detect progression to multiple myeloma before the onset of overt symptoms or complications.

M proteins can be found in benign and malignant conditions other than the plasma cell dyscrasias (Table 49-5). About 10% of patients with CLL have detectable levels of monoclonal IgG or IgM in their sera. M proteins can also be detected in a variety of autoreactive or infectious disorders.

TABLE 49-5 CLASSIFICATION OF DISORDERS ASSOCIATED WITH MONOCLONAL IMMUNOGLOBULIN (M PROTEIN) SECRETION

DISORDER	M PROTEIN PATTERN
PLASMA CELL NEOPLASMS	
Multiple myeloma	IgG > IgA > IgD; \pm free light chain or light chain alone ($\kappa > \lambda$)
Solitary myeloma of bone	IgG > IgA > IgD; \pm free light chain or light chain alone ($\kappa > \lambda$)
Extramedullary plasmacytoma	IgA > IgG > IgD; \pm free light chain or light chain alone ($\kappa > \lambda$)
Waldenström macroglobulinemia	IgM \pm free light chain ($\kappa > \lambda$)
Heavy-chain disease	γ , α , or μ heavy chain or fragment
Primary amyloidosis	Free light chain ($\lambda > \kappa$)
Monoclonal gammopathy of unknown significance	IgG > IgM > IgA, usually without urinary light-chain secretion
OTHER B-CELL NEOPLASMS	
Chronic lymphocytic leukemia	M protein occasionally secreted; IgM > IgG
B-cell non-Hodgkin's lymphomas; Hodgkin's disease	M protein occasionally secreted; IgM > IgG
NONLYMPHOID NEOPLASMS	
Chronic myelogenous leukemia	No consistent patterns
Carcinomas (e.g., colon, breast, prostate)	No consistent patterns
AUTOIMMUNE OR AUTOREACTIVE DISORDERS	
Cold agglutinin disease	IgM κ most common
Mixed cryoglobulinemia	IgM or IgA
Sjögren syndrome	IgM
MISCELLANEOUS INFLAMMATORY, STORAGE, OR INFECTIOUS DISORDERS	
Lichen myxedematosus	IgG λ
Gaucher's disease	IgG
Cirrhosis, sarcoid, parasitic diseases, renal acidosis	No consistent pattern

Ig, Immunoglobulin.

Multiple Myeloma

Definition and Epidemiology

Multiple myeloma is a malignant plasma cell disorder characterized by neoplastic infiltration of the bone marrow and bone and by monoclonal immunoglobulin or light chains in the serum or urine. The cause of myeloma is uncertain.

The disease is more common in men than women and in American blacks than whites. Myeloma risk increases with age, with a median age of 69 years at diagnosis (SEER data). Myeloma risk is increased for patients with first-degree relatives with a plasma cell dyscrasia. Associations have been described with occupational exposures to organic solvents, pesticides, petroleum products, and ionizing radiation, but these risk factors are rarely seen in affected individuals.

Pathology

The tumor cell of these disorders exhibits features of a differentiated plasma cell that is adapted to synthesize and secrete immunoglobulin at a high rate. Biopsies of bone marrow or targeted bone biopsies of tumor sites reveal infiltration by plasma cells with light-chain restriction, defining clonality. Cell surface markers useful in identifying and enumerating plasma cells include CD38, CD 138, and immunoglobulin light chains; the B-cell marker CD20 is typically absent and aids in distinguishing other lymphoproliferative disorders from myeloma.

Genetic aberrations are detectable in most patients with myeloma if adequately sensitive tests are applied. Standard karyotyping and FISH are performed routinely on marrow samples to determine abnormalities of prognostic significance, including translocations involving the immunoglobulin heavy-chain locus on chromosome 14, hyperploidy, or deletions of chromosomes 1, 13, or 17.

Diagnosis and Differential Diagnosis

Myeloma must be distinguished from related disorders, including MGUS and plasmacytoma. The diagnosis of multiple myeloma is made by identifying some combination of an increase (>10%) in the number of plasma cells in the bone marrow, a serum M protein other than IgM exceeding 3 g/dL, or a clonal protein in the urine. Asymptomatic myeloma (i.e., stage I myeloma or "smoldering myeloma") is diagnosed when clonal plasma cells are found in more than 10% of the bone marrow or monoclonal protein occurs in an amount greater than 3 g/dL in the absence of end-organ-related injury, or both.

Patients with disease-related organ dysfunction (e.g., anemia, lytic bone lesions, hypercalcemia, renal dysfunction) are considered to have symptomatic myeloma, for which therapy is indicated. Recurrent infection with hypogammaglobulinemia is also considered a criterion for symptomatic myeloma. Solitary plasmacytoma is diagnosed when a single clonal plasma cell tumor is identified in bone or soft tissue in the absence of bone marrow involvement or other end organ-related injury.

Evaluation of the patient with suspected myeloma includes bone marrow biopsy; measurement of hemoglobin, calcium, renal function, and the serum free κ -to- λ light-chain ratio; serum or urine protein electrophoresis; immunoelectrophoresis; and a skeletal survey.

PET and MRI are considered to further evaluate bone disease and may be necessary for patients with oligosecretory or nonsecretory disease to define disease and evaluate after therapy. Conventional bone scans are less useful due to the osteolytic nature of myeloma.

About 20% of patients with multiple myeloma do not have detectable serum M protein by standard electrophoresis but have circulating free light chains that may be detectable by serum free light-chain assays. Free light chains may appear in the urine (i.e., Bence Jones protein) and can also be detected in a 24-hour urine collection by urine protein electrophoresis. In rare cases, patients with nonsecretory myeloma have neither detectable serum nor urine M protein. Free light-chain assays are quite sensitive and may provide measurement of clonal protein in patients thought to have nonsecretory disease by other methods. Free light chains have a relatively short half-life (2 to 6 hours) in the circulation compared with weeks for intact immunoglobulin molecules and may therefore be used to obtain a more rapid assessment of disease response for patients on therapy.

Clinical Presentation

The clinical manifestations of multiple myeloma are the direct effects of bone marrow and bone infiltration by malignant plasma cells, the systemic effects of the M protein, and the effects of the concomitant deficiency in humoral immunity that occurs in this disease. The most common symptom in multiple myeloma is bone pain. Bone radiographs typically show pure osteolytic punched-out lesions, often in association with generalized osteopenia and pathologic fractures. Bony lesions can show as expansile masses associated with spinal cord compression. Hypercalcemia caused by extensive bony involvement is common in myeloma and may dominate the clinical picture. Anemia occurs in most patients as a result of marrow infiltration and suppression of hematopoiesis and causes fatigue; granulocytopenia and thrombocytopenia are less common.

Patients with myeloma are susceptible to bacterial infections because of impaired production and increased catabolism of normal immunoglobulins. Gram-negative urinary tract infections are common, as are respiratory tract infections caused by *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Klebsiella pneumoniae*.

Renal insufficiency occurs in about 25% of patients with myeloma. The cause of renal failure is often multifactorial; hypercalcemia, hyperuricemia, infection, and amyloid deposition can contribute. However, direct tubular damage from light-chain excretion invariably occurs. Because of their physicochemical properties, M proteins can cause a host of diverse effects, including cryoglobulinemia, hyperviscosity, amyloidosis, and clotting abnormalities resulting from interaction of the M protein with platelets or clotting factors.

Several staging or classification systems exist for myeloma. The International Staging System (ISS) for myeloma identifies three stages with distinct prognoses based on only two variables: β_2 -microglobulin and albumin levels (Table 49-6).

Treatment

Most patients with myeloma exhibit symptomatic, advanced-stage disease and require therapy. Patients with stage I disease or

TABLE 49-6 INTERNATIONAL STAGING SYSTEM FOR MULTIPLE MYELOMA

STAGE	CRITERIA	SURVIVAL TIME (mo)
I	B2M <3.5 mg/L Albumin \geq 3.5 g/dL	62
II	Not stage I or III	44
III	B2M >5.5 mg/L	29

B2M, β_2 -Microglobulin.

asymptomatic myeloma may have an indolent course and do not always require immediate therapy. Disease progression occurs at a rate of 5% to 10% per year, and patients should be monitored for disease progression by serial quantification of the M protein and evaluation for disease-related signs or symptoms. For patients with solitary bone or extramedullary plasmacytomas, particularly in the head and neck region, local radiation therapy can induce long-term remissions and is the treatment of choice. Patients with a solitary plasmacytoma of bone are often found on routine MRI of the spine to have asymptomatic bone disease and are at higher risk for progression to myeloma.

Patients with symptomatic myeloma require systemic therapy and meticulous supportive care. Although myeloma is not a curable malignancy, systemic therapy can prolong survival and dramatically improve quality of life. Options for treatment have expanded in the past decade to include multiple compounds in two broad classes of agents, the immunomodulatory drugs (IMiDs) and proteasome inhibitors. These agents may be used as single agents or in combinations for more intensive therapy. They are typically administered in combination with high doses of dexamethasone, which is a potent antimyeloma therapy. The IMiDs include thalidomide, lenalidomide, and pomalidomide. Proteasome inhibitors include bortezomib and carfilzomib. These agents have largely supplanted traditional chemotherapeutic agents as the cornerstone of initial and secondary therapies because they are efficacious and usually well tolerated. Multiple combination regimens have been devised that also incorporate chemotherapeutic agents in modest doses.

Thalidomide is the first-in-class IMiD and was initially used as a sedative in the United Kingdom in the 1960s, but it was found to cause birth defects when used to combat nausea during pregnancy. The antiangiogenic properties of thalidomide subsequently led to its development as an anticancer agent. Although the mechanism of action of the IMiDs is unclear, they are now thought to exert antitumor effects primarily through stimulation of immune effectors. The IMiDs are typically used in combination with dexamethasone, and when used as initial therapy, they have good tolerability and result in high response rates.

Toxicity related to thalidomide includes peripheral neuropathy, constipation, somnolence, and rash. Later-generation IMiDs have a more favorable side effect profile. Myelosuppression is more likely, but neuropathy and constitutional symptoms occur less frequently. The second-generation IMiD lenalidomide is more commonly used in North America due its favorable tolerability. A troublesome and unique side effect of the IMiD-steroid combination programs is development of deep vein

thrombosis in up to 25% of patients, and some form of preventative therapy is typically prescribed.

Bortezomib is the first-in-class proteasome inhibitor and is a favored therapy for patients with adverse cytogenetic risk factors. Bortezomib is typically administered subcutaneously and may cause thrombocytopenia, asthenia, and neuropathy.

Most patients respond to initial therapy with a reduction in bone pain, hypercalcemia, and anemia in association with a decline in the M protein level. The selection of initial therapy depends on stage, cytogenetic risk, and candidacy for high-dose chemotherapy and autologous stem cell transplantation. The use of high-dose chemotherapy with alkylating agents followed by autologous peripheral stem cell infusion during first or second remission has improved survival and quality of life compared with standard doses of chemotherapy. Although this approach is not curative, it does represent an important treatment option for some patients and has an acceptable toxicity profile, even in older patients. The relative value of autologous stem cell transplantation compared with ongoing therapy with the newer agents is unknown and is an area of active clinical investigation. Allogeneic stem cell or bone marrow transplantation may be associated with durable remission in selected patients, but it carries a much higher near-term risk of morbidity and mortality. Patients who experience relapse after standard therapy or transplantation may be treated with alternate chemotherapy regimens or with novel combination therapies, including newer agents and chemotherapy drugs.

Supportive care directed toward anticipated complications of myeloma is an important aspect of the management of this disease. Bone resorption can be reduced with regular injections of the diphosphonates zoledronic acid or pamidronate, reducing pain and pathologic fractures. Bony lesions, particularly those involving weight-bearing bones, may require palliative irradiation for controlling pain and preventing pathologic fractures. Vertebral bony lesions may lead to spinal cord compression, with increasing back pain and neurologic symptoms. Symptoms suggesting cord compression require prompt evaluation with spinal MRI and, if necessary, local irradiation of involved areas.

Avoidance of nephrotoxins, including intravenous dyes, is important to prevent renal failure. All patients should receive pneumococcal and *H. influenzae* vaccines, and intravenous gamma globulin may be useful in preventing recurrent infections in patients with profound hypogammaglobulinemia. Use of erythropoietin may alleviate anemia and decrease the need for blood transfusions.

Prognosis

Multiple myeloma is considered incurable, but the overall survival of these patients has improved considerably with the widespread use of autologous stem cell transplantation and development of newer agents. For example, median survival reported by the Mayo Clinic has increased from 29 to 44 months.

The prognosis depends on the stage of disease and cytogenetic profile. Patients with an adverse karyotype, including t(14;16) and 17p deletion, have a less favorable prognosis and are considered for more intensive therapies or clinical investigation. Adverse factors also include advanced stage, impaired renal function, elevated LDH levels, abnormal bone marrow cytogenetics,

depressed serum albumin levels, and elevated β_2 -microglobulin levels.

Waldenström Macroglobulinemia

Waldenström macroglobulinemia is a malignancy of plasmacytoid lymphocytes that secrete large quantities of IgM. It is a chronic disorder affecting elderly patients (median age of 64 years) that shares features of the low-grade lymphomas and myeloma. Unlike myeloma, Waldenström macroglobulinemia is associated with lymphadenopathy and hepatosplenomegaly, and although bone marrow involvement invariably occurs, lytic lesions and hypercalcemia are rare.

The major clinical manifestations of Waldenström macroglobulinemia include symptomatic anemia and the hyperviscosity syndrome caused by the physical properties of IgM. In contrast to IgG, IgM remains largely confined to the intravascular space, and as IgM levels rise, plasma viscosity increases. Epistaxis, retinal hemorrhages, dizziness, confusion, and congestive heart failure may occur as a result of the hyperviscosity syndrome. About 10% of IgM proteins have properties of cryoglobulins, and patients show symptoms of cryoglobulinemia or cold agglutinin syndrome demonstrated as acrocyanosis, Raynaud's phenomenon, and vascular symptoms or hemolytic anemia precipitated by exposure to cold. Some patients with Waldenström macroglobulinemia may develop a peripheral neuropathy that may antedate the appearance of the neoplastic process.

The approach to and treatment of Waldenström macroglobulinemia are similar to those of other low-grade B-cell lymphomas. The use of nucleoside analogues such as fludarabine or an alkylating agent, alone or in combination with prednisone, is effective in decreasing adenopathy and splenomegaly and controlling the M spike, but it is not curative. Rituximab has activity against Waldenström macroglobulinemia, as has the proteasome inhibitor bortezomib. The use of rituximab may be complicated by initial worsening of hyperviscosity in patients with high IgM burdens. Plasmapheresis is highly effective in acutely decreasing serum IgM levels and is often needed initially to treat hyperviscosity. Although complete remissions are rare, patients who respond to therapy have median survivals of 4 years, and some patients survive more than a decade.

Rare Plasma Cell Disorders

Heavy-chain disease is a rare lymphoplasmacytoid neoplasm characterized by production of a defective heavy chain of the γ , α , or μ type. The clinical manifestations vary with the type of heavy chain secreted. The γ -type heavy-chain disease is associated with lymphadenopathy, Waldeyer's ring involvement with palatal edema, and constitutional symptoms. The α -type heavy-chain disease, also known as Mediterranean lymphoma, is characterized by lymphoid infiltration of the small intestine with associated diarrhea and malabsorption. The μ -type heavy-chain disease is associated with CLL.

Primary amyloidosis is a systemic illness characterized by deposition of immunoglobulin light chains in organs and tissue, resulting in an array of symptoms caused by organ dysfunction. Congestive heart failure, bleeding diathesis, nephrotic syndrome, and peripheral neuropathy are common complications. Patients with primary amyloidosis may respond to selected treatments

similar to therapy for myeloma. The combination of bortezomib, cyclophosphamide, and dexamethasone is effective in some patients. Selected patients may respond well to high-dose chemotherapy and autologous stem cell support, but there are increased risks of morbidity and mortality if significant end-organ dysfunction such as cardiomyopathy occurs.

POEMS syndrome is a rare disorder characterized by polyneuropathy, sclerotic bone lesions, endocrinopathy, monoclonal gammopathy, and skin lesions. The cause of POEMS syndrome is unknown, but the disease may be progressive, causing severe disability, third spacing of fluid, and elevated vascular endothelial growth factor (VEGF) levels. Monoclonal λ light chains are typically elevated. Limited bone disease may be treated with radiotherapy. High-dose therapy and autologous stem cell transplantation is effective in patients with extensive disease.

 For a deeper discussion of these topics, please see Chapter 187, "Plasma Cell Disorders," and Chapter 188, "Amyloidosis," in Goldman-Cecil Medicine, 25th Edition.

CONGENITAL AND ACQUIRED DISORDERS OF LYMPHOCYTE FUNCTION

Several congenital disorders affect lymphocyte maturation or function, resulting in immunodeficiency disorders. Acquired disorders of lymphocyte function are far more common than congenital disorders. HIV infection is the most important infectious cause of acquired immunodeficiency (see Chapter 109). Patients with HIV infection are at increased risk for NHL. NHLs that occur in the setting of HIV have the diffuse, aggressive B-cell histology and include DLBCL and Burkitt's lymphoma, and they are frequently associated with EBV infection and are often advanced stage (III or IV) at diagnosis, with extranodal sites of involvement.

Patients with HIV-associated NHL are potentially curable with the multidrug chemotherapy regimens used for treating the NHL subtypes found in the general population. Treatment of the underlying HIV infection with highly active antiretroviral therapy (HAART) has improved the outcome and prognosis of patients with HIV-associated NHL.

Patients who have undergone allogeneic organ transplantation require potent immunosuppressive drugs (e.g., cyclosporine, tacrolimus, mycophenolate, corticosteroids, methotrexate) to prevent graft-versus-host disease in the case of bone marrow transplantation or allograft rejection in the case of solid organ transplantation. These medications can cause profound defects in T-cell function with an associated acquired immunodeficiency state, and transplant recipients are susceptible to a host of viral and protozoal infections.

Patients who receive potent immunosuppressive drugs are at risk for a lymphoproliferative disorder (i.e., post-transplantation lymphoproliferative disorder [PTLD]) that can behave clinically as an aggressive lymphoma. PTLD is an EBV-associated lymphoproliferative disorder characterized by a polymorphous or

monomorphous population of B cells that can be monoclonal or polyclonal. Patients who develop PTLD are treated by reducing the doses of immunosuppressive drugs whenever possible. Patients with polymorphous disease early after organ transplantation may respond well to this approach. Patients who are not candidates for withdrawal of immunosuppression because of allograft rejection or who develop late monophorphic disease may respond better to treatment with rituximab alone or in combination with chemotherapy.

Normal Hemostasis

Alexa J. Siddon, Henry M. Rinder, and Christopher A. Tormey

INTRODUCTION

Hemostasis is the physiologic balance of procoagulant and anticoagulant forces that maintains both liquid blood flow and the structural integrity of the vasculature. Vascular damage results in initiation of clotting that produces a *localized* platelet-fibrin plug to prevent blood loss; this action is followed by processes that lead to clot containment, wound healing, clot dissolution, tissue regeneration, and remodeling. In healthy persons, all these reactions occur continuously and in a balanced fashion so that bleeding is contained while blood vessels simultaneously remain patent to deliver adequate organ blood flow. If any of these processes are disrupted because of inherited defects or acquired abnormalities, disordered hemostasis may result in either bleeding or thromboembolic complications.

Blood flow in the arterial system is different from that in the venous system and imposes different needs on the coagulation system. In the pressurized arteries, relatively minor vascular damage can rapidly result in massive blood loss; therefore, the procoagulant response in arteries must rapidly arrest bleeding. Platelets are critical to this arterial response; they initially contain the blood loss and then provide an active surface for soluble coagulation factors to both localize and accelerate formation of fibrin and, ultimately, clot formation. By contrast, the slower flow rates in the venous circulation produce slower bleeding, a feature that makes platelets less critical; instead, the balance of venous hemostasis is most dependent on the rate of thrombin generation. These differences are underscored clinically by the anticoagulant agents used in these distinct settings: antiplatelet agents such as aspirin and clopidogrel to prevent coronary and cerebral artery thrombus, whereas interventions that inhibit thrombin, including the heparins and warfarin, are used for treatment and prophylaxis of venous thromboembolic disease. Recently, new anticoagulants have been introduced, including direct thrombin inhibitors (e.g., dabigatran etexilate) and Xa inhibitors (e.g., rivaroxaban); they selectively inhibit activated coagulation factors for prophylaxis against systemic embolism from atrial fibrillation and from venous thromboembolism, respectively.

This chapter briefly details the physiologic and interdependent mechanisms of vascular hemostasis, including the normal balance of procoagulant and anticoagulant functions of the blood vessel wall, platelet physiologic factors and receptor-ligand interactions that are critical for hemostasis, and the highly complex, interwoven pathways that represent the coagulation cascade.

VASCULAR WALL PHYSIOLOGY

Vascular endothelial cells (ECs) are capable of orchestrating both procoagulant and anticoagulant events depending on circumstances. When the vasculature is intact, healthy ECs exert tonic anticoagulant activity, helping to maintain blood fluidity. In part, they provide a passive barrier function, separating the blood from subendothelial procoagulants such as collagen and tissue factor (TF). In addition, healthy ECs actively regulate the hemostatic balance of activity in their microenvironment through their secreted products (Table 50-1). These include prostacyclin and nitric oxide, both of which induce vascular smooth muscle relaxation and reduced shear when released in an abluminal direction. When secreted into the blood, they promote the generation of platelet cyclic adenosine monophosphate (cAMP), thus inhibiting platelet activation and aggregation. ECs also secrete adenosine diphosphatase, which degrades extracellular platelet-released adenosine diphosphate (ADP), thereby inhibiting platelet recruitment into the growing platelet clot. Soluble coagulation factors are also regulated by ECs in both tonic and inducible fashion. Tissue factor pathway inhibitor (TFPI) in its nascent circulating form blunts the initiation of coagulation; TFPI is subsequently primed for increased activity by exposure to small amounts of factor Xa. Quiescent thrombomodulin and tissue plasminogen activator are localized at the EC extracellular matrix, ready to be activated by local formation of thrombin and fibrin, respectively, to carry out their anticoagulant and fibrinolytic functions.

When ECs are physically damaged or become activated, their balance of coagulant properties is shifted to favor a procoagulant state. This function is mediated both by the ECs themselves and by the underlying subendothelial matrix that is exposed by vascular injury. ECs that have become activated (e.g., by toxins or

TABLE 50-1 PROPERTIES OF ENDOTHELIAL CELL COAGULANTS

von Willebrand factor	Tissue plasminogen activator

secreted factors) express adhesive ligands on their surface, including the selectins (both E-selectin and P-selectin), β_1 and β_2 integrins, platelet endothelial cell adhesion molecule-1 (PECAM-1), and von Willebrand factor (vWF) multimers (see [Table 50-1](#)). On the EC surface, vWF multimers localize and promote platelet adhesion, whereas integrins mediate adhesion and subsequent transendothelial migration of leukocytes into the tissues. After EC damage, exposed subendothelial matrix also binds vWF multimers ([Fig. 50-1A](#)) to localize platelet adhesion. Subendothelial procoagulant proteins, including thrombospondin, fibronectin, and collagen, function both as ligands to capture platelets and as activators of adherent platelets. Collagen, in particular, is both a platelet ligand and a strong platelet agonist. The latter capability causes platelets to undergo dense granule release and to express conformationally active ligands such as glycoprotein IIb/IIIa (GPIIb/IIIa; see later discussion). Another critical procoagulant mediator exposed by EC damage is TF, which is constitutively expressed by subendothelial smooth muscle cells and fibroblasts. As outlined later, TF is the major initiator of the soluble coagulation system which, along with activated platelets, results in the formation of a definitive platelet-fibrin clot ([Fig. 50-2](#)).

PLATELET PHYSIOLOGY

The platelet functions as the cellular-based platform for hemostasis. Platelet surface receptors mediate primary hemostasis and allow platelets to bind directly to endothelium and subendothelium at sites of damage (see [Fig. 50-1B](#)). Platelet interactions with their ligands cause transmembrane signaling through surface receptors to induce platelet activation and promote procoagulant function through various pathways, including translocation of additional receptors to the membrane surface, receptor conformational change to active forms, release of granule contents that recruit platelet adhesion, and exposure of procoagulant membrane phospholipids. The procoagulant surface of the platelet then serves as a platform for enhanced assembly of the coagulation cascade to generate thrombin. Thrombin feeds back on platelets and the clotting cascade to amplify the procoagulant response and also produces fibrin to provide secondary, long-lasting hemostasis. Finally, the platelets assist thrombin in clot consolidation and in protection from fibrinolysis by contributing factor XIII and platelet factor 4, respectively, to the clot milieu ([Table 50-2](#)).

Platelet Hemostasis

Platelets are anucleate cells between 2 and 4 μm in diameter with a volume between 6 and 11 fL. Platelets are derived from the megakaryocyte cytoplasm after a maturation time of about 4 days, with each megakaryocyte contributing 1000 to 3000 circulating platelets in its lifetime. When platelets are released into the circulation, they survive for 7 to 10 days; platelets leave the circulation through a combination of senescence and the normal maintenance of vascular structural integrity. For the latter, very few platelets are needed; approximately 7100 platelets/ μL are required for hemostasis per day if vascular structures are intact (e.g., no recent surgery or trauma) and if there is no increase in normal platelet consumption (e.g., sepsis).

The normal platelet count ranges between 150,000 and 450,000/ μL , depending on the population used to establish the

reference range. With platelet counts in the normal range and normal platelet function, the bleeding time, an *in vivo* measure of platelet function, is typically less than 8 minutes. However, if the number of normal functioning platelets is less than 100,000/ μL , the bleeding time is prolonged. Therefore, in the presence of thrombocytopenia, the bleeding time cannot be used to determine whether bleeding is caused by abnormal platelet function or by connective tissue disease. The bleeding time is an operator-dependent, highly variable *in vivo* assay that can leave scars; many laboratories have therefore switched to a so-called *in vitro* bleeding time test such as the Platelet Function Analyzer-100 (PFA-100), which uses anticoagulated whole blood to examine “closure time” (details on the PFA-100 and other platelet function platforms are provided in [Chapter 51](#)). However, the PFA-100 and other like-minded tests are similar to the bleeding time test in that they are unable to distinguish between thrombocytopenia and abnormal platelet function when platelet counts are lower than 100,000/ μL .

Shear-Induced Adhesion

The interaction between platelets and the vessel wall has been well characterized at the high flow velocities of the arterial circulation. The interaction between the vasculature and flowing blood, as shown on the left side of [Figure 50-1A](#), creates parallel planes of blood moving at different velocities; the blood closest to the vessel wall moves more slowly than blood that is closer to the center of the vessel. These different velocities create shear stress that is greatest at the vessel wall and least at the center of the vessel. Shear rate therefore changes inversely with the vessel diameter, with levels estimated to vary between 500 s^{-1} in larger arteries and 5000 s^{-1} in the smallest arterioles. Shear rates at the surface of atherosclerotic plaques with modest (50%) stenosis reach 3000 to 10,000 s^{-1} , with even greater shear in more clinically significant stenoses. The high-velocity aspect of arterial blood flow actually opposes the tendencies to clot by (1) limiting the time available for procoagulant reactions to occur and (2) disrupting cells and proteins that are not tightly adherent to the vessel wall. However, once the vessel wall is damaged and bleeding occurs, platelets can rapidly and decisively respond to the loss of endothelial integrity while they simultaneously resist the tendency to be swept downstream.

One of the forces enhancing platelet readiness for wall adhesion in the arterial circulation is radial dispersion, the tendency of larger cells (erythrocytes and leukocytes) to stream in the center of the vessel, where shear is lowest. This process effectively pushes the smaller platelets toward the vessel wall and optimally positions them to respond to hemostatic challenges. This size-dependent flow may also explain the seemingly paradoxical ability of red blood cell transfusions to slow or stop bleeding in patients with thrombocytopenia or consumptive coagulopathy (see [Chapter 51](#)). This effect also underscores the importance of platelets in arterial hemostasis; reductions in platelet number or function may be associated with severe arterial hemorrhage after surgery or trauma. By contrast, the lesser shear forces experienced in the venous circulation permit more random cell movement and greater time for coagulation reactions to occur; for this reason, the minimum requirements for platelet number and function in venous hemostasis are less stringent.

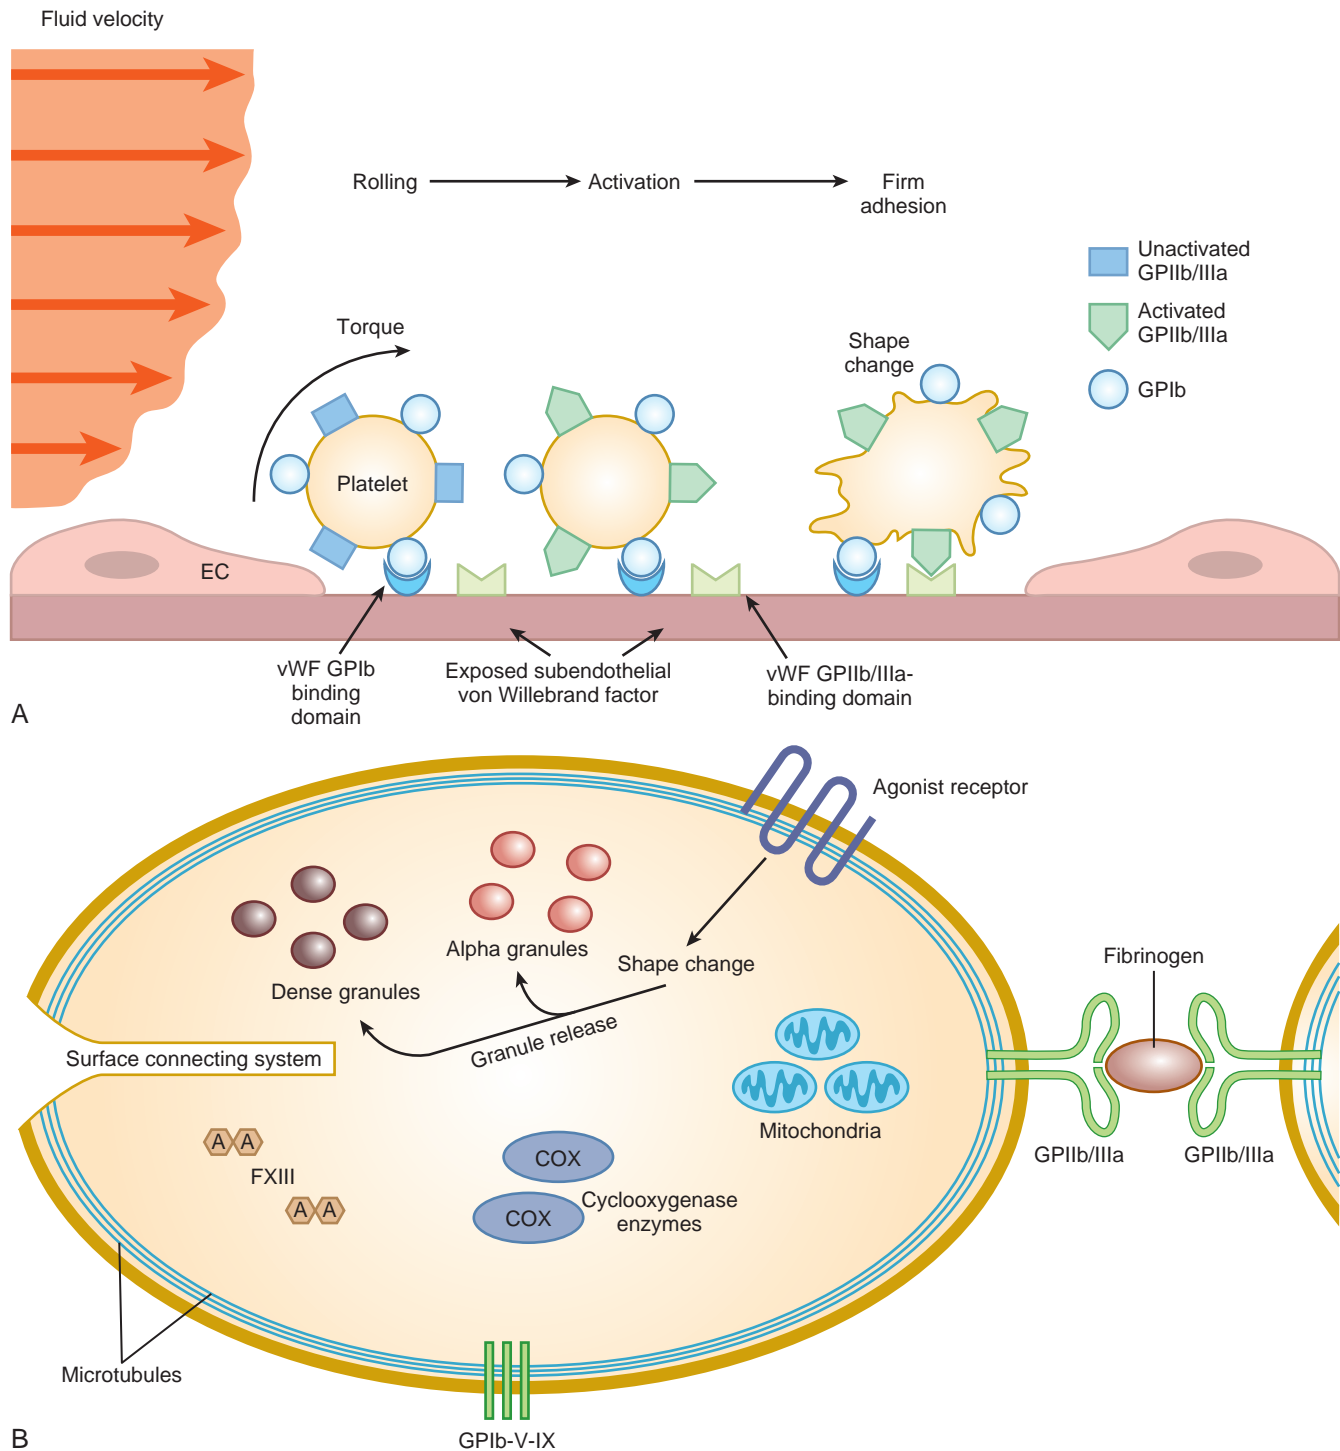

FIGURE 50-1 **A**, The adhesive interactions that produce stable platelet attachment to subendothelial von Willebrand factor (vWF). The initial attachment between platelet glycoprotein Ib (GPIb) and its binding domain on vWF is rapid but has a short half-life, and the result is a rolling movement caused by torque generated by flowing blood. The vWF-GPIb interaction produces transmembrane signaling that activates the platelet to change shape and simultaneously transforms GPIIb/IIIa into an activated conformation capable of binding to a distinct arginine-glycine-aspartate domain on vWF. This secondary adhesion causes the platelet to firmly adhere to the exposed subendothelial vWF. **B**, The internal and external anatomy of a platelet. The platelet consists of several important external, transmembrane, and internal components that help to promote platelet activation, adhesion, aggregation/agglutination, and general coagulation factor–based hemostasis. The most important and most clinically relevant aspects of platelet anatomy are shown. Details regarding the steps leading to platelet activation and release of granules and cytosolic contents are discussed in the text. A, A subunits of Factor XIII; COX, Cyclooxygenase; EC, Endothelial cell; FXIII, factor XIII; GP, glycoprotein complex.

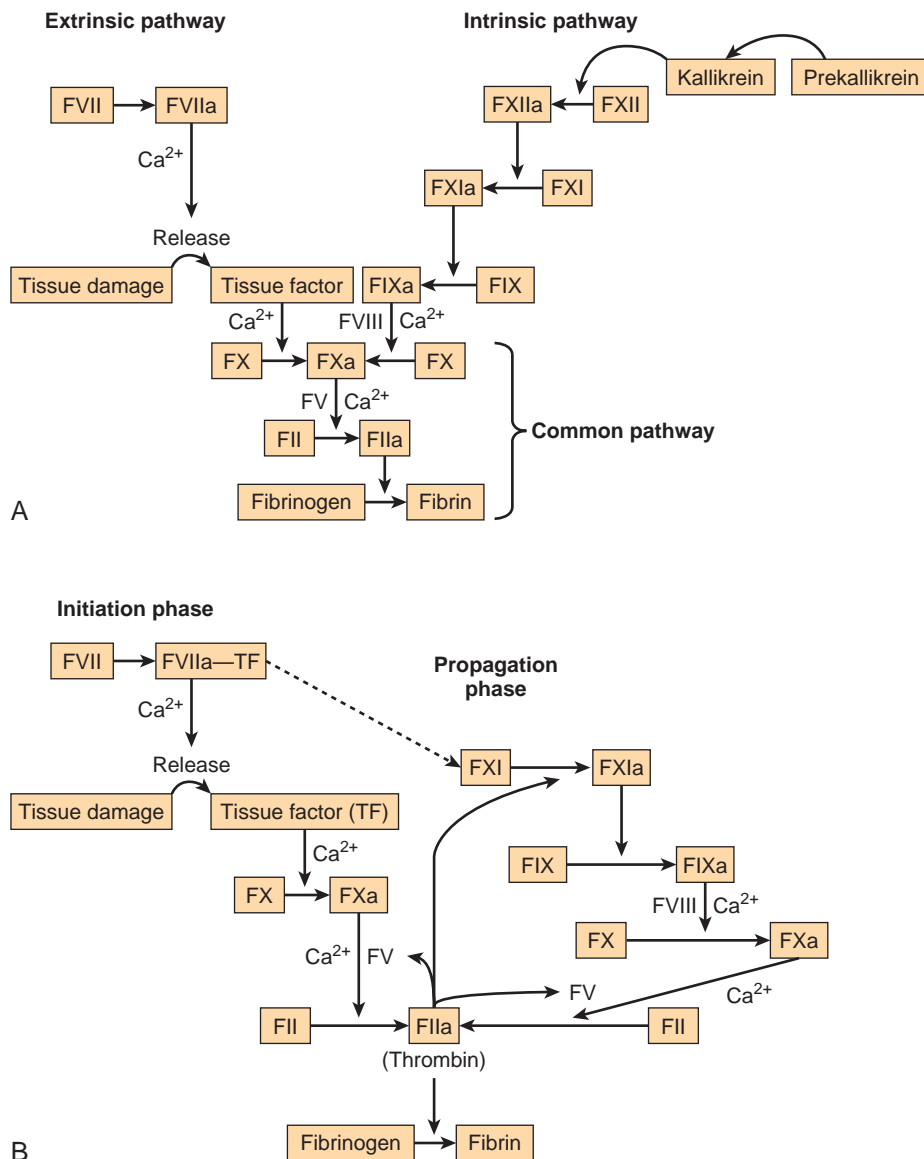

FIGURE 50-2 **A**, The classic view of the coagulation cascade. The laboratory-defined *extrinsic* and *intrinsic* pathways allow monitoring of anticoagulation by serial measurements of the prothrombin time (PT) and partial thromboplastin time (PTT), respectively. The PT primarily monitors factor VII activity, whereas the PTT is the best measure of XI and the hemophilic factors IX and VIII; both assays will detect deficiency of the common pathway factors (X, V, and II). **B**, In the more modern view of the coagulation cascade, initiation of clotting begins with exposure to tissue factor (TF), which combines with small amounts of circulating factor (F)VIIa to form the extrinsic tenase (Xase) complex and generate FXa. FXa forms the prothrombinase complex with FVa and FII, generating small amounts of thrombin (FIIa), which begins to cleave fibrinogen into weak fibrin monomers in the initiation phase of coagulation. Thrombin's ability to activate factors, especially on the activated platelet surface, is responsible for propagation of the coagulant response. Thrombin generates FXIa, which, in turn, activates FIX; the TF-VIIa complex (before it is shut down by TFPI) also generates FIXa. Thrombin-activated FVIIIa then combines with IXa to form the intrinsic Xase complex, generating large amounts of FXa and prothrombinase complex on the platelet surface to further amplify thrombin generation. The large amounts of thrombin now generate enough fibrin monomers to form stable polymers and fibrin clot. HMWK, High-molecular-weight kininogen; PK, prekallikrein; TFPI, tissue factor pathway inhibitor.

In the setting of high-velocity blood flow at an arterial bleeding site, platelets must activate and adhere to the injured vessel almost instantaneously (see Fig. 50-1A). Two molecules that are present in the subendothelium are critical for this process: vWF and collagen. Control of bleeding in vessels under the highest shear stresses absolutely depends on the presence and function of vWF. vWF is a large molecule synthesized as multimeric *strings* in ECs and megakaryocytes, and multimeric vWF is both constitutively secreted into blood and stored in Weibel-Palade bodies of ECs. The *ultralarge* vWF multimers are the most active at

binding platelets, particularly when *unfolded*, either by shear stress or after tethering to the vessel surface. The multimeric forms of vWF, which are immobilized by adherence to exposed subendothelial collagen, bind to the GPIb-IX-V complex on the platelet surface when normally cryptic loci are exposed by high shear stress. This binding is extremely rapid but has low affinity; therefore, the platelets are slowed at this interface, but they are left only weakly adherent to subendothelial vWF. With platelets no longer streaming by, but instead tumbling or sliding over the subendothelium, the high shear stress in tandem with

transmembrane signaling produced by the GPIb-V-IX-vWF interaction results in loss of the normal platelet discoid shape and conformational change in another platelet receptor, GPIIb/IIIa (see Fig. 50-1A).

Ligands

The activated GPIIb/IIIa receptor then binds either to fibrinogen or to the larger vWF multimers at a site distinct from the GPIb-IX-V binding site. This secondary adhesion is a higher-affinity interaction, and it secures the platelets firmly to the subendothelium (see Fig. 50-1B). At shear rates that approximate arterial occlusion, platelet adhesion to vWF multimers can be mediated entirely through GPIb-V-IX-vWF binding without platelet activation. One important regulator of this process of platelet binding and activation through vWF is the circulating vWF-cleaving protease in plasma; this is a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS-13). ADAMTS-13 modulates the activity of vWF by cleaving the ultralarge multimers into smaller fragments that have reduced overall affinity for platelet binding. Besides directly activating platelets, thrombin causes proteolysis of ADAMTS-13, thereby promoting the persistence of large vWF multimers and enhanced platelet recruitment into areas of vessel injury. Congenital or acquired pathologic loss of the ADAMTS-13 cleaving protease activity results in unchecked platelet adhesion to ultralarge vWF multimers and widespread microvascular thrombosis (see the discussion of *thrombotic thrombocytopenic purpura* in Chapter 52).

At more moderate shear rates, GPIb-V-IX-vWF adhesion is supplemented by platelet binding to subendothelial collagen, an adhesive moiety that is capable of arresting the platelet by binding to GPIa/IIa (see Table 50-2). Thus, subendothelial vWF and collagen act cooperatively to initiate platelet adhesion, with the former predominating at higher shear. Collagen is unique in that

it can anchor platelets at one locus by binding to platelet GPIa/IIa and activate platelets at a second locus by binding to platelet GPVI; both platelet receptors are critical for physiologic platelet function. Indeed, the congenital absence of any of the critical platelet adhesion receptors—GPIIb/IIIa, GPIb/IX-V, GPVI, or GPIa/IIa—results in a significant hemostatic defect, correctable only by platelet transfusion. This finding is further reinforced by the fact that the α chain of GPIb normally serves as a cofactor for thrombin activation of platelets through both the GPV receptor and the protease-activated receptor (PAR). Like defects in platelet receptors, decreases in the vWF ligand, especially the larger multimeric forms, can lead to bleeding.

Once a layer of platelets is adherent to the site of injury, vWF bound to GPIb-IX-V on the luminal side of the adherent platelets serves to recruit additional platelets from the flowing blood into the growing platelet plug. Platelet recruitment is further enhanced by platelet activation and release of serotonin and ADP, which serve to activate and adhere platelets from the circulation to the growing platelet clot (see Fig. 50-1B and Table 50-1). Platelet activation is actually a series of interdependent processes with five major effects: (1) local release of ligands essential to stabilization of the platelet-platelet matrix, (2) continued recruitment of additional platelets, (3) vasoconstriction of smaller arteries to slow bleeding, (4) localization and acceleration of platelet-associated fibrin formation, and (5) protection of the clot from fibrinolysis.

The basis of the platelet plug is a platelet-ligand-platelet matrix with fibrinogen, fibronectin, and vWF serving as bridging ligands (Fig. 50-3). Both fibrinogen and vWF are endocytosed from plasma and stored in alpha granules inside the resting platelet, and both are released with activation. Fibrinogen plays the predominant role of binding to a GPIIb/IIIa receptor on each of two platelets, thereby linking them. Some data suggest that vWF is capable of a similar role. As mentioned earlier, platelet GPIIb/IIIa undergoes a calcium-dependent conformational change that allows it to bind to a locus containing the amino acid sequence arginine-glycine-aspartate (RGD) on fibrinogen, fibronectin, or vWF. Each fibrinogen molecule has two RGD sites on its polar ends, and the larger vWF multimers have several RGD sites, all capable of binding to conformationally altered GPIIb/IIIa and creating the platelet-ligand-platelet matrix. GPIIb/IIIa is the most abundant glycoprotein on the platelet surface, with about 50,000 copies on the *resting* platelet and additional GPIIb/IIIa receptors within the platelet cytosol that are mobilized to the surface after activation.

Activation

Platelets are also recruited into the platelet plug by local agonists (collagen, epinephrine, and thrombin) and by platelet release of agonists into the local microenvironment (see Fig. 50-1B). Both collagen (as noted previously) and thrombin interact with their specific platelet receptors to activate platelets strongly; although epinephrine alone is not a powerful platelet agonist, stimulation of the α -adrenergic receptor on platelets primes them for synergistic activation by even relatively weak agonists such as ADP. Activating compounds released directly from the platelet include thromboxane A_2 (TXA₂), which is formed in the platelet cytosol after cyclooxygenase 1 (COX1)-mediated

FIGURE 50-3 Endogenous anticoagulant pathways. Tissue factor pathway inhibitor (TFPI) shuts off tissue factor (TF) stimulation and blocks the TF-VIIa-X complex; in addition, the clotting cascade is further downregulated by the natural anticoagulants. This inhibition is partly generated by thrombin, which activates thrombomodulin. Circulating antithrombin inhibits thrombin activity and Xa generation of thrombin. The complex of thrombin and thrombomodulin activates protein C (PC) to become activated protein C (APC), which combines with protein S (PS) to cleave and inactivate VIIIa and Va, further blocking thrombin generation.

cleavage of arachidonic acid and then released into the clot milieu. TXA_2 is both a platelet agonist and a vasoconstrictor, and it is rapidly degraded to its inert byproduct, thromboxane B_2 .

Platelet COX1 activity is *irreversibly* inhibited by aspirin, which blocks TXA_2 formation for the lifetime of that platelet. Aspirin irreversibly and covalently binds to a specific serine residue on COX1 and causes steric hindrance of the active site, a tyrosine molecule across from the serine residue. Nonsteroidal anti-inflammatory drugs (NSAIDs) do not covalently bind through acetylation at serine. Instead, they reversibly and competitively bind at the active, catalytic tyrosine site. Therefore, in contrast to aspirin, the antiplatelet effects of NSAIDs are dependent on the continual presence of plasma levels of the NSAID.

COX2 is an induced isoform within leukocytes that mediates inflammation and pain. Because mature platelets do not appear to possess COX2 activity, one rationale for development of the highly selective COX2 inhibitors for inflammatory diseases was to avoid the bleeding caused by platelet dysfunction by not affecting platelet COX1 activity. However, it appears that vascular ECs use COX2 activity to synthesize the antithrombotic compound, prostacyclin (see Table 50-1 and Chapter 50). Downregulation of EC prostacyclin, coupled with preserved platelet prothrombotic function, may tip the hemostatic balance in favor of clot formation, and large-scale clinical trials have now shown that some highly selective COX2 inhibitors increase the likelihood of hypertension and vascular arterial events, including myocardial infarction and stroke.

Other platelet agonists are liberated into the extracellular fluid by fusion of the dense granules and alpha granules with the platelet canalicular membrane, and the result is extrusion of granule contents (see Fig. 50-1B). The dense granules contain serotonin, which, like TXA_2 , is both a platelet agonist and a vasoconstrictor.

Another dense granule constituent, ADP, acts purely as a platelet agonist through the G protein–linked P2RY12 receptor and has no vasoactive properties (see Table 50-2). The importance of TXA_2 - and serotonin-induced vasoconstriction is not entirely clear. However, by decreasing the vessel diameter, vasoconstriction may increase shear stress and thereby facilitate recruitment of platelets to the injured site.

The importance of dense-granule release to the maintenance of hemostasis is underscored by the severe bleeding seen in patients with congenital dense-granule deficiencies (e.g., Hermansky-Pudlak syndrome). Platelet activation therefore serves to amplify platelet adhesion and to optimize the platelet surface for interaction with soluble coagulation factors, resulting in the explosive generation of thrombin and fibrin (see later discussion). Finally, other components present in platelets, such as cytosolic factor XIII, are also released into the vascular space on activation. In this case, factor XIII serves as a clot stabilizer, once again reflecting the additional role that activated platelets play in promoting hemostasis.

SOLUBLE COAGULATION

Coagulation Models

The classic “cascade” model of soluble coagulation (see Fig. 50-2A), as first described more than 40 years ago, features two starting points that converge to a common pathway leading to thrombin and fibrin generation. This model allowed great strides to be made in identifying the proteolytic reactions that culminate in fibrin clot, and it dovetailed well with the prothrombin time (PT) and activated partial thromboplastin time (aPTT) assays that guide warfarin and heparin dosing, respectively. Although the model is workable for some clinical scenarios, bleeding in a disease such as hemophilia contradicts its prediction that when

one of these pathways is dysfunctional, activity of the other should be sufficient to maintain adequate clot formation. More recent models have made significant strides in clarifying the dynamics of coagulation (see Figs. 50-2B and 50-3).

Regulation of coagulation proteins is characterized by continuous low-grade factor activation and coordinated assembly of enzyme complexes, which are downregulated by circulating inhibitor proteins. These enzyme complexes consist of serine proteases, their cofactors, and zymogen substrates. In the absence of overt blood vessel disruption, enzyme complex formation and the resultant thrombin generation are both minimal and relatively slow; circulating anticoagulants are sufficient to inactivate these procoagulant complexes and prevent clot formation. However, once a procoagulant stimulus occurs that generates significant amounts of activated factors, formation of these enzyme complexes is rapidly amplified—partly by their assembly on a favorable membrane (phospholipid) surface—leading to intense thrombin formation and subsequent fibrin formation.

Clot Initiation

Coagulation *in vivo* occurs after exposure of the blood to a source of TF, typically on the surface of a fibroblast coming into contact with blood through a break in the vessel wall. The intrinsic or contact pathway of coagulation has no role in the earliest events in clotting. TF-initiated coagulation has two phases: an *initiation* phase and a *propagation* phase (see Fig. 50-2B). The initiation phase begins as the exposed TF binds to factor VIIa, picomolar amounts of which are present in the circulation at all times. This VIIa-TF complex catalyzes the conversion of very small amounts of factor X to Xa, which in turn, generates nanomolar amounts of thrombin. The seemingly trivial amount of thrombin formed during the initiation phase sparks the inception of the propagation phase, successful completion of which culminates in explosive thrombin generation and, ultimately, fibrin deposition.

Clot Propagation

Thrombin generated during the initiation phase is a potent platelet activator, supplying the developing clot with an activated platelet surface membrane and abundant platelet-released factor V. More than 96% of the total thrombin that is generated during clotting occurs during the propagation phase. Factor V is then promptly activated to Va by thrombin. Factor VIII, conveniently brought to the bleeding site by its carrier, vWF, is also activated by thrombin, a step that causes its release by vWF. VIIIa then complexes with the picomolar amounts of factor IXa generated by the TF-VIIa complex during the initiation phase to create the VIIIa-IXa complex. The formation of this complex on the platelet surface heralds the switch of the primary path of Xa generation from the TF-VIIa complex (the extrinsic Xase) to the intrinsic Xase (the VIIIa-IXa complex). This switch is of significant kinetic advantage, with the intrinsic Xase complex exhibiting 50-fold higher efficiency than the extrinsic Xase. The bleeding diathesis associated with hemophilia is testament to the physiologic importance of the exuberant thrombin generation engendered by the switch from extrinsic to intrinsic Xase. The aPTT, which measures the initiation phase of clotting begun by an artificial *in vitro* stimulant, is prolonged by severe deficiencies of either VIII or IX, but it is thrombin generation during the propagation phase, a

function not evaluated by the aPTT, that is most impaired in hemophilia.

The activated platelet expresses receptors for VIIIa and IXa, and binding of these active proteases in complex with membrane phosphatidylserine enhances the binding of the enzyme's substrate, factor X, increasing the kinetic efficiency of the intrinsic Xase complex. Assembly of the prothrombinase complex is similarly dependent on the activated platelet surface for optimal activity. Like the Xase complex, the membrane-bound prothrombinase complex activates prothrombin with a rate enhancement 300,000-fold higher than that of free Xa acting on prothrombin in solution. Platelet-bound Xa is the rate-limiting enzyme in prothrombin cleavage for both the initiation and the propagation phases of clotting; its substrate, prothrombin, binds to GPIIb/IIIa on both activated and unactivated platelets. The net kinetic advantage conferred by platelet binding is such that assembly of the entire reaction on the platelet membrane increases the catalytic efficiency by 13 million-fold compared with proteases free in solution.

What roles do other intrinsic pathway factors play in coagulation? Evidence is growing that factor XI further amplifies the propagation phase of coagulation. Factor Xa is particularly rate-limiting once the switch to the intrinsic Xase has been made. Although small amounts of IXa are generated by the TF-VIIa complex, IXa generation in this manner is limited by TFPI. To generate Xa in amounts sufficient to fuel the propagation phase, a kinetically superior source of IXa is required. Factor XI is another zymogen activated by very small amounts of initiation phase-generated thrombin, but this activation is restricted to the activated platelet surface. Platelet-bound XIa activates IX on the platelet surface, thereby favoring assembly of the intrinsic Xase complex. Moreover, binding to the platelet surface protects XIa from its inhibitor, protease nexin 2. In summary, XIa generation on the activated platelet is instrumental for providing IXa in amounts sufficient to maintain peak Xa generation through the efficient intrinsic Xase complex.

Limiting Soluble Coagulation

Endogenous anticoagulants can either inactivate formed thrombin or prevent thrombin generation (see Fig. 50-3). The most important natural anticoagulant that inactivates thrombin is antithrombin (AT). AT is physiologically present at more than twice the concentration (3.2 $\mu\text{mol/L}$) of the highest local thrombin concentration (1.4 $\mu\text{mol/L}$) that can be reached during clotting, and AT activity against thrombin is potentiated 1000-fold by endogenous EC-associated heparan sulfate proteoglycans. Platelet surface membranes and platelet-released platelet factor 4 protect thrombin from inactivation at the clot. However, any thrombin that escapes into the circulation is immediately (<1 minute) inhibited by plasma AT, and in the microenvironment of healthy ECs that bind about 60,000 molecules of AT per cell, free thrombin is neutralized almost instantaneously. Therefore, early thrombin generation is critically dependent on protection by the activated platelet membrane to allow sufficient time to make the transition from the initiation to the propagation phase.

Among endogenous anticoagulants that target thrombin generation, the earliest in the coagulation process is TFPI, which inactivates factor Xa and the TF-VIIa complex. TFPI is

constitutively released by ECs into the microvasculature. Under normal conditions, TFPI is largely localized to the endothelial surface by binding to EC-associated glycosaminoglycans, but it can be displaced by heparin. Nascent TFPI has direct activity only against Xa, but after exposure to Xa, TFPI acquires activity against the TF-VIIa complex. During the initiation phase, platelet-bound Xa is protected from inactivation by both TFPI and AT. Preservation of the small amounts of Xa that are generated during this early stage of coagulation is critical to formation of the nanomolar amounts of thrombin needed to begin the propagation phase of clotting.

Activated protein C (APC) has anticoagulant, anti-inflammatory, and profibrinolytic properties that make it an important regulator of both thrombosis and inflammation. Like TFPI, protein C becomes activated only after coagulation is underway. Formed thrombin binds to thrombomodulin, a proteoglycan associated with endothelial and monocyte cell surfaces. Thrombomodulin-bound thrombin loses its ability to activate platelets and instead activates protein C. On the EC surface, nascent protein C binds to endothelial cell protein C receptor (EPCR), which positions it for activation by the adjacent thrombomodulin-bound thrombin. In a reaction that is enhanced by EPCR and protein S, APC inactivates factors VIIIa and Va, (components of the Xase and prothrombinase complexes, respectively), thereby limiting procoagulant self-amplification (Fig. 50-4). As with other coagulation factors, the activated platelet membrane protects VIIIa and Va from APC inactivation. In addition to its effects on thrombin generation, APC neutralizes plasminogen activator inhibitor-1 (PAI-1) to enhance clot remodeling. APC has anti-inflammatory properties as well; recombinant APC reduces production of tumor necrosis factor- α after endotoxin challenge, and protein C-deficient mice (heterozygotes) exhibit higher levels of proinflammatory cytokines with systemic endotoxemia.

The liver is the major site of synthesis of all coagulation factors. Factor VIII levels are not usually diminished in liver disease because VIII is also produced by EC and the reticuloendothelial system. The subset of coagulation factors that depend on vitamin K for synthesis include prothrombin (II), VII, IX, and X and the

anticoagulants, protein C and protein S. Post-translational modification (through a vitamin K-dependent carboxylase) of the amino-terminal domain of these proteins adds 10 to 12 γ -carboxyglutamate residues; these residues are critical for calcium binding and for determining the functional three-dimensional structure of the proteins and their proper orientation for binding to membrane surfaces. Warfarin blocks vitamin K epoxide reductase and thereby decreases generation of vitamin K (from vitamin K epoxide) in the vitamin K cycle.

CLOT VIABILITY AND MATURATION

Evidence is growing that initial formation of a thrombus does not ensure sustained hemostasis. Events initiated during generation of both fibrin-rich clots in the venous circulation and platelet-rich clots in the arterial circulation that are critical to clot stability operate after the clot is formed.

Fibrin Clot Architecture

The architecture of a fibrin clot is surprisingly variable. Although genetic factors unquestionably play a role in determining clot structure, two dominant factors are the local concentrations of thrombin and fibrinogen, whose reactions yield the fibrin strands. A thrombin-rich microenvironment typically results in thinner, more tightly cross-linked fibers, making the overall fibrin clot virtually impermeable to lytic enzymes. In thrombin-poor locations, the fibrin strands are thicker and the structure is more porous, making the clot vulnerable to thrombolysis. Similarly, high fibrinogen concentrations are associated with large thrombi whose tight, rigid meshwork makes them less deformable and more resistant to lysis. Low fibrinogen concentrations produce a less compact clot that is highly lysis prone.

Fibrin Cross-Linking by Factor XIIIa

Factor XIII also plays a critical role in stabilization of the forming clot. Factor XIII circulates in the plasma and is also stored within platelets; indeed, fully 50% of the total fibrin-stabilizing activity in blood resides in the platelet and is released by activation. In plasma, factor XIII is a tetrameric molecule consisting of two α subunits, which contain the active site of the enzyme, and two β

FIGURE 50-4 Balanced fibrinolysis limits the platelet-fibrin clot. The platelet plug and fibrin matrices are strengthened by incorporation of factor XIIIa into the fibrin clot. Factor XIIIa also binds α_2 -antiplasmin to the clot to protect it from plasmin-mediated fibrinolysis. At the same time, nearby intact endothelial cells (ECs) secrete tissue plasminogen activator (t-PA). t-PA that evades plasminogen activator inhibitor-1 (PAI-1) converts clot-bound plasminogen to plasmin and leads to fibrin clot degradation and release of soluble fibrin peptides and D-dimer. Therefore, detection of circulating D-dimer usually indicates active fibrinolysis.

subunits, which increase the zymogen's plasma half-life but must be dissociated for full enzyme activity. Platelet factor XIII, by contrast, is a dimer that contains only the two α subunits. Both forms of the zymogen require thrombin cleavage and fibrin as a cofactor, but plasma factor XIII activation proceeds at a considerably slower rate owing to the need for dissociation of the β subunits. Thrombin-activated factor XIIIa binds to fibrin and cross-links the fibrin units, thereby rendering them less permeable and more resistant to lysis. Furthermore, factor XIIIa cross-links the major plasmin inhibitor, α_2 -antiplasmin, directly to fibrin, positioning it for neutralization of any invading plasmin.

Fibrinolysis

The fibrinolytic system operates to prevent fibrin from occluding healthy vessels. During clot formation, Xa and thrombin stimulate healthy ECs to release tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA), both of which are capable of cleaving plasminogen into plasmin. The vast excess of plasminogen in the plasma dictates that under normal circumstances, the concentration of these enzymes is rate-limiting for plasmin formation. The kinetic efficiency of t-PA is improved by at least an order of magnitude by the presence of fibrin. This helps to keep t-PA most active in the microenvironment of the clot. By contrast, u-PA appears to require binding to activated platelets for its ability to liberate plasmin.

Acting to contain fibrinolysis are plasma mediators that either inactivate formed plasmin (such as α_2 -antiplasmin and possibly α_2 -macroglobulin) or block plasmin formation. Foremost among the latter is PAI-1. PAI-1 is present in several-fold molar excess in the plasma and is also released by activated platelets, thereby protecting clots from premature lysis. Plasma levels of PAI-1 can be highly variable, in part because of its circadian pattern of secretion, but also because of polymorphisms of the PAI-1 gene. The 4G promoter region polymorphism of PAI-1 is associated with higher PAI-1 levels and a higher risk for thromboembolic disease (see Chapter 52).

Another mediator that limits fibrinolysis in the vicinity of the clot is thrombin activator fibrinolysis inhibitor (TAFI). TAFI is synthesized in an inactive form by the liver and circulates in the plasma, possibly in a complex with plasminogen. TAFI cleaves specific fibrin lysine residues that would otherwise promote binding of fibrinolytic enzymes (e.g., plasmin). TAFI requires either plasmin or thrombin for activation; however, thrombin activation of TAFI requires extraordinarily large amounts of *free* thrombin. By contrast, EC-associated thrombomodulin increases thrombin-induced TAFI activation 1250-fold, making this an essential cofactor and one that is predominantly available only at the interface between the blood and the vessel wall.

In addition to the EC surface, macrophages are also critical to fibrinolysis. Macrophages degrade fibrin clot through lysosomal proteolysis by a plasmin-independent mechanism. The macrophage binds to fibrin and fibrinogen through its surface integrin receptor, CD11b/CD18; this binding is followed by internalization of the complex into the lysosome, where fibrin and fibrinogen are degraded.

Tissue repair and regeneration are the physiologic end points of clotting, and they eventually lead to dissolution of the fibrin-based clot. Besides t-PA and urokinase, the intrinsic pathway

activators kallikrein, XIIa, and XIa also generate active plasmin from plasminogen. Plasminogen binding to cell surface receptors promotes its own activation to plasmin by placing it in proximity to t-PA and fibrin clot and protects plasmin from inactivation by circulating (not clot-bound) α_2 -antiplasmin (see Fig. 50-4). Plasmin eventually dissolves the fibrin matrix to produce soluble fibrin peptides and D-dimer; it also activates metalloproteinases that further degrade damaged tissue. Fibroblasts and leukocytes migrate into the wound, the latter mediated by selectin binding, and these inflammatory cells act in concert with growth factors secreted by leukocytes and activated platelets (e.g., transforming growth factor- β) to enhance vascular repair and tissue regeneration.

Laboratory Testing of Coagulation

For purposes of laboratory testing, the coagulation cascade is artificially divided into extrinsic and intrinsic pathways, measured as PT and PTT, respectively. These converge to form a common pathway that leads to thrombin and fibrin generation (see Fig. 50-2A). In the laboratory, the *extrinsic* pathway (PT) is assessed by measuring the interaction of circulating VIIa with exogenously added TF (also known as *thromboplastin*). The PT is highly sensitive to deficiencies of factors II, VII, V, and X, all of which are associated with significant bleeding. Because II, VII, and X are also vitamin K dependent factors, with VII having the shortest circulating half-life, the PT is currently the best test for monitoring warfarin (Coumadin) therapy. The PT is unaffected by intrinsic pathway deficiencies of XII, XI, IX, or VIII. The degree of prolongation of the PT by warfarin depends on the strength of the particular thromboplastin (based on its international sensitivity index [ISI]) and the specific coagulation instrument used for the assay. The international normalized ratio (INR) takes these factors into account to standardize among laboratories for variations in prolongation of the PT induced by warfarin. The INR is calculated for each patient as follows: (patient PT/mean control PT)^{ISI}. Therapeutic INRs with warfarin allow for global application of anticoagulant recommendations; these vary according to the specific disease indication and are covered in Chapter 51. In contrast, the PT is relatively insensitive to therapeutic anticoagulation with unfractionated heparin except in very high doses.

The aPTT measurement is based on *in vitro* contact activation (e.g., plasma stimulation with a negatively charged compound such as kaolin). The aPTT is sensitive to deficiencies of contact factors—prekallikrein (PK), high-molecular-weight kininogen (HMWK), and factor XII—and to deficiencies of coagulation factors of the intrinsic pathway (XI, IX, and VIII) and the common pathway (V, X, and prothrombin). Deficiencies of PK, HMWK, and XII prolong the aPTT but do not result in clinical bleeding, implying that these factors are irrelevant to physiologic hemostasis. By contrast, severe deficiencies of XI, and especially IX and VIII, cause significant bleeding. The aPTT is also highly sensitive to unfractionated heparin and is used to monitor therapeutic heparin anticoagulation. Compared with the INR for anticoagulation with warfarin, the range for therapeutic aPTT levels with unfractionated heparin is much wider and not as easily standardized. Therapeutic unfractionated heparin levels can be measured by sensitive assays of anti-Xa activity; therapeutic levels of

0.3 to 0.7 anti-Xa U/mL typically correspond to aPTT values between 1.8 and 2.5 times greater than the patient's baseline PTT (before starting heparin) or the mean PTT of a control population.

Most of the commonly used laboratory tests of soluble coagulation measure the kinetics of the initiation phase only. The PT and PTT have as their end points the first appearance of fibrin gel, which occurs when less than 5% of the total reaction has been completed and when only minimal levels of prothrombin have been activated. The PT and PTT are very sensitive for detecting congenital abnormalities associated with severe factor deficits (e.g., hemophilia) and for guiding heparin and warfarin therapy. However, these tests fail to give information relevant to thrombin generation during the propagation phase, which determines whether a persistent clot forms or the endogenous anticoagulants and fibrinolytic regulators constrain it from excess growth.

In surgical settings and in intensive care units, there is a need for immediate turnaround in coagulation testing. One specific point-of-care test used for coagulation testing is thromboelastometry (TEG). TEG uses whole blood to detect

hyperfibrinolysis and can also assess for platelet dysfunction. As the whole blood begins to solidify in the presence of a prothrombotic agent (e.g., kaolin) a detector collects information about the speed and strength of clot formation.

Disorders of Hemostasis: Bleeding

Christopher A. Tormey and Henry M. Rinder

INTRODUCTION

The approach to an individual with a bleeding disorder considers whether bleeding has been a lifelong issue (i.e., congenital) or has recently become a problem (i.e., acquired). The approach also considers the underlying pathophysiology, such as defects in the vasculature, platelets, or coagulation factor proteins that predispose the patient to bleeding. This chapter explores clinical concepts and tools that should aid the development of an appropriate framework for evaluating and treating patients with hemostatic defects.

CLINICAL AND LABORATORY EVALUATION OF BLEEDING

The evaluation of bleeding requires a careful history, physical examination, and laboratory evaluation. The patient's history should include a description of bleeding (e.g., epistaxis, menorrhagia, hematoma formation), the circumstances in which bleeding occurs (e.g., trauma, surgery, dental procedures), and whether blood products (and what kind) were required to staunch the bleeding. The temporal addition of medications such as aspirin can be associated with bleeding, as can concomitant medical illnesses such as infection or liver disease. Determining a family history of bleeding is important, and the physician may need to question several generations and second-degree relations (e.g., maternal uncles) if hemophilia is suggested in the proband.

The physical examination may yield some clues as to the origin of bleeding by differentiating small vessel bleeding, such as petechial (pinpoint) hemorrhage, from larger vessel bleeding, which usually produces hematomas and purpura (i.e., large bruises). Small vessel bleeding in the skin, mucous membranes, or gastrointestinal (GI) tract tends to occur more often in patients with thrombocytopenia (i.e., decreased platelet counts), qualitative platelet defects, vascular abnormalities, or von Willebrand disease (vWD). In women, menorrhagia may be the only symptom of a bleeding disorder, and it should never be attributed solely to a gynecologic cause. Large vessel bleeding in organs, joints, deep tissue, or muscles is more commonly associated with factor deficiencies (e.g., hemophilia).

Screening laboratory assays are useful in the initial assessment of the bleeding patient (Table 51-1) and should include blood cell counts (especially the platelet count) and examination of a peripheral blood smear; prothrombin time (PT), which is highly sensitive to defects in vitamin K-dependent coagulation factors (particularly factor VII); and activated partial thromboplastin time (aPTT), which detects deficiencies in factors VIII, IX, and

XI (Fig. 51-1). Abnormalities of factors X, V, I (fibrinogen), and II (prothrombin) elevate the PT and aPTT. If the PT or aPTT is prolonged, a mixing study should be performed: The patient's plasma is combined with normal plasma and the clotting time study is repeated. The mixing study distinguishes between factor deficiency (i.e., PT or aPTT corrects to the normal range) and the presence of a circulating inhibitor (i.e., clotting time remains prolonged). Another readily available test for the patient with bleeding is the thrombin time, which assays the functional fibrinogen level. The physiology of the coagulation cascade is explained in Chapter 52.

Platelet function traditionally has been assessed by the *in vivo* bleeding time, an invasive measure of the time required to halt bleeding in a skin incision (see Chapter 52). The bleeding time is prolonged by qualitative platelet defects and by rare connective tissue disorders. The bleeding time test depends on the expertise of the technician performing the test. Its poor reproducibility and the difficulty of performing the test in infants and neonates have limited its use.

TABLE 51-1 SCREENING ASSAYS FOR HEMOSTASIS

LABORATORY TEST	ASPECT OF HEMOSTASIS TESTED	CAUSES OF ABNORMALITIES
Blood counts and peripheral blood smear	Platelet count and morphologic features	Thrombocytopenia, thrombocytosis, gray platelet and giant platelet syndromes
Prothrombin time	Factor VII-dependent pathways	Vitamin K deficiency and warfarin, liver disease, DIC, factor deficiency (VII, V, X, II), factor inhibitor
Partial thromboplastin time	Factor XI-, IX-, and VIII-dependent pathways	Heparin, DIC, lupus anticoagulant,* vWD, factor deficiency (XI, IX, VIII, V, X, II), factor inhibitor
Thrombin time	Fibrinogen	Heparin, hypofibrinogenemia, dysfibrinogenemia, DIC
Platelet function analysis Mixing study	Platelet and vWF function Factor inhibitors or deficiencies	Aspirin, vWD, storage pool disease Abnormal clotting time corrects for a deficiency; does not correct for an inhibitor

DIC, Disseminated intravascular coagulation; vWD, von Willebrand disease; vWF, von Willebrand factor.

*Lupus anticoagulant is not associated with bleeding.

FIGURE 51-1 Basic methodology underlying measurement of prothrombin (PT) and activated partial thromboplastin time (aPTT). **A**, Typical laboratory instrument used to perform basic and complex coagulation assays. **B**, Plasma specimens are incubated at 37° C and then mixed with tissue factor and phospholipid (PT) or a surface activator and phospholipid (aPTT). The time it takes for clot formation to block light passage through the specimen is measured and compared with a reference range. Prolongation of the PT or aPTT clotting time can be associated many congenital or acquired coagulation factor defects. Abnormal PT or aPTT values are typically followed by more specific coagulation factor assays, depending on the type of prolongation and the suspected underlying clinical disease.

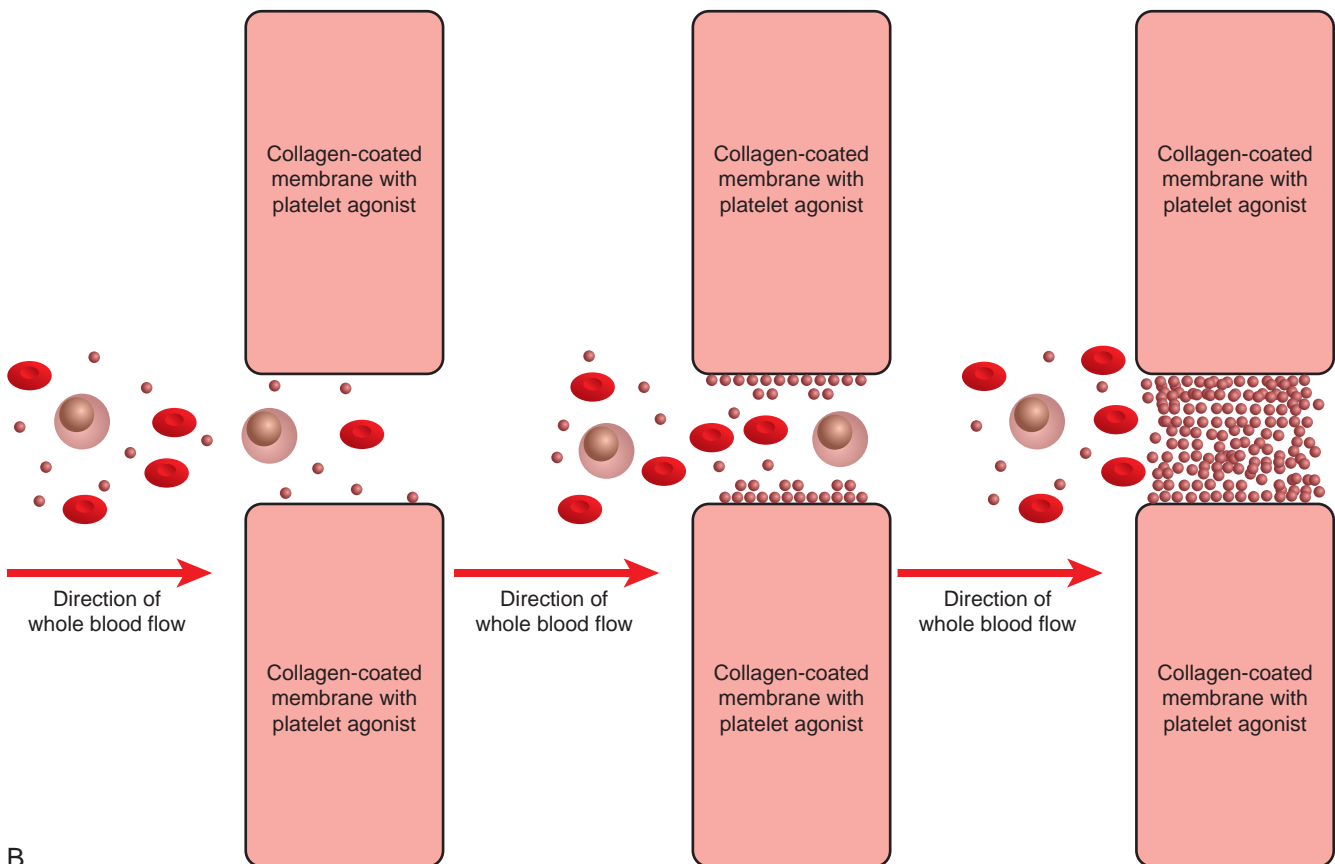

Several instruments use phlebotomized whole blood for in vitro assessment of platelet function. One that delivers an in vitro bleeding time is the Platelet Function Analyzer-100 (PFA-100). Citrate-anticoagulated whole blood is passed through a small orifice in a cartridge impregnated with platelet activators such as collagen, adenosine diphosphate (ADP), and epinephrine. As the platelets become activated and adhere, the orifice gradually becomes obstructed, and the time needed for complete occlusion by the platelet plug is measured as the closure time (Fig. 51-2). The closure time is prolonged by qualitative platelet defects such as those caused by aspirin and vWD. Although thrombocytopenia (<100,000 platelets/ μ L) obviates use of the closure time (similar to the in vivo bleeding time), these in vitro tests are gradually supplanting the measurement of bleeding time.

Another laboratory study for evaluation of a prolonged aPTT, especially in the inpatient setting, is use of the aPTT with an added substance (e.g., hexadimethrine bromide [Polybrene], protamine, heparinase) to neutralize any contaminating heparin resulting from drawing of the blood through an intravenous line. A prolonged aPTT that does not correct in the mixing study may also be observed in patients with a lupus anticoagulant, often in the context of thrombosis. The diagnosis of a lupus anticoagulant can be confirmed by documenting the correction of the aPTT with the addition of excess phospholipid and with other specific tests for lupus anticoagulant (see Antiphospholipid Antibody Syndrome in Chapter 54).

A rapid approach to identifying possible causes of bleeding (Fig. 51-3) considers several major disease categories: (1) vWD,

A

B

FIGURE 51-2 Methodology underlying the Platelet Function Analyzer-100 (PFA-100). **A**, Whole blood platelets are streamed toward a collagen-based aperture. The membrane is infused with a potent platelet agonist (i.e., adenosine diphosphate or epinephrine). **B**, Streaming the platelets through the instrument channels induces shear-based activation, which in conjunction with the agonists, should yield an initial wave of platelet adhesion and aggregation. Over time, activated platelets continue to aggregate, closing off the aperture to whole blood flow. The time it takes for aperture closing is measured in seconds and compared with a reference range. Abnormally prolonged closure times can be associated with von Willebrand disease due to the reliance on adhesion in this assay or with a platelet functional defect due to the reliance on aggregation for complete aperture closure.

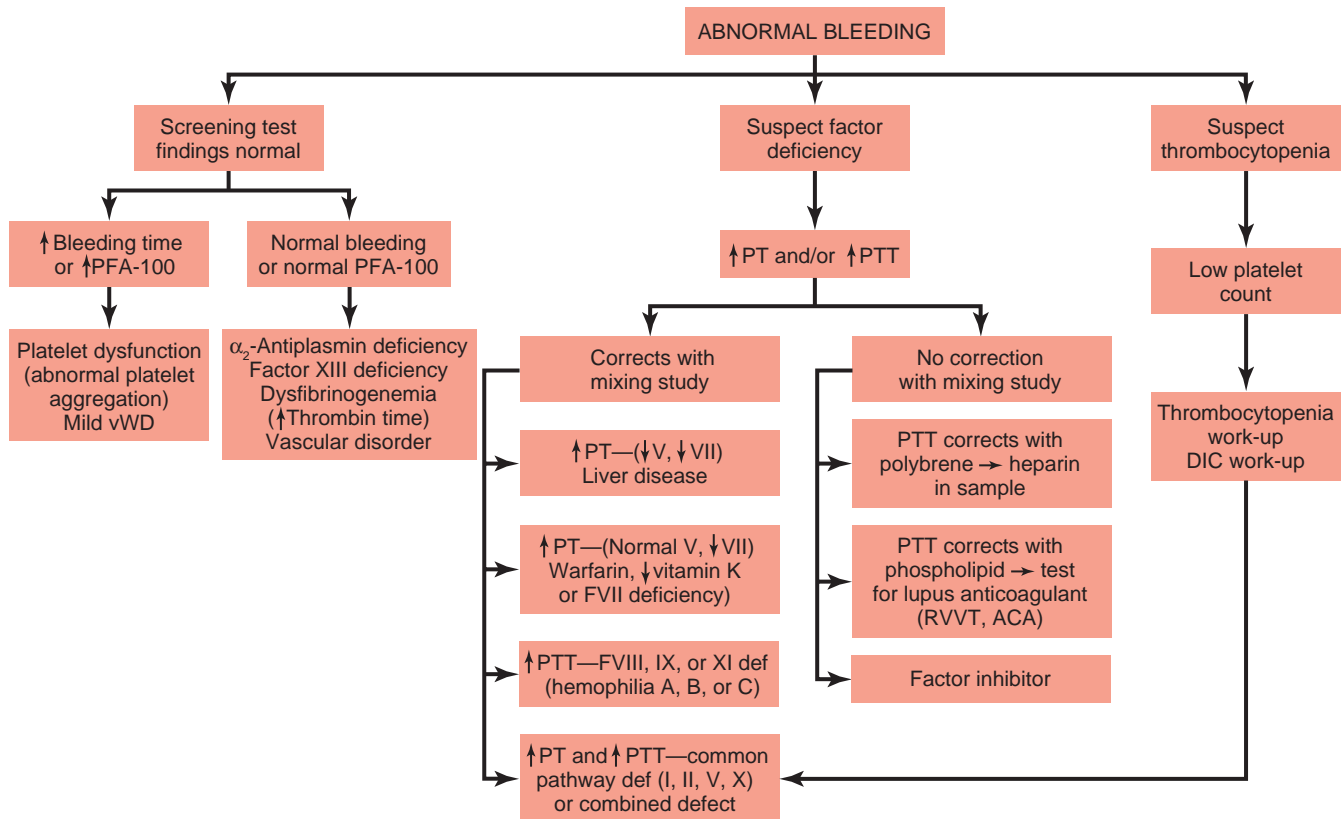

FIGURE 51-3 Algorithm for the evaluation of bleeding. Screening laboratory tests for platelet and factor deficiencies are used to narrow the work-up for bleeding, followed by specific factor and other coagulation studies (e.g., mixing studies, D-dimer) to confirm the diagnosis. ACA, Anti-cardiolipin antibody; DIC, disseminated intravascular coagulation; FVIII, factor VIII; PFA-100, Platelet Function Analyzer-100; PT, prothrombin time; PTT, partial thromboplastin time; RVVT, Russell viper venom time; vWD, von Willebrand disease; ↑, increased; ↓, decreased.

thrombocytopenia, or abnormal platelet function; (2) low levels of multiple coagulation factors resulting from vitamin K deficiency, liver disease, or disseminated intravascular coagulation (DIC); (3) single-factor deficiency (usually inherited); and, more rarely, (4) an acquired inhibitor to a coagulation factor such as factor VIII. The laboratory evaluation is most efficient when it is performed in this context.

BLEEDING CAUSED BY VASCULAR DISORDERS

Vascular purpura (i.e., bruising) is defined as bleeding caused by intrinsic structural abnormalities of blood vessels or by inflammatory infiltration of blood vessels (i.e., vasculitis). Although vascular purpura usually causes bleeding in the setting of normal platelet counts and normal coagulation study results, vasculitis and vessel damage may be severe enough to cause secondary consumption of platelets and coagulation factors.

Collagen breakdown and thinning of the subcutaneous tissue that overlies blood vessels is often observed in older patients (i.e., senile purpura), and similar atrophic skin changes are a common effect of steroid therapy. Another acquired cause of vascular purpura is scurvy (i.e., deficiency of vitamin C [ascorbic acid]). Patients with scurvy have bleeding around individual hair fibers (i.e., perifollicular hemorrhage) and corkscrew-shaped hairs. Bruising occurs in a classic saddle pattern over the upper thighs. The bleeding gums are caused by gingivitis and not by the subcutaneous tissue defect. Edentulous patients with scurvy do not

have bleeding gums, and scurvy should not be excluded on this basis.

Congenital defects of the vessel wall can cause bruising. These rare syndromes include pseudoxanthoma elasticum, a defect of the elastic fibers of the vasculature that is associated with severe GI and genitourinary bleeding, and Ehlers-Danlos syndrome, which is characterized by abnormal collagen molecules in blood vessels and subcutaneous tissue. Both syndromes cause bruising in the skin, but only patients with pseudoxanthoma elasticum develop significant GI bleeding.

Another inherited vessel wall defect associated with GI bleeding is hereditary hemorrhagic telangiectasia (i.e., Osler-Weber-Rendu syndrome). This disorder is characterized by degeneration of the blood vessel wall that results in angiomatous lesions resembling blood blisters on mucous membranes, including the lips and GI tract. The frequency of bleeding caused by breakdown of these lesions increases with age, and GI lesions commonly cause significant chronic bleeding, often resulting in iron deficiency.

The sudden onset of palpable purpura (i.e., localized, raised hemorrhages in the skin) associated with rash and fever may be caused by aseptic or septic vasculitis. Septic vasculitis can be caused by meningococemia and other bacterial infections and is often accompanied by thrombocytopenia and prolongation of clotting times. One cause of aseptic vasculitis in young children and adolescents is Henoch-Schönlein purpura, a vasculitis of the skin, GI tract, and kidneys that is usually accompanied by

abdominal pain from bleeding into the bowel wall. This syndrome may occur after a viral prodrome and appears to be caused by an immunoglobulin A (IgA) hypersensitivity reaction, as evidenced by serum IgA immune complexes and renal histopathologic features resembling IgA nephropathy. For example, hypersensitivity to allopurinol can produce extensive cutaneous purpura.

The therapy for bleeding from vascular disorders is straightforward. Senile purpura and steroid-induced purpura do not usually require treatment. Scurvy is corrected by vitamin C supplementation. In congenital disorders, including Ehlers-Danlos syndrome, hereditary hemorrhagic telangiectasia, and pseudo-xanthoma elasticum, patients should avoid medications (e.g., aspirin) that may aggravate their bleeding tendencies, and they should receive supportive therapy (e.g., iron supplementation, red blood cell transfusion). Systemic administration of estrogen to patients with hereditary hemorrhagic telangiectasia may help to decrease epistaxis by inducing squamous metaplasia of the nasal mucosa, which protects lesions from trauma.

Treatment of septic vasculitis focuses on appropriate antibiotic therapy. In the case of aseptic vasculitis, steroids and immunosuppressive agents are most effective. When vasculitis is severe enough to cause consumption of platelets and coagulation factors (see Disseminated Intravascular Coagulation), transfusions of platelets, cryoprecipitate, or fresh-frozen plasma (FFP) may be indicated.

BLEEDING CAUSED BY THROMBOCYTOPENIA

Thrombocytopenia ($<150,000$ platelets/ μL) is one of the most common problems in hospitalized patients. The initial diagnostic approach to thrombocytopenia involves classifying whether the low platelet count is caused by decreased platelet production, increased platelet sequestration, or increased platelet destruction (Fig. 51-4).

Evaluation of the number and morphologic features of marrow megakaryocytes has been the traditional diagnostic test for differentiating decreased platelet production from peripheral sequestration (e.g., splenomegaly) or destruction (e.g., immune thrombocytopenic purpura [ITP]). The reticulated platelet count is used as a peripheral blood index of platelet kinetics in the evaluation of thrombocytopenia.

Decreased Marrow Production of Platelets

Decreased production of platelets in the bone marrow is characterized by decreased or absent megakaryocytes on the bone marrow aspirate and biopsy and a low percentage of circulating reticulated platelets. Suppression of normal megakaryocytopoiesis occurs after marrow damage and destruction of stem cells (such as occurs with cytotoxic chemotherapy); destruction of the normal marrow microenvironment and replacement of normal stem cells by invasive malignant disease, aplasia, infection (e.g., miliary tuberculosis), or myelofibrosis; specific but rare intrinsic defects of the megakaryocytic stem cells; and metabolic abnormalities affecting megakaryocyte maturation.

Drug- and Nutrition-Associated Thrombocytopenia

Thrombocytopenia may result from cytotoxic or immunosuppressive chemotherapy for malignant or autoimmune disease. The pathophysiology of decreased platelets is typically directly attributable to the toxicity of the drug or metabolite, or both. For example, myeloablative chemotherapy drugs inhibit stem cell proliferation, leading to megakaryocyte death in the bone marrow and reduced circulating mature platelets. Other commonly used drugs such as thiazide diuretics, alcohol, and estrogens may damage bone marrow megakaryocytes in a similar fashion.

Although the diagnosis of these disorders can be complex, it frequently is made by withdrawing the offending drug.

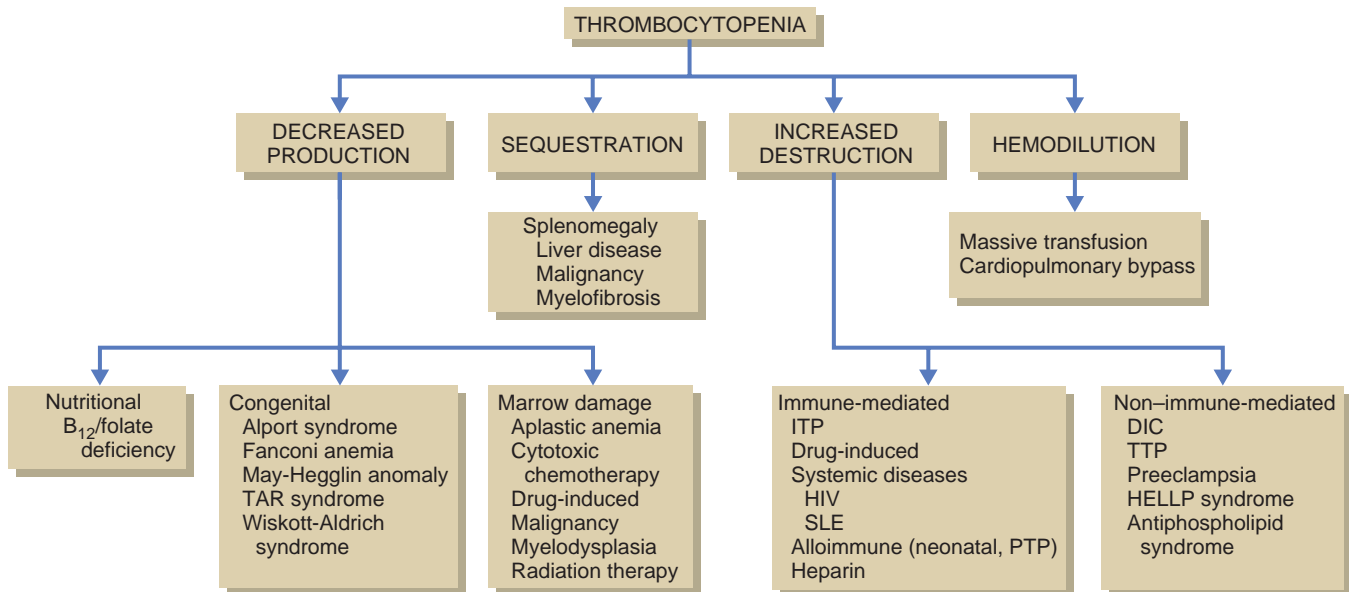

FIGURE 51-4 Differential diagnosis of thrombocytopenia. Disorders resulting in a decreased circulating platelet number can be classified by four main pathophysiologic mechanisms: hypoproduction, sequestration, peripheral destruction, and hemodilution. The history, physical examination, and bone marrow evaluation usually narrow the range of possible causes. DIC, Disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, and low-platelet count in association with pregnancy; HIV, human immunodeficiency virus; ITP, immune thrombocytopenic purpura; PTP, post-transfusion purpura; SLE, systemic lupus erythematosus; TAR, thrombocytopenia-absent radius syndrome; TTP, thrombotic thrombocytopenic purpura.

Other helpful assays measure the reticulated platelet count and immature platelet fraction. In principle, RNA-rich immature platelet elements should be readily identifiable in peripheral blood. In the setting of thrombocytopenia, the normal compensatory response of a healthy bone marrow is to increase platelet production, and increased production correlates with increased numbers of immature platelets. However, in the setting of marrow-suppressive drug therapy, immature platelet counts are typically low, indicating hypoproliferative megakaryocytes. A decreased reticulated platelet fraction in the setting of a known offending drug can help to confirm the diagnosis.

Drug-associated thrombocytopenia is usually reversible, and platelet production rebounds as megakaryocytic stem cells eventually recover and regenerate after cessation of the toxic therapy. However, repeated or intensive chemotherapy (e.g., stem cell transplantation) may permanently damage the megakaryocytic stem cells and supporting stromal environment and cause chronic thrombocytopenia. This condition may be accompanied by leukopenia and anemia.

Similar to drug-related marrow suppression, nutritional disorders, especially alcoholism and abnormal folate or cobalamin (vitamin B₁₂) metabolism, are commonly associated with thrombocytopenia. Like destructive drug therapy, the lack of essential nutrients such as vitamin B₁₂ or folate paralyzes normal megakaryocyte development, resulting in decreased mature platelet production. The diagnosis of a nutritional deficiency can be confirmed by testing vitamin B₁₂ and folate levels in peripheral blood. Platelet counts should respond to abstinence from alcohol and to appropriate multivitamin replacement therapy for deficient nutrients.

Malignancy-Associated Thrombocytopenia

Platelet production is suppressed by intrinsic malignant diseases of the bone marrow (e.g., leukemia, multiple myeloma) and by malignant diseases that secondarily invade the bone marrow (e.g., non-Hodgkin's lymphoma, small cell lung cancer, breast and prostate cancers). The pathophysiology often is attributable to the toxic nature of the bone marrow milieu; normal megakaryocyte development is frequently suppressed by scores of abnormal bone marrow elements or invasive tumors.

The diagnosis of malignancy-associated thrombocytopenia is typically based on a bone marrow aspirate, which characteristically shows decreased megakaryocytes and occasionally shows malignant cells. Bone marrow biopsy has a much higher yield for diagnosing malignant involvement of the marrow. Flow cytometric evaluation for clonal B cells in the marrow aspirate is also highly sensitive for detecting monoclonal B-cell lymphoproliferative disease (e.g., non-Hodgkin's lymphoma). Definitive treatment of the thrombocytopenia relies on aggressively treating the underlying disease process.

Although not strictly an invasive cellular process, myelofibrosis (i.e., increase in reticulin fibers and sometimes collagen) of the marrow may lead to thrombocytopenia or pancytopenia. Myelofibrosis occurs most commonly in myeloproliferative disorders, mastocytosis, and mycobacterial and other infections involving the marrow. It is occasionally seen in patients with myelodysplasia or acute megakaryocytic leukemia and rarely occurs on a congenital basis (i.e., osteogenesis imperfecta).

Like pure malignancy-associated forms of decreased platelet production, myelofibrosis is diagnosed by bone marrow studies. Treating the underlying disorder is the best approach to addressing myelofibrotic thrombocytopenia.

Congenital Thrombocytopenia Syndromes

Thrombocytopenia in children can result from congenital defects of megakaryocyte production, as seen in thrombocytopenia-absent radii syndrome, congenital amegakaryocytic thrombocytopenia (i.e., mutation in the thrombopoietin receptor), and Fanconi's anemia (i.e., congenital aplastic anemia with renal hypoplasia and skin hyperpigmentation). Other disorders that are intrinsic to the bone marrow include the May-Hegglin anomaly and related myosin heavy chain 9 gene (*MYH9*) diseases, characterized by giant platelets and Döhle bodies (i.e., basophilic inclusions in leukocytes and platelets).

Thrombocytopenia with small platelets is characteristic of Wiskott-Aldrich syndrome, an X-linked disorder with eczema and immunodeficiency that can be diagnosed by the lack of CD43 expression on T lymphocytes. When accompanied by nerve deafness and nephritis, congenital hypoproliferative thrombocytopenia is called *Alport's syndrome*.

The defects and detailed approaches to the diagnosis of decreased platelet production associated with the previously described conditions are outside the scope of this chapter. Nonetheless, the definitive treatment for many of the congenital thrombocytopenia problems is allogeneic stem cell transplantation, in which the abnormal, endogenous progenitor cell elements are eliminated and replaced by normal precursors capable of producing typical levels of functioning, mature platelets.

Platelet Sequestration

Up to 30% of circulating platelets are normally sequestered within the spleen at any time. Thrombocytopenia due to sequestration is common in advanced liver disease, myeloproliferative disorders accompanied by splenomegaly (e.g., chronic myelogenous leukemia, chronic idiopathic myelofibrosis), and malignant disease involving the spleen. In each of these conditions, increased trapping of platelets in the splenic system decreases platelet counts to between 50,000 and 100,000/ μL , although rarely lower.

The diagnosis of platelet sequestration may be suspected by physical examination findings or imaging studies demonstrating splenomegaly. The reticulated platelet counts or immature platelet fractions may be normal or slightly elevated, and bone marrow studies typically reveal normal megakaryocyte numbers and morphology. Given the lack of specific tests for platelet sequestration, the diagnosis often is one of exclusion of other causes of hypoproliferative and destructive thrombocytopenia.

Treatment of thrombocytopenia due to splenomegaly frequently depends on the underlying cause for increased spleen size. Splenectomy may be indicated in some conditions such as myeloproliferative disease, but it is rarely used to treat thrombocytopenia resulting from portal hypertension. The decision to perform splenectomy for thrombocytopenia in patients with myeloproliferative syndromes must be individualized and weighed against the possibilities of surgical complications, loss of the spleen's extramedullary hematopoietic ability, and rebound thrombocytosis. Medications that help to control underlying disorders (e.g., chemotherapy for malignancy) or actions such as

liver transplantation (e.g., for end-stage liver disease and portal hypertension) may help to decrease spleen size and decrease platelet trapping.

Platelet Destruction

One of the first major considerations in thrombocytopenia believed to be caused by platelet destruction is whether such destruction is due caused by immune mechanisms (e.g., antibody-mediated platelet clearance) or nonimmune mechanisms (e.g., microangiopathic processes). This division is important because the pathophysiology, diagnosis, and treatment of these two types of platelet destruction are widely divergent.

Immune-Mediated Platelet Destruction

Immune platelet destruction typically refers to antibody-mediated clearance. Platelet destruction can be further divided into autoimmune forms (i.e., antibody against self-antigens) and alloimmune forms (i.e., antibody against nonself-antigens). Autoimmune thrombocytopenia is the most commonly encountered form of immune-mediated platelet destruction. It may be a primary disorder directed only at platelets or a secondary complication of another autoimmune disease, such as systemic lupus erythematosus. Alloimmune-mediated platelet destruction is rare and is usually encountered only in neonates as a result of maternal antibodies formed against fetal platelet antigens or in chronically transfused individuals, who form alloantibodies against foreign platelet antigens.

In autoimmune and alloimmune thrombocytopenia, immune platelet destruction is caused by increased levels of polyclonal antiplatelet antibodies directed against platelet membrane glycoprotein receptors, most often cryptic neoepitopes of glycoprotein IIb/IIIa (GPIIb/IIIa) and less commonly glycoprotein Ib (GPIb) or human leukocyte antigens (HLAs). Coating of the platelet with these antibodies leads to opsonization of platelets by Fc receptors on cells of the reticuloendothelial system (RES). Antibody-coated platelets are cleared by the spleen and, to a lesser extent, by the liver.

These disorders involve a dramatic increase in marrow platelet production reflected by increased numbers of marrow megakaryocytes. The younger platelets produced have relatively high granule contents, providing increased hemostatic function. Bone marrow examination for increased or normal megakaryocyte numbers is the traditional means of distinguishing platelet destruction from decreased production. However, increased percentages of reticulated platelets are associated with destructive, especially immune-mediated, thrombocytopenia and may be sufficient for diagnosing platelet destruction.

Thrombocytopenia resulting from immune clearance may be severe, and platelet survival is often reduced from the normal 7 to 10 days to less than 1 day. Despite severe thrombocytopenia, serious bleeding or hemorrhagic death is uncommon, partly because the function of young platelets is increased and partly because the number of circulating platelets required to maintain vascular integrity is relatively low, estimated at 7100/ μL per day.

Immune Thrombocytopenic Purpura

In children, acute ITP is often preceded by a viral infection such as varicella. Patients with ITP exhibit petechial hemorrhage and

mucosal bleeding, and platelet counts are often lower than 20,000/ μL . The blood smear shows large platelets but no other abnormal cells such as blasts, which accompany childhood leukemia. The bone marrow has increased or occasionally normal numbers of megakaryocytes. The diagnosis of ITP is partly made by exclusion. Fever, organomegaly, pancytopenia, lymphadenopathy, or abnormal peripheral blood cells should prompt an evaluation for malignant disease, such as leukemia, neuroblastoma, Wilms' tumor, or other bone marrow disorders.

Laboratory tests may complement the clinical evaluation but are not required to make the diagnosis of ITP. Tests may demonstrate an increased percentage of reticulated platelets in the peripheral blood or detect platelet autoantibodies in serum or on the platelet (i.e., platelet-associated immunoglobulin). Assays of platelet-associated antibodies, although sensitive, are not specific for ITP because levels of immunoglobulins that bind nonspecifically to platelets are often increased in patients with thrombocytopenia due to liver disease or human immunodeficiency virus (HIV) infection. Techniques that measure serum antibodies to specific platelet glycoproteins have greater specificity but are relatively insensitive. An increase in mean platelet volume is also a relatively insensitive indicator of destructive thrombocytopenia, in part because of the wide range of normal values. An increase in the reticulated platelet percentage is consistent with increased platelet destruction but cannot distinguish between ITP and other causes of platelet destruction such as heparin-induced thrombocytopenia (HIT) and thrombotic thrombocytopenic purpura (TTP) (see [Chapter 54](#)).

Acute ITP in children can resolve without therapy, but clinicians may prefer to treat children with steroids or intravenous immunoglobulin (IVIG), particularly in severe or complex cases. IVIG therapy for ITP is thought to work by three mechanisms. First, high immunoglobulin G (IgG) concentrations block Fc receptors on phagocytes of the RES and on cellular effectors of antibody-dependent cytotoxicity. Second, infusion of IgG increases the fractional rate of IgG catabolism and thereby increases the destruction of antiplatelet IgG in direct proportion to its concentration. Third, clearance of antiplatelet immunoglobulin may increase through anti-idiotypic effects (i.e., generating an immunologic response to the ITP antibodies).

More than 80% of children with acute ITP have a rapid remission, and ITP does not recur. A subset of 10% to 20% of children eventually develops recurrent thrombocytopenia (i.e., chronic ITP); however, more than 70% of them respond completely to splenectomy. For those with chronic courses after splenectomy, episodic IVIG, Rh immunoglobulin, and in severe cases, immunotherapy with rituximab (Rituxan) are used. Hemorrhagic deaths are rare in acute childhood ITP (<2%), but mortality rates of 2% to 5% are associated with chronic, refractory ITP.

The diagnosis of ITP in adults, as in children, is made largely by exclusion, but acute ITP in adults rarely remits spontaneously, and it evolves to chronic ITP in more than 50% of cases. Petechial hemorrhage and mucosal bleeding are accompanied by platelet counts commonly lower than 20,000/ μL and often as low as 1000 to 2000/ μL . Fewer than 10% of adults with ITP die of hemorrhage.

ITP in adults may be associated with diseases such as HIV or hepatitis C infection. ITP may be the initial manifestation of HIV

infection, whereas thrombocytopenia in more advanced stages of HIV infection is often caused by bone marrow failure resulting from megakaryocyte infection with HIV, mycobacterial infection of the bone marrow, and nutritional deficiencies of end-stage HIV disease.

ITP occurs in patients with autoimmune disorders such as systemic lupus erythematosus, inflammatory bowel disease, and nonviral hepatitis. In some patients, ITP is accompanied by autoimmune hemolytic anemia, also called *Evans' syndrome*. The direct Coombs test is usually positive, indicating a warm-reactive autoantibody against erythrocytes. Initial treatment may not be significantly different from that for ITP alone, but chronic Evans' syndrome is thought to respond poorly to splenectomy, unlike ITP alone.

In the setting of systemic lupus erythematosus, ITP may result from factors associated with the autoimmune disease itself, including immune complex deposition on the platelet surface and active vasculitis, both of which may lead to increased platelet clearance and low counts. Therapy for ITP and the underlying autoimmune disorder is usually complementary. When the lupus anticoagulant or anticardiolipin antibody is associated with systemic lupus erythematosus and thrombocytopenia, the diagnosis of secondary antiphospholipid antibody syndrome is made, and this entity most commonly has thromboembolic complications (see [Chapter 54](#)).

The first-line treatment of acute ITP in adults is steroids, usually 1 to 2 mg/kg of prednisone per day. Studies have suggested that high-dose dexamethasone given in pulses every 14 or 28 days for six to eight doses may result in superior control of disease. Platelet transfusions typically are not used in ITP because transfused-platelet survival is brief and bleeding complications are uncommon. However, in patients with significant bleeding or who require surgery, platelet transfusions have been safely used and may transiently increase the platelet count, although usually for less than 24 hours.

In patients with acute ITP with severe thrombocytopenia ($<5000/\mu\text{L}$) or with life-threatening bleeding, high-dose methylprednisolone (1 g/day for 3 days) may be administered alone or in combination with IVIG (1-2 g/kg in divided doses over 2 to 5 days) and platelet transfusion. For recurrent ITP, chronic steroid treatment is often necessary but is usually accompanied by significant side effects. High-dose pulse dexamethasone given for 4 days every 2 weeks is associated with prolonged responses in about two thirds of patients with chronic ITP.

Children and adults with chronic ITP who initially respond to IVIG therapy usually respond well to splenectomy, whereas those who do not respond to IVIG are less likely to have disease remission after splenectomy. More than 50% of chronic ITP patients have some degree of disease remission after splenectomy. If ITP does recur after splenectomy, an accessory spleen must be ruled out, usually by liver and spleen scanning, because Howell-Jolly bodies may still be found.

Recurrent disease often is episodic, especially after viral infections, and these patients can be treated with IVIG. Alternatively, patients who are positive for the blood group Rh(D) antigen can be treated with Rh immunoglobulin (RhoGAM), a preparation of IgG class anti-Rh(D) antibodies. Anti-D induces red cell hemolysis (usually mild), presumably causing Fc receptor

blockade of the RES and decreased platelet uptake by the spleen and liver.

Some patients with ITP, especially those with HIV infection, have significant, even fatal, hemoglobinemia or hemoglobinuria after anti-Rh(D) therapy, which should be carefully monitored. Rh immunoglobulin is usually ineffective in patients who have undergone splenectomy. In patients who fail to respond to splenectomy, steroid administration may be avoided by the addition of a combination of IVIG, vincristine, and anti-Rh(D) with danazol and immunosuppressive therapy (e.g., azathioprine).

Some patients with chronic ITP have responded to infusions of the anti-CD20 monoclonal antibody rituximab. Chronic ITP with normal marrow cellularity can respond to stimulation of thrombopoiesis using thrombopoietin mimetics and agonist antibodies, which have shown promise in experimental trials and clinical practice. However, because many patients with chronic ITP never achieve normal platelet counts, the goal for therapy is often to keep platelet counts higher than $30,000/\mu\text{L}$ to avoid significant bleeding. About 5% of adults with ITP die of chronic, refractory disease and the complications of its therapy.

Drug-Induced Platelet Destruction

Immune-mediated platelet destruction associated with specific drugs is an often overlooked cause of thrombocytopenia. Unlike some of the drugs mentioned earlier (e.g., chemotherapeutic agents) that act by directly suppressing megakaryocyte production, drugs in this category of thrombocytopenia induce an immune response against platelet antigens.

Drugs may induce an autoimmune response by several mechanisms. One is the development of an antibody response against soluble drug molecules. When soluble drugs bind to the platelet membrane, drug-induced antibodies act to destroy circulating platelets through the RES. Other mechanisms of drug-induced thrombocytopenia include formation of an immunogenic neoantigen through drug-platelet interactions (hapten response) with autoantibodies directed against drugs that cross-react with platelet antigens. Occasionally, immune complexes that include the drug and circulating platelets are formed.

Historically, quinidine or quinine-based formulations were among the first classes of drugs to be associated with platelet antibodies. The antibodies can be detected by tests using a drug coupled to a carrier protein. As awareness of drug-induced thrombocytopenia has grown, scores of drugs, including antibiotics, anticonvulsants, psychotropic drugs, and antiplatelet agents, have been reported to mediate platelet destruction ([Table 51-2](#)).

Heparin also induces thrombocytopenia, but unlike other drugs, this reaction paradoxically leads to a prothrombotic state. The mechanism of heparin-induced thrombocytopenia and its prothrombotic effects are discussed in greater detail in [Chapter 54](#).

When eliciting the medical history from patients with acute-onset thrombocytopenia, a careful review of all medications, particularly those initiated just before the development of low platelet counts, may help to deduce the cause and reverse the platelet count decline. Regardless of the mechanism of induction, development of thrombocytopenia is temporally related to exposure to the drug and is usually rapid. Discontinuation of the

offending drug usually results in an equally rapid rise in the platelet count. For some patients with prolonged thrombocytopenia after drug removal, immunosuppression with agents such as IVIG (2 g/kg in two to three divided doses) or steroids may restore baseline platelet counts.

Although confirmation of drug-induced thrombocytopenia can often be made by testing for antibodies with drug specificities, these tests are usually routinely performed only by specialty reference laboratories. When drug-induced thrombocytopenia is suspected, clinicians should not wait for specific antibody testing results before discontinuing potential offending agents.

Fetal and Neonatal Alloimmune Thrombocytopenia

Fetal and neonatal alloimmune thrombocytopenia (FNAIT) occurs when a mother is homozygous for an uncommon platelet alloantigen, most often human platelet antigen 1b (HPA-1b) on the platelet GPIIIa receptor, and a child expresses the HPA-1a haplotype inherited from the father. The pathogenesis of alloimmune thrombocytopenia is analogous to the mechanism by which Rh(D) sensitization induces hemolytic disease of the

newborn. The mother is exposed to the HPA-1a antigen during a first pregnancy, and during that or subsequent pregnancies, she produces high-titer IgG antibody against HPA-1a. These antibodies cross the placenta, react with HPA-1a–positive fetal platelets, and cause peripheral-platelet destruction through the RES.

A diagnosis of FNAIT is frequently suspected when in utero fetal bleeding is observed by imaging studies or when an otherwise healthy newborn has unexpected bleeding associated with thrombocytopenia (typically with platelet counts of 50,000 to 75,000/ μ L or lower). A maternal history of FNAIT is a strong predictor of its occurrence during future pregnancies.

After a diagnosis of FNAIT is suspected, it may be confirmed by examining maternal sera for anti-HPA alloantibodies. Although bleeding may be severe in cases of FNAIT, the antibody does not necessarily predict whether bleeding will occur in utero, at delivery, or in the first days of life, and it is used primarily for confirmatory purposes.

Transfusion of washed maternal platelets (or random platelets lacking the HPA-1a antigen) and IVIG are useful for treating bleeding and restoring the platelet count. For newborns who recover from bleeding, there are few long-lasting deficits from FNAIT after circulating maternal antibodies are cleared from the circulation.

TABLE 51-2 COMMONLY USED DRUGS ASSOCIATED WITH IMMUNE THROMBOCYTOPENIA

DRUG CLASS	EXAMPLES
Antibiotics	Penicillins
	Cephalosporins (cephalothin, ceftazidime)
	Vancomycin
	Sulfonamides (sulfisoxazole)
	Rifampin
	Linezolid
	Quinine
Antiepileptics, antipsychotics, and sedative-hypnotics	Benzodiazepines (diazepam)
	Haloperidol
	Carbamazepine
	Lithium
	Phenytoin
Antihypertensives	Diuretics (chlorothiazide)
	Angiotensin-converting enzyme inhibitors (ramipril)
	Methyldopa
	Acetaminophen
Analgesics and anti-inflammatories	Ibuprofen
	Naproxen
	Abciximab
Antiplatelet agents	Tirofiban
	Heparin
Anticoagulants	Low-molecular-weight heparin

Post-transfusion Purpura

Alloimmune thrombocytopenia can occur in adults after transfusion (i.e., post-transfusion purpura [PTP]). As in neonates, this condition is based on exposure to a common platelet alloantigen that is not present on the patient's native platelets. For instance, PTP can occur after transfusion of a blood product in an individual who lacks HPA-1a and who has been previously alloimmunized to this antigen during a prior pregnancy or transfusion. Because more than 95% of blood donors express HPA-1a and the antigen is shed by platelets, any blood product can contain HPA-1a. Although not clearly understood, some investigators have speculated that soluble HPA antigens are deposited onto endogenous platelets, resulting in their rapid clearance by anti-HPA alloantibodies.

The diagnosis of PTP can be confirmed by demonstrating anti-HPA antibodies in the serum of an affected individual. Patients are typically treated with IVIG, and additional transfusions must be derived from donors lacking the implicated HPA. Although HPA-1a is the most common cause of alloimmune thrombocytopenia, other platelet alloantigens can cause this clinical syndrome (Table 51-3).

TABLE 51-3 MOLECULAR BASIS FOR ALLOIMMUNE THROMBOCYTOPENIA

GLYCOPROTEIN	ALLELES (ALLOANTIGENS)	PHENOTYPE/FREQUENCY	AMINO ACID AND LOCATION

Non-Immune-Mediated Platelet Destruction

Disseminated Intravascular Coagulation

One of the most common and potentially life-threatening causes of nonimmune platelet destruction is DIC, which is associated with sepsis, malignancy, advanced liver disease, and other disorders that trigger endotoxin release or cause severe tissue damage (Table 51-4). In DIC caused by bacterial sepsis, circulating endotoxin induces expression of tissue factor on circulating monocytes and endothelial cells, a process leading to overwhelming thrombin and fibrin generation. Deposition of fibrin occurs throughout the vasculature, with relatively inadequate concurrent fibrinolysis leading to a thrombotic or microangiopathic vasculopathy and subsequent organ damage. Thrombin activation of platelets and circulating factors eventually overwhelms the bone marrow and liver synthetic capability, respectively, resulting in thrombocytopenia and prolongation of the PT and aPTT.

Although the primary lesion of DIC is thrombin and clot generation, the clinical end point is usually a consumptive coagulopathy with depletion of platelets and coagulation factors. Mucosal bleeding, especially in the GI tract, and oozing from intravenous puncture sites are early signs of DIC.

Fibrinogen levels are usually low but may be normal in DIC because the acute phase reaction to sepsis or the underlying disorder may increase fibrinogen secretion. DIC should not be ruled out because fibrinogen is in the normal range. Fibrinolysis in DIC is triggered by fibrin clot formation and the action of tissue-type plasminogen activator. Laboratory testing shows increased levels of fibrin split products to more than 40 $\mu\text{g}/\text{mL}$ (i.e., cleavage of fibrin monomers) and D-dimer to more than 0.5 mg/mL (i.e., cleavage of fibrin-fibrin bonds). Although levels of fibrin split products are usually elevated in patients with DIC, this finding is nonspecific. An elevated D-dimer level is more specific for DIC and is often used to confirm or replace the fibrin split product screening assay. The blood smear may also help in the diagnosis of DIC by showing significant numbers of schistocytes, but this result is not specific for DIC and is found in other microangiopathies such as TTP (see Chapter 54).

Chronic DIC may be triggered by consumption of platelets and factors in large clots associated with aneurysms, hemangiomas, and mural thrombi. Another cause of chronic DIC is

malignant disease, often adenocarcinoma or acute promyelocytic leukemia. Malignant cells in these disorders promote thrombin formation through secretion of tissue factor, elaboration of cysteine proteases that activate factor X, induction of platelet-ligand binding, and upregulation of endothelial cell plasminogen activator inhibitor-1 (PAI-1) or cyclooxygenase 2 (COX2). Chronic DIC associated with malignancy usually causes enough factor consumption that the PT and aPTT are prolonged. Clinically, patients exhibit migratory thrombophlebitis (i.e., Trousseau's syndrome) or nonbacterial thrombotic (marantic) endocarditis.

Therapy for DIC should be aimed at (1) treatment of the underlying disorder, such as antibiotics for sepsis or chemotherapy for malignant disease; (2) supportive hemostatic therapy, including platelets, cryoprecipitate (for fibrinogen), and FFP; and (3) disruption of the activation of coagulation factors and platelets. For the last approach, anticoagulation is usually not indicated unless the balance of procoagulant with anticoagulant activity actively favors clotting, such as arterial thromboemboli with mural thrombus or migratory thrombophlebitis with Trousseau's syndrome. These thrombotic complications of chronic DIC are often resistant to warfarin therapy and usually require more intensive anti-Xa therapy with unfractionated or low-molecular-weight heparin. In DIC precipitated by sepsis, use of pharmacologic activated protein C has significantly decreased mortality.

Thrombocytopenia with Pregnancy-Induced Hypertension

Mild thrombocytopenia in pregnant women is related to hemodilution, a normal physiologic response of pregnancy that can bring platelet counts into the range of 100,000 to 150,000/ μL ; these counts are not associated with maternal or fetal complications. However, pregnancy-induced hypertension can result in platelet counts of less than 100,000/ μL , and these conditions can be associated with complications.

The spectrum of pregnancy-induced hypertension includes hypertension progressing to proteinuria and renal dysfunction (i.e., preeclampsia) and to cerebral edema and seizures (i.e., eclampsia). Thrombocytopenia may appear as a late finding accompanying pregnancy-induced hypertension, often occurring at the time of delivery or late in the third trimester. The HELLP syndrome in pregnancy (characterized by hemolysis, elevated liver enzymes, and low platelet counts) is occasionally associated with hypertension. The thrombocytopenia associated with pregnancy-induced hypertension or HELLP may result from abnormal vascular prostaglandin metabolism or placental dysfunction that leads to platelet consumption, vasculopathy, and microvascular occlusions. Both disorders are usually reversed by delivery of the fetus and placenta. Occasionally, IVIG or plasmapheresis has been required when the disorder does not resolve after delivery.

Other conditions sometimes associated with pregnancy that mediate nonimmune platelet destruction include TTP, hemolytic-uremic syndrome (HUS), and antiphospholipid syndrome. However, these platelet-consumptive processes usually yield a thrombotic state rather than a bleeding tendency, despite the associated thrombocytopenia. These medical problems associated with thrombocytopenia are discussed in Chapter 54.

TABLE 51-4 CAUSES OF DISSEMINATED INTRAVASCULAR COAGULATION

SEPSIS OR ENDOTOXIN	PRIMARY VASCULAR DISORDERS
Gram-negative bacteremia	Vasculitis
TISSUE DAMAGE	Giant hemangioma (Kasabach-Merritt syndrome)
Trauma	Aortic aneurysm
Closed-head injury	Cardiac mural thrombus

Hypoperfusion or hypotension	Snake venom
MALIGNANT DISEASE	Activated-factor infusions (prothrombin-complex concentrate)
Adenocarcinoma	
Acute promyelocytic leukemia	

Consumption and Dilutional Thrombocytopenia

In addition to sequestration, hypoproliferative, and destructive causes of thrombocytopenia, low platelet counts occasionally result from consumption and hemodilution. The pathophysiology of thrombocytopenia in these cases is directly attributable to the underlying cause of the bleeding, frequently large-scale trauma.

Overwhelming hemorrhage causes the consumption of endogenous platelets in an attempt to curb bleeding, and platelets are consumed faster than they can be released by the spleen or generated in the bone marrow. Resuscitative efforts after trauma, including infusion of massive volumes of intravenous solutions, red blood cells, and FFP, result in the dilution of circulating platelet numbers. The combination of platelet consumption and dilution during trauma can have catastrophic consequences and historically has been a leading cause of death in this setting. In addition to identifying the source of a large bleed, aggressive platelet transfusions in the setting of trauma may provide the greatest benefit in overcoming the effects of consumption and dilution (discussed later).

BLEEDING CAUSED BY PLATELET FUNCTION DEFECTS

The ability of platelets to adhere to damaged vasculature and to recruit additional platelets into the clot is essential for primary hemostasis, especially when patients are challenged by trauma or surgery. Unlike bleeding caused by thrombocytopenia, individuals with platelet function defects bleed because their platelets cannot adhere or aggregate appropriately in response to *in vivo* stimuli.

These qualitative platelet disorders are most frequently encountered in individuals with normal or near-normal platelet counts. Evaluation often relies on tests that assess the function (rather than the number) of circulating platelets. From an epidemiologic standpoint, acquired qualitative platelet defects are much more frequently encountered than their congenital counterparts.

Acquired Causes of Platelet Dysfunction

Aspirin and Antiplatelet Therapy

The patient's history and preoperative screening should assess whether patients are taking medications that interfere with platelet function, such as aspirin. Aspirin irreversibly blocks normal

arachidonic acid metabolism, and all exposed platelets are irreversibly affected and do not respond to stimulation even after aspirin is discontinued. The characteristic aspirin-induced platelet aggregation pattern is shown in [Table 51-5](#) and [Figure 51-5](#).

Nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., indomethacin) reversibly inhibit COX, and platelet function is restored within 24 to 48 hours after discontinuing the drug. Bleeding after most surgical procedures that is associated with aspirin or NSAIDs is usually mild, and aspirin may not need to be discontinued before surgery, especially because aspirin-induced platelet dysfunction is desirable in patients at risk for stroke or myocardial infarction.

The aspirin effect is restricted to COX1, and various NSAIDs have different relative affinities for COX1 and COX2. COX2 is an inducible enzyme that is synthesized in endothelial cells in response to inflammatory cytokines. Suppression of COX2 reduces synthesis of endothelial cell prostaglandin I₂ (i.e., prostacyclin), a molecule that exhibits antithrombotic effects through inhibition of platelet aggregation. The net effect of nonselective NSAIDs on the prothrombotic or antithrombotic balance favors bleeding because NSAID-induced COX1 inhibition means that thromboxane A₂ production in platelets is blocked. In contrast, the increased cardiovascular risk with administration of more selective COX2 inhibitors is probably attributable to the COX2-induced lack of endothelial cell prostacyclin production, coupled with intact platelet function (i.e., no inhibition of thromboxane A₂ by COX2 blockade). Recent data show that NSAIDs given before aspirin compete for COX1 binding sites and diminish aspirin's antiplatelet effect, another possible factor in the coagulant balance of concomitant use of NSAIDs and aspirin.

Another category of antiplatelet agents acts independently of the COX1/2 pathways. These drugs are P2Y₁₂ receptor antagonists (e.g., clopidogrel; prasugrel). They disrupt function by irreversibly binding to the surface receptor for the platelet agonist, ADP. P2Y₁₂ receptor antagonists are primarily used as adjunctive anticoagulant therapy for individuals at risk for thrombosis associated with coronary artery disease and stroke. If an individual taking a P2Y₁₂ receptor antagonist experiences bleeding, these drugs can inhibit platelet activation at the site of injury, not unlike the effect in an individual taking aspirin.

Regardless of the type of agent used, discontinuing an antiplatelet drug is a reasonable first step for a patient who has moderate to severe bleeding while on the therapy. Discontinuation of the drug has no effect on anticoagulated platelets given for

TABLE 51-5 DISORDERS CAUSING ABNORMAL PLATELET AGGREGATION

DISORDER	RESPONSE TO AGONIST				
	Epinephrine	ADP	Collagen	Arachidonic Acid	Ristocetin
Aspirin and NSAIDs	PW	PW	NL, ↓*	↓	NL

von Willebrand disease	NL	NL	NL	NL	↓, NL†

ADP, Adenosine diphosphate; NL, normal; NSAIDs, nonsteroidal anti-inflammatory drugs; PW, primary wave aggregation only; ↓, decreased.

*Aspirin results in decreased aggregation with most collagen doses.

†In von Willebrand disease type 2B, patients have increased aggregation with low-dose ristocetin and decreased or normal aggregation with standard doses of ristocetin.

FIGURE 51-5 Methodology underlying light transmission aggregometry. **A**, Typical laboratory light transmission aggregometer. **B**, Platelet function is directly proportional to light transmission in this assay. Platelet-rich plasma, which prevents light transmission, is exposed to various agonists (i.e., adenosine diphosphate, epinephrine, collagen, arachidonic acid, and ristocetin). As platelets begin to aggregate or agglutinate, light transmission increases over time and is typically reflected as a primary or secondary wave of aggregation for most agonists. Low or no increase in light transmission typically correlates with diminished platelet function.

irreversible inhibitors, but this action should allow newly produced platelets to be free of drugs effects and to function appropriately at the site of an injury.

Beyond stopping the offending drug, bleeding caused by aspirin or other antiplatelet agents may be addressed by infusion of 1-deamino-(8-D-arginine)-vasopressin (DDAVP). This agent has been effective in decreasing the bleeding time of platelet anticoagulated patients. Occasionally, platelet transfusion is appropriate. In most cases, a single platelet transfusion of 4 to 6 random donor units (or one apheresis unit) contributes enough normal platelets (>10% of total circulating number) to restore primary

hemostasis. Platelet dysfunction and bleeding caused by other drugs is similarly treated by discontinuing the drug and providing platelet transfusions when needed (Table 51-6).

Uremic Platelet Dysfunction

Renal insufficiency can be associated with the accumulation of toxic proteins such as guanidinosuccinic acid, which induces high levels of nitric oxide formation by vascular endothelial cells to inhibit platelet function. The uremic state can also suppress platelet secretory pathways and platelet adhesion to exposed endothelium through mechanisms that are not well understood.

TABLE 51-6 DRUGS AFFECTING PLATELET FUNCTION

STRONG INHIBITORS	Dextran Fibrinolytics Heparin Hetastarch
Abciximab (and other anti-GPIIb/IIIa or anti-RGD compounds) Aspirin (often contained in over-the-counter medications) Clopidogrel, ticlopidine (ADP-receptor blockers) Nonsteroidal anti-inflammatory drugs	WEAK INHIBITORS Alcohol Nitroglycerin Nitroprusside
MODERATE INHIBITORS	
Antibiotics (penicillins, cephalosporins, nitrofurantoin)	

ADP, Adenosine diphosphate; GP, glycoprotein; RGD, arginine-glycine-aspartate.

Nonetheless, the uremic state does put an individual at risk for platelet dysfunction–related bleeding. Because no formal tests are available, the diagnosis should be suspected in individuals with acute or chronic renal failure who demonstrate platelet-like bleeding disorders.

Short-term treatment of uremic platelet dysfunction includes administration of DDAVP and cryoprecipitate. Both increase circulating von Willebrand antigens, which can help to overcome some of the uremia-associated platelet deficits. Conjugated estrogens are of some benefit for long-term treatment. Platelet transfusions may be marginally useful in patients with life-threatening bleeding and acute renal failure, but the effect of this treatment is short lived because the transfused platelets rapidly acquire the uremic defect. Platelet transfusion should not be considered as a first-line therapy for most forms of uremic bleeding.

Congenital Causes of Platelet Dysfunction

Platelet Glycoprotein Defects

Inherited qualitative platelet defects include abnormalities of platelet receptors and granules. Two rare but well-characterized platelet receptor disorders are Bernard-Soulier syndrome and Glanzmann's thrombasthenia.

Bernard-Soulier syndrome is caused by decreased surface expression of platelet GPIb (i.e., primary von Willebrand factor [vWF] receptor) and less commonly by diminished GPIb function. The syndrome is characterized by mild thrombocytopenia, increased bleeding time, large platelets, and mild to moderate bleeding symptoms. The diagnosis is usually made in children, but some may not show symptoms until adulthood. Laboratory testing for Bernard-Soulier syndrome shows an absent platelet aggregation response to ristocetin (see Table 51-5 and Fig. 51-5) despite adequate vWF levels and function, such as normal ristocetin cofactor (Rcof) activity.

Glanzmann's thrombasthenia is characterized by an increased bleeding time and abnormally low levels of expression of platelet GPIIb/IIIa (i.e., receptor for vWF and fibrinogen) or, less commonly, normal expression but absent GPIIb/IIIa function. Patients usually exhibit bleeding in childhood. In cases of Glanzmann's thrombasthenia, platelet aggregation testing confirms an absent or diminished response to all agonists except ristocetin (see Table 51-5 and Fig. 51-5).

Platelet transfusions correct the bleeding in Bernard-Soulier syndrome and Glanzmann's thrombasthenia. However, because of the high risk for alloimmunization with frequent platelet transfusions (i.e., patients lack GPIb or GPIIb/IIIa), this therapy should be used sparingly and only as clinically needed.

Platelet Granule or Secretory Defects

Inherited platelet granule disorders are defined by the type of granule that is absent or defective. Storage pool disease is characterized by a relative decrease or absence of dense granules and correspondingly moderate to severe mucosal bleeding. Release of dense granule constituents that recruit and activate platelets is impaired. Storage pool disease has a diminished or absent secondary wave of aggregation in response to most agonists (see Table 51-5 and Fig. 51-5).

Hermansky-Pudlak syndrome is a dense granule deficiency associated with oculocutaneous albinism and mild thrombocytopenia. Patients have significant bleeding, which may occur spontaneously but more often occurs with surgical procedures.

Chédiak-Higashi syndrome is a rare granule disorder characterized by mild bleeding, partial albinism, and recurrent pyogenic infections. Large, irregular, gray-blue inclusions are seen in neutrophils and monocytes.

Gray platelet syndrome is characterized by colorless or gray platelets that lack normal staining on the peripheral smear, and electron microscopy confirms the loss of α -granules or their contents. Patients with gray platelet syndrome have a history of mild bleeding, and aggregation testing detects diminished responses to epinephrine, ADP, and collagen.

All the platelet granule disorders are successfully treated by avoiding aspirin and other antiplatelet drugs and by hormonal control of menses in women. Platelet transfusions are used when bleeding occurs.

Platelet Transfusion Therapy

Standard Platelet Therapy

Platelet transfusions derived from the whole blood of healthy donors can be used to stop or prevent bleeding. The two broad categories of platelet transfusion support are based on the conditions previously discussed: prophylactic platelet transfusions for thrombocytopenia in nonbleeding patients and platelet transfusion for acute bleeding.

For the nonbleeding thrombocytopenic patient, several triggers can prompt platelet transfusion in the absence of frank hemorrhage. Patients receiving chemotherapy may be severely thrombocytopenic and should be transfused when their platelet counts are less than 10,000/ μ L to prevent spontaneous bleeding. This is a safe and appropriate threshold for patients with relatively uncomplicated clinical pictures without fever, sepsis, or GI bleeding. The threshold of 10,000/ μ L, which was rigorously established through several prospective, randomized, controlled trials, significantly decreases the frequency of platelet transfusion and thereby reduces risks associated with multiple blood product exposures. If the patient has complicating circumstances or is being treated on an outpatient basis, prophylactic transfusions

may be given when platelet counts are lower than 20,000/ μL , although this threshold is not rigorously based on clinical trial evidence.

For patients undergoing invasive procedures (e.g., surgery) or those with trauma, it is reasonable to transfuse platelets when counts are lower than 50,000/ μL . Higher platelet counts are suggested for patients undergoing neurologic or ophthalmologic operations; platelet counts greater than 100,000/ μL are recommended, if possible, because of the catastrophic nature of bleeding in these anatomic locations. The thresholds of 50,000 and 100,000/ μL are based primarily on experience and nationally published guidelines, and clinical trials are lacking in these settings.

For the acutely bleeding patient, the decision to transfuse platelets depends on several factors, of which thrombocytopenia is the most straightforward and useful criterion. Platelet counts higher than 50,000/ μL are a reasonable goal for most cases of acute bleeding, whereas counts higher than 100,000/ μL may be necessary for neurologic bleeding.

Congenital or acquired platelet dysfunction must be considered for acutely bleeding patients. Those with significant bleeding who have taken an antiplatelet drug such as aspirin may benefit from platelet transfusion regardless of baseline counts. Another consideration is the volume of blood products and fluids received. Trauma patients may receive more than 10 units of transfused red blood cells in addition to plasma, volume expanders, and saline. Resuscitation with large fluid volumes (≥ 10 units transfused) reduces the platelet count to less than 50% of baseline, resulting in a significant dilutional coagulopathy. In these scenarios, repeated platelet counts must be obtained and platelets liberally transfused to maintain adequate hemostasis.

When the decision to transfuse platelets has been made, platelet units can be requested from the blood bank or transfusion service. Blood banks provide random-donor pooled platelets and apheresis platelets (E-Fig 51-1). Random-donor pooled platelets consist of platelet concentrates from four to six donors combined (pooled) into one large dose. For the adult patient with uncomplicated thrombocytopenia, a single random-donor platelet concentrate unit typically raises the platelet count by about 8000 to 10,000/ μL . Between 4 and 6 units pooled together can be expected to raise counts by 30,000 to 60,000 platelets/ μL . Apheresis platelets are collected from one donor using automated apheresis instruments. The dose of these *single-donor platelets* is almost equivalent to that of a 6-unit platelet pool and is estimated to increase platelet counts by up to 50,000/ μL in the uncomplicated patient.

Based on the expected increments and typical transfusion goals outlined previously, one random-donor platelet pool or one apheresis platelet product should sufficiently raise platelet counts to correct thrombocytopenia and prevent spontaneous bleeding. These doses should also be sufficient to stop or prevent bleeding associated with thrombocytopenia in the setting of invasive procedures, mild to moderate trauma, or bleeding associated with platelet dysfunction. For the complicated patient (e.g., thrombocytopenia with intracranial hemorrhage, massive trauma), additional platelet doses may be necessary over time to achieve adequate hemostasis.

Platelet Transfusion Failure and Platelet Refractoriness

Platelet transfusions in thrombocytopenic patients are not successful in all cases. Uremia causes an acquired dysfunction of transfused platelets, limiting their hemostatic capabilities in vivo. Patients who are thrombocytopenic due to conditions such as ITP usually do not show increased platelet counts after transfusion because circulating autoantibodies cause rapid destruction of both endogenous and infused platelets. This phenomenon, known as *platelet transfusion refractoriness*, can be caused by many other recipient problems, including fever, sepsis, splenomegaly, and DIC. Although the pathophysiology of refractoriness is well understood for conditions such as ITP or DIC (in which platelets are cleared from the circulation), few data are available to suggest why individuals with conditions such as fever or infection have an inappropriate response to platelet transfusion.

When approaching a patient with platelet transfusion refractoriness, the physician should consider whether it is mediated by nonimmune or immune factors. Immune refractoriness indicates antibody-mediated clearance. For nonimmune-mediated refractoriness, as in the setting of fever or DIC, the underlying conditions usually decrease transfused platelet survival over time but do not affect immediate platelet recovery.

A standard diagnostic approach to platelet refractoriness involves measuring the platelet count 10 minutes to 1 hour after completion of the platelet transfusion. The patient with non-immune-mediated refractoriness typically shows an initial but blunted increase in the platelet count 1 hour after transfusion, with a subsequent decline at a steeper rate than expected because of the underlying disorder. For patients with this type of platelet refractoriness, addressing the underlying illness often increases the effectiveness of platelet transfusions.

For patients with immune-mediated platelet refractoriness, there is virtually no increase in the platelet count, even minutes after completion of a transfusion. The antiplatelet antibodies are most frequently encountered in individuals who have been chronically transfused. Repeated exposures to transfused products can induce alloantibodies, most commonly to HLA antigens. Over time and with multiple transfusion exposures, the titer of alloantibodies can increase sharply and cause rapid clearance of incompatible platelets after infusion.

For the alloimmunized patient, immunosuppression fails to decrease platelet alloantibodies, and efforts to improve platelet recovery after transfusion are focused on finding compatible platelet units. The first step in managing transfusion of the alloimmunized patient is to provide ABO antigen–matched platelets to minimize clearance caused by naturally occurring ABO antibodies; this is often helpful because platelets express A and B antigens on their surface. If this step fails to yield increases in platelet counts, donor platelets that lack target antigens for the detected alloantibodies should be pursued. One strategy is to use the patient's serum to crossmatch platelet donor units, with selection of those units demonstrating compatibility for subsequent transfusion.

If crossmatch-compatible platelets fail to induce adequate platelet recovery, blood banks should provide platelets that are matched to the recipient's HLA system in the hope of evading

E-FIGURE 51-1 An apheresis platelet unit. Platelet units, collected from donors by phlebotomy or apheresis instrumentation, contain a total volume of about 250 to 300 mL, usually corresponding to a total platelet count greater than 3.0×10^6 cells/ μL in the final unit. Platelets are stored at room temperature and typically have a shelf life of 5 days. They are indicated for the prevention or cessation of bleeding associated with thrombocytopenia or platelet function defects.

HLA-based antibodies. HLA-matched platelets are collected from compatible donors using apheresis at frequent intervals until the patient's platelet count recovers, and they are no longer transfusion dependent. Many blood banks and transfusion services have attempted to address the problem of platelet HLA alloimmunization through prevention. They provide blood products that have undergone filtration to reduce their white blood cell content, a process called *leukoreduction*. Because contaminating leukocytes are the primary sources of exposure to HLAs, their removal can be quite effective in preventing subsequent alloimmunization, even in chronically transfused patients.

BLEEDING CAUSED BY VON WILLEBRAND DISEASE

Disorders of the functional ligands for platelet adhesion to the vasculature cause bleeding that clinically resembles the bleeding associated with platelet or vascular disorders (e.g., epistaxis, GI bleeding). vWF is synthesized in endothelial cells and megakaryocytes and functions in plasma to mediate platelet adhesion to the damaged site (see Fig. 51-1). vWF is a large, multimeric protein; the largest multimers contain the greatest number of adhesive sites and confer greater hemostatic ability than smaller vWF molecules. In patients with low vWF levels, platelet adhesion to damaged vessels is delayed and results in mucosal bleeding and a prolonged bleeding time. vWF is also the carrier protein for factor VIII, and deficiency of vWF or abnormal vWF-VIII binding leads to rapid clearance of factor VIII, decreased factor VIII levels, and a prolonged aPTT.

vWD can manifest clinically with bleeding that resembles a platelet defect and a coagulation factor defect. The many mutations in the *VWF* gene have been phenotypically grouped into three major subtypes of vWD (E-Table 51-1).

Type 1 von Willebrand Disease

Most patients have type 1 vWD, a mild to moderate quantitative decrease in all vWF multimers. This condition is commonly caused by a heterozygous mutation and has a dominant pattern of inheritance. Type 1 vWD is characterized by equivalent decreases in factor VIII, vWF antigen, and Rcof activity. Rcof measures the ability of the patient's plasma (which contains vWF) to agglutinate normal platelets in the presence of ristocetin. Patients with type 1 vWD usually have mild to moderate bleeding, often only in relation to surgery or dental procedures.

Patients with type 1 vWD are treated with DDAVP, which stimulates endothelial cells to release stored vWF and leads to an increase in plasma vWF antigen, Rcof, and factor VIII levels. DDAVP, given subcutaneously at a dose of 0.3 µg/kg, usually yields excellent results. However, tachyphylaxis to DDAVP occurs because endothelial cells require time to synthesize new vWF after repeated DDAVP administration.

vWF concentrates must sometimes be used in patients with more severe type 1 vWD or in those who are undergoing a more prolonged hemostatic challenge. Bleeding in type 1 vWD during pregnancy is rare. Because the vWF level rises significantly in pregnancy, vWF antigen and Rcof levels usually normalize during the second or third trimester and eliminate the bleeding risk at that time. Most pregnant women with type 1 vWD have no bleeding complications with delivery and do not require therapy during pregnancy or in the early postpartum period.

Type 2 von Willebrand Disease

Type 2 vWD is characterized by heterozygous mutations of variable penetrance that produce a qualitative defect in the vWF molecule. The most common type 2 disorders have a relative lack of the larger vWF multimers (see E-Table 51-1). High-molecular-weight vWF multimers are absent in type 2A disease, and these patients show disproportionately low Rcof activity compared with the vWF antigen level.

The molecular defect is related to mutations in the A2 domain of vWF that render the molecule more susceptible to the vWF-cleaving protease (i.e., ADAMTS13). Patients with type 2A vWD respond to vWF concentrate and less commonly to DDAVP.

The abnormal vWF molecule in type 2B vWD has an increased affinity for platelets, which causes the loss of high-molecular-weight multimers from the circulation and often produces thrombocytopenia. Platelet aggregometry in type 2B vWD (see E-Table 51-1) shows an abnormal increase in low-dose ristocetin-induced platelet agglutination; in the laboratory, the addition of the patient's vWF to normal platelets similarly increases ristocetin-induced platelet agglutination and confirms the abnormal vWF. DDAVP induces release of the abnormal vWF in patients with type 2B vWD, causing thrombocytopenia and is therefore contraindicated. vWF concentrate should be used instead.

Type 2M vWD has laboratory findings similar to those in type 2A, but it has high-molecular-weight multimers. The defect in this rare type of vWF is most often a mutation in the vWF that reduces binding to its platelet ligand GPIb α . Some patients with type 2M vWD respond to DDAVP, but most require vWF concentrate.

In type 2N vWD, the abnormal vWF molecule has decreased binding affinity for factor VIII, which decreases factor VIII survival and produces a bleeding phenotype similar to hemophilia A. The low factor VIII levels do not respond to high-purity factor VIII infusions, unlike true hemophilia A, but they improve with vWF concentrate. Rcof and vWF antigen levels are normal in type 2N vWD because the mutation in the factor VIII binding site does not affect vWF function or survival. The diagnosis of type 2N vWD should be considered in females who have hemophilia A. Tests for vWF binding to factor VIII are available in reference laboratories.

Type 3 von Willebrand Disease

The rare patient with type 3 vWD has a complete deficiency of vWF, often as a result of the inheritance of two abnormal vWF alleles (i.e., compound heterozygote). Patients with type 3 vWD have no or extremely low levels of Rcof and vWF antigen and factor VIII levels of 3% to 10% of normal, and they usually have severe bleeding that may mimic hemophilia. Type 3 vWD does not respond to DDAVP and requires vWF concentrates to treat bleeding.

Acquired von Willebrand Disease

The acquired form of vWD usually appears as a severe, type 2A-like defect without larger vWF multimers in a patient with no history of bleeding. Acquired vWD is caused by abnormal clearance of the larger vWF multimers and is associated with monoclonal gammopathies, lymphoproliferative disorders, myeloma,

and other malignant and myeloproliferative diseases characterized by thrombocytosis. In these cases, acquired vWD has been successfully treated with IVIG and therapy for the underlying disease.

Another cause of abnormal vWF multimer clearance resulting in acquired vWD is critical aortic stenosis. It is corrected with successful surgical repair.

BLEEDING CAUSED BY COAGULATION FACTOR DISORDERS

Normal platelet hemostasis initiates plugging of vascular lesions and maintains mucosal integrity. Because of abnormalities of coagulation factors, the initial platelet plug is not solidified by secondary hemostasis, and the effects are clot breakdown and bleeding. This bleeding is different from platelet-type bleeding. Coagulation factor deficiencies lead to bleeding in deep tissues and joints, and milder deficiencies result in bleeding in a delayed fashion after surgery.

Most patients with significant factor deficiencies have abnormal screening laboratory test results (E-Table 51-2; see Fig. 51-1), although patients with mild deficiencies can have bleeding and only borderline-abnormal coagulation factor values. Like other hemostasis abnormalities previously discussed, coagulation factor problems can be classified as congenital deficiencies and those acquired from medications or underlying medical conditions.

Congenital Factor Deficiencies

Hemophilia A and B

The X-linked deficiencies of factor VIII (i.e., hemophilia A) and factor IX (i.e., hemophilia B) are the most common factor deficiencies after vWD. Hemophilia A is about six times more common than hemophilia B.

About 50% or more of cases of severe hemophilia A arise as a result of an inversion of a major portion of the gene that results in complete loss of activity. Other mutations tend to result in milder disease. Most patients with hemophilia B have mutations that result in a functionally abnormal factor IX with no activity. The combined results of antigenic and functional assays can resolve whether a deficiency results from a loss of the protein or loss of its normal function.

Both hemophilia A and hemophilia B are categorized by their factor levels. Severe deficiency is characterized by less than 1% of factor VIII or IX, whereas patients with moderate and mild hemophilia have factor levels of 1% to 5% and more than 5%, respectively.

Symptoms and signs of severe hemophilia A and hemophilia B develop in childhood with bleeding into muscles, joints, and soft tissue. Because they are X-linked disorders, they are observed primarily in male patients; the mother of an affected male patient is a carrier, and 50% of maternal uncles have the disease. However, about 25% to 30% of cases of hemophilia result from new mutations and have no relevant family history. In rare instances, a female carrier with extremely skewed X-inactivation may have a mild bleeding disorder with factor levels lower than 30%.

Bleeding in severe hemophilia is often spontaneous and is common after any type of surgery or even mild trauma. Hemorrhage in this condition frequently manifests as hemarthrosis (i.e., bleeding into joints) or retroperitoneal bleeding, or both. Hematuria and mucosal or intracranial bleeding can also occur. Patients with moderate hemophilia have less spontaneous bleeding, but they are still at significant risk for hemorrhagic complications of surgery or trauma. Patients with mild hemophilia may be undiagnosed into adulthood and then only because of bleeding after major surgery.

The complications of hemophilia stem from chronic bleeding into joints and muscles, which leads to severe deformities, arthritis, muscle atrophy, and contractures. These complications require intensive physical therapy and orthopedic care, often culminating in joint replacement. Patients with hemophilia who received pooled-factor concentrates before the era of viral inactivation have complications related to transfusion-transmitted infections, including HIV and hepatitis B and C. Current therapy uses factor concentrates that are virally inactivated or recombinant.

Non-hemophilia A or B Congenital Factor Deficiencies

Inherited bleeding disorders caused by deficiencies of coagulation factors V, VII, X, and XI (see E-Table 51-2) are much less common than hemophilia A and B. Patients with factor V deficiency usually lack plasma factor V and platelet factor V and have joint and muscle bleeding similar to patients with hemophilia. Some patients who are plasma factor V deficient are asymptomatic until they are challenged with the stress of surgery or trauma, and these patients are thought to have normal platelet factor V levels. Rarely, patients inherit factor deficiencies in tandem, such as combined factors V and VIII deficiencies.

Patients with factor XI deficiency usually have a milder bleeding disorder (even with factor XI levels <5%) than patients with hemophilia A or B, whereas factor X deficiency is usually more severe. Factor XI deficiency is an autosomal recessive disorder seen with increased frequency among Ashkenazi Jews, often manifesting late in adulthood and in the clinical settings of increased fibrinolysis, such as after prostate surgery. Acquired factor X deficiency can occur in patients with amyloidosis, a condition in which the abnormal circulating light chains adsorb to and clear factor X, producing low levels and occasional bleeding.

Fibrinogen (factor I) functions as a bridging ligand for the platelet receptor GPIIb/IIIa in the platelet-platelet matrix at sites of vascular damage. Fibrinogen also functions in the final steps of the coagulation cascade to form the fibrin clot. Congenital hypofibrinogenemias and afibrinogenemias are rare. Patients with these disorders produce very low amounts of fibrinogen. Alternatively, some individuals produce an abnormally functioning fibrinogen, which is typically associated with genetic mutations affecting fibrin cross-linking and polymerization. These disorders are referred to as *congenital dysfibrinogenemias*.

Because of fibrinogen's dual role in promoting platelet and coagulation factor hemostasis, patients with congenital fibrinogen disorders can have moderate to severe bleeding problems from early in life. It is not uncommon for patients to have the mucosal membrane bleeding associated with platelet

E-TABLE 51-2 SCREENING LABORATORY RESULTS FOR COAGULATION FACTOR DEFICIENCIES

DEFICIENT FACTOR	FREQUENCY	PT	PTT	TT
I (fibrinogen)	Rare	↑	↑	↑
II (prothrombin)	Rare	↑	↑	↑
V	1 : 1,000,000	↑	↑	NL
VII	1 : 500,000	↑	NL	NL
VIII	1 : 5000 (male patients)	NL	↑	NL
IX	1 : 30,000 (male patients)	NL	↑	NL
X	1 : 500,000	↑	↑	NL
XI	Rare*	NL	↑	NL

XIII	Rare	NL	NL	NL

HMWK, High-molecular-weight kininogen; NL, normal; PK, prekallikrein; PT, prothrombin time; PTT, partial thromboplastin time; TT, thrombin time; ↑, increased over normal range.

*Except in those of Ashkenazi Jewish descent (about 4% of whom are heterozygous for factor XI deficiency).

[†]Not associated with clinical bleeding.

disorders and the deep tissue or joint bleeding classically associated with coagulation factor deficiencies.

The diagnosis of congenital afibrinogenemia or dysfibrinogenemia can be established by screening assays (see [E-Table 51-2](#)), laboratory assays to measure fibrinogen levels, and tests such as the thrombin time that are designed to measure fibrinogen function. Treatment depends on replacement of fibrinogen by infusion of cryoprecipitate or a fibrinogen concentrate (discussed later).

Acquired Coagulation Factor Disorders

Factor Inhibitors in Congenital Factor Deficiencies

About 25% of patients with hemophilia A develop alloantibodies to transfused factor VIII. An inhibitor acts functionally and can be measured in the laboratory as Bethesda units (BU); 1 BU is defined as the amount of inhibitor that neutralizes 50% of factor activity. High-level inhibitors (>10 BU) completely neutralize the activity of infused factor concentrates, negating their effectiveness in bleeding episodes.

Bleeding requires therapeutic regimens with factor VIII inhibitor bypass activity (FEIBA) or recombinant factor VIIa. For long-term treatment, suppression of an inhibitor is accomplished by a combination of IVIG, immunosuppressive therapy, plasmapheresis, and induction of immune tolerance using high-dose concentrate infusions. Patients with hemophilia B have a lower incidence of inhibitors (2% to 6%), but bleeding in the setting of these inhibitors is treated in a similar fashion with high-dose FEIBA or recombinant VIIa; similar strategies for long-term suppression of the antibody are typically employed.

Acquired Factor Inhibitors

Acquired inhibitors to factor VIII (and rarely to other coagulation factors) occasionally are found in patients (usually older) who do not have a history of bleeding. In contrast to the antibodies in patients with severe congenital hemophilia, acquired inhibitors are typically autoantibodies.

Acquired factor VIII inhibitor titers can be extremely high and are sometimes associated with pregnancy, autoimmune disorders, and malignant diseases, especially lymphoproliferative disorders. Association with these underlying disorders implies some form of immune dysregulation, but the mechanisms underlying acquired factor inhibitors remain poorly understood.

The diagnosis of an acquired inhibitor can be made by laboratory techniques similar to those detailed for patients with congenital hemophilia. For the treatment of bleeding, patients with acquired inhibitors to factor VIII are administered factor VIIa or FEIBA to promote hemostasis. Intensive immunosuppressive therapy with rituximab, an anti-CD20 agent, has become the mainstay of successful treatment and should be started as soon as possible to eradicate the inhibitor.

Vitamin K Deficiency

Bleeding in inpatients and outpatients who are severely ill may be caused by acquired coagulation factor deficiencies resulting from nutritional deficiencies. Foremost among these is vitamin K deficiency, which has several causes. Biliary tract disease can

interfere with enterohepatic circulation, leading to decreased absorption of vitamin K. Drugs, especially antibiotics, can sterilize the gut and reduce bacterial sources of vitamin K or other drugs (e.g., cholestyramine) that directly block vitamin K absorption; this category also includes cephalosporins, which interfere with intrahepatic metabolism of fat-soluble vitamin K. Vitamin K deficiency also may reflect poor nutritional status due to malabsorption, chronic disease, or reduced oral intake in patients who are acutely ill.

Factors II, VII, IX, and X are vitamin K–dependent procoagulant factors, as are the natural anticoagulants proteins C and S. In addition to disease-associated vitamin K deficiency, the anticoagulant warfarin blocks vitamin K–dependent γ -carboxylation of factors II, VII, IX, and X and causes an acute decrease in functional factor VII levels because factor VII has the shortest half-life (6 hours) of all vitamin K–dependent factors in vivo. Individuals who experience bleeding while on warfarin may be treated by repletion of vitamin K.

Dilutional Coagulopathy

As with platelets, coagulation factors can be depleted through the dilutional effects of a pure red blood cell transfusion or with the administration of massive amounts of volume expanders or saline solutions. For every 10 units of red cells acutely transfused, there is a concomitant increase in the international normalized ratio (INR) to greater than 2. This also occurs in conjunction with depletion and consumption of circulating coagulation factors due to acute bleeding.

In the setting of trauma, it is important to maintain adequate coagulation factor activity through plasma transfusion. Evidence from the trauma literature suggests that transfusion ratios of red cells to plasma should approach 1 : 1 to optimize hemostasis. The effects of dilutional coagulopathy should be monitored by repeated testing of PT and aPTT with a liberal plasma transfusion strategy.

Liver Disease

Unlike patients with vitamin K deficiency or those receiving warfarin, patients with liver disease have low levels of most factors, not just the vitamin K–dependent factors; the exception is factor VIII. Although liver transplantation increases factor VIII levels in patients with hemophilia, factor VIII levels are usually normal or increased with liver disease, a finding corresponding to RES and megakaryocytic sources of factor VIII production. If factor VIII levels are decreased in patients with liver disease, consideration should be given to superimposed DIC.

When a prolonged PT is evaluated for its cause, measurement of factor VII and a non–vitamin K–dependent factor, such as factor V, is useful. In vitamin K deficiency, the level of factor VII is low, and that of factor V is normal; levels of both factors are low in patients with generalized liver disease. The PT is a sensitive measure of liver function and becomes prolonged in patients with even mild liver disorders; elevation precedes a significant decrease in the albumin or prealbumin levels and is usually coincident with transaminase changes. In patients with mild to moderate liver disease, the PT is prolonged, but the aPTT usually remains within the normal range. In severe liver disease, the PT

becomes even more prolonged, and the aPTT also becomes abnormal.

Other causes of bleeding in liver disease include decreased clearance of fibrin split products or associated DIC, inhibition of platelet function, and increased levels of tissue plasminogen activator. Treatment of bleeding associated with liver disease is based primarily on replacement of coagulation factors by plasma transfusions, although they only temporarily correct abnormalities. Liver transplantation is the only definitive treatment for these synthetic defects.

Fibrinogen Loss or Acquired Defects

Low fibrinogen levels are most commonly seen with consumptive disorders such as DIC, the pathophysiology of which was described earlier. Dysfibrinogenemia, which is occasionally a congenital disorder, is much more often acquired with liver disease. In this setting, diseased hepatocytes produce abnormal fibrinogen molecules arising from defects in post-translational modifications. The abnormal fibrinogen molecules cannot undergo normal cross-linking or polymerization, resulting in bleeding disorders.

The PT and aPTT are prolonged by abnormalities of fibrinogen quantity or function (see E-Table 51-2). A prolonged thrombin time is diagnostically more specific for a low fibrinogen level or abnormal molecule, although inhibitors such as heparin and fibrin split products also prolong the thrombin time. The reptilase time, which is insensitive to heparin, can be used to eliminate the possibility of an increased thrombin time resulting from heparin contamination of the sample and can help to confirm a diagnosis of dysfibrinogenemia.

BLEEDING IN PATIENTS WITH NORMAL LABORATORY VALUES

Some patients with factor- or platelet-dependent bleeding disorders do not exhibit any abnormalities in screening laboratory assays (e.g., PT, aPTT). Vascular purpuras and other bleeding variants follow this pattern. Patients with bleeding caused by mild vWD may have a normal aPTT, but additional studies usually show mild decreases in factor VIII, vWF antigen, or vWF Rcof. Multimeric analysis may demonstrate abnormal levels in patients with mild type 2A vWD. Similarly, mild deficiencies of factor II, V, VII, VIII, IX, or XI may not prolong the PT or aPTT, but specific-factor assays demonstrate levels lower than the normal range.

Mild bleeding, often with a delayed onset after surgery or trauma, may occur in patients with clot instability resulting from factor XIII deficiency or dysfibrinogenemia. In neonates, factor XIII deficiency manifests with late umbilical stump bleeding. Factor XIII deficiency is diagnosed in the laboratory by screening for increased clot solubility in urea; if the clot dissolves abnormally quickly in 8 mol/L of urea, an enzyme-linked immunosorbent assay for the precise XIII level should be performed. Factor XIII deficiency is treated with cryoprecipitate transfusion or an approved factor XIII concentrate. Because of the long half-life of factor XIII, prophylactic therapy for severe deficiency need be provided only in single doses on a 3- to 4-week recurring schedule.

Plasma and Coagulation Factor Transfusion Therapy

For patients with one or multiple defects in coagulation proteins, there are several options for replacement therapy. The most widely used product for replacement of coagulation factors is FFP (E-Fig 51-2). It is collected from the whole blood of healthy donors and is frozen within 8 hours of collection. It contains normal (i.e., therapeutic) levels of all coagulation factors necessary to maintain hemostasis. FFP is the best choice for replacement of coagulation factors for many conditions, including liver failure and deficiencies of factors II, V, X, and XI.

FFP is commonly used with vitamin K therapy for the reversal of warfarin therapy before invasive procedures or with the onset of bleeding. The appropriate dose of FFP is weight based and does not depend on the extent of prolongation in coagulation studies alone. Administration of FFP at 10 to 15 mL/kg should be sufficient to replace deficient coagulation factors and correct abnormal coagulation values. Assuming a volume of about 200 mL per unit of FFP, a reasonable dose for a 70-kg individual is 3 to 4 units of FFP. Administration is time sensitive because coagulation factors degrade at standard half-lives on infusion, and FFP should be provided immediately before an intended procedure to ensure adequate hemostasis.

In some cases, patients may not be able to tolerate the infusion of the large volumes of FFP required to reverse coagulopathic states, and other treatment modalities are available. Prothrombin complex concentrate (PCC) quickly reverses prolonged PTs without the need for large volumes of FFP. PCC is a concentrated, lyophilized, human-derived concentrate containing factors II, VII, IX, and X that can be reconstituted in small volumes and provided by intravenous bolus injection. A true four-factor PCC was approved for clinical use in 2013 by the U.S. Food and Drug Administration (FDA). A variant, human-derived PCC, FEIBA, contains factors II, IX, and X and factor VII that has been modified to be in its active form; FVIIa is the major difference between FEIBA and standard PCC. FEIBA is typically administered in doses of 50-100 U/kg every 8 to 12 hours.

PCC is a good alternative to FFP for bleeding in the setting of warfarin anticoagulation, and FEIBA is primarily used to overcome bleeding in the setting of a coagulation factor inhibitor. Vitamin K should also be considered as an alternative to plasma infusion. Oral or parenteral replacement of vitamin K (1 to 10 mg/day for 3 days) restores coagulation factor synthesis in patients with normal liver function and the vitamin deficiency.

For patients with hemophilia A or B, several virally inactivated, human-derived or recombinant factor VIII and IX concentrates are available. These products were developed because of the high morbidity and mortality rates caused by HIV and hepatitis virus contamination of the pooled products used during the 1980s.

For hemophilia, factor replacement is the key to effective therapy. Patients with severe hemophilia often infuse themselves with low doses of prophylactic factor on a regular basis (25 to 40 U/kg three times per week) and boost their dose or frequency of infusion when they sense internal bleeding, sustain trauma, or undergo dental procedures (E-Table 51-3). Patients with mild

E-FIGURE 51-2 Single unit of fresh-frozen plasma (FFP). Plasma units, collected from donors by phlebotomy or apheresis instrumentation, contain a total volume of about 200 to 250 mL. FFP possesses all elements found in peripheral blood plasma, including coagulation factors, albumin, complement, and immunoglobulins, although they are primarily administered for coagulation factor defects. FFP is stored in the frozen state (shown) at less than -18°C and must be thawed before issuing and administration. The shelf life while frozen is 1 year.

E-TABLE 51-3 FACTOR REPLACEMENT GUIDELINES FOR HEMOPHILIA A AND B

INJURY	FACTOR VIII INITIAL DOSE (U/kg)*	FACTOR IX INITIAL DOSE (U/kg) [†]
Dental prophylaxis	15-25	20-30
Hemarthrosis	15-25	30-50
Muscle hematoma	15-25	30-50
Trauma or surgery	50	100

*Dosing intervals should be based on a Factor VIII half-life of about 12 hours. Maintenance doses of one half the listed dose may be additionally provided at these intervals.

[†]Dosing intervals should be based on a Factor IX half-life of about 18 to 24 hours. Maintenance doses of one half the listed dose may be additionally provided at these intervals.

hemophilia A may not need factor infusions for minor surgery. Their disease often is managed with ϵ -aminocaproic acid, an antifibrinolytic agent, using 4 g every 4 to 6 hours with or without infusions (0.3 $\mu\text{g}/\text{kg}$) of DDAVP.

Most patients with hemophilia require factor infusions prophylactically or at times of surgery or trauma. Factor VIII products are infused every 8 to 12 hours, and 1 U/kg of factor VIII concentrate raises plasma factor VIII activity by 2%; 50 U/kg of factor VIII theoretically yields 100% factor VIII activity in a patient with severe hemophilia A. Factor IX has a longer half-life and is infused every 18 to 24 hours; factor IX requires 2 U/kg for a 2% increase in factor IX activity (i.e., 100 U/kg for 100% activity). Major surgery in patients with hemophilia requires intensive factor therapy to achieve normal factor levels (>80%) in the intraoperative period and the early postoperative period to prevent wound hematoma formation. The dose of factors (see [E-Table 51-3](#)) is adjusted downward from this intensity, depending on the severity of the insult, the patient's response to previous factor infusions, and whether factor inhibitors have developed.

Patients with severe hemophilia A or B can develop alloantibodies (inhibitors) directed against factor VIII or IX. Standard doses of factor do not reverse the coagulopathy because administered factors are rapidly cleared and bleeding persists. Several therapies have been developed to bypass the intrinsic pathway of coagulation, thereby eliminating the need for active factor VIII or IX in the coagulation cascade. FEIBA has been employed for this purpose at doses of 50 to 100 U/kg.

Another widely used bypass agent is activated factor VII (fVIIa), a recombinant factor protein. For a patient with hemophilia A or B and a strong factor inhibitor who has bleeding, fVIIa is usually administered at 90 $\mu\text{g}/\text{kg}$ every 2 hours until the bleeding is controlled. This agent has been quite successful at controlling bleeding in hemophilia inhibitor populations, in patients with congenital factor VII deficiency, and those with acquired coagulation factor inhibitors. Based on its success in treating bleeding associated with hemophilia, trials of fVIIa have been performed for non-hemophilia-associated bleeding. Because of their limited success, the FDA has approved the use of fVIIa only in the setting of factor VII deficiency (15 to 30 $\mu\text{g}/\text{kg}$) or for treatment of bleeding associated with a factor inhibitor or Glanzmann's thrombasthenia.

Several virally inactivated, intermediate-purity factor VIII concentrate products (not recombinant or monoclonal antibody purified) are available. These factors usually contain large amounts of vWF (e.g., Humate-P) and are particularly useful for bleeding or prophylaxis in moderate to severe vWD, as effective replacement immediately before major invasive procedures, or in vWD patients who have failed or do not qualify for DDAVP therapy.

Cryoprecipitate Transfusion Therapy

Cryoprecipitated antihemophilic factor (i.e., cryoprecipitate or cryo) is an often overlooked but important blood product for the treatment of a variety of bleeding disorders. Cryoprecipitate is prepared by thawing frozen plasma at very cold temperatures and removing the precipitated portion. It contains a narrow array of coagulation factors, but fibrinogen, fibronectin, factor VIII, vWF, and factor XIII occur in high concentrations. A major advantage

of cryoprecipitate is that the average single unit is only 10 to 20 mL ([E-Fig 51-3](#)).

Based on its contents and small volume, cryoprecipitate is useful for the replacement of fibrinogen in DIC or in patients with hypofibrinogenemia or dysfibrinogenemia. The product may be helpful for isolated factor XIII deficiency or factor XIII consumption in DIC. Mounting evidence suggests that the vWF and factor VIII in cryoprecipitate can be used to overcome bleeding in uremia by enhancing the adhesive properties of circulating platelets.

Cryoprecipitate is most frequently administered for hypofibrinogenemia, and appropriate dosing should take into account a patient's total plasma volume, baseline fibrinogen levels, and goal fibrinogen levels. For most bleeding associated with hypofibrinogenemia, a concentration of more than 100 mg/dL of fibrinogen is reasonable. For a 70-kg adult with a fibrinogen level less than 100 mg/dL, a 10-unit pool (total volume of about 150 to 200 mL) should be sufficient to provide adequate fibrinogen and enhance other hemostatic properties. For more advanced dosage protocols, such as for children, large patients, or those with extreme hypofibrinogenemia, consultation with the transfusion service is strongly recommended for specific calculations.

PROSPECTUS FOR THE FUTURE

Novel modalities continue to be developed for the diagnosis of patients with bleeding disorders. For instance, assays measuring thrombin generation offer a quantitative view of coagulation that may provide greater insight into the source of abnormal bleeding than current tests. Alternatives and improvements in transfusion are also being developed, including cells harvested from induced progenitor cells that can be customized for specific needs and fibrin-coated albumin particles that can evade immune-mediated platelet destruction while yielding important therapeutic impact. Progress continues to be made in the development and application of human-derived and recombinant coagulation factors for the treatment of hemophilia, with a focus on preparation of factors that are less immunogenic and therefore less prone to induce the development of significant inhibitors.

Disorders of Hemostasis: Thrombosis

Richard Torres and Henry M. Rinder

PATHOLOGY OF THROMBOSIS

The Virchow triad defines the pathologic mechanisms underlying thrombosis: diminished blood flow, damage to the vascular wall, and an imbalance favoring procoagulant over anticoagulant factors. The first two factors are clearly localized to specific vascular beds; although the last element of the triad may be systemic, data show at least partial regulation of the hemostatic balance by anatomic region. For example, congenital deficiency of AT, protein C, or protein S typically leads to venous thromboembolism (VTE) of the lower extremities. In contrast, the inherited hypercoagulable disorders associated with the factor V Leiden and prothrombin G20210A mutations not only produce lower extremity VTE but also are associated with thrombosis of the cerebral veins and sinuses.

This hemostatic regulation in vascular tissues is mediated by multiple factors that include (1) microenvironmental signals, such as shear stress resulting from turbulence in the disrupted flow of damaged vessels, that affect endothelial cell (EC) expression of thrombomodulin, tissue factor, and nitric oxide synthase as well as platelet activation; (2) EC subtype-specific signaling (e.g., shear stress upregulates aortic, but not pulmonary artery, nitric oxide synthase); (3) differences in EC transcriptional regulation of proteins such as von Willebrand factor (vWF) and its cleaving protease, ADAMTS-13; and (4) the increasingly appreciated important link between inflammation and thrombosis that is mediated in both physiologies by selectin and integrin ligands.

Atherothrombosis

This section briefly discusses hematologic factors that predispose to thrombosis in the setting of atherosclerotic plaque (atherothrombosis); the pathophysiologic mechanisms of atherogenesis are discussed in [Chapter 8](#).

Atherothrombosis and Fibrinolysis

In addition to EC-directed regulation of hemostasis, the interaction of EC with the fibrinolytic system is important in the development of atherothrombotic disease because it affects the degree of clot propagation. The breakdown of stable fibrin polymers into fibrin split products, including the D-dimer segments that are routinely measured in the laboratory to detect recent thrombosis, is mediated by plasmin. Plasmin is converted from its inactive form, plasminogen, by tissue-type plasminogen activator (t-PA), the activity of which is regulated by plasminogen activator inhibitor-1 (PAI-1). Abnormal levels of both t-PA and PAI-1 are epidemiologically associated with an increased risk for arterial

thrombosis, but the degree to which absolute levels contribute to arterial thrombosis remains controversial. For this reason, the current clinical utility of t-PA and PAI-1 measurements is limited.

The fact that it is high t-PA levels (rather than high PAI-1 levels) that are associated with higher rates of atherothrombosis, specifically acute myocardial infarction and stroke, is a curious phenomenon. It may be a manifestation of upregulation of t-PA serving as a surrogate marker for high de novo PAI-1 levels, although a direct correlation of PAI-1 levels and overall arterial thrombosis rates remains weak. Notably, PAI-1 is markedly increased in generalized inflammation. The strong association between abnormal hemostasis and high PAI-1 levels in patients with the metabolic syndrome or vascular disease in type 2 diabetes may be related to inflammatory roles for PAI-1, emphasizing the importance of the thrombosis-inflammation interplay. Relatedly, the risk for acute myocardial infarction is elevated in the subset of patients with angina pectoris who have increased PAI-1 activity levels, and there is evidence for a direct contribution of PAI-1 levels to the risk of stent restenosis after angioplasty. From a genetic risk standpoint, the 4G isoform of PAI-1 (compared with the 5G form) results in higher levels of PAI-1 but only a small increase in relative risk for arterial thrombosis. By contrast, t-PA polymorphisms and plasminogen levels do not correlate with atherothrombotic risk.

Hyperhomocysteinemia in Arterial Disease

Increased levels of plasma homocysteine (HCY) are linked to atherothrombosis. The rare congenital syndromes (e.g., cystathionine β -synthase deficiency) that are characterized by homocysteinuria and hyperhomocysteinemia are associated with both VTE and premature atherosclerosis. Elevated HCY induces EC dysfunction and apoptosis, triggering normal coagulation pathways designed to respond to EC damage but without the corresponding upregulation of EC-dependent anticoagulant function (e.g., activated protein C [APC]). Even moderate elevations in HCY may thus contribute to coronary, peripheral, and cerebral arterial disease. Mildly elevated HCY levels are associated with the thermolabile form of the methylene tetrahydrofolate reductase (MTHFR) enzyme, which results from a polymorphism (C677T) in the coding region of the MTHFR binding site. This isoform occurs in 30% to 40% of the general population and introduces a higher set point for regulation of HCY concentration (the substrate for MTHFR), particularly when a relative folate deficiency exists. In fact, deficiency of any of the vitamin cofactors of HCY metabolism (folate, vitamin B₆, and vitamin B₁₂) may lead to mild hyperhomocysteinemia.

Reduction in HCY levels by supplementation with vitamin B₆, vitamin B₁₂, and folate is probably the most effective means of reducing modest HCY elevations, but such supplementation does not decrease atherothrombotic risk, regardless of the cause of hyperhomocysteinemia or the presence of the MTHFR polymorphism. Therefore, the origin of the connection between high HCY and thrombosis remains incomplete, and the search for associated factors that link HCY and hypercoagulability continues.

Role of Platelets in Atherothrombosis

Although EC-associated abnormalities clearly influence hemostasis, platelet activation and adhesion are also critical to the development of atherothrombosis, especially in patients with acute coronary syndrome or ischemic stroke. Antiplatelet therapies are the primary modalities for maintaining short- and long-term patency in arteries, especially after coronary revascularization. Antiplatelet therapy can be targeted against specific platelet functions, including cyclooxygenase-mediated formation of thromboxane A₂, interaction of adenosine diphosphate (ADP) with its platelet receptor, and binding of the glycoprotein IIb/IIIa complex (GPIIb/IIIa) to fibrinogen for aggregation (Table 52-1).

Aspirin has long been a mainstay in the treatment of myocardial infarction, angina, and stroke because of its irreversible inhibition of platelet cyclooxygenase, a process that blocks the release of thromboxane A₂. Aspirin effectively prevents platelet aggregation to weak physiologic agonists (see Table 51-5 in Chapter 51) over the lifetime of a platelet (7 to 10 days); however, aspirin poorly inhibits platelet stimulation by thrombin and other strong agonists such as collagen. Therefore, blockade of other platelet activation pathways is important for patients who are at risk for arterial thrombosis.

Some drugs used to treat stroke or coronary disease (i.e., clopidogrel and prasugrel) specifically block platelet P2RY12, the ADP receptor, from interaction with ADP in the clot milieu, thereby decreasing platelet recruitment by preventing locally released ADP from activating additional platelets. Clopidogrel is effective in combination with aspirin for preventing ischemic stroke and for blocking stent thrombosis after revascularization; however, a significant proportion (up to one third) of patients demonstrate functional platelet resistance to clopidogrel. Under such circumstances, clopidogrel is poorly metabolized to its active form because of the presence of polymorphisms in the cytochrome P-450 gene, *CYP2C19*, that cause loss of function.

The more potent inhibitor, prasugrel, is not affected by cytochrome P-450 genotypes, although nongenetic factors such as platelet turnover, absorption, and compliance also play important roles in response variability.

Antiplatelet therapy with aspirin and a P2RY12 inhibitor (clopidogrel, prasugrel, or ticagrelor) reduces the risk of stent thrombosis and subsequent cardiovascular events after percutaneous coronary intervention and should be administered for 12 months unless the patient is at high risk for bleeding. In acute coronary syndrome, prasugrel and ticagrelor further reduce cardiovascular ischemic events compared with clopidogrel, although they are associated with higher bleeding risk. This effect occurs because drug interactions and variant cytochrome genotypes do not significantly affect production of the active metabolites of prasugrel and ticagrelor; the result is greater and more rapid inhibition of P2RY12 receptor-mediated platelet aggregation in most patients.

A third avenue for blocking platelet activation targets GPIIb/IIIa, the primary platelet receptor for binding to fibrinogen and vWF. Abciximab, a modified monoclonal antibody, prevents GPIIb/IIIa from binding to fibrinogen and blocks platelet aggregation after angioplasty, stent placement, or pharmacologic thrombolysis. Abciximab has been shown to reduce the incidence of recurrent acute ischemic events after percutaneous coronary revascularization in patients with myocardial infarction or unstable angina, mainly by decreasing the incidence of platelet-mediated thrombosis within the infarct-related vessel during and after the procedure. Other GPIIb/IIIa blockers, including eptifibatid (Integrilin) and tirofiban (Aggrastat), interfere with the GPIIb/IIIa arginine-glycine-aspartate (RGD) binding sites; they are used acutely for parenteral administration in patients with acute coronary syndrome or to maintain coronary patency after percutaneous coronary intervention. Thrombocytopenia is an uncommon (<2%) complication of all the GPIIb/IIIa inhibitors; it is most likely related to exposure of neoepitopes on the receptor and immune-mediated platelet destruction. Clearance of the drug typically resolves the thrombocytopenia within 1 week. Platelet transfusion should be considered only if there is significant thrombocytopenic bleeding because of the association of this procedure with a high incidence of stent thrombosis after stent implantation.

Additional novel strategies for mediating platelet activity include inhibition of cyclic nucleotide phosphodiesterases (e.g., dipyridamole, cilostazol) and blockade of proteinase-activated receptor 1 (PAR-1). Phosphodiesterase inhibitors most likely have multiple mechanisms of action. They result in decreased signal transduction within platelets, which impairs their responsiveness. PAR-1 is one of two principal recognized targets for thrombin stimulation of platelets, the other being PAR-4. The potential benefit of adding phosphodiesterase or PAR-1 inhibitors to aspirin and/or clopidogrel (e.g., prevention of restenosis in atherothrombosis) is being evaluated.

Venous Thromboembolism: Inherited Risk Factors

The balance between thrombin formation and anticoagulant pathways has been extensively studied in patients with inherited deficiencies of naturally occurring anticoagulants (Table 52-2).

TABLE 52-1 ANTIPLATELET THERAPIES

INHIBITORS OF CYCLOOXYGENASE	PHOSPHODIESTERASE INHIBITORS
Aspirin	Dipyridamole
Nonaspirin NSAIDs (not COX2 selective)	Prostacyclin
P2RY12 ANTAGONISTS	GPIIb/IIIa BLOCKERS
Prasugrel	Abciximab
Ticagrelor	Integrilin
Clopidogrel	Tirofiban

COX2, Cyclooxygenase 2; GPIIb/IIIa, glycoprotein IIb/IIIa complex; NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 52-2 PREVALENCE AND THROMBOTIC RELATIVE RISK ASSOCIATIONS OF LABORATORY FINDINGS*

PREVALENCE IN GENERAL POPULATION	VENOUS RR	ARTERIAL RR
Hyperhomocysteinemia (25%)	1-2	1.16
Activated protein C resistance (5%)		
Heterozygous FVL	7	1
Homozygous FVL	20-80	
Prothrombin G20210A mutation (1-2%)		
Heterozygous	2-5	1
Homozygous	>5	1
Platelet GPIIb/IIIa HPA-1b homozygosity (2-3%)		4 (MI in men)
Protein C deficiency (0.2-0.5%)	7	1
Protein S deficiency (0.1%)	8.5	1
AT deficiency (0.02-0.05%)	8	1
Dysfibrinogenemia (rare)	~1	1.5

AT, Antithrombin; FVL, factor V Leiden; GPIIb/IIIa, glycoprotein IIb/IIIa complex; HPA-1b, human platelet antigen-1b; MI, myocardial infarction; RR, relative risk.

*Data on prevalence and relative risk vary widely, often with conflicting results. This information represents an interpretation of data collected from various sources, mainly meta-analyses.

These patients are predisposed to VTE, which includes deep vein thrombosis (DVT) and pulmonary embolism (PE).

Factor V Leiden

The most common inherited disorder leading to VTE is the FVL mutation. About 5% of individuals with European ancestry are heterozygous for FVL. The FVL mutation increases VTE risk by decreasing the susceptibility of factor Va to APC-mediated inactivation and by impairing the APC-cofactor activity of factor V in factor VIIIa inactivation, all of which lead to increased thrombin generation. APC resistance can be demonstrated by specialized clotting tests in which the addition of APC fails to inhibit thrombin generation. About one fourth of patients with their first VTE are heterozygous for FVL, and this percentage increases to almost 60% among those with recurrent VTE or a strong family history of VTE.

Heterozygous FVL conveys a seven-fold increased risk for VTE. However, at 50 years of age, only 25% of persons with heterozygous FVL have had VTE, compared with much higher percentages in other inherited thrombophilias. It is with concomitant *acquired* risk factors such as immobilization, pregnancy, or oral contraceptive use that the risk for VTE in persons with FVL becomes more significant. The prothrombin G20210A mutation demonstrates a synergistic effect with FVL, but the MTHFR mutation does not. Homozygous FVL individuals have a 20- to 80-fold increased risk for VTE. APC resistance *without* the FVL mutation occurs rarely. Factor V Cambridge, although much less common than FVL, has a similar mutation at an APC cleavage site (Arg306) and is associated with APC resistance and thrombosis. Other minor alleles of factor V, including the 6755 A/G (D2194G) R2 haplotype, may enhance APC resistance. When this haplotype is on a different chromosome than the FVL mutation, it diminishes normal factor V transcription and increases the ratio of FVL to normal factor V.

Prothrombin G20210A

Another mutation associated with inherited thrombophilia is the prothrombin G20210A mutation, which occurs in the

3'-untranslated region of the prothrombin gene. This mutation leads to higher than normal prothrombin levels and a two-fold increased risk for VTE. The heterozygous mutation is present in about 3% of European-derived populations but is identified in about 15% of patients with VTE. Patients homozygous for prothrombin G20210A are rare, but their relative risk for VTE is thought to be about 10-fold. Exactly how the prothrombin mutation affects thrombus development has not been fully defined, but changes in polyadenylation of the prothrombin messenger RNA (mRNA) during transcription appear to be involved. Diagnosis of the G20210A genotype is made by examination of the patient's DNA for this specific mutation; no screening or functional assays are available.

Inherited Deficiency of Natural Anticoagulants

Deficiencies in the natural anticoagulant proteins (AT, protein C, and protein S) are less common than FVL or prothrombin G20210A, but they are more likely to produce symptomatic VTE at an earlier age. Only about one half of the cases of VTE occurring in patients with these deficiencies are associated with acquired risk factors such as pregnancy, surgery, or immobilization. Deficiencies of AT, protein C, or protein S are detected by functional or antigenic assays because some mutations cause a quantitative decrease in the factor, whereas others produce a dysfunctional protein. Many gene mutations have been associated with these deficiencies, but none is predominant. Deficiencies of AT, protein C, and protein S in the aggregate account for fewer than 5% to 10% of all patients with VTE.

AT is a naturally occurring anticoagulant that complexes with endogenous heparan sulfates to inhibit both formed thrombin and factor Xa. Heterozygous AT deficiency leads to AT activity levels less than 70% of normal and a 20-fold increase in the risk for VTE; VTE usually occurs by the age of 25 years in 50% of such patients. More than 200 associated mutations are known. Homozygous mutations are very rare, likely because of lethality in utero. Rare homozygous mutations show mild impairment in heparin binding or thrombin inhibition.

Acquired causes of AT deficiency are more common. Because AT has a low molecular weight, it is lost in the proteinuria of nephrotic syndrome. Acquired AT deficiency (as well as protein C deficiency) may also be associated with severe hepatic veno-occlusive disease after stem cell transplantation; AT and protein C may be excessively consumed in the damaged hepatic microvasculature. Low levels of AT are also associated with poorer outcomes in severely ill patients. Successful treatment of symptomatic patients with heterozygous AT deficiency has included short-term replacement with fresh-frozen plasma or recombinant AT protein, usually coupled with unfractionated heparin (UFH) anticoagulation; long-term therapy for congenitally deficient patients has consisted primarily of warfarin.

The complex of thrombin and thrombomodulin on the EC surface activates protein C; APC coupled with its cofactor, protein S, cleaves and inactivates factors Va and VIIIa. These actions downregulate the prothrombinase and tenase complexes, respectively, to slow the rate of thrombin generation. Like AT deficiency, heterozygous protein C and protein S deficiencies are observed with venous, and occasionally arterial, thrombosis at in younger patients (median age at occurrence, 20 to 40 years).

The rare homozygous protein C deficiency manifests in the neonate as *purpura fulminans* with widespread VTE and skin necrosis. A similar clinical presentation has been reported in heterozygous protein C–deficient adults after institution of warfarin therapy without simultaneous heparinization; this is called *warfarin-induced skin necrosis*. About one third of these patients are deficient in protein C on a hereditary basis, whereas the rest appear to have acquired protein C deficiency, possibly associated with vitamin K deficiency. Warfarin is a vitamin K antagonist that inhibits production of vitamin K–dependent protein C synthesis; and because of its short half-life, protein C levels rapidly fall before a decline in the levels of the procoagulant factors II, IX, and X. This imbalance shortly after starting warfarin favors a procoagulant state and may result in widespread microvascular thrombosis. Therefore, patients with active VTE should be fully anticoagulated with UFH or low-molecular-weight heparin (LMWH) before concurrent warfarin therapy is begun. UFH/LMWH should be continued until warfarin is therapeutic for at least 48 hours.

Inherited deficiency of protein S has similarly been implicated in warfarin-induced skin necrosis. Protein S deficiency is commonly acquired in acute illness. Protein S circulates in a free form and is bound by complement 4b (C4b)-binding protein; only free protein S is active as a cofactor for protein C. Because C4b-binding protein is an acute phase reactant, its increase with severe illness can decrease the level of free protein S. A similar effect is seen in normal pregnancy.

Short-term therapy for homozygous protein C deficiency or for doubly heterozygous protein C or S deficiency, especially in the setting of neonatal purpura fulminans, has included plasma or protein C concentrate with full-dose UFH anticoagulation. Functional and antigenic levels of AT, protein S, and protein C can be assessed to define whether functional deficiency is caused by a dysfunctional protein or by diminished synthesis. As with AT deficiency, initial heparin therapy followed by long-term treatment with warfarin has been successful in heterozygous protein C or S deficiency. As expected, both protein C and protein S levels are decreased during warfarin therapy; therefore, for adequate evaluation of protein C and S, the patient must not be taking warfarin when tested.

Venous Thrombosis: Acquired Risk Factors

Surgery and Medical Hospitalization

Medical and surgical illnesses convey increased thrombotic risk; these *acquired* risk factors are well accepted, even though the pathophysiologic features favoring thrombosis may be uncertain (Table 52-3). Stasis of blood flow is a clear risk factor for thrombus formation (e.g., VTE in immobilized inpatients). Other high-risk situations, including surgery (especially orthopedic) and trauma, are similarly associated with immobilization and stasis of lower extremity blood flow. When evidence of thrombosis is thoroughly sought, both surgery and trauma can be shown to be associated with extremely high (>50%) incidences of VTE. Fat embolism and tissue damage may also contribute to the risk for VTE with surgery and trauma, particularly in closed head injuries that result in massive tissue factor release. Prophylactic permanent or temporary inferior vena cava (IVC) filters are often

TABLE 52-3 ACQUIRED RISK FACTORS FOR THROMBOSIS

MEDICAL AND SURGICAL ILLNESSES	
Antiphospholipid antibody, lupus anticoagulant	Immobilization
Artificial heart valves	Malignancy
Atrial fibrillation (nonvalvular)	Myeloproliferative disorders with thrombocytosis
Congestive heart failure	Nephrotic syndrome
Hemolytic anemias (autoimmune hemolysis, sickle cell, thrombotic thrombocytopenic purpura, paroxysmal nocturnal hemoglobinuria)	Orthopedic procedures
Hyperlipidemia	Pregnancy
	Trauma, fat embolism
	MEDICATIONS
	Heparin-induced thrombocytopenia
	Oral contraceptives, hormone replacement therapy
	Prothrombin complex concentrates

placed in trauma patients to protect against PE, especially in high-risk patients for whom anticoagulation is contraindicated because of the increased risk for bleeding.

All hospitalized medical patients should be considered for venous thromboprophylaxis with LMWH. Bleeding risk attributes that argue against anticoagulation include thrombocytopenia, coagulopathy (with or without liver disease), and recent hemorrhage. Risk factors that most argue for prophylaxis include malignancy, prior VTE, immobilization, and thrombophilic conditions.

Pregnancy and Fetal Loss

Pregnancy is a hypercoagulable state associated with venous stasis; the risk for VTE during pregnancy and in the postpartum period for women with identified thrombophilia is about five-fold higher than it is for nonpregnant women. Pregnancy increases procoagulant proteins, including fibrinogen, vWF, and factors VII, VIII, and X, and decreases anticoagulants such as protein S and AT as well as fibrinolytic inhibitors such as PAI-1 and thrombin activator fibrinolysis inhibitor (TAFI). VTE can occur at any time during pregnancy or the puerperium. The risk of postpartum VTE is significantly higher in women with any of the following conditions: stillbirth, pre-term delivery, obstetric hemorrhage, caesarean procedure, medical comorbidities, or a prepregnancy body mass index greater than 30 kg/m².

Inherited maternal thrombophilia can compound the procoagulant state of pregnancy and predispose to both fetal loss and VTE in the mother. The principal inherited associated risk factors for fetal loss are FVL, the G20210A prothrombin mutation, AT deficiency, and protein C or protein S deficiency. The relative risk for fetal loss is markedly higher in those mothers with a history of prior VTE, although this particular risk appears to be restricted to the period after 9 weeks of gestation. In fact, inherited thrombophilia may be protective against fetal loss during the first 9 weeks, possibly by limiting oxygen toxicity to the early embryo. Therefore, recommended indications for evaluating the inherited thrombophilia risk in women seeking to become pregnant are a history of VTE or recurrent fetal loss after 9 weeks of gestation when no other specific cause (e.g., antiphospholipid syndrome) can be identified. Both AT deficiency and hyperhomocysteinemia have also been associated with placental abruption.

In the absence of an identified inherited thrombophilia or a diagnosis of antiphospholipid syndrome (discussed later), no

role has been identified for prophylactic anticoagulant therapy with recurrent pregnancy loss.

Oral Contraceptives and Hormone Replacement

Oral contraceptive use conveys an increased risk for VTE, and a similar increased risk is seen early after institution of hormone replacement therapy in postmenopausal women. Concomitant heterozygosity for FVL synergistically increases the risk for VTE in women who take oral contraceptives or hormone replacement therapy. Cigarette use in women using oral contraceptives also increases the risk of thrombosis, possibly through increased platelet reactivity mediated by increased thromboxane synthesis. On the arterial side, epidemiologic evidence clearly points to smoking as the main cardiovascular risk factor. Paradoxically, most data suggest a protective role for hormone replacement therapy in cardiovascular disease. As discussed previously, acquired APC resistance and decreases in the levels of both free and functional protein S occur with oral contraceptive use.

Other Prothrombotic Disease States

As described earlier, thrombosis in nephrotic syndrome is associated with loss of AT through the kidneys. Hemolysis is a general prothrombotic state that appears to be mediated through blood cell destruction, perhaps through increased exposure to procoagulant membrane phospholipids; hemolysis with thromboembolic complications has been observed in patients who have artificial heart valves, sickle cell disease, and other hemolytic anemias, including Coombs-positive autoimmune hemolytic anemia. In the case of paroxysmal nocturnal hemoglobinuria (PNH), complement activation may directly mediate platelet activation, and therapy with the complement inhibitor eculizumab has significantly decreased the rate of thromboembolic disease in PNH.

Platelet activation and clearance appear to be the primary prothrombotic manifestations of heparin-induced thrombocytopenia (HIT) and thrombotic thrombocytopenic purpura (TTP). Although chronic disseminated intravascular coagulation (DIC) is classically associated with certain malignancies such as mucinous adenocarcinoma and promyelocytic leukemia, in that setting, known as Trousseau syndrome, there is an increased risk in malignancy for VTE that is not related to DIC. Indeed, VTE occurs in a wide spectrum of malignancies, including lung, breast, gastrointestinal, and any metastatic solid tumor. However, when idiopathic VTE occurs in a cancer-free individual, an intensive work-up to find an occult malignancy is not warranted and has not been shown to improve subsequent cancer-related morbidity or mortality. However, once a cancer diagnosis is established in patients with prior VTE, they are at increased risk for subsequent VTE events, especially if the FVL or G20210A prothrombin mutation is present. LMWH prophylaxis after malignancy-associated VTE achieves superior prevention compared to warfarin, possibly because of better maintenance of an anticoagulated state. In the special case of myeloproliferative disorders (e.g., essential thrombocythemia), abnormal platelet physiologic mechanisms causing hyperaggregability are often present and require platelet-specific inhibition (See Hypercoagulability and Platelet Disorders).

Antiphospholipid Antibody Syndrome

Another acquired prothrombotic disorder is the antiphospholipid antibody syndrome (APS). APS is a primary disorder, unlike the occasional association of lupus anticoagulant or antiphospholipid antibodies with other autoimmune diseases such as systemic lupus erythematosus (SLE). The etiologic connection with SLE has not been fully defined, but replacement of the host immune system after hematopoietic stem cell transplantation for refractory SLE has the potential to eradicate the lupus anticoagulant and thromboembolic risk. All of the manifestations of APS are related to hypercoagulability, including recurrent venous or arterial thrombosis, thrombocytopenia caused by microcirculatory platelet clearance, and recurrent fetal loss resulting from placental vascular insufficiency. Serologic markers of APS include *anticardiolipin antibodies*, *anti- β_2 -glycoprotein I antibodies*, and *lupus anticoagulants*. The Sydney Consensus Criteria for Antiphospholipid Syndrome is the current standard for diagnosis of APS. Diagnosis requires both the clinical criterion of radiologically or pathologically confirmed thrombosis or thrombosis-related fetal loss and the laboratory criterion of positive tests on two or more occasions at least 12 weeks apart. Anticardiolipin and anti-glycoprotein antibodies are detected by enzyme-linked immunosorbent assay (ELISA), whereas lupus anticoagulants are defined by correction of prolonged phospholipid-dependent clotting tests (most commonly hexagonal phase partial thromboplastin time [PTT] or Russell viper venom clotting time), with addition of excess phospholipid. Therefore, *lupus anticoagulant* is a misnomer; its presence predisposes the patient to clotting rather than to bleeding, and the risk for thrombosis is highest when a lupus anticoagulant is detectable. Another misleading aspect of this nomenclature is that phospholipid-reactive antibodies are actually directed against phospholipid-binding proteins in plasma (e.g., β_2 -glycoprotein I antibody, annexin V, prothrombin). Anti- β_2 -glycoprotein I antibody is detected by immunoassay, and high titers of this marker are also correlated with thromboembolic risk.

In patients with recurrent pregnancy loss in the context of APS, LMWH during pregnancy can help reduce further miscarriages.

Hypercoagulability and Platelet Disorders

Essential thrombocythemia and polycythemia vera are clonal myeloproliferative disorders associated with mutations in the *JAK2* gene. They are wholly (essential thrombocythemia) or partially (polycythemia vera) characterized by thrombocytosis, and patients with these disorders are at increased risk for thrombosis. Platelet aggregometry in these disorders often shows abnormal responses, especially to epinephrine and ADP; however, the abnormal aggregation does not correspond to either bleeding or thrombosis risk. Patients with polycythemia vera in particular have a high incidence of thrombosis in the mesenteric, portal, and hepatic venous circulation.

Thrombotic complications, both arterial and venous, occur in essential thrombocythemia, even in young patients. The risk of arterial thrombosis in essential thrombocythemia (and probably also in primary myelofibrosis and polycythemia vera) is most increased by a history of previous thrombosis or the

presence of the *JAK2 V617F* mutation. Therefore, prophylaxis with low-dose aspirin is probably justified in patients with high-risk essential thrombocythemia and other myeloproliferative disorders.

Increased platelet turnover in thrombocytosis is also associated with thromboembolic complications, but this does not necessarily involve high platelet counts, as has been demonstrated by radioactive platelet survival studies and an increase in reticulated (young) platelets in thrombotic essential thrombocytopenia. Moreover, successful treatment of symptomatic patients with aspirin increases platelet survival by decreasing platelet clearance. Concomitant therapy to prevent thrombotic complications of thrombocytosis includes lowering the platelet count with hydroxyurea. Evidence suggests that patients with essential thrombocythemia who are at high risk for arterial thrombosis are most effectively treated with the combination of hydroxyurea and low-dose aspirin. Patients with reactive (secondary) thrombocytosis resulting from iron deficiency anemia, chronic infection, rheumatoid arthritis, or the postsplenectomy state do not generally have increased thrombotic risk and do not require aspirin prophylaxis.

Heparin-Induced Thrombocytopenia

HIT must be distinguished from other drug-induced forms of immune thrombocytopenia because of its potentially catastrophic *thrombotic* complications and its unique pathophysiologic features. Almost 25% of patients who are exposed to UFH develop antibodies (detected by ELISA) that recognize the complex of heparin and platelet factor 4 (PF4), the latter being released from activated platelets. When such patients receive heparin again, between 5% and 10% develop HIT, most with platelet counts between 50,000 and 100,000/ μL . HIT rarely occurs in patients who have not been previously exposed to heparin (0.3% incidence).

Surgery is a specific risk factor for HIT; the incidence of HIT in surgical patients is about 2.6%, compared with 1.7% in medical patients. HIT antibodies occur with high frequency in patients undergoing either cardiac surgery with cardiopulmonary bypass or an orthopedic procedure such as hip replacement. The incidence of HIT in patients who have received only LMWH is far lower, only about one-tenth the rate seen with UFH. However, the mechanism of thrombocytopenia for both UFH and LMWH appears to be similar: Platelet Fc-receptor binding of the heparin-PF4 antibody complex causes signal transduction and platelet activation with enhanced thrombin generation on the platelet surface.

The diagnosis is predominantly clinical (e.g., using the 4Ts algorithm for scoring HIT—magnitude of thrombocytopenia, timing of platelet fall, thrombotic sequelae, and ruling out other causes of thrombocytopenia), but the rapid ELISA test will detect heparin-PF4 antibodies in serum. The main drawback of ELISA is that it does not indicate whether the antibody complex is a functional activator of platelets; therefore, it is sensitive but not specific for HIT. The serotonin release assay is the functional test for HIT; it detects platelet activation after exposure to serum antibody in the presence of a therapeutic heparin level. However, a low probability for HIT based on the 4Ts score can be used to exclude the HIT diagnosis.

The thrombin-based procoagulant response in HIT incorporates platelets into microcirculatory clots, leading to thrombocytopenia; about 30% of HIT patients have overt thromboembolic complications, which can be severe or life-threatening. Thromboembolic events can occur before, concurrent with, and after development of thrombocytopenia in HIT, with about equal frequency. Although thrombosis is more frequent in patients with both HIT and concomitant cardiovascular disease and in those receiving full-dose heparin, any heparin dose (even heparin flushes) can result in thrombosis in HIT. Arterial and venous thromboembolic disease can occur even weeks after heparin has been discontinued, an effect perhaps mediated by EC glycosaminoglycan binding to PF4, which serves as a target for circulating HIT antibodies.

Discontinuation of all heparin is critical; moreover, although the antibody may have been induced by treatment with UFH, more than 80% of these antibodies cross-react with LMWH. Therefore, the preferred therapy for short-term anticoagulation in patients with HIT is a direct thrombin inhibitor (DTI), such as argatroban or bivalirudin, which is not a target for the heparin-PF4 antibodies. Indeed, because the event rate for subsequent thrombosis, limb amputation, and death is increased in patients with HIT even if they do not have thrombosis at presentation, DTI therapy is mandated after discontinuation of heparin. The choice of DTI may be dictated by other clinical conditions; for example, renal insufficiency slows bivalirudin clearance, increasing the bleeding risk, whereas argatroban is cleared by hepatic metabolism. For patients who develop HIT after warfarin has already been started, in addition to substituting a DTI, one should administer vitamin K to correct protein C levels. Although it has not been approved by the U.S. Food and Drug Administration (FDA) for this clinical scenario, the Xa inhibitor fondaparinux has the advantages of once-daily subcutaneous administration without need for laboratory monitoring and of having no effect on the international normalized ratio (INR).

DTI therapy should be continued until the platelet count is higher than 100-150,000/ μL . Warfarin can then be added, and the two therapies should overlap for at least 5 days and with the INR at a therapeutic level for at least 48 hours. Because DTIs prolong the INR, a therapeutic warfarin level after 5 days may result in a supratherapeutic INR (usually >4); gradual downward titration of the DTI as the INR increases is a logical management strategy. Once DTIs are stopped, it is essential to repeat the INR measurement after 4 to 6 hours to confirm that it remains within the therapeutic range.

If there is no thrombosis with HIT, the total duration of anticoagulation should be 4 weeks; if thrombosis is present, anticoagulation should be continued for 3 to 6 months. Warfarin should never be used primarily to treat HIT, and it should not be instituted without simultaneous DTI coverage because it may induce acquired protein C deficiency leading to venous limb gangrene. One hallmark of protein C depletion in HIT is a sudden rise in the INR (to >3.5) after a single warfarin dose; in that circumstance, warfarin should be discontinued and the patient repleted with vitamin K. Patients with a history of HIT who need surgery requiring cardiopulmonary bypass can be safely reexposed to brief systemic UFH if ELISA testing is negative for the antibody at least 100 days after the previous UFH exposure.

Thrombotic Thrombocytopenic Purpura

Another cause of thrombocytopenia resulting from platelet activation and clearance is TTP. In patients with congenital or familial TTP, mutations in the vWF-cleaving protease, ADAMTS-13 (*a disintegrin and metalloproteinase with thrombospondin type 1 motif, member 13*), abrogate its activity. Patients with acquired TTP usually have an antibody that blocks the normal function of vWF-cleaving protease to less than 10% of normal. Ultralarge vWF multimers released by EC normally anchor to EC through P-selectin and form long strings that adhere and aggregate platelets in the microcirculation. ADAMTS-13 downregulates the size of these multimers by docking to the A1/A3 vWF domains and cleaving within the A2 site. Deficient cleaving protease function in TTP leads to an increase in the larger, highest-molecular-weight vWF multimers, which are most effective in anchoring and activating platelets. These, in turn, cause increased platelet adhesion and clearance *without* activating the coagulation cascade. Therefore, both the prothrombin time (PT) and the PTT are normal in TTP, unlike in DIC.

TTP after chemotherapy (mitomycin C) or in association with pregnancy, stem cell transplantation, lupus, or HIV infection appears to have a similar pathogenic mechanism of thrombosis. Thrombocytopenia (often severe) is accompanied by microangiopathy with schistocytes on smear and increased serum lactate dehydrogenase. Microvascular occlusions in multiple organs cause symptoms, especially in the kidney and brain. The classic pentad (fever, thrombocytopenia, microangiopathic hemolysis, neurologic symptoms, and renal insufficiency) is present in fewer than 25% of patients with TTP. The diagnosis is typically made based on the clinical assessment of thrombocytopenia and microangiopathic hemolytic anemia; assays for ADAMTS-13 activity and inhibitor do not have a rapid turnaround time in most laboratories.

Treatment of familial TTP is based on replenishment of cleaving protease activity with plasma transfusion; acquired TTP additionally requires removal of the antibody. The latter is accomplished by plasma exchange, whereby patient plasma is removed (plasmapheresis) and replaced with fresh-frozen plasma, which often had been made “cryo-poor” to reduce ultralarge vWF multimers in transfused plasma. Steroids and antiplatelet drugs (e.g., aspirin, dipyridamole) are often administered simultaneously, but any added benefit to plasma exchange remains unclear. Platelet transfusions are relatively contraindicated in TTP because of the risk of thrombosis, and they should not be given for thrombocytopenia in the absence of significant bleeding. When plasma exchange fails to remit acquired TTP or when early relapse occurs, immunosuppressive therapy with anti-CD20 may be successful. The mortality rate associated with severe TTP (defined as undetectable ADAMTS-13 activity) is still significant, almost 10% at 18 months after therapy with plasma exchange. Replacement of ADAMTS-13, which is present in fresh-frozen plasma and in cryoprecipitate, is a potential treatment.

The *hemolytic-uremic syndrome* (HUS) is part of the TTP spectrum of disease and also is associated with microvascular platelet thrombi. However, the hemolytic anemia and renal failure of HUS are not usually accompanied by neurologic impairment,

and HUS usually does not produce the same degree of thrombocytopenia or microangiopathy as TTP. Moreover, fewer than 3% of HUS cases are associated with decreased vWF-cleaving protease activity. Unlike TTP, HUS is primarily diagnosed in children (and less commonly in adults) who have hemorrhagic colitis caused by Shiga-like, toxin-producing bacteria, especially the *Escherichia coli* O157:H7 serotype. Atypical HUS (i.e., without diarrhea or Shiga-like toxin) is rarely associated with other bacterial infections or with complement dysregulation due to mutations or polymorphisms in factors H, I, and B. These mutations increase platelet activation through complement (C3) deposition on the platelet surface. Atypical HUS cases are those that are clinically consistent with HUS but are not associated with toxin-producing bacteria. Some HUS cases, particularly atypical forms, may respond to plasmapheresis with plasma exchange along with maintenance hemodialysis until renal function recovers. Data increasingly suggest that anti-C5a complement therapy can help prevent the complement-mediated damage associated with this disease.

CLINICAL EVALUATION OF THROMBOSIS

The approach to patients with thromboembolism is defined by the clinical history, results of laboratory studies, and even physical findings. Events that trigger VTE disease include immobilization, orthopedic and other surgical procedures, use of oral contraceptives, and pregnancy. VTE that is recurrent (thrombophilia) may manifest at an early age or at unusual thrombotic sites (e.g., cerebral vessels) and may be accompanied by a family history of VTE suggesting an inherited disorder. Acquired VTE risk may be associated with systemic disorders such as hemolysis (e.g., PNH, autoimmune hemolytic anemia), collagen vascular disorders (e.g., lupus), or various malignant diseases (e.g., adenocarcinoma). In contrast, arterial thromboembolic disease is more commonly superimposed on ruptured atherosclerotic plaque (e.g., coronary artery disease) or on atheroembolic disorders (e.g., ischemic stroke, peripheral arterial disease). Arterial vascular disease is mainly associated with metabolic risk factors including hypertension, hypercholesterolemia, and diabetes. The clinical approach to thrombotic disease is tailored to the location of the disease (arterial versus venous and the specific vascular bed) and whether there are abnormalities of the vascular endothelium, platelets, or soluble coagulation factors that predispose the patient to thromboembolic risk.

Laboratory Diagnostics

Recurrent VTE is a strong indication for laboratory testing for causes of thrombophilia, especially in patients younger than 50 years of age, in those with unexplained VTE, and in those with a family history of VTE. Any risk factors that may predispose these individuals to recurrence must be defined, as well as any inherited disorders that may necessitate family counseling or avoidance of additional environmental risks. The current work-up for VTE thrombophilia includes the following: (1) APC resistance, (2) genotyping for prothrombin G20210A, (3) lupus anticoagulant assay and anticardiolipin and anti- β_2 -glycoprotein I antibody serologies, (4) functional AT and protein C levels, and (5) free protein S (Table 52-4). Genotyping for the FVL mutation can substitute for APC resistance and also determines whether the

TABLE 52-4 LABORATORY EVALUATION OF VENOUS THROMBOSIS

Homocysteine level: fasting or after methionine load	Free protein S level

patient is heterozygous or homozygous, although it may miss rare variants of APC resistance.

The utility of laboratory testing in the setting of atherothrombosis and arterial thromboembolism is unclear. In the setting of a myeloproliferative disorder, the platelet count and platelet function (e.g., aggregation and closure times) can justify hydroxyurea and/or aspirin therapy. In patients with unusual or recurrent arterial disease, other assays can be justified, including testing for t-PA and PAI-1 levels and for dysfibrinogenemia (thrombin time and antigen: activity ratio), all of which should be performed in consultation with specialists in hemostasis.

● THERAPY FOR VENOUS THROMBOEMBOLISM

Once VTE has been diagnosed, immediate therapy is required. In most patients, anticoagulation is accomplished on a short-term basis with heparin compounds and on a long-term basis with warfarin. Thrombolytic therapy is indicated for patients with extensive proximal venous clots or PE. IVC filters are used in patients with contraindications to anticoagulation, complications of anticoagulation (usually active bleeding), or failure of anticoagulation (recurrent PE). IVC filters clearly decrease the incidence of early PE, but their use is also associated with thrombosis at the insertion site and late complications of IVC thrombosis as well as a 10% to 20% incidence of postphlebotic syndrome. Temporary IVC filters are often used in trauma patients and appear to be most efficacious when they are placed for fewer than 7 to 10 days.

UFH is often the anticoagulation therapy of choice for inpatients because of its short half-life and reversibility, but LMWH is increasingly used for this indication. UFH is begun as a bolus intravenous infusion of 80 U/kg, followed by a continuous infusion of 18 U/kg/hour; UFH doses in excess of 30,000 U/day have been shown to be most efficacious at preventing recurrent VTE. UFH is monitored by the PTT, and the therapeutic PTT range determined by each hospital corresponds to anti-Xa levels of 0.3 to 0.7 U/mL. All hospitals have established protocols for adjustment of UFH infusion based on the patient's weight and PTT monitoring.

UFH should be continued for at least 4 days (longer in patients with extensive clots) and may be discontinued after the patient has been fully anticoagulated with warfarin (INR ≥ 2 for 2 consecutive days). Some patients receiving large doses of heparin (usually $>40,000$ U/day) do not develop a therapeutic PTT. This *heparin resistance* can be caused by a variety of mechanisms, including increased heparin-binding proteins, counteracting medications (e.g., protamine), and decreased AT. An *apparent* heparin resistance is often seen in patients with coexistent inflammatory disease with high plasma levels of factor

VIII and fibrinogen; direct monitoring of anti-Xa levels is indicated.

LMWH is an excellent alternative to UFH in the treatment of thromboembolism and acute coronary events. The small controlled-size elements of LMWH stimulate AT activity that is more restricted to factor Xa compared with UFH, which has effects on thrombin, factor IX, and factor XI, in addition to others. The practical advantages of LMWH over UFH include increased plasma half-life, more predictable dose response allowing for intermittent fixed dosing, a lower de novo incidence of HIT (10% to 20% of the rate for UFH), and significantly reduced monitoring requirements. LMWH levels are prolonged in renal failure and in those circumstances may need to be monitored and adjusted based on anti-Xa levels. Peak anti-Xa levels (0.5 to 1 U/mL for twice-daily dosing and 1 to 2 U/mL for once-daily dosing) typically occur between 3 and 5 hours after subcutaneous LMWH injection. As with UFH, switching from LMWH to warfarin for long-term management can be accomplished after therapeutic INR values have been present for at least 2 days.

Warfarin and LMWH are used for long-term prophylaxis of VTE. Warfarin should be begun during the first 24 hours after presentation with VTE, concurrent with heparin treatment. The PT is prolonged within hours by warfarin because of a rapid decrease in factor VII levels; however, therapeutic warfarin anticoagulation does not occur until other vitamin K-dependent factors (II, IX, and X) also decrease. Therapeutic warfarin anticoagulation is usually achieved within 4 to 5 days with adequate warfarin dosing; UFH or LMWH may be discontinued after the INR has been greater than 2 for at least 2 consecutive days. One long-standing problem with warfarin anticoagulation is the interindividual variability in INR response; at least 50% of this variability in sensitivity to warfarin may be explained by polymorphisms in the *CYP2C9* and *VKORC1* genes. Although these have been incorporated into models for predicting safe and therapeutic warfarin dosing, most clinicians simply begin dosing and adjust therapy as needed based on periodic monitoring.

The therapeutic INR range depends on the condition predisposing the patient to thromboembolism. Prophylaxis after uncomplicated VTE in a patient without known risk factors requires an INR between 2 and 3; in contrast, warfarin prophylaxis for patients with APS and recurrent VTE may require INR values between 3 and 4 (Table 52-5).

The duration of warfarin or LMWH prophylaxis varies depending on the circumstances of the VTE, the risk for bleeding, and the potential for recurrence. In general, the longer the period of anticoagulation with warfarin, the less the chance of recurrence. Short-term warfarin (6 weeks) is less effective at preventing recurrence than longer courses (6 months). Patients with definite transient risk factors such as orthopedic surgery have low recurrence rates, even with short-term therapy; still, prolonged thromboprophylaxis (>21 days) after total hip replacement is more efficacious than shorter therapy (7 to 10 days). It is not clear that oral Xa inhibitors and dabigatran provide any benefit over LMWH for thromboprophylaxis after total hip or knee replacement (Table 52-6).

In contrast, patients with "unprovoked" VTE (i.e., outside the setting of trauma, surgery, immobilization, pregnancy, or cancer) have significant recurrence rates, even after 3 to 6 months of

TABLE 52-5 THERAPEUTIC INTERNATIONAL NORMALIZED RATIO (INR) RANGES FOR WARFARIN

NOAC	INDICATIONS
Dabigatran	Direct thrombin inhibitor for nonvalvular atrial fibrillation (to prevent stroke and non-CNS embolism)
Rivaroxaban	Anti-Xa for nonvalvular atrial fibrillation (to prevent stroke and non-CNS embolism); treatment of VTE and subsequent prophylaxis; and prophylaxis of VTE after hip or knee replacement
Apixaban	Anti-Xa for nonvalvular atrial fibrillation (to prevent stroke and non-CNS embolism)
Edoxaban	Anti-Xa for prevention of VTE in surgical patients; prevention of embolism in atrial fibrillation
Ticagrelor	Platelet P2RY12 inhibitor for prevention of thrombosis in acute coronary syndromes

CNS, Central nervous system; VTE, venous thromboembolism; Xa, activated factor X.

warfarin therapy. Because the risk for recurrence in patients with unprovoked proximal VTE or PE is relatively low when D-dimer levels are normal 3 weeks after cessation of anticoagulation, this measure may help providers decide whether anticoagulation past 3 to 6 months is necessary.

Evidence also indicates that inherited hypercoagulable disorders (e.g., FVL) probably confer a lifelong increased risk for VTE or PE. Some studies have shown that the bleeding risks incurred by long-term, low-intensity warfarin use are favorably balanced by the decreased incidence of recurrent thrombosis. Therefore, the presence of inherited thrombophilia may warrant continuation of warfarin therapy for a longer period, depending on the patient's other medical illnesses and whether transient circumstances may have predisposed the patient to VTE. Patients who develop recurrent VTE after discontinuation of warfarin should receive long-term anticoagulation regardless of whether they have a defined cause of thrombophilia. Patients with APS and a first episode of VTE are at very high risk for recurrent VTE (up to 50% per year) after anticoagulation is discontinued, clearly supporting the rationale of testing for antiphospholipid. [Table 52-7](#) suggests broad guidelines for the duration of warfarin therapy in specific patient subgroups. Because warfarin is a teratogen, effective contraception should be used concurrently in women of childbearing age.

Supratherapeutic INR levels commonly occur with warfarin therapy, with or without bleeding. In patients with moderately

TABLE 52-7 GUIDELINES FOR DURATION OF PROPHYLACTIC ANTICOAGULATION AFTER VTE

CONDITION	DURATION OF THERAPY
Distal or superficial vein thrombus	3-12 wk
FIRST PROXIMAL VTE	
No risk factors	3-6 mo*
Correctable risk factor (e.g., surgery, trauma)	3-6 mo
Malignancy	Long-term†
Antiphospholipid syndrome	Long-term
Inherited risk factor‡	>6 mo
Recurrent VTE/PE	Lifelong

PE, Pulmonary embolism; VTE, venous thromboembolism (includes deep vein thrombosis, pulmonary embolism, and sinus or cerebral thrombosis).

*Evaluation of D-dimer after 3-6 mo may assist in the decision to stop prophylaxis.

†Long-term therapy must be adjusted individually according to presence of other diseases, risks for bleeding, presence of transient risk factors, and ease of compliance.

‡Inherited risk factors include factor V Leiden; prothrombin 20210A; deficiencies of antithrombin, protein C, or protein S.

TABLE 52-8 DRUGS THAT AFFECT WARFARIN LEVELS

INCREASED WARFARIN LEVELS: PROLONGED INR	DECREASED WARFARIN LEVELS: SUBTHERAPEUTIC INR

Metronidazole	Rifampin
Trimethoprim-sulfamethoxazole	↓ Warfarin absorption
↓ Warfarin-protein binding	Cholestyramine
Phenylbutazone	
↑ Vitamin K turnover	
Clofibrate	

↑, Increased; ↓, decreased; INR, international normalized ratio.

elevated INR values (>5) and little or no bleeding, temporary discontinuation of warfarin and reinstatement of the drug at a lower maintenance dose may be sufficient. Patients with higher INR values (5 to 9) who are without serious bleeding should have warfarin withheld and should receive low doses (1 to 2.5 mg/day) of oral vitamin K to reach therapeutic INR levels; parenteral vitamin K may be given if gastrointestinal function is problematic. If serious active bleeding occurs with high INR values, especially if surgery is required to correct the bleeding, a combination of vitamin K and transfusion of plasma (see [Chapter 51](#)) will rapidly correct the INR. The INR can become elevated as a result of concurrent use of drugs that increase free warfarin levels ([Table 52-8](#)). Whenever bleeding occurs as a complication of anticoagulation, serious consideration must be given to future bleeding risks and to whether the patient requires placement of an IVC filter for prophylaxis.

Antithrombotic Therapy during Pregnancy

Heparins, both UFH and LMWH, are the safest therapy for venous thrombosis during pregnancy. Heparin does not cross the placenta, unlike warfarin, which causes a characteristic fetal embryopathy. Warfarin also causes fetal hemorrhage and placental abruption and should be avoided during pregnancy. VTE or PE during pregnancy should be treated with intravenous UFH for 5 to 10 days, followed by an adjusted-dose regimen of subcutaneous UFH, starting with 20,000 U every 12 hours and adjusted to achieve a PTT higher than 1.5 times baseline at 6 hours after

injection. An attractive alternative to UFH during pregnancy is LMWH, which can be given subcutaneously once or twice daily and does not require monitoring. Suprarenal IVC filters have also been used successfully during pregnancy without significant morbidity. In women with APS who become pregnant, therapy is critical to prevent fetal loss; aspirin (160 mg) is combined with prophylactic doses of either subcutaneous UFH (10,000 to 15,000 U/day in divided doses) or LMWH (to achieve an anti-Xa level of 0.1 to 0.3 U/mL). When such women have a history of thromboembolic disease, therapeutic doses of LMWH or UFH plus aspirin are employed.

Heparin should be discontinued at the time of labor and delivery, although the risk for hemorrhage is not high during delivery, especially if anti-Xa levels are less than 0.7 U/mL. One concern with residual anticoagulation at delivery is the risk for spinal hematoma with epidural anesthesia; this concern has been reported with both UFH and LMWH. The anti-Xa level that is safe for an epidural procedure is not known. Protamine sulfate can be used to neutralize UFH if the PTT is prolonged during labor and delivery; however, LMWH is only partially (10%) reversed by protamine.

Anticoagulation during the postpartum period can be carried out with heparin or warfarin; neither drug is contraindicated during breast-feeding. Women receiving long-term warfarin therapy (e.g., for valvular heart disease) who wish to become pregnant need to be switched to a fully anticoagulating dose of UFH or LMWH; warfarin treatment may be restarted after delivery.

Perioperative Anticoagulation

A common clinical problem is the management of anticoagulation in patients who require surgery. The principles of care in this situation reflect the need for adequate hemostasis during and immediately after surgical procedures as well as the critical importance of restarting anticoagulation as soon as possible postoperatively, especially because surgery itself represents a relative hypercoagulable state. The perceived risk for thromboembolism in patients with atrial fibrillation clearly affects the management of perioperative anticoagulation; in this clinical situation, the CHADS-2 score (cardiac failure, hypertension, age, diabetes, and stroke) may estimate postoperative stroke risk and thus dictate the need for bridging anticoagulation with UFH/LMWH when stopping vitamin K antagonist. For patients with VTE who are anticoagulated on a short-term basis (<1 month), elective surgical procedures should be postponed; if such patients must

undergo surgery, discontinuation of anticoagulation and placement of a temporary IVC filter may be the best option. In most patients receiving long-term anticoagulation for VTE, preoperative heparin is not typically used; vitamin K antagonist should be discontinued for at least 4 days preoperatively to allow the INR to decrease gradually to less than 1.5, a level that is safe for surgery. Postoperatively, intravenous heparin (or SC LMWH) can be safely used for anticoagulation until therapeutic INR levels are reached after warfarin has been restarted. As with all guidelines, individual patient circumstances may dictate changes. For example, institution of heparin immediately after a major surgical procedure may be contraindicated because of the high risk for hemorrhage; reinstatement of anticoagulation may need to be delayed for 12 to 24 hours postoperatively.

INTRODUCTION

Cancer is a complex genetic disease that is defined by the transition of a normal cell, governed by processes that control its replication and behavior, into a cancer cell that is typified by unrestrained proliferation and dissemination, leading ultimately to a state of disease and/or death. The underlying landscape of cancer genetics is now fully defined for many cancers, aided by the evolving technologies in gene sequencing. Many therapeutic advances of the last decade have successfully focused on targets identified by the study of genetic mutations. Whereas genetic changes, usually acquired by cells over time, are at the ontologic core of cancer, many other patient factors affect its formation and the course of disease, including concurrent disease of the target organ, the immunologic response, and the underlying metabolic state. This chapter reviews the essential elements of cancer biology and key underlying genetic alterations driving this biology.

HALLMARKS OF CANCER

Cancer has many effects on the human body. This heterogeneity of clinical behaviors results from the various organs and tissues affected and the different ways in which cancers can alter normal physiologic function, and it is mirrored in the appearance of different cancers at the microscopic and genetic levels. Even among cancers originating from the same organ or cell type, there is wide diversity of behaviors. More than 100 types of cancer have been identified, and they are separated into categories based on the organ and tissue from which they arose and the histologic appearance. However, with further investigations into genetic subtypes of tumors, we may come to appreciate thousands of different diseases in years to come.

Despite the clinical, histologic, and genetic diversity of cancers, they tend to share common abilities and traits. Hanahan and Weinberg first defined the acquired capabilities that are essential for tumor growth in 2000 and then updated their conceptual framework for understanding cancer through the addition of “emerging hallmarks” and “enabling characteristics” (Table 53-1).

TABLE 53-1 THE CANCER PHENOTYPE

HALLMARKS OF CANCER	EMERGING HALLMARKS
Self-sufficiency in growth signals	Immune evasion
Insensitivity to anti-growth signals	Metabolic dysregulation
Evasion of apoptosis	ENABLING CHARACTERISTICS
Limitless replicative potential	Genomic instability
Induction of angiogenesis	Inflammation
Tissue invasion and metastasis	

Normal cellular division is controlled both by the restriction of growth and division signals to times of tissue injury and repair and by the presence of inhibitors of cell division and growth. In contrast, tumor cells universally are *self-sufficient in growth signals* and *insensitive to anti-growth signals*. *Resistance to apoptosis* (programmed cell death) also allows cancers to bypass another evolutionarily conserved mechanism that restrains cell survival. In addition, normal cells undergo only a set number of divisions, limiting their growth potential. Tumor cells, in contrast, are immortalized and have *limitless replicative potential*. Beyond factors inherent in the tumor cells themselves are two capabilities in the environment. *Angiogenesis*, or the establishment of a blood supply, provides tumors with the oxygen and nutrients needed to grow beyond a size of 1 to 2 mm. *Invasion and metastasis* allow tumor cells to escape their primary sites and establish colonies at new sites. Metastatic disease is the cause of death in more than 90% of cancer patients.

Recent research has redirected attention to areas of cancer biology that are important for cancer prevention and treatment. Emerging hallmarks include the *distinct metabolic requirements* of cancer cells, with a growing number of metabolic genes (e.g., *IDH1/2*, *FH*, and *SDHB*) identified as mutated in cancers. Also recognized as essential is the tumor’s capacity to *evade the body’s immune response*, which is reflected in the clinical efficacy of drugs targeting the immune-modulating molecule PD1.

Enabling characteristics of cancer include *genomic instability*, which is important for the development of cancers as well for the resistance to treatments that can emerge during systemic therapy. Tumor-promoting inflammation probably accounts for the stepwise progression of tumors and may sustain cancers by providing an inflammatory environment.

In many instances, identification of these hallmark cancer traits has led to novel therapeutic approaches. Examples include drugs that target growth-stimulating proteins and pathways by means of inhibitors developed against epidermal growth factor receptor (EGFR) in lung and colon cancer, HER2/neu (ERBB2) in breast cancer, and RAF and MEK in melanoma. Similarly, drugs that block angiogenesis (e.g., vascular endothelial growth factor [VEGF]) are now used in cancer therapy.

THE GENETICS OF CANCER

Cancers falls along a spectrum, ranging from minor genetic derangements in some malignancies (e.g., *BCR-ABL* translocation in chronic myelogenous leukemia [CML]) to a genetically complex, multistep process in others (e.g., in colon, pancreas, and breast cancer). A cell that is undergoing malignant transformation acquires a growth or survival advantage relative to normal

cells. Most invasive cancers develop only after multiple genes are mutated, and they seem to retain genetic flexibility or a mutator phenotype. Mutations can occur on exposure to environmental carcinogens, in the setting of dysregulated DNA repair, as a consequence of random replication errors during cell turnover and normal aging, or, occasionally, in families with hereditary germline mutations in a cancer gene. Mutations in cancer are classified into three categories depending on the functional consequence of the mutation: oncogenes, tumor suppressor genes, and stability or caretaker genes. However, there are newly discovered mutations that do not fall neatly into one of these categories. Table 53-2 shows the clinical consequences of selected mutations.

Oncogenes

Oncogene mutations convert a normal cell into a cancerous cell; they include chromosomal translocations, gene amplifications, and intragenic mutations. Oncogenes often activate pathways that are important for cancer. For example, CML occurs when the proto-oncogene *ABL* from chromosome 9 translocates to the *BCR* gene on chromosome 22. The new protein formed by expression of the combined gene *BCR-ABL* sends unchecked growth-promoting signals to the nucleus. An activating mutation in one allele of an oncogene is usually sufficient to promote tumorigenesis (e.g., in *KRAS*).

Because oncogenes activate pathways that drive cancer growth, their discovery has led to specifically designed drugs that target the products of these genes and the pathways they control. For example, among patients with breast cancer, HER2 amplification serves as a biomarker that identifies those who will

benefit from treatment with the anti-HER2 monoclonal antibody, trastuzumab. Similarly, activating mutations in EGFR serve to identify patients with non-small cell lung cancer who will improve with the use of drugs that specifically inhibit the mutated form of EGFR. Another example is BRAF mutations in melanoma. This paradigm—identify a mutated oncogene, find a specific drug that inhibits the activated mutant protein, and treat patients who have the specific mutation with a drug that affects the mutated protein—has repeatedly been proven to be a successful approach.

Tumor Suppressor Genes

Tumor suppressor genes control cellular replication and growth. Point mutations or deletions of tumor suppressor genes give cells harboring these mutations a growth advantage. Inactivation of tumor suppressor genes may lead to diminished activity of the protein product by several mechanisms: silencing or inactivating point mutations, large DNA deletions or rearrangements, or methylation and chromatin remodeling of the regions harboring the gene. In contrast to oncogene activation, inactivation of both alleles of a tumor suppressor gene is required for tumorigenesis. For instance, an inherited mutation in a single retinoblastoma gene (*RBI*, a tumor suppressor gene) may not, by itself, cause retinoblastoma in a young child. However, a “second hit” after birth (i.e., an *RBI* somatic mutation) can result in multiple tumors including bilateral retinoblastomas. The tumor suppressor gene *TP53* is the most commonly mutated gene in sporadic human cancers. Deletion of this gene can be inherited, and families with inherited mutations have higher rates of a variety of cancers, including breast and brain tumors, leukemia, and sarcoma, a pattern termed the *Li-Fraumeni syndrome*.

TABLE 53-2 CANCERS ASSOCIATED WITH SELECTED GENETIC MUTATIONS

GENE	ASSOCIATED HEREDITARY SYNDROME	MAJOR TUMOR TYPES
ONCOGENES		
<i>KRAS</i>	—	Pancreatic, lung, bladder, and colon cancers
<i>BCR-ABL</i> translocation	—	Chronic myelogenous leukemia
<i>BCL2</i>	—	Chronic lymphocytic leukemia
<i>KIT, PDGFRA</i>	Familial gastrointestinal stromal tumors	Gastrointestinal stromal tumors
TUMOR SUPPRESSOR GENES		
<i>TP53 (p53)</i>	Li-Fraumeni syndrome	Breast, sarcoma, adrenal, brain, multiple others
<i>APC</i>	Familial adenomatous polyposis	Colon, stomach, intestine
<i>VHL</i>	Von Hippel-Lindau syndrome	Kidney
<i>SMAD4</i>	Juvenile polyposis/hereditary hemorrhagic telangiectasia syndrome	Colon, gastric, and pancreatic cancer
<i>CDKN2A (p16)</i>	Familial atypical multiple mole melanoma syndrome	Melanoma, pancreatic adenocarcinoma, non-small cell lung cancer
STABILITY GENES		
<i>BRCA1, BRCA2</i>	Hereditary breast cancer	Breast, ovary
<i>MSH2, MLH1</i>	Lynch syndrome	Colon, uterus, stomach

Stability Genes

Mutations in stability or caretaker genes can also promote tumorigenesis. These genes are responsible for the repair of errors in normal DNA replication. They include mismatch repair genes, base-excision repair genes, and nucleotide-excision repair genes. Mutations in stability genes lead to increased errors in DNA replication. Eventually, DNA replication errors (mutations) are introduced in oncogenes and tumor suppressor genes, resulting in malignant transformation. Lynch syndrome, also called hereditary nonpolyposis colon cancer, is an inherited syndrome of defects in DNA mismatch repair genes. Colon and endometrial cancers are commonly observed in families with this syndrome, and rates of many gastrointestinal cancers are also higher in these families.

THE ORIGINS OF CANCER

Steps Toward Cancer

Many malignancies, including colon, breast, pancreas, and liver cancers, develop in a stepwise progression from normal to cancerous cells that is driven by a cascade of genetic events. This model was first articulated in colon cancer, where precancerous polyps were found to harbor some of the same mutations found in advanced cancers. This type of progression provides the genetic and biologic basis for the efficacy of many cancer screening and prevention programs that focus on identifying

and treating preneoplastic lesions to prevent progression to malignancy. Well-known examples of such approaches include colonoscopy for colon cancer and Papanicolaou (Pap) smears for cervical cancer.

Cancer Stem Cells

The concept of cancer stem cells has gained traction in some malignancies. Observations of a hierarchy of cells within a malignancy, wherein some cells retain a proliferative self-renewing capacity and others do not, support this concept. These populations of cells may be responsible for treatment resistance.

Cancer Epidemiology

Gary H. Lyman and Nicole M. Kuderer

INTRODUCTION

Globally, more than 11 million individuals are diagnosed with cancer and some 7 million die from the disease annually. At the same time, it is estimated that there are more than 22 million cancer survivors worldwide, and their number is increasing dramatically each year. In the United States in 2014, it was estimated that 1.7 million individuals would be diagnosed with cancer, for an age-adjusted incidence rate of 470 per 100,000 population. At the same time, it was estimated that more than 585,000 individuals would die of cancer, for an age-adjusted death rate of 176 per 100,000. Cancer is the leading cause of mortality among both women and men between the ages of 40 and 80 years, and it is the second leading cause of death for most other age groups, including children between 1 and 14 years of age.

The leading types of new invasive cancer cases and cancer-specific deaths are shown in [Figure 54-1](#). Although breast cancer in women and prostate cancer in men are the most common noncutaneous forms of cancer, lung cancer is now the leading cause of cancer-specific mortality, accounting for almost 30% of cancer deaths in both genders. Mortality rates for gastric and cervical cancers have decreased steadily for decades, and overall cancer death rates have decreased some 20% since their height in the early 1990s, with the greatest declines observed for colorectal, prostate, and lung cancers in men and colorectal and breast cancer in women ([Fig. 54-2](#)). Death rates over the last decade have also declined by more than 8% for chronic myeloid leukemia and more than 3% for non-Hodgkin's lymphoma. Cancer mortality rates in developed countries are consistently higher among those from racial and ethnic minority groups, especially African Americans in the United States, and among those from lower socioeconomic strata. Greater mortality rates among racial and ethnic minorities are not fully explained by differences in the stage at diagnosis. Socioeconomic factors, access to appropriate treatment, and comorbidities represent additional determinants of greater cancer mortality.

CANCER EPIDEMIOLOGY METHODS

Epidemiologists study disease variation among populations and the factors that influence such variation. The proportion of individuals with disease in the population at a given point in time is the *prevalence*. *Incidence and mortality rates* represent the number of events in a population over a defined period of time (e.g., cancers per 100,000 per year). To facilitate comparisons among populations, rates are often adjusted for age, sex, race, or other demographic characteristics.

The association between a characteristic or exposure and cancer risk is typically assessed in either cohort or case-control studies. Cohort studies are usually prospective and evaluate disease experience in exposed and unexposed individuals. Case-control studies assess the exposure experience of individuals with and without the disease of interest. The *relative risk* (RR) is a measure of association between exposure and disease, with estimates greater than 1.0 representing an increase in risk. In case-control studies, RR is estimated by the *odds ratio* (OR), because the sizes of the exposed and unexposed populations are often not known. The larger the study population, the more precise is the estimate of association between exposure and disease. However, proper interpretation of the results must explore whether any systematic error or bias was introduced during the study design or analysis.

Confounding factors may obscure or weaken a true association or create a false association (i.e., because of an association between the factor itself and both exposure and disease). Confounding can be evaluated and adjusted for in stratified or multivariate analysis if the potential confounder is recognized and has been properly measured in the data. It is usually not safe to assume that all possible confounding factors have been considered. Therefore, causal inference is seldom justified on the basis of a single study but evolves gradually with study repetition and consideration of other information, including results from animal and other laboratory findings, the strength of the association, and a careful consideration of likely confounding factors.

Interventions for cancer prevention and screening are typically studied in randomized controlled trials that require large numbers of participants, close monitoring for adherence to the intervention, long-term follow-up, and appropriate ascertainment of disease and disease-free status.

RISK FACTORS

Genetic

Risk factors for cancer can be grouped as either genetic (inherited) or acquired. Although they are important for understanding carcinogenesis, only a small proportion of cancers are inherited in a mendelian fashion. Neoplasms inherited in an autosomal dominant manner include retinoblastomas, multiple endocrine neoplasia syndromes, and polyposis coli. Several additional preneoplastic conditions demonstrate mendelian inheritance with variable penetrance. Some common malignancies demonstrate familial risk patterns with low penetrance, including breast cancer and colorectal cancer. Genetic testing and potential preventive measures are available for some inherited cancer syndromes

Estimated New Cases

			Males	Females			
Prostate	238,590	28%			Breast	232,340	29%
Lung and bronchus	118,080	14%			Lung and bronchus	110,110	14%
Colorectum	73,680	9%			Colorectum	69,140	9%
Urinary bladder	54,610	6%			Uterine corpus	49,560	6%
Melanoma of the skin	45,060	5%			Thyroid	45,310	6%
Kidney and renal pelvis	40,430	5%			Non-Hodgkin lymphoma	32,140	4%
Non-Hodgkin lymphoma	37,600	4%			Melanoma of the skin	31,630	4%
Oral cavity and pharynx	29,620	3%			Kidney and renal pelvis	24,720	3%
Leukemia	27,880	3%			Pancreas	22,480	3%
Pancreas	22,740	3%			Ovary	22,240	3%
All Sites	854,790	100%			All Sites	805,500	100%

Estimated Deaths

			Males	Females			
Lung and bronchus	87,260	28%			Lung and bronchus	72,220	26%
Prostate	29,720	10%			Breast	39,620	14%
Colorectum	26,300	9%			Colorectum	24,530	9%
Pancreas	19,480	6%			Pancreas	18,980	7%
Liver and intrahepatic bile duct	14,890	5%			Ovary	14,030	5%
Leukemia	13,660	4%			Leukemia	10,060	4%
Esophagus	12,220	4%			Non-Hodgkin lymphoma	8,430	3%
Urinary bladder	10,820	4%			Uterine corpus	8,190	3%
Non-Hodgkin lymphoma	10,590	3%			Liver and intrahepatic bile duct	6,780	2%
Kidney and renal pelvis	8,780	3%			Brain and other nervous system	6,150	2%
All Sites	306,920	100%			All Sites	273,430	100%

FIGURE 54-1 U.S. cancer statistics, 2013: estimated new cases and deaths. Estimates are rounded to the nearest 10 and exclude basal cell and squamous cell skin cancers and in situ carcinoma except urinary bladder. (Modified from Siegel R, Naishadham D, Jemal A: Cancer statistics, 2013. CA Cancer J Clin 63:11–30, 2013 [Figure 1]. Available at <http://onlinelibrary.wiley.com/doi/10.3322/caac.21166/full#fig1>. Accessed June 27, 2014.)

(Table 54-1). Although genetic testing is available for several identified cancer susceptibility genes, care must be taken in selecting individuals for such testing. Genetic testing requires a reasonable understanding of cancer genetics as well as the target population along with relevant ethical, economic, and societal issues.

Acquired somatic mutations are universally identified in malignant cells, and some clearly drive the development and progression of cancer. Although random genetic mutations occur frequently, proto-oncogenes involved in cell growth and proliferation, tumor suppressor genes involved in regulation of cellular proliferation, and mismatch repair genes associated with chromosomal instability play critical roles in carcinogenesis, tumor growth, progression, invasion, and metastasis. Because the spontaneous mutation rate is relatively low, more than one mutational event is usually necessary for complete carcinogenic transformation resulting in a malignancy.

Lifestyle

Acquired risk factors for cancer include lifestyle factors as well as occupational and other environmental exposures to carcinogenic substances. Major lifestyle risk factors include tobacco, alcohol and other dietary factors, and lack of physical activity (Table 54-2).

Tobacco

Tobacco products are, by far, the single greatest contributor to cancer incidence and mortality worldwide. Cigarette smokers have a 20-fold or greater risk for developing cancer compared with nonsmokers, and smoking is the single largest cause of lung cancer. Tobacco accounts for one third of all cancers in the United States. Worldwide, more than 1 million people are estimated to die from tobacco-induced cancers every year. The vast majority of lung cancers are attributable to cigarette smoking, and exposure to secondhand smoke increases the risk for lung cancer

FIGURE 54-2 U.S. cancer mortality rates, 1930-2009. (Modified from Siegel R, Naishadham D, Jemal A: Cancer statistics, 2013. CA Cancer J Clin 63:11-30, 2013 [Figures 4 and 5]. Available at <http://onlinelibrary.wiley.com/doi/10.3322/caac.21166/full#fig1>. Accessed June 27, 2014.)

in nonsmokers. Cigarette and cigar smoking and tobacco chewing are major risk factors for head, neck, mouth, and esophageal cancers. Although tobacco use has declined in the United States over the last 2 decades, it remains unacceptably high, especially among younger women, and continues to increase in many parts of the developing world.

Nutrition

Diet and body weight appear to play an important role in cancer causation. Excess alcohol use is clearly a significant risk factor for cancers of the liver, head and neck, esophagus, and breast. Obesity and dietary fat intake are associated with colon and breast cancers, but the exact nature of the relationship is still

under investigation. Central or visceral adiposity in both men and women is associated with increased incidence and mortality from a number of cancers, including those of the endometrium, breast (in postmenopausal women), kidney, gallbladder, pancreas, esophagus, colon, and prostate.

Infection

Several chronic infections have been associated with an increased risk of different types of cancer, including bacterial, viral, and parasitic infections. In certain parts of the developing world, infection with *Schistosoma haematobium* is a major cause of squamous cell carcinoma of the bladder. Viruses associated with human malignancies include the Epstein-Barr virus (EBV,

TABLE 54-1 GENETIC TESTING FOR SELECTED HEREDITARY CANCER SYNDROMES

TYPE OF CANCER AND INVOLVED GENES	PREVENTION MEASURES
BREAST	
<i>BRCA1, BRCA2</i> <i>PTEN, STK11, TP53</i>	Prophylactic mastectomy Selective estrogen receptor modulators Lifestyle measures Increased intensity of screening, including breast MRI
LOBULAR BREAST CANCER AND GASTRIC CANCER

MRI, Magnetic resonance imaging; MYH, mutY homologue; NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 54-2 CANCER RISK FACTORS

LIFESTYLE FACTOR	ASSOCIATED CANCERS
Tobacco	Lung, bronchus, esophagus, head and neck, stomach, pancreas, kidney, bladder, cervix
High alcohol consumption	Liver, rectum, breast, oral cavity, pharynx, larynx, esophagus
Obesity, high dietary fat	Colon, breast, endometrium, kidney, pancreas, esophagus, prostate
Low dietary fiber	Colon
Sedentary lifestyle	Colon, breast
Environmental exposures	
Human papillomavirus: types 16, 18	Cervical
Hepatitis B and C viruses	Liver and hepatocellular cancers
Asbestos	Mesothelioma and other types of lung cancer
Radon	Lung
Ultraviolet radiation	Melanoma, basal and squamous cell carcinomas
Ionizing radiation	Leukemia, thyroid, lung, breast

with nasopharyngeal cancer and Burkitt's lymphoma) and human T-cell leukemia virus type I (HTLV-I). Patients with the acquired immunodeficiency syndrome, which is associated with the human immunodeficiency virus (HIV), are at increased risk for Kaposi's sarcoma, non-Hodgkin's lymphoma, and

anogenital squamous cell carcinoma. Chronic hepatitis B and C viral infections have been linked with the development of hepatocellular carcinoma. Human papillomaviruses 16 and 18 have been linked with cervical cancer, and vaccines against these virus strains and those causing genital warts are now on the market.

Radiation

Non-ionizing Radiation

Ultraviolet (UV) radiation is unquestionably associated with an increase risk of skin cancers, including basal and squamous cell carcinomas as well as cutaneous melanoma, with observed rates increasing directly with the amount of daily sunlight exposure. Most of the harmful effects from sun exposure are related to direct DNA damage associated with exposure to intermediate-wavelength UVB. The use of tanning beds and frequent exposure to sunlight are of particular concern given the rapid increase in rates of melanoma among younger individuals.

Ionizing Radiation

Ionizing radiation is an extensively studied carcinogen; it is unequivocally associated with an increased risk for both hematologic malignancies and various solid tumors in humans. Radiation-induced malignancies including leukemia and solid tumors have been most extensively studied in occupational settings among radiation workers and miners, among survivors of the atomic weapons used in Hiroshima and Nagasaki in World War II, and among those exposed to radiation for medical indications. Excess cancer risk from radiation exposure has a latency period ranging from a few years (leukemia) to decades (solid tumors) and correlates with the cumulative exposure dose. As the survivors of the atomic bombing of Japan age, estimates of the associated risk of cancer have continued to increase.

Natural sources account for at least 80% of human exposure to radiation, most notably from radon. Radon exposure is estimated to be the second leading cause of lung cancer due to widespread low-level exposure in the residential setting. In the occupational setting, there is a strong interaction between smoking and radon, such that most radon-induced lung cancers occur among smokers. Medical exposure accounts for most of the remaining average annual radiation exposure in the United States. Repeated exposure to radiation from multiple imaging studies (e.g., CT scans), especially at a young age, is associated with an increased risk of cancer later in life.

Chemicals

Various pharmacologic agents have been associated with an increased risk for specific cancers. As with radiation, these agents may be used in the occupational setting, for diagnostic or therapeutic medical use, and for various purposes in the home setting. Organic and inorganic chemical compounds linked to human cancers include benzene (leukemia), benzidine (bladder), arsenic, soot and coal tars (lung and skin), and wood dusts (nasal). Arguably, asbestos is the most common cause of occupational cancer because of its link with the development of mesothelioma and other types of lung cancer. Almost all mesotheliomas diagnosed in the United States are associated with prior asbestos

exposure. A strong interaction exists between asbestos exposure and cigarette smoking leading to lung cancer.

A range of medications are associated with increased cancer risk, including the alkylating agents, anthracyclines, and other classes of cancer chemotherapy agents and immunosuppressants. Estrogen use in postmenopausal women increases the risk of endometrial cancer; the rates drop when estrogen is combined with progesterone. Synthetic estrogens, such as diethylstilbestrol (DES), administered to mothers during pregnancy increase the risk of vaginal cancer in offspring. Lifestyle exposures to carcinogenic chemicals include multiple carcinogens in tobacco products and dietary factors, including aflatoxins, in many parts of the world.

CANCER PREVENTION

Cancer prevention strategies are either primary or secondary based on whether they reduce risk of exposure or detect cancer at an early stage when intervention can change the natural history of the disease. Primary prevention strategies include reductions in lifestyle risks (e.g., smoking cessation; use of sunscreen; adherence to a low-fat, high-fiber diet), avoidance of occupational or environmental risks, and chemoprevention (see Table 54-2).

Lifestyle Changes

Smoking cessation is unquestionably the most direct and effective cancer prevention strategy available. More than 1 million people die from tobacco-induced cancers globally each year, and tobacco accounts for one third of all cancer diagnoses in the United States. Although tobacco prevention and control programs have resulted in a decline in smoking prevalence in the United States, tobacco use continues to be high and has been increasing in a number of countries. There is also evidence from epidemiologic studies that other lifestyle changes, including regular exercise and dietary modification, may also reduce the risk of cancer. Central adiposity is associated with increased incidence of and mortality from a number of cancers, including breast and endometrial cancers. Sufficient dietary intake of fruits and vegetables appears to reduce the risk for gastric and esophageal cancers. Avoidance of excessive sun exposure and artificial tanning devices may reverse the recent upward trend in cutaneous malignancies. Reduction in exposures to known carcinogenic agents is an important goal in both occupational and domestic settings. Evidence for an association between air pollution and lung cancer incidence illustrates how difficult such reductions may be. However, limiting the use of potentially carcinogenic chemicals and of radiation in the medical setting is sensible.

Chemoprevention

Chemopreventive agents are drugs, vaccines, or micronutrients (e.g., minerals, vitamins) that prevent the development of cancer. Both randomized trials and epidemiologic studies suggest that a number of strategies can reduce the risk of some common types of cancer. Daily aspirin use may reduce the risks of colon cancer and melanoma. Hepatitis B vaccination may reduce the incidence of hepatocellular cancer. The vaccine directed against specific strains of the human papillomavirus (HPV) promises to prevent cervical cancer.

CANCER SCREENING

Cancer screening programs should detect premalignant states or early-stage cancers before the onset of symptoms with relatively high sensitivity. For cancer screening to be useful, there must be a treatment available that improves the outcome for patients with premalignant or early-stage disease. Ideally, such screening programs should also be noninvasive, inexpensive, and associated with high specificity (i.e., low rate of false-positive results). Identification of high-risk individuals assists in genetic counseling and testing as well as in cancer screening efforts.

Proper interpretation of the results of cancer screening studies must consider both *lead-time bias* and *length-time bias*. Lead time is the time between detection of disease by screening and the actual appearance of symptomatic disease. If screening leads to early diagnosis, it may appear that the patient lived longer than would have been the case without screening even when the survival of the patient from the onset of disease has not been altered. Length-time bias occurs when subsets of the cancer under study have different growth rates. Screening is more likely to detect cancers that grow slowly because of the greater prevalence of asymptomatic people with slow-growing tumors than those with fast-growing tumors. Patients with cancer that is detected by screening may appear to have longer survival times as a result of screening when in fact the longer course of their disease results from the behavior of the tumor itself. Although randomized controlled trials of cancer screening programs require large numbers of participants and take years to complete, such trials are needed to quantitate the value of screening and to address both lead-time and length-time bias.

Screening tests may also be associated with false-negative and false-positive results. False-negative results fail to identify a proper diagnosis and patients therefore are not provided the opportunity for effective early treatment. False-positive results may also cause harm by leading to unnecessary testing and treatment and by contributing to patient costs and emotional stress.

Currently, recommended cancer screening tests include clinical examination and mammography to detect breast cancer, Papanicolaou smears and HPV DNA tests to detect cervical dysplasia or cancer, colonoscopy to detect polyps or colon cancer, and digital rectal examination and serum prostate-specific antigen (PSA) measurement to detect prostate cancer. Although issues remain to be resolved, low-dose computed tomographic scanning to screen appropriate high-risk individuals for lung cancer has recently been recommended based on results from the National Lung Cancer Screening Trial.

Principles of Cancer Therapy

Davendra P.S. Sohal and Alok A. Khorana

INTRODUCTION

The treatment of cancer is evolving rapidly. Chemotherapy is the mainstay of systemic treatment, but the explosive increase in knowledge of cancer biology has allowed research efforts to focus on the development of more specific “targeted” agents. The annual number of new drugs approved for cancer treatment has increased several-fold since the 1990s. In addition, almost 400 anticancer agents are in clinical trials, more than for any other class of medicine. Surgery and radiation therapy are safe and effective treatments for localized cancers, and techniques continue to be refined. However, cancer remains the second leading cause of death in the United States, requiring that resources be devoted to palliative care as well. The treatment of cancer requires various specialists, including surgeons and medical and radiation oncologists, to work in an integrated fashion to deliver optimal care to the patient. This chapter reviews the principles of surgical, radiation, and medical approaches to cancer treatment; it also considers diagnosis and staging as well as supportive care interventions that are integral to the care of patients with cancer.

DIAGNOSIS AND STAGING

Definitive treatment for cancer usually requires an adequate histologic diagnosis. This typically involves performance of an invasive biopsy to obtain sufficient material to evaluate the morphology and invasiveness of the tumor and the expression of various molecular markers. Noninvasive tests such as radiologic imaging are seldom substitutes for tissue diagnosis. There are some exceptions, such as an elevated α -fetoprotein level along with imaging evidence, which can be used to make a diagnosis of hepatocellular carcinoma.

Once the diagnosis of cancer has been made, the next step is to systematically determine the extent of tumor spread, a process called *staging*. Tumor staging can be clinical or pathologic. *Clinical staging* involves physical examination and imaging studies, including targeted ultrasound, computed tomography scans, magnetic resonance imaging, whole-body positron-emission tomography scans, radionuclide scans, or a combination thereof. The choice of studies for particular tumors depends on their propensity to spread to particular organs. *Pathologic staging* is more definitive and follows the tumor-node-metastasis (TNM) method developed by the American Joint Committee on Cancer and the International Union against Cancer. This system requires a careful evaluation of the primary resection specimen for three measurements: (1) the size and extent of invasion of the primary tumor (the T score), (2) the number and location of histologically involved regional lymph nodes (the N score), and (3) the

presence or absence of distant metastases (the M score). The M score is based on information derived from both clinical and pathologic staging. TNM scores are then grouped into a pathologic stage, from I through IV, reflecting an increasing burden of disease. The final TNM stage has both prognostic and therapeutic implications. For instance, a resected colon cancer that invades the muscularis propria, involves 2 of 16 lymph nodes, but shows no evidence of distant metastases is staged as a T2 N1 M0 (stage III) colon cancer. The likelihood of tumor recurrence is 40% to 50%; a patient receives 6 months of chemotherapy after surgery. On the other hand, if no lymph nodes are involved (T2 N0 M0, stage I), the likelihood of recurrence is less than 10%, and chemotherapy is not recommended.

Biomarkers provide additional prognostic information, such as the absence of hormone receptors or expression of HER2 in breast cancer, which are indicative of a poor prognosis. Such markers can also be predictive; for instance, overexpression of HER2 in breast cancer predicts response to trastuzumab. Similarly, *KRAS* mutations in colorectal cancer predict lack of response to antibodies (e.g., cetuximab, panitumumab) that are directed against the epidermal growth factor receptor (EGFR). Both prognostic and predictive biomarkers provide important information in addition to the formal TNM stage. Gene expression signatures also provide additional prognostic or predictive information. A 21-gene signature is commonly used for clinical decision making regarding adjuvant therapy in patients with certain estrogen receptor–positive breast cancers. For certain tumors, measurement of serum levels of tumor markers (e.g., carcinoembryonic antigen in colon cancer, α -fetoprotein in testicular and liver cancers) can also be of prognostic importance. All of this information is compiled into a final assessment of whether the cancer is curable or not.

The next step is to evaluate the patient’s overall clinical condition with respect to comorbidities affecting major organ function and the patient’s functional ability, termed *performance status*. Performance status is assessed with the use of various history-based methods, such as the Eastern Cooperative Oncology Group or Karnofsky performance score. Patients with poor performance status or major comorbid conditions may not derive a benefit from cancer-directed therapy and are at greater risk for adverse events. This comprehensive assessment—diagnosis, stage, prognostic and predictive markers, and patient condition—dictates the management plan: either curative or palliative.

PRINCIPLES OF CANCER SURGERY

Surgery can prevent cancer by removal of precancerous lesions or organs that are at high risk for cancer (e.g., bilateral

mastectomy in those with hereditary defects that can lead to breast cancer). Surgery can also make the diagnosis of cancer by biopsy; assist in staging by sampling lymph nodes; provide definitive treatment by removing the primary tumor; reconstruct the limb or organ sacrificed; and provide palliative treatment of cancer (e.g., intestinal bypass for obstruction, spinal cord decompression, or orthopedic procedures to prevent or treat pathologic fractures). Invasive procedures, such as biopsies and the insertion of various access devices, tubes, stents, catheters, and drains, are also performed by interventional specialists, including radiologists, gastroenterologists, and pulmonologists.

When a solid organ cancer is localized, surgery is the most effective curative treatment available. The intent is to completely remove the tumor, regional lymph nodes, and adjacent involved tissue, along with a safe margin of normal tissue. At surgery, the tumor is isolated and is almost never opened during the procedure. Refinements in cancer surgery include increasing use of laparoscopic procedures in selected cancers and the identification of a sentinel lymph node by injection of a dye during surgery, which avoids a full lymph node dissection if the sentinel node is uninvolved by cancer.

PRINCIPLES OF RADIATION THERAPY

Many cancer patients receive radiation therapy at some point during the course of their disease. Radiation therapy can sometimes be used as definitive treatment, either alone or in combination with chemotherapy. Unlike surgery, local or regional treatment with radiation can preserve organ structure and function, improving quality of life for patients. For example, use of radiation with chemotherapy for treatment of localized laryngeal cancer has outcomes similar to those of surgery but allows preservation of the larynx. Radiation therapy is also effective in the palliative setting, where it is used to control various cancer-related problems such as pain, dysphagia, and bleeding.

Ionizing radiation damages cellular DNA directly or indirectly through free radical intermediates. Cells are most susceptible to radiation during the M and G₂ phases of the cell cycle. The aim of radiation therapy is to deliver the highest dose possible to the tumor with minimal toxicity to adjacent normal tissues. Dividing the total planned radiation dose into small daily fractions takes advantage of the difference in repair capability between normal and malignant tissue and improves the tolerance of normal tissue. The biologic effects of radiation can be modified by numerous factors, including the amount of oxygen in the irradiated tissue and the use of chemotherapy for sensitizing tissue to radiation.

The goal of treatment planning for radiation therapy is to precisely define the dose and volume to be irradiated. The dose of radiation is measured in units of absorbed dose, Gray (Gy), which has replaced the older unit, rad (1 Gy = 100 rad). Conventional radiation treatments deliver 1.8 to 2 Gy/day on 5 days per week, over a period of 5 to 6 weeks. For palliative treatment, higher doses per fraction may be used to deliver an effective dose over a shorter period.

Ionizing radiation can be administered as external-beam therapy with the use of a linear accelerator to generate electrons or high-energy x-rays. Electrons have a limited depth of penetration and are useful for superficial tumors. High-energy x-rays

TABLE 55-1 ACUTE AND LATE EFFECTS OF RADIATION THERAPY

ORGAN	ACUTE	LATE	DOSE (GY) ASSOCIATED WITH ADVERSE EFFECTS
Bone marrow	Aplasia	Leukemia, myelodysplasia	25
Spinal cord	None	Myelopathy	45
Heart	None	Pericarditis, cardiomyopathy, coronary artery disease	45
Rectum	Diarrhea, tenesmus	Stricture, obstruction	60
Eye	Conjunctivitis	Retinopathy	55
Lung	Pneumonitis	Chronic pneumonitis	25

deliver the radiation deep into the body while reducing the dose to the skin as they enter. Brachytherapy uses radioactive sources to deliver ionizing radiation (gamma rays) directly to the tumor. An example is the implantation of iodine-125 seeds into the prostate as definitive therapy for early prostate cancer. Current approaches to improving radiation therapy include the use of advanced technology that allows delivery of a higher dose of radiation to specific areas of the tumor and sparing of normal tissue (conformal and intensity-modulated radiation therapy).

Injury to normal tissue from radiation therapy can be either acute or late (Table 55-1). Acute effects occur within days to weeks after irradiation and are seen primarily in rapidly proliferating tissues such as skin and gastrointestinal mucosa. The severity depends on the total dose, but the damage can usually be repaired. Late effects, such as necrosis, fibrosis, or organ failure, appear months or years after irradiation and are dependent on fraction size. Another late complication of radiation therapy is the development of secondary malignancies (e.g., after radiation for breast cancer or Hodgkin's disease).

PRINCIPLES OF MEDICAL THERAPY

The term *chemotherapy* refers to the use of cytotoxic agents, singly or in combination, for the systemic treatment of cancer. Most such agents are general antiproliferative agents that are more effective against rapidly growing tumors and have significant adverse effects on normal tissues that also divide rapidly, such as bone marrow and digestive tract mucosa. Newer agents, including monoclonal antibodies and signal transduction inhibitors, are directed against targets that are relatively specific to tumor cells and therefore may have less toxicity. These drugs are classified separately from chemotherapy as *targeted therapy* agents.

Mechanisms of Chemotherapy

Chemotherapeutic agents can be cell cycle specific or cell cycle nonspecific. Cell cycle–nonspecific agents have a greater effect on cells traversing the cell cycle but also affect noncycling cells; cell cycle–specific agents affect only cycling cells. Chemotherapy agents are further classified according to their mechanism of action into alkylating agents, antimetabolites, antitumor antibiotics, and mitotic spindle inhibitors (Table 55-2). Most chemotherapy agents suppress the bone marrow, leading to infections

TABLE 55-2 COMMONLY USED CHEMOTHERAPY AGENTS

DRUG	CANCERS TREATED	SPECIFIC CLASS OR MECHANISM OF ACTION	COMMON SIDE EFFECTS
CELL CYCLE SPECIFIC			
5-Fluorouracil	Gastrointestinal, head and neck, breast	Antimetabolite, inhibits thymidylate synthase	Myelosuppression, mucositis, diarrhea
Gemcitabine	Pancreas, lung, breast, bladder	Antimetabolite, deoxycytidine analogue	Myelosuppression, nausea, emesis
Methotrexate	ALL, choriocarcinoma, bladder, lymphoma	Antimetabolite, folic acid antagonist	Myelosuppression, mucositis, acute renal failure
Doxorubicin	Breast, lung, NHL	Anthracycline, intercalates into DNA	Myelosuppression, nausea, emesis, cardiomyopathy
Irinotecan	Colorectal, lung	Camptothecin, topoisomerase I inhibitor	Myelosuppression, diarrhea
Paclitaxel	Breast, lung, Kaposi sarcoma, ovarian	Plant alkaloid, inhibits microtubule formation	Myelosuppression, hypersensitivity reaction, neuropathy
Vincristine	ALL, lymphomas, myeloma, sarcoma	Plant alkaloid, disrupts microtubule assembly	Peripheral neuropathy, constipation
CELL CYCLE NONSPECIFIC			
Cyclophosphamide	Breast, NHL, CLL, sarcoma	Alkylating agent, cross-links DNA	Myelosuppression, hemorrhagic cystitis, nausea, emesis
Cisplatin	Lung, bladder, ovarian, testicular, head and neck	Alkylating agent, cross-links DNA	Nephrotoxicity, nausea, emesis, ototoxicity, sensory neuropathy

ALL, Acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; NHL, non-Hodgkin's lymphoma.

from neutropenia and life-threatening bleeding from thrombocytopenia. For most drugs, treatment schedules give successive doses every 2 to 4 weeks. This interval between successive doses, the *cycle* of chemotherapy, allows recovery of blood counts and other side effects before administration of the next dose. The concept of *dose intensity* is also important. Cellular killing with chemotherapy follows first-order kinetics: A given dose of drug kills only a fraction of tumor cells. The dose-response curve for chemotherapy drugs is steep. Therefore, the greater the dose administered, the greater the kill: A 2-fold increase in dose can lead to a 10-fold increase in tumor cell kill. This also means that dose reductions may adversely affect the eventual cure rate. Arbitrary reductions in doses of chemotherapy to spare patients toxicity should be avoided. Shortening of the duration of cycles of chemotherapy using growth factor support—a “dose-dense” approach—has been shown to improve survival in selected patients when compared with traditional chemotherapy for breast cancer.

Single chemotherapy agents seldom cure cancer. Combination chemotherapy regimens have therefore been developed for a variety of cancers. Combination therapy provides maximal cell kill and broader coverage of resistant cells; it may also prevent or slow the development of resistant cells. Drugs used in a combination are chosen because they have known efficacy as single agents but have differing mechanisms of action and non-overlapping toxicity profiles. These regimens are commonly referred to by acronyms, such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) for lymphoma or FOLFOX (5-fluorouracil, leucovorin, and oxaliplatin) for colorectal cancer.

Indications for Chemotherapy

Chemotherapy for localized or advanced cancers is summarized in (Table 55-3). *Adjuvant* chemotherapy refers to its use after the primary tumor has been resected. Here, chemotherapy is directed against presumed systemic micrometastases in patients who are at high risk for recurrence. In the example of stage III colon cancer (described earlier), 6 months of adjuvant

TABLE 55-3 EFFICACY OF MEDICAL THERAPY IN SELECTED CANCERS

CURE POSSIBLE IN ADVANCED SETTING

 Hepatocellular cancer
 Renal cancer
 Multiple myeloma

chemotherapy after colonic resection can reduce the patient's likelihood of developing recurrent cancer from 50% to 25%. Adjuvant chemotherapy has been shown to increase cure rates in other cancers.

Neoadjuvant or *preoperative* chemotherapy refers to the use of chemotherapy before surgery, sometimes in combination with radiation therapy. If successful, neoadjuvant therapy can reduce the size of the tumor and consequently permit less removal of normal tissue, such as a lumpectomy instead of a mastectomy in breast cancer or limb-sparing surgery instead of amputation in extremity sarcoma. In certain tumor sites, such as the larynx or the anal canal, neoadjuvant therapy can obliterate the tumor and avoid the need for surgery altogether.

Chemotherapy is most often employed in the treatment of metastatic disease for which surgery or radiation therapy is ineffective. Chemotherapy can sometimes be curative, (e.g., in certain lymphomas or testicular cancers). Even when it is not curative, chemotherapy often extends survival and improves cancer-related symptoms and quality of life.

Limitations of Chemotherapy

Chemotherapy is curative only under certain circumstances, because it is inherently limited by side effects (i.e., the dose ceiling). There are several reasons for the inability of standard doses of chemotherapy to cure cancer. First, tumor cell kinetics naturally protect against chemotherapy. When chemotherapy was initially developed, it was believed that tumors contained a percentage of cells traversing the cell cycle. However, most human tumors display Gompertzian growth kinetics—that is, the rate of tumor cell doubling *slows* progressively as tumor size increases. Therefore, the growth fraction of tumors is greatest when a tumor is clinically undetectable. By the time the patient is symptomatic and has clinically evident disease, the growth fraction of tumors can be less than 5%. Chemotherapy can be successful in the adjuvant setting (when the burden of disease is minimal), but it rarely results in cure in the metastatic setting.

Second, cancer cells can be resistant to chemotherapy. One of the most important forms of resistance is intrinsic and is mediated by an evolutionarily conserved cell membrane efflux pump called *P-glycoprotein*. Resistance can also be acquired after a period of exposure to chemotherapy agents by a variety of mechanisms; for example, tumor cells can decrease the uptake of methotrexate by decreasing the expression of the folate transporter, or they can amplify expression of the target enzyme thymidylate synthase when treated with 5-fluorouracil.

Third, mutations in the *TP53* gene are common in various cancers. The TP53 protein causes cell-cycle arrest and mediates apoptosis when DNA damage occurs. In the absence of a functioning TP53, cancer cells are protected from chemotherapy-induced apoptosis.

Stem Cell Transplantation

One way of overcoming the limitations of chemotherapy is to increase the dose given to patients. However, delivery of higher doses can lead to life-threatening complications as a result of bone marrow suppression and other end-organ damage. Stem cell transplantation is a procedure whereby patients are given myeloablative doses of chemotherapy (sometimes with radiation therapy) and then “rescued” with infusions of peripheral blood or bone marrow stem cells that reconstitute the ablated bone marrow. The source of stem cells can be the patients themselves (*autologous* transplantation) or a human leukocyte antigen-matched related or unrelated donor (*allogeneic* transplantation). Stem cell transplantation improves survival in selected patients with chronic myelogenous leukemia (CML), relapsed Hodgkin’s and non-Hodgkin’s lymphoma, refractory acute myelogenous leukemia, or multiple myeloma.

Allogeneic transplantations are more successful in inducing cures than autologous transplantations, owing to the immunologic response mounted by the donor cells, termed *graft-versus-tumor* effect. Newer approaches to stem cell transplantation take

advantage of this phenomenon by using lower, nonmyeloablative doses of chemotherapy and relying on the graft-versus-tumor effect to achieve tumor remissions. However, allogeneic transplantations can be offered only to a minority of patients because of the limited availability of matched donors (particularly in ethnic minority populations) and the inability of older patients and those with comorbid illnesses to tolerate this procedure. To increase the availability of donors, umbilical cord blood is being studied as a source of stem cells.

The complications of stem cell transplantation are primarily related to the toxicity of chemotherapy and radiation therapy to vital organs, including lungs and liver. Long-term morbidity and mortality after allogeneic transplantation can result from *graft-versus-host disease* and from complications of immunosuppressive agents used to treat it.

Endocrine Therapy

Cancers originating from tissues that are regulated by hormones, such as breast and prostate tissues, may be susceptible to hormonal control mechanisms even when metastatic. Endocrine therapy includes the use of both hormonal and anti-hormonal agents that work as antagonists or partial agonists.

Many patients with metastatic breast cancer express hormone receptors (estrogen or progesterone) in tumor cells. More than 60% of these patients respond either to tamoxifen, an estrogen receptor modulator, or to aromatase inhibitors (letrozole, anastrozole, or exemestane), which inhibit adrenal steroid production. Similar responses are observed in men with metastatic prostate cancer treated with the luteinizing hormone–releasing hormone agonists leuprolide or goserelin, which decrease testosterone to castrate levels.

In selected breast and prostate cancer patients, metastatic disease can be controlled for years with only endocrine therapy. Tamoxifen and the aromatase inhibitors are also highly effective adjuvant treatment after breast cancer resection. Furthermore, tamoxifen has been shown to reduce the incidence of breast cancer by 50% in healthy women who are at high risk for developing breast cancer.

Targeted Therapy

The limitations of chemotherapy, coupled with a greater understanding of cancer cell biology, have led to the development of a new class of drugs directed against targets that are relatively specific to cancer cells: growth factors and signaling molecules that are essential for proliferation of tumor cells; cell-cycle proteins; regulators of apoptosis; and molecules mediating host-tumor interactions such as angiogenesis and tumor immunity (Fig. 55-1). These agents include monoclonal antibodies directed against cell surface antigens or growth factors, specific or multi-targeted receptor tyrosine kinase inhibitors, specific pathway signal transduction inhibitors, antisense oligonucleotides, and gene therapies. Additional agents are under development. The usual side effects of chemotherapy, such as myelosuppression, nausea, emesis, diarrhea, and alopecia, are not observed with these drugs. However, other toxicities require careful monitoring and management (Table 55-4).

The best-known targeted therapy agent is imatinib, which inhibits both BCR-ABL, the constitutively active fusion product

FIGURE 55-1 The epidermal growth factor receptor (EGFR) pathway and related therapeutic targets. This figure depicts the transmembrane receptors of the EGFR family and the molecules involved in downstream signal transduction that ultimately lead to control of key proteins affecting cell survival, growth, and proliferation. Approved therapeutic agents targeting these molecules include cetuximab and panitumumab (EGFR); erlotinib and gefitinib (EGFR tyrosine kinases); trastuzumab, pertuzumab, and lapatinib (ERBB2); and sorafenib and vemurafenib (RAF). Several other agents are currently in clinical development, including those targeting P13K, AKT, MAPK, and ERBB3. HB-EBF, Heparin-binding EGF-like growth factor; IGF-IR, insulin-like growth factor-I receptor; NRGs, neuregulins; P, elemental phosphorus; RTKs, receptor tyrosine kinases; TNF- α , tumor necrosis factor- α . (Modified from Doebele RC, Oton AB, Peled N, et al: New strategies to overcome limitations of reversible EGFR tyrosine kinase inhibitor therapy in non-small cell lung cancer. *Lung Cancer* 69:1–12, 2010.)

arising from the Philadelphia chromosome of CML, and KIT (c-kit, CD117), which is overexpressed in gastrointestinal stromal tumors (GIST). The daily oral administration of imatinib results in complete hematologic responses in more than 90% of patients in chronic-phase CML and partial responses in more than 50% of patients with metastatic GIST. Although imatinib is a major advance, it is not considered curative in most patients. Cancer cells rapidly evolve to escape cell kill from targeted therapies by employing new mutations and redundant intracellular pathways. Multiple parallel clones evolve within a given tumor, and some are resistant to the targeted therapy. Drug resistance to imatinib occurs in the form of a mutation in the kinase domain of *ABL* that leads to poor binding of the drug.

The success of imatinib as a single agent is unlikely to be replicated in many other malignancies, in which multiple redundant signaling pathways are dysregulated. Increasingly, tyrosine kinase inhibitors with multiple (as opposed to specific) targets are being studied. Sorafenib and sunitinib are two examples of such agents that inhibit various pathways, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and KIT. Studies have shown these drugs to be effective in renal and liver cancers.

Targeted therapy drugs can increase the efficacy of chemotherapy through various mechanisms. For instance, bevacizumab, an anti-angiogenic agent directed against the pro-angiogenic VEGF, increases both response and survival rates when

**TABLE 55-4** COMMONLY USED TARGETED THERAPY AGENTS

DRUG	CANCERS TREATED	TARGETS	COMMON SIDE EFFECTS
MONOCLONAL ANTIBODIES			
Alemtuzumab	CLL	CD52	Myelosuppression, fever, rash
Bevacizumab	Colorectal, renal, lung	VEGF	Hypertension, proteinuria, bleeding, thromboembolism
Cetuximab	Colorectal	EGFR	Rash
Ipilimumab	Metastatic melanoma	CTLA4	Cytokine release storm
Ofatumumab	CLL	CD20	Rash, diarrhea, respiratory tract infections
Panitumumab	Colorectal	EGFR	Rash
Pertuzumab	Breast	HER2	Rash, diarrhea
Rituximab	NHL	CD20	Infusional reaction, skin reactions
Trastuzumab	Breast	HER2/Neu	Infusional reaction, congestive heart failure
SIGNAL TRANSDUCTION INHIBITORS			
Axitinib	Renal	VEGF, PDGF, KIT	Hypertension, hand-foot syndrome, diarrhea
Crizotinib	Lung	EML4-ALK	Edema, diarrhea
Dasatinib	CML	BCR-ABL	Myelosuppression, pleural effusions
Imatinib	CML, GIST	BCR-ABL	Diarrhea, fluid retention, myelosuppression
Erlotinib	Lung, pancreas	EGFR tyrosine kinase	Rash, diarrhea
Gefitinib	Lung	EGFR tyrosine kinase	Rash, hypertension
Lapatinib	Breast	HER2, EGFR	Rash, diarrhea
Regorafenib	GIST, colorectal	VEGF	Hypertension, hepatotoxicity, dysphonia
Sunitinib	Renal, GIST	VEGF, PDGF, KIT	Rash, diarrhea, fatigue
Sorafenib	Liver, renal	VEGF, PDGF, KIT	Hypertension, fatigue, diarrhea, hand-foot syndrome
Vandetanib	Medullary thyroid	VEGF, EGFR, RET	Rash, abdominal pain, diarrhea
Vemurafenib	Melanoma	BRAF	Rash, skin lesions, arthralgia
OTHERS			
All- <i>trans</i> -retinoic-acid	Acute promyelocytic leukemia	Differentiating agent	Vitamin A toxicity, retinoic acid syndrome, hyperlipidemia
Azacitidine	Myelodysplasia	Hypomethylating agent	Myelosuppression, injection site reactions
Bortezomib	Lymphoma, myeloma	Proteasome inhibitor	Rash, nausea, emesis, neuropathy
Everolimus	Renal, breast, neuroendocrine	mTOR inhibitor	Hyperglycemia, diarrhea, fatigue

CLL, Chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CTLA4, cytotoxic T lymphocyte-associated protein 4; EGFR, epidermal growth factor receptor; GIST, gastrointestinal stromal tumor; mTOR, mammalian target of rapamycin; NHL, non-Hodgkin's lymphoma; VEGF, vascular endothelial growth factor.

combined with standard chemotherapy in advanced colorectal cancer. Similarly, the EGFR antagonists, cetuximab and panitumumab, increase the efficacy of irinotecan-based chemotherapy in colorectal cancer and that of definitive radiation therapy in oropharyngeal cancers. The availability of these agents has increased the number of drug combinations that can be used in particular cancers. For example, multiple combinations of chemotherapy and targeted therapy are now available for the treatment of advanced colon cancer. Correspondingly, the median survival time of patients with this disease has doubled.

Biologic and Immunologic Therapy

Cytokines that use host immunomodulatory effects as their primary mechanism of action are classified as *biologic response modifiers* or *biologic agents*. Monoclonal antibodies are sometimes classified as biologic agents, although here they have been reviewed under targeted therapy (see earlier discussion). Interferons are commonly used in CML, although they are not as successful as imatinib in inducing responses. Interferons are also used for the treatment of hairy cell leukemia, Kaposi's sarcoma, and selected melanomas and renal cell carcinomas. Interleukin-2 (IL-2) functions as a T-cell growth factor and induces lymphokine-activated and natural killer cell activity. IL-2 can induce responses in 10% to 20% of patients with metastatic melanoma or renal cell carcinoma. In a minority of these patients, responses are complete and last for years. However, IL-2 has toxicity—in particular, a capillary leak syndrome that leads to hypotension, edema, renal insufficiency, and even death.

Immunotherapy agents act by altering the host immune response to the tumor. Cancer vaccines, such as the dendritic cell vaccine sipuleucel-T for prostate cancer, are primed to target cells with specific tumor antigens. Molecules that achieve immune checkpoint blockade have some benefit in melanoma. These agents block T-cell inhibitory molecules such as cytotoxic T lymphocyte-associated protein 4 and programmed cell death 1, thereby releasing T-cells to actively target cancer cells.

Personalized Medicine

The field of oncology is rapidly moving toward an era in which individual patient biospecimens can be evaluated using advanced techniques to reveal specific molecular aberrations that can then be targeted with precise therapeutic agents. Such an approach is referred to by various names, including *precision* or *personalized medicine* and *genomics-driven therapeutics*. The time and costs involved in analyzing the whole genome from a patient's tumor are now much reduced and continue to fall rapidly. In addition to DNA, whole transcriptome (RNA), epigenome (DNA methylation), and single-nucleotide polymorphism (SNP array) analyses can also be performed. Several cancers have already been sequenced completely. Such work creates "reference libraries" against which a patient's tumor can be tested. Based on findings from such analyses, specific drugs or regimens can be recommended for individual patients. Currently used assays include a 21-gene expression profile in breast cancer, *KRAS* in colorectal cancer, *EGFR* and *EML4-ALK* in lung cancer, and *BRAF* in melanoma. Such evaluation of tumor tissues allows patients to

participate in clinical trials of targeted therapies, which may ultimately identify agents that further improve clinical outcomes.

EVALUATION OF RESPONSE

The efficacy of cancer-directed therapies is gauged by various methods and has been granted its own vocabulary. In patients with metastatic disease, all known sites of disease are monitored by physical examinations and serial radiologic imaging. Responses are judged according to the internationally accepted Response Evaluation Criteria in Solid Tumors (RECIST) rules. Disappearance of all known lesions is called a *complete response*, whereas a 30% or greater reduction in size is called a *partial response*. Appearance of new lesions or an increase in the size of known lesions by 20% is termed *progression of disease* and implies failure of treatment. A tumor that is neither responding nor progressing is termed *stable disease*.

The percentage of patients who experience a response is called the *response rate* to the agent or agents being administered. New drugs are often evaluated on the basis of response rates. However, a “response” does not imply cure. Even a drug with a 100% response rate is not curative if all patients relapse. Therefore, the “gold standard” for measuring the efficacy of a drug is considered to be an improvement in *survival*, or its surrogate, *disease-free survival*—the time interval during which the patient is alive without disease. The use of effective second-line therapies may minimize the survival differences between two treatments prescribed as initial therapy, and in this context, disease-free survival can serve as an important end point in evaluating new regimens. Increasingly, quality-of-life end points such as use of pain medications or patient-reported outcomes are being used to assess the efficacy of drugs in palliation. In patients receiving adjuvant therapy, response rates cannot be measured because there is no clinically evident disease: Disease-free survival and overall survival are the only end points of efficacy in this setting. Serial measurement of tumor markers can also be useful in identifying recurrence of cancer and monitoring response to therapy in patients with some cancers.

SUPPORTIVE CARE

Supportive care interventions can improve the safety and tolerability of cancer treatments. Many drugs can moderate

chemotherapy-related side effects. Serotonin receptor antagonists and neurokinin-1 receptor antagonists, in combination with older antiemetic drugs, may control chemotherapy-induced nausea and vomiting. Granulocyte colony-stimulating factor (filgrastim) and granulocyte-macrophage colony-stimulating factor (sargramostim) stimulate the proliferation and differentiation of myeloid progenitor cells and can prevent or minimize the duration of chemotherapy-induced neutropenia and reduce the likelihood of neutropenic fever. These agents are also used to mobilize and collect stem cells for transplantation. Filgrastim can shorten the duration of cycles of chemotherapy, permitting the dose-dense approach in adjuvant treatment of breast cancer (see earlier discussion). Recombinant human keratinocyte growth factor (palifermin) reduces chemotherapy- and radiation therapy-induced mucositis.

Supportive care is an integral part of the treatment of cancer, particularly in noncurative settings. Palliative aspects of treating cancer address not only physical symptoms, in particular pain syndromes, but also psychosocial and spiritual concerns. Chemotherapy and radiation therapy are often used with palliative intent and can improve quality of life.

Lung Cancer

Patrick C. Ma

DEFINITION AND EPIDEMIOLOGY

Lung cancer is the second most common cancer in both women and men; however, it is the leading cause of cancer death in both genders in the United States, and an estimated 1 million people die worldwide of lung cancer each year. Despite recent advances in understanding of the biology and genetics of lung cancer and the advent of novel therapeutic agents for its treatment, the 5-year survival rate for patients with lung cancer is only about 15%. The relatively poor rate of long-term survival partly stems from the fact that most patients with lung cancer have an advanced stage of the disease at the time of diagnosis.

There are two major types of bronchogenic carcinoma: *small cell carcinoma* (SCLC) (E-Fig. 56-1) and *non-small cell carcinoma* (NSCLC). NSCLCs are more common and include adenocarcinoma (32%) (E-Fig. 56-2), squamous cell carcinoma (30%) (E-Fig. 56-3), large cell carcinoma (10%) (E-Fig. 56-4), and some more poorly differentiated histologic subtypes not otherwise specified (NOS). SCLCs account for fewer than 20% of all bronchogenic carcinomas.

A current or prior cigarette smoking history remains the leading known risk factor for the development of lung cancer, although up to 15% of newly diagnosed NSCLC cases, often of the adenocarcinoma subtype, are seen in nonsmokers. It has been estimated that 1 in 5 adults is a current everyday cigarette smoker, implying that lung cancer will continue to be a major public health burden in the coming decades. SCLC is predominantly correlated with cigarette smoking, which plays a key pathogenic role in the disease, whereas NSCLC is commonly diagnosed in never-smokers or in those with only a light-smoking history. In recent years, it has been recognized that lung cancer in smokers is a different disease from lung cancer in nonsmokers at both the molecular and the genetic/genomic levels.

The risk for lung cancer is generally proportionate to number of cigarette pack-years smoked (packs per day \times years smoked), and the incidence peaks in the sixth and seventh decades. Ex-smokers show a persistent risk for lung cancer throughout life. Passive smoking also contributes as a cause of lung cancer in a portion of nonsmokers who develop the disease. Nonsmokers who live with smokers have a more than 30% increased risk of developing lung cancer. Other risk factors for lung cancer include environmental hazards such as asbestos and petroleum exposure. Smoking is considered an important cofactor of lung cancer in the setting of asbestos exposure. Radon exposure also increases the risk for lung cancer (see Chapter 54).

Understanding of the underlying pathogenic mechanisms of lung cancer has evolved to recognize the disease as a genetic

or even genomic disease. An ever-growing list of oncogenic alterations identified in both proto-oncogenes and tumor suppressor genes is accumulating as a result of the genomic analysis effort in recent years, including The Cancer Genome Atlas (TCGA) project sponsored by the National Institutes of Health (NIH) in the United States (see later discussion).

Unique molecular-genomic subgroups of lung cancer have been recognized, including those harboring (1) mutated epidermal growth factor receptor (*EGFR/ERBB1*), (2) mutated Kirsten rat sarcoma viral oncogene homolog (*KRAS*), and (3) anaplastic lymphoma kinase (*ALK*) 2p23 chromosomal rearrangement, more commonly as *EML4-ALK*, a fusion with echinoderm microtubule-associated protein-like 4 (*EML4*). Importantly, these oncogenic genomic alterations provide therapeutic windows of opportunity, especially in the context of oncogenic addiction resulting from these alterations in the tumor cells.

Several targeted therapies have been approved by the U.S. Food and Drug Administration (FDA) for treatment of advanced NSCLCs containing mutated *EGFR* (erlotinib, afatinib, and gefitinib) or the *ALK* 2p23 rearrangement (crizotinib). Lung cancers with *EGFR* mutations are more frequently identified in never-smokers or in those with a light-smoking history, are more often of the adenocarcinoma subtype, and are more often, but not exclusively, diagnosed in females and in patients of East Asian ethnicity. *KRAS*-mutated lung cancers are found primarily in patients with heavier smoking exposure. Lung cancers with mutated *EGFR* and those with the *ALK* 2p23 rearrangement are typically seen in younger patient populations, with the median age at diagnosis being approximately 55 years.

PATHOLOGY

Histologic Subgroups

Non-Small Cell Lung Carcinomas

Most lung cancers fall under the major histologic subgroup of NSCLCs. Of these, *adenocarcinomas* and *squamous cell carcinomas* are the most common.

Adenocarcinomas

Adenocarcinoma is the most commonly diagnosed subtype of lung cancer, accounting for approximately 40% of lung cancer diagnoses and 65,000 deaths each year in the United States. It is the histologic subtype most commonly diagnosed in nonsmokers. Primary lung adenocarcinomas are usually found in the periphery of the lung (75%) (E-Fig. 56-5), in contrast to squamous cell carcinomas.

E-FIGURE 56-1 Small cell lung carcinoma.

E-FIGURE 56-2 Adenocarcinoma of the lung.

E-FIGURE 56-3 Squamous cell carcinoma of the lung.

E-FIGURE 56-4 Large cell undifferentiated carcinoma of the lung.

E-FIGURE 56-5 Peripheral tumor of lung cancer (*arrow*). Peripherally located primary lung cancer most commonly occurs with adenocarcinoma of the lung, as shown here.

Pathologically, adenocarcinomas typically form glandular structures and produce mucus. *EGFR* mutations are more commonly associated with nonmucinous lung adenocarcinoma, whereas the mucinous subtype is more commonly associated with mutated *KRAS*. The tumor cells typically stain positive for cytokeratin 7 (CK7), thyroid transcription factor 1 (TTF-1), carcinoembryonic antigen (CEA), mucin, and surfactant apoprotein and negative for cytokeratin 20 (CK20). Adenocarcinomas respond poorly to therapy and have a poor prognosis.

Bronchoalveolar cell carcinomas (BAC), a subset of adenocarcinomas, are the most common form of lung cancer found in non-smokers and young patients. They manifest as lung infiltrates or as a solitary nodule and can be accompanied by bronchorrhea. BAC cells can grow in a lepidic (scaly) pattern and spread along alveolar walls.

Squamous Cell Carcinomas

Squamous cell carcinomas arise from the epithelial layer of the bronchial wall. Normal columnar epithelial cells undergo metaplasia, dysplasia, and then localized carcinoma (*carcinoma in situ*) formation; this can then further extend and invade beyond the bronchial mucosa as it acquires a full malignant invasive phenotype (carcinoma). Because most squamous cell carcinomas arise within central airways (E-Fig. 56-6), the airway lumen may become obstructed, leading to collapse of the lung (atelectasis) or postobstructive pneumonia. Although necrosis and cavity formation can occur in any lung tumor, this feature is more common in squamous cell carcinomas. Because of their slow rate of growth, these tumors have the lowest propensity for metastasis of all types of lung cancer. Pathologically, squamous cell carcinomas can be distinguished from other NSCLCs by the presence of keratinization, pearl formation, and intercellular bridging.

Adenosquamous Carcinomas

Adenosquamous carcinomas constitute between 0.4% and 4% of cases and may have a worse prognosis. They have components of both adenocarcinoma and squamous cell carcinoma, each comprising at least 10% of the tumor.

Large Cell Carcinomas

Large cell carcinomas frequently develop as a peripheral lesion and may be associated with pneumonitis and hilar adenopathy. The two main subtypes are *giant cell carcinoma*, an anaplastic tumor that has a median survival time of less than 1 year; and *clear cell carcinoma*, a tumor that resembles renal cell carcinoma and has fewer malignant features.

NSCLC Not Otherwise Specified

Despite one's best efforts in defining subtype differentiation of a NSCLC through histology and immunophenotyping, there may remain poorly differentiated tumors that defy such classification. These are designated NSCLC-NOS.

Small Cell Lung Carcinoma

SCLC cells are of pulmonary neuroendocrine cell origin and are often associated with paraneoplastic syndromes (Table 56-1). SCLCs typically are perihilar in location, not infrequently

TABLE 56-1 PARANEOPLASTIC SYNDROMES ASSOCIATED WITH LUNG CANCER

SYNDROME	CELL TYPE	MECHANISM
Hypertrophic pulmonary osteoarthropathy and clubbing	All except small cell	Unknown
Hyponatremia	Small cell most common; may be any type	SIADH, ectopic antidiuretic hormone production by tumor
Hypercalcemia	Usually squamous cell	Bone metastases, osteoclast-activating factor, parathyroid hormone–like hormone, prostaglandins
Cushing syndrome	Usually small cell	Ectopic ACTH production
Eaton-Lambert myasthenic syndrome	Usually small cell	Voltage-sensitive calcium channel antibodies in >75%; affects presynaptic neuronal calcium channel activity
Other neuromyopathic disorders	Small cell most common; may be any type	Antineuronal nuclear antibodies, also known as anti-Hu; others unknown
Thrombophlebitis	All types	Unknown

ACTH, Adrenocorticotropic hormone; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

originate in the main bronchi, and often have associated malignant adenopathy (E-Fig. 56-7). These tumors have a high propensity for metastasis, most commonly to the thoracic lymph nodes, bones, liver, adrenal glands, and brain. Most patients are already affected with metastatic disease at the time of presentation. SCLC has traditionally been staged as *limited disease* (confined to one hemithorax) or *extensive disease* (distant metastases); although a TNM staging system has recently been suggested. SCLC is an aggressive lung tumor; without treatment, the median survival time of patients with this cancer is less than 5 months. The overall survival at 5 years is 5% and has not improved over the past several decades.

Molecular-Genomic Subtypes

Lung cancer is now increasingly regarded as a disease with collections of often very distinct and heterogeneous molecular and genomic subclasses or disease subgroups (Table 56-2). Many of these molecular-genomic alterations can inform the use of targeted therapeutics and predict responses.

Mutant *EGFR*

EGFR mutation testing and targeting therapy are part of routine clinical care of patients with NSCLC worldwide. Specific somatic *EGFR* gene kinase domain–activating mutations, predominantly occurring in lung adenocarcinoma, predict sensitivity and clinical response to the *EGFR* inhibitors gefitinib and erlotinib. These mutations are usually found in never-smokers or female light smokers with adenocarcinoma. *EGFR* mutations are more prevalent in Asian patients (30%, compared with 7-10% in Caucasians). Molecular tumor selection by profiling is superior to clinical selection.

ALK 2p23 Rearrangement

The *EML4-ALK* fusion in NSCLC is an oncogenic driver fusion-kinase. Oncogenic *ALK*-rearrangements occur in 3% to 7% of NSCLCs, in light smokers (<10 pack-years) or never-smokers. In

E-FIGURE 56-6 Central tumor of lung cancer (squamous cell tumor). Examples of centrally located primary lung cancer include squamous cell carcinoma of the lung and small cell lung carcinoma.

E-FIGURE 56-7 Malignant adenopathy in primary lung cancer. This patient has a small cell carcinoma with adenopathy and collapse of the left upper lobe.

**TABLE 56-2** MOLECULAR-GENOMIC SUBTYPES OF NSCLC

ONCOGENE	CLASS OF MOLECULAR-GENOMIC ALTERATIONS	CHARACTERISTICS
<i>EGFR</i> -mutant	Somatic missense mutations (most common with L858R in exon 21) and exon 19 deletions	More frequent in Asians, females, never-smokers or light smokers; most frequently adenocarcinoma subtype Sensitizing to <i>EGFR</i> inhibitors erlotinib, gefitinib, and afatinib T790M mutation in <i>EGFR</i> is resistant to the inhibitors.
<i>EML4-ALK</i>	<i>ALK</i> 2p23 chromosomal translocation	3-7% of NSCLCs More common in light smokers (<10 pack-years) or never-smokers Sensitizing to <i>ALK</i> inhibitor crizotinib
<i>KRAS</i> -mutant	Somatic mutations	Found in 15-25% lung adenocarcinomas Less common but can be present in squamous cell carcinomas More commonly seen in former or current cigarette smokers No effective targeted treatment at present
<i>PIK3CA</i> -mutant	Somatic mutations	The <i>PIK3CA</i> gene encodes the p110 α , one of the catalytic subunits, of PI3K, which belongs to a family of lipid kinases involved in many cellular processes, including cell growth, proliferation, survival and motility. Mutated in 1-3% of all NSCLCs More common in squamous cell carcinoma <i>PIK3CA</i> shows significant potential as a candidate for targeted therapy
<i>BRAF</i> -mutant	Somatic mutations	Belong to a family of serine-threonine protein kinases Identified in 1-3% of cases Sensitizing to a mutated <i>BRAF</i> -specific inhibitor, vemurafenib, which has been approved by the FDA for treatment in V600E- <i>BRAF</i> -mediated cutaneous melanoma
<i>HER2</i>	Amplification, mutations, small insertions	<i>HER2</i> alterations were identified in ~2% to 4% of NSCLCs In the selected population of <i>EGFR/KRAS/ALK</i> -mutation-negative patients, <i>HER2</i> mutations can reach up to 6% Predominantly found in females, nonsmokers; predominantly adenocarcinoma subtype May be associated with sensitivity to <i>HER2</i> -targeting drugs (trastuzumab, lapatinib, pertuzumab, and T-DM1) used in breast cancer
<i>LKB1</i>	Inactivating mutations, deletion	A tumor suppressor gene also known as <i>STK11</i> Mutational frequency about 17-35% of NSCLCs in Caucasians but only 3-7% in the Asian population
<i>RET</i> -fusion	Chromosomal translocations	Recently found in some lung adenocarcinomas (1-2%)
<i>ROS1</i> -fusion	Chromosomal translocations	<i>ROS1</i> is a receptor tyrosine kinase of the insulin receptor family <i>ROS1</i> -fusions were identified in ~2% of NSCLCs More commonly found in younger people, more likely in never-smokers, and Asian patients are overrepresented <i>ROS1</i> -positive status may be associated with response to the kinase inhibitor crizotinib (<i>ALK/MET</i> inhibitor)
<i>FGFR1</i>	Amplification and mutations	Gene belongs to the family of <i>FGFR</i> TK members that includes <i>FGFR</i> types 1, 2, 3 and 4. Genomic alterations of <i>FGFR1</i> have been identified predominantly in the squamous subtypes of lung cancer, raising the possibility of targeted therapy in this unique cancer subtype
<i>MET</i>	Alternative spliced variant, mutations, amplification, receptor overexpression	The <i>MET</i> proto-oncogene is a key invasive signaling axis. <i>MET</i> gene amplification can be found in 2-4% of NSCLCs, whereas overexpression of its receptor protein is much more common <i>MET</i> overexpression has been correlated with poor prognosis. A number of <i>MET</i> -targeting therapeutic agents have entered clinical trial studies. <i>MET</i> high expression may be a predictive biomarker of treatment response.
<i>BCL2</i>	Amplification, receptor overexpression	<i>BCL2</i> overexpression is more common in SCLC than in NSCLC. Various BH3 mimetics have been developed to target the mitochondrial antiapoptotic marker <i>BCL2</i> in human cancers (e.g. SCLC, CLL).

CLL, Chronic lymphocytic leukemia; *EGFR*, epithelial growth factor receptor; FDA, U.S. Food and Drug Administration; *FGFR*, fibroblast growth factor receptor; NSCLC, non-small cell lung cancer; PI3K, phosphatidyl 3-kinase; SCLC, small cell lung cancer; TK, tyrosine kinase.

most cases, *EML4-ALK* fusions do not overlap with other oncogenic mutations of *EGFR* or *KRAS*.

Mutant *KRAS*

KRAS gene mutations are uncommon in squamous cell carcinomas but are present in 15% to 25% of lung adenocarcinomas. *KRAS* mutations are more commonly seen in former or current cigarette smokers than in never-smokers or light smokers. There is currently no effective targeted treatment for mutated *KRAS*.

The Lung Cancer Genome

In the last decade, the TCGA project in comprehensive genomic analysis of human cancers has brought forth a renewed understanding of lung cancer at the genomic level.

The TCGA analysis mapped the hallmarks of lung adenocarcinoma and identified a relatively high exonic somatic mutation rate (mean, 12.0 events per megabase), similar to the rate found in squamous cell lung carcinoma. These lung cancer types also have similar copy number profiles. Three distinct expression subtypes of lung adenocarcinoma were identified from RNA-sequencing data: bronchioid, magnoid, and squamoid. In addition, multiple gene fusions were found to be expressed in lung adenocarcinomas, and multiple mechanisms for *CDKN2A* inactivation were uncovered.

For squamous cell NSCLCs, a most unexpected finding in the TCGA study was the identification of loss-of-function mutations in the *HLA-A* gene, which encodes a major histocompatibility complex that plays an important immune regulatory role on the

tumor cell surface in antigen presentation and immune recognition. This is regarded as the first evidence of somatic cancer genome alterations evading the immune system by changing their surface antigens. Potential therapeutic targets were identified in most tumors, offering new therapeutic avenues of investigation for targeted therapy in lung cancer.

CLINICAL PRESENTATION

Initial symptoms of lung cancer are usually nonspecific—cough, dyspnea, sputum production, chest pain, and weight loss—and are often attributed to bronchitis or pneumonia. The cancer has often invaded adjacent structures or metastasized when first recognized, causing symptoms that reflect the site of involvement, such as hemoptysis, pleuritic chest pain, and pleura or chest wall invasion; hoarseness (left recurrent laryngeal nerve); pleural effusion related to direct tumor involvement of the pleura or obstruction of lymph flow from the mediastinal nodes (E-Fig. 56-8); dysphagia (esophageal involvement); *malignant pericardial effusion*, which can progress to *cardiac tamponade*; *spinal cord compression*; and brain metastasis. A malignant pleural effusion precludes resection. Superior vena cava obstruction may result in the *superior vena cava syndrome*, with edema of the face and upper extremities due to impaired venous return.

The Physical examination can be normal but may reveal changes in the lungs that reflect the effect of the tumor, such as crackles (e.g., postobstructive pneumonia [E-Fig. 56-9]); inspiratory wheezes, suggestive of airway obstruction; dullness to percussion at the lung bases from underlying pleural effusion; and lymph node enlargement in the supraclavicular (E-Fig. 56-10) or cervical and axillary (distant) areas. The most common sites of metastases are the lymph nodes, liver (E-Fig. 56-11), brain, adrenal glands, kidneys, and lungs.

Lung cancers that occur in the apex of the chest and invade apical chest wall structures are known as *superior sulcus* or *Pancoast tumors* (E-Fig. 56-12). The classic description involves a syndrome of pain radiating down the arm due to tumor erosion into the brachial plexus. Tumor erosion into the cervical sympathetic chain causes *Horner syndrome*, with ptosis, miosis, and anhidrosis over the face and forehead.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diagnostic and Staging Work-Up

When possible lung cancer is identified, either incidentally or because of symptoms, a tissue diagnosis is essential unless the patient is not eligible for treatment because of comorbidity. After assessment for metastases, the site of biopsy should be chosen to determine the greatest extent of spread or highest stage of the tumor, if this is feasible. If the apparent tumor is confined to the chest, bronchoscopy is appropriate for central masses, and a transthoracic needle aspiration would be suitable for peripheral lesions. Pleural effusion should be sampled to assess for malignant cells, which would indicate metastatic-stage disease (M1a).

Solitary Pulmonary Nodule

A *solitary pulmonary nodule* (SPN) is a single, rounded lesion in the lung that is 3 cm in diameter or smaller. Although these lesions are commonly lung cancers in certain patient populations, the differential diagnosis of SPN includes many other

malignant and benign etiologies. In addition to primary lung cancer (adenocarcinoma; see E-Fig. 56-5), other possible causes include bronchial carcinoid tumors and metastases from extrapulmonary malignancies (e.g., malignant melanoma, sarcoma, colon, kidney, breast, and testicle). Benign etiologies include benign tumors of the lung (hamartomas) (E-Fig. 56-13), infectious granulomas (from fungal diseases including histoplasmosis and coccidioidomycosis as well as mycobacterial disease), lung abscess, vascular abnormalities (arteriovenous malformation), rounded atelectasis, and pseudotumor (pleural fluid trapped within a fissure).

Accurate and early determination is essential and can potentially lead to cure in the case of a malignant tumor. In a benign nodule, it may preclude surgery with its associated risks and complications. Diagnostic evaluation should consider the patient's age, gender, smoking history, family history of lung and other types of cancer, and other relevant risk factors.

Radiographic features of an SPN can be helpful diagnostically. Larger lesions are more likely to be malignant. Lesions 4 to 7 mm in diameter in patients without a history of cancer have a 0.9% chance of being malignant; this probability rises to 18% for lesions 8 mm to 2 cm in diameter, and 50% for those larger than 2 cm. Benign tumors tend to have smooth and discrete borders, whereas irregular and spiculated borders are more likely in malignant SPNs. A benign tumor tends to have a diffuse, central, laminated (onion-skin), or popcorn calcification pattern. Conversely, lesions with peripheral or eccentric (asymmetrical) calcifications are more likely to be malignant. It is important to assess the rate of occurrence of an SPN and its stability by comparing imaging studies with previous scans whenever available. An SPN that has not changed in size for more than 2 years is unlikely to be malignant.

Once a diagnosis of lung cancer is established, staging is necessary for prognostication and treatment. Staging in NSCLC determines whether surgical resection for cure or chemotherapy or radiation therapy is indicated. The tumor-node-metastasis (TNM) system is used (Table 56-3). For staging of SCLC, the Veterans Administration Lung Study Group designations of limited-stage (confined to one hemithorax) and extensive-stage (beyond one hemithorax) are used. Combined chemoradiation therapy with curative intent is considered for the former, but palliative chemotherapy is the treatment of choice for the latter.

Chest computed tomography (CT), including images of the abdomen, is useful to delineate the location and size of the primary tumor and to examine for mediastinal lymph nodes, pleural disease, and adrenal or liver metastases. However, CT has limited ability to distinguish benign from malignant lymphadenopathy in the mediastinum. Positron emission tomography (PET) using 18-fluorodeoxyglucose (FDG) is more sensitive and more specific than CT in the detection of mediastinal lymph node metastases and may also detect unexpected metastases elsewhere. In principle, any suspected mediastinal or extrathoracic metastases identified by imaging alone should be confirmed with tissue sampling before the patient is excluded from being considered an operative candidate. Techniques for invasive staging of the mediastinal lymph nodes include bronchoscopic transbronchial needle aspiration and mediastinoscopy. Mediastinoscopy can also assess mediastinal spread of disease in patients

TABLE 56-3 TNM STAGING SYSTEM FOR LUNG CANCER (2010)**T (PRIMARY TUMOR)**

TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤ 3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)*
T1a	Tumor ≤ 2 cm in greatest dimension
T1b	Tumor > 2 cm but ≤ 3 cm in greatest dimension
T2	Tumor > 3 cm but ≤ 7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if ≤ 5 cm): Involves main bronchus, ≥ 2 cm distal to the carina Invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor > 3 cm but ≤ 5 cm in greatest dimension
T2b	Tumor > 5 cm but ≤ 7 cm in greatest dimension
T3	Tumor > 7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus (< 2 cm distal to the carina* but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina, separate tumor nodule(s) in a different ipsilateral lobe

N (REGIONAL LYMPH NODES)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)

M (DISTANT METASTASIS)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion [†]
M1b	Distant metastasis

From Edge S, Byrd DR, Compton CC, et al, editors: AJCC Cancer Staging Manual, ed 7, New York, 2010, Springer.

*The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximally to the main bronchus, is also classified as T1a.

[†]Most pleural (and pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple cytopathologic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be classified as M0.

without definite imaging evidence of lymph node involvement before definitive resection of the lung cancer. PET scanning is limited in its ability to detect brain lesions, and magnetic resonance imaging (MRI) of the brain with intravenous contrast (or CT scanning if MRI cannot be done) should be performed if brain metastasis is suspected. Bone scans are useful for suspected symptomatic bony metastases.

Metastatic disease is now subdivided into those lesions that occurred with “local intrathoracic spread” (M1a)—malignant pleural/pericardial effusion or separate tumor nodule(s) in the contralateral lung—and those that already have “disseminated (extrathoracic) disease” (M1b) in liver, bone, brain, or adrenal gland. M1a disease has a better prognosis than M1b disease.

TREATMENT

Prevention by avoiding or stopping smoking is a responsibility of all physicians (Chapter 54). The United States Preventive Services Task Force (USPSTF) supports lung cancer screening for the high-risk populations: current and former smokers, aged 55 to 80 years, with a smoking history equivalent to 1 pack per day for 30 years or 2 packs per day for 15 years. The recommendation for screening includes those who have quit within the past 15 years.

Small Cell Lung Cancer

SCLCs can occasionally be resected if no evidence of metastasis is found, but most SCLCs are treated with chemotherapy for systemic disease. SCLC is staged as limited-stage, for which definitive treatment using combination chemoradiation with curative intent is pursued, and extensive-stage, for which chemotherapy with palliative intent is the mainstay of treatment. Combinations of cisplatin/carboplatin and etoposide constitute the standard front-line chemotherapeutic regimen. Topotecan is used for salvage therapy during disease relapse. SCLC responses to both chemotherapy and radiation therapy and long-term survival are possible. However, relapse with progressive therapeutic resistance is usual despite initial treatment response. Prophylactic cranial irradiation enhances overall survival in both limited-stage disease after completion of chemoradiation and extensive disease with response to chemotherapy.

Non-Small Cell Lung Cancer

Early-Stage Disease (Stages I and II)

Surgery is potentially curative for early-stage NSCLC and is indicated for patients with stage I or II disease who are eligible as operative candidates. Lobectomy (or greater) is considered

unless the patient has medical comorbidities or is of advanced age. Wedge resection may be considered as an alternative to lobectomy, but patients also may be offered local ablative radiation therapy techniques such as stereotactic body radiation therapy (SBRT) or CyberKnife radiosurgery.

Locally Advanced Disease (Stages IIIA and IIIB)

Patients with stage III disease are heterogeneous, and the optimal treatment strategy is unclear. For stage IIIA disease, curative surgery, in combination with neoadjuvant chemotherapy and radiation, may be offered. Most patients with stage IIIB NSCLC are not surgical candidates, and 5-year survival is poor for this group. Concurrent chemotherapy and radiotherapy are preferable to radiotherapy alone.

Advanced Metastatic Disease (Stage IV)

Chemotherapy improves survival and provides palliation for symptoms in stage IV disease. Patients with high performance often receive doublet chemotherapy, combining a platinum agent (cisplatin or carboplatin) and a second agent (e.g., paclitaxel, pemetrexed, gemcitabine). Histology-specific personalized therapy is now becoming possible; for the adenocarcinoma subtype, pemetrexed is used, and for the squamous cell subtype, gemcitabine.

Genomics-Guided Precision Therapy

Mutational analysis and genomic profiling hold promise for “precision therapy” or “personalized targeted therapy.” For example, NSCLC, especially adenocarcinoma, can be viewed as having distinct subgroups of mutated oncogenes, some known to be “actionable” or “targetable” with novel treatment (E-Fig. 56-14). In *EGFR*-mutant lung cancer, the *EGFR* inhibitor gefitinib or erlotinib improved the progression-free survival rate better than chemotherapy treatment did. An era in which “molecular profiling” trumps profiling by clinical parameters has arrived.

Targeted therapy in lung cancer has already made an impact in terms of a treatment paradigm shift and in clinical outcome. The major obstacle in fully unleashing the power of targeted therapy

lies in the invariable development of acquired drug resistance, which ultimately leads to disease progression and death of the patient. The predominant mechanism in erlotinib resistance is the emergence of *EGFR* T790M mutation in exon 20, which accounts for about half of all resistant cases. Other novel mechanisms of acquired erlotinib resistance have come to light more recently, including *MET* amplification or the RTK activation, *PIK3CA* mutation, *EGFR* amplification, *AXL* upregulation, and even histologic SCLC transformation. Various mechanisms of resistance against crizotinib in *ALK*-genotype specific targeted therapy are also being uncovered at a rapid pace.

Currently, a number of Clinical Laboratory Improvement Amendments (CLIA)-certified genomics laboratories perform tumor genomic profiling, but what constitutes the best lung cancer genomic profiling method remains uncertain.

PROGNOSIS

The most important prognostic factor in lung cancer is the TNM stage of the disease at the time of presentation. Poor performance status and weight loss are also negative prognostic factors for survival of patients with lung cancer.

For a deeper discussion on this topic, please see Chapter 191, “Lung Cancer and Other Pulmonary Neoplasms,” in *Goldman-Cecil Medicine, 25th Edition*.

Gastrointestinal Cancers

Davendra P.S. Sohal and Alok A. Khorana

INTRODUCTION

Cancers arising in the gastrointestinal system are among the most common cancers worldwide. Every year, they account for more than 2.7 million deaths globally and approximately 145,000 deaths in the United States. Gastrointestinal cancers are typically epithelial malignancies—carcinomas—with well-defined pathologic patterns of neoplastic transformation. Risk factors and presentations are site specific, and management usually involves multimodality therapy including surgery, chemotherapy, and radiation therapy. Additional contributors to morbidity from these cancers are the complications of malignancy, including intestinal or biliary obstruction and impaired nutrition due to anatomic and physiologic alteration of the digestive system. Therefore, interventions to palliate symptoms and maintain adequate nutrition are an important component of care.

ESOPHAGEAL CANCER

Epidemiology

Population trends of esophageal cancer are slowly evolving. In the United States, the incidence of esophageal squamous cell carcinoma is declining but the incidence of esophageal adenocarcinoma is rising. These changes mirror the demographic trends in risk factors: prevalence of tobacco and alcohol use, linked to the former, is declining, whereas obesity, reflux disease, and metabolic syndrome, associated with the latter, are increasing.

Pathology

Squamous cell carcinoma is commonly seen in the upper esophagus; it develops, like head and neck cancer, from chronic mucosal injury caused by carcinogens in tobacco smoke and exacerbated by alcohol use. Adenocarcinoma usually arises in the setting of chronic acid reflux and from a background of Barrett's esophagus, involving epithelial metaplasia in the distal esophagus or the gastroesophageal junction. People with Barrett's esophagus have an annual risk of 0.12% of developing this disease, an 11-fold elevation over the general population.

Clinical Presentation

The cardinal symptom of esophageal cancer is dysphagia. Long-standing gastroesophageal reflux disease is often present in adenocarcinoma. Unintentional weight loss due to limited oral intake and other factors is a common clinical association.

Diagnosis

Endoscopy remains the preferred diagnostic test. Visualization for masses and mucosal irregularities yields a quick clinical diagnosis; biopsy of suspicious areas provides histologic confirmation. Endoscopic ultrasound is a useful modality in assessing the T and N components of staging (i.e., depth of tumor invasion into the esophageal wall and beyond, and surrounding lymph node involvement, respectively). Fine-needle aspiration of suspicious lymph nodes can further improve N-staging. Imaging for systemic disease (M-staging) is performed before the therapeutic plan is finalized, preferably with contrast-enhanced computed tomography (CT).

Treatment

If esophageal cancer is diagnosed early (stage I), surgical resection is the treatment of choice. The esophagectomy can be performed with a transthoracic (Ivor-Lewis) or a transhiatal technique, with comparable clinical outcomes. For locally advanced disease (stages II and III), multimodality therapy is required. This consists of chemotherapy, radiation therapy, and surgery. Combined chemoradiation using 5-fluorouracil (5-FU) and cisplatin remains the standard of care for squamous cell cancer; in this setting, surgery may be foregone, especially for cervical esophagus tumors, because chemoradiation can provide good disease control. For adenocarcinomas of the distal esophagus and gastroesophageal junction, there are competing standards of care, including perioperative chemotherapy using epirubicin, cisplatin, and 5-FU; preoperative chemoradiation using paclitaxel and carboplatin; or surgery followed by adjuvant chemotherapy and radiation using 5-FU-based regimens.

For advanced disease (stage IV), combination chemotherapy can improve survival. Trastuzumab is a monoclonal antibody directed against human epidermal growth factor receptor 2 (HER2), a cell surface receptor that signals cellular proliferation. The addition of this agent to standard chemotherapy is of benefit in adenocarcinomas of the gastroesophageal junction that exhibit overexpression of HER2. Supportive care and palliative interventions for dysphagia, such as local irradiation and placement of a feeding tube, can improve quality of life.

Prognosis

Early-stage (stage I) esophageal cancer is curable. Rates of cure for locally advanced (stage II or III) disease are lower, and metastatic disease (stage IV) remains incurable. Five-year survival rates with appropriate treatment are 70%, 40%, 30%, and 5% for stages I, II, III, and IV, respectively.

● GASTRIC CANCER

Epidemiology

Gastric adenocarcinoma is one of the rare malignancies that has shown a remarkable decline in incidence and mortality in the United States over the 20th century. Much of this decline can be attributed to refrigeration, which obviated the use of food preservatives that harbor carcinogenic nitrites and nitrosamines. Improved hygiene and sanitation also lowered the prevalence of *Helicobacter pylori* infection, which is associated with gastric cancer. However, this disease remains common in Asian countries (China, Japan, and Korea), in the Middle East, and in Eastern Europe, placing it among the five most common cancers worldwide.

Pathology

Traditionally, two main histologic subtypes exist: diffuse and intestinal. The diffuse type is associated with younger age, poor differentiation, signet ring cells, an increasing incidence, and a worse prognosis. Carriers of inactivating mutations in the E-cadherin gene (*CDH1*), such as those with hereditary diffuse gastric cancer syndrome, are prone to such cancers. The intestinal type is seen in older patients, is differentiated with a background of intestinal metaplasia, and has a declining incidence and a somewhat better prognosis. In many cases, however, this histologic distinction is not possible and does not alter management.

Clinical Presentation

The classic triad is anemia, anorexia, and asthenia. Early satiety (linitis plastica), dysphagia (gastroesophageal junction or cardia tumors), epigastric pain, nausea, vomiting, and gastrointestinal bleeding are also commonly seen. Metastatic spread causing peritoneal carcinomatosis can lead to ascites.

Diagnosis

Esophagogastroduodenoscopy is the preferred diagnostic test. Biopsies to confirm disease should follow, and then metastatic disease assessment by CT. If linitis plastica is suspected, blind biopsies may be needed, because overt mucosal lesions are often not evident. Screening endoscopy is recommended in high-incidence countries such as Japan.

Treatment

Surgery remains the cornerstone of treatment for nonmetastatic disease. The extent of dissection is debated. In high-incidence countries such as Japan and Korea, extended surgery (D2 dissection) to remove the stomach, all surrounding lymph nodes, and the spleen is performed and is associated with clinical benefit. However, this benefit has not been seen in the Western population. For locally advanced disease, in addition to surgery, either perioperative chemotherapy with epirubicin, cisplatin, and 5-FU or postoperative chemoradiation with 5-FU is an acceptable approach. For metastatic disease, first- and second-line palliative chemotherapy can improve outcomes, including survival. For patients with HER2-overexpressing tumors, the addition of trastuzumab to chemotherapy further extends survival.

Prognosis

Clinical outcomes depend on the stage at diagnosis. Early-stage cancer can be cured; 5-year survival rates are 65%, 40%, 15%, and 5% for stages I, II, III, and IV, respectively. Survival outcomes in Japan and Korea are better than in most Western countries; this disparity may be attributable to routine screening endoscopies or to differences in disease biology.

● PANCREATOBILIARY CANCERS

Epidemiology

The incidence and mortality of pancreatic ductal adenocarcinoma are slowly but steadily increasing. It is the tenth most common cancer but the fourth leading cause of cancer-related death in the United States. Smoking and chronic pancreatitis are established clinical risk factors. Pancreatic cancer risk increases with inherited mutations in *BRCA1*, *BRCA2*, and *PALB2* and with familial syndromes such as the Peutz-Jeghers and Lynch syndromes. Pancreatic neuroendocrine tumors are uncommon malignancies that originate from the endocrine cells in the pancreas. They may be nonfunctional, or they may secrete hormones such as insulin (insulinoma), gastrin (gastrinoma), glucagon (glucagonoma), or vasoactive intestinal peptide (VIPoma).

Cholangiocarcinoma, defined as cancer arising from the biliary epithelium, comprises intrahepatic and extrahepatic cholangiocarcinoma and gallbladder cancer. It is an uncommon malignancy. Established risk factors include conditions that cause chronic inflammation of the biliary system, such as primary sclerosing cholangitis, cholelithiasis, and infection with liver flukes (*Clonorchis*, *Opisthorcis*), and anatomic abnormalities of the biliary tree (e.g., Caroli's disease, choledochal cysts). Gallbladder cancer is particularly prevalent in Chile and northern India.

Pathology

Pancreatic adenocarcinoma develops with an accumulation of mutations in the pancreatic duct epithelium; the affected genes are *KRAS*, followed by *CDKN2A* (*p16*), *TP53*, *SMAD4* (*DPC4*), and others. Histologic progression occurs in various stages of pancreatic intraepithelial neoplasia, leading to invasive adenocarcinoma. Desmoplastic reaction—the production of abundant fibrotic stroma—is often seen in pancreatic cancer.

Clinical Presentation

Painless jaundice is a frequent presenting symptom and is caused by biliary obstruction. Epigastric pain radiating through to the back and new-onset type 2 diabetes mellitus in an adult older 50 years of age without overt obesity-related risk factors should raise suspicion for pancreatic cancer. Constitutional symptoms include anorexia, unintentional weight loss, and malaise. Steatorrhea occurs because of exocrine pancreatic insufficiency. Venous thromboembolism, seen with various malignancies, is most associated with pancreatic cancer and can be a presenting feature. Gallbladder cancer is sometimes an incidental finding during the evaluation of histologic specimens after cholecystectomy, which is commonly performed for presumed cholelithiasis or cholecystitis. Secretory pancreatic neuroendocrine tumors can cause symptoms related to excess hormone production, including

hypoglycemia (insulinoma), Zollinger-Ellison syndrome (gastrinoma), hyperglycemia (glucagonoma), and diarrhea with electrolyte disturbances (VIPoma).

Diagnosis

Imaging of the pancreatobiliary system using ultrasound, CT, or magnetic resonance imaging (MRI) can identify lesions. However, small intrapancreatic, periampullary, and biliary system lesions causing pancreatobiliary obstruction may not be evident on imaging. If a malignancy is suspected, endoscopic ultrasound and endoscopic retrograde cholangiopancreatography are very useful tests. During these procedures, lesions can be visualized better, obstruction can be relieved by stent placement, and histologic confirmation can be obtained by biopsies, fine-needle aspirations, and bile duct brushings. Somatostatin-receptor scintigraphy can be helpful in localizing occult neuroendocrine tumors.

Treatment

Pancreatobiliary malignancies are some of the most difficult cancers to treat. Their anatomic locations make them poor candidates for resection: Pancreatic cancer frequently involves the celiac arterial axis and superior mesenteric artery, and biliary cancers can obstruct the entire biliary outflow (Klatskin tumors). Aggressive surgeries such as the Whipple procedure (pancreatoduodenectomy), radical cholecystectomy (resection of the gallbladder, porta hepatis, liver segments IV and V), and segmental liver resection with biliary tree reconstruction (for cholangiocarcinoma) can be attempted. However, the 5-year overall survival rate after pancreatic adenocarcinoma resection is less than 20%.

Recent studies with multiagent regimens such as a combination of 5-FU, irinotecan, and oxaliplatin, or combined gemcitabine and nab-paclitaxel, have demonstrated improved overall survival for metastatic pancreatic cancer. Gemcitabine with cisplatin has emerged as a standard for cholangiocarcinoma. Octreotide, a somatostatin analogue, is useful in the management of neuroendocrine tumors. Recent studies in neuroendocrine tumors have also shown improvement in outcomes with targeted agents such as everolimus and sunitinib. Palliation of symptoms is a large component of care. Opioid analgesics and celiac nerve plexus blocks for pain; biliary stents and percutaneous tubes for obstructive jaundice; palliative surgeries for gastric outlet and biliary obstruction; appetite stimulants such as olanzapine, megestrol, and dronabinol for anorexia; and supplemental pancreatic enzymes for malabsorption are all interventions that can improve patients' quality of life.

Prognosis

Pancreatobiliary malignancies have some of the worst outcomes; the 5-year overall survival rate remains less than 10%. Survival has not improved significantly over the last few decades, in contrast to several other cancers.

HEPATOCELLULAR CARCINOMA

Epidemiology

Hepatocellular carcinoma (HCC), or primary liver cancer, is a common disease around the world. It is the second most common cause of cancer-related death in men, worldwide.

Pathology

Most HCCs arise in the setting of underlying cirrhosis, with alcohol use, hepatitis B, and hepatitis C being the most common causes. Other diseases causing cirrhosis are also contributory, such as hemochromatosis, primary biliary cirrhosis, and α_1 -antitrypsin deficiency. Cirrhosis involves chronic hepatocyte injury and ensuing cell regeneration, which provides the substrate for cancer development: inflammatory cytokine stress, constant cell cycling, and aberrant cell development and differentiation.

Clinical Presentation

HCC is frequently masked by the underlying liver disease. Abdominal distention from ascites, fatigue, muscle wasting, anorexia, and encephalopathy are features of cirrhosis. Acute hepatic decompensation or right upper quadrant pain may herald the development of HCC. HCC can also be an incidental finding during routine surveillance by screening ultrasound for patients with cirrhosis.

Diagnosis

HCC is one of those rare malignancies for which a diagnosis can be made without histologic confirmation. Nonhistologic criteria for diagnosis include underlying cirrhosis, elevated α -fetoprotein level (>400 ng/mL), and a characteristic appearance on contrast-enhanced CT or MRI (arterial enhancement and rapid washout). In the absence of underlying cirrhosis, a tissue diagnosis must be obtained. For patients with cirrhosis, a surveillance program incorporating regular measurements of α -fetoprotein and ultrasound imaging can detect early lesions.

Treatment

For small lesions, surgical resection can be curative. Preoperative assessment of liver function to ensure that the patient is an appropriate candidate for partial liver resection is critical. Liver transplantation is an option that can treat HCC as well as the underlying cirrhosis. Strict criteria, such as the Milan criteria (i.e., single tumor ≤ 5 cm, or up to three tumors each < 3 cm, and no vascular invasion), are used to determine which patients are eligible for transplantation. For those who are ineligible for surgical approaches, radiofrequency ablation, transarterial chemoembolization, yttrium-90 embolization, and percutaneous ethanol injection can provide local control. Sorafenib, a multikinase inhibitor that targets RAF kinases (CRAF, BRAF), vascular endothelial growth factor receptors (VEGFR-1, VEGFR-2, VEGFR-3), and other cell surface kinase receptors (PDGFR- β , KIT, FLT3, and RET), has been shown to improve clinical outcomes for metastatic disease.

Prognosis

The 5-year survival rate approaches 50% with complete surgical resection or liver transplantation. For advanced HCC, the median overall survival time with sorafenib therapy remains less than 1 year. It is important to note that prognosis in HCC is often determined by the severity of the underlying liver disease.

COLORECTAL CANCER

Epidemiology

Colorectal cancer is the third most common cancer as well as the third most common cause of cancer-related death in the United States, with approximately 150,000 new cases diagnosed each year. Worldwide, it is a growing problem and is one of the most common cancers. There appears to be an increased association with high dietary fat, red meat consumption, low dietary fiber, obesity, and alcohol use. Conversely, increased physical activity and use of supplemental estrogen, folate vitamin, aspirin, and nonsteroidal anti-inflammatory drugs appear to be protective. A history of inflammatory bowel disease is a risk factor for colorectal cancer.

Pathology

Adenocarcinoma of the colon progresses from normal epithelium to frank cancer in a stepwise fashion, as illustrated in Figure 57-1. Most colon cancers arise in polyps. Typically, hamartomatous polyps are non-neoplastic, serrated, and hyperplastic; they have low neoplastic potential, whereas adenomatous polyps can progress to cancer. Sporadic colon cancers arise by one of three major molecular pathways:

1. The classic adenoma-carcinoma sequence, accounting for about 75% of all colon cancers, is initiated by a somatic mutation of the adenomatous polyposis coli (*APC*) gene. This leads to dysregulation of the *WNT* signaling pathway through release of β -catenin and subsequent upregulation of *MYC* and *CCND1* (*Cyclin D1*), two key cell proliferation genes, causing adenoma formation. As disease progresses, chromosomal instability and mutations in other genes, such as *KRAS*, *TP53*, and *SMAD2/4* accumulate, leading to eventual development of adenocarcinoma.
2. In the DNA mismatch repair pathway, mutations accumulate, leading to the formation of “microsatellites.” This condition, termed *microsatellite instability*, is associated with 15% of all colon cancers. Increased methylation of tandem repeats of cytosine and guanine, called CpG islands, in the promoter region of various genes in this pathway (e.g., *MLH1*), promote

carcinogenesis. *BRAF* mutations are commonly seen in association with this pathway.

3. Promoter methylation, in the absence of microsatellite instability, can also lead to colon cancer formation. These tumors also develop *KRAS*, but not *BRAF*, mutations. Such cases account for about 5% of all colon cancers.

Inherited abnormalities in many of the genes mentioned earlier lead to a genetic predisposition to colon cancer. Such syndromes are responsible for 3% to 5% of all colon cancers. They can be divided into syndromes associated with underlying polyps and those without polyps. Classic familial adenomatous polyposis (FAP) is caused by an autosomal dominant mutation in the *APC* gene. The colon is full of polyps—hundreds to thousands—that start forming during adolescence, leading to development of cancer in early adulthood. Patients with attenuated FAP have fewer polyps and later development of malignancy. *MYH*-associated polyposis is caused by an autosomal recessive mutation in the *MYH* gene, and the phenotype mimics that of attenuated FAP. Peutz-Jeghers syndrome, juvenile polyposis, and Cowden’s syndrome are other uncommon conditions that are associated with an inherited predisposition to colorectal polyps leading to cancer.

The classic nonpolyposis syndrome is hereditary nonpolyposis colorectal cancer, also called Lynch syndrome. Germline recessive mutations in genes involved in the mismatch repair pathway (*MSH2*, *MSH3*, *MSH6*, *MLH1*, *MLH3*, *PMS1*, *PMS2*) lead to adenocarcinoma. These cases are indistinguishable from sporadic cases associated with defective mismatch repair except for the family history of colon and other associated cancers in the inherited syndrome.

Clinical Presentation

Hematochezia and altered bowel habits are the classic symptoms of colon cancer. Early cases are essentially asymptomatic and are typically identified by screening. Advanced cases can manifest with bowel obstruction or perforation, frank rectal bleeding, weight loss, abdominal pain, and ascites due to hepatic or peritoneal metastases. Cancers associated with the mismatch repair pathway have certain typical features: They are right-sided, occur

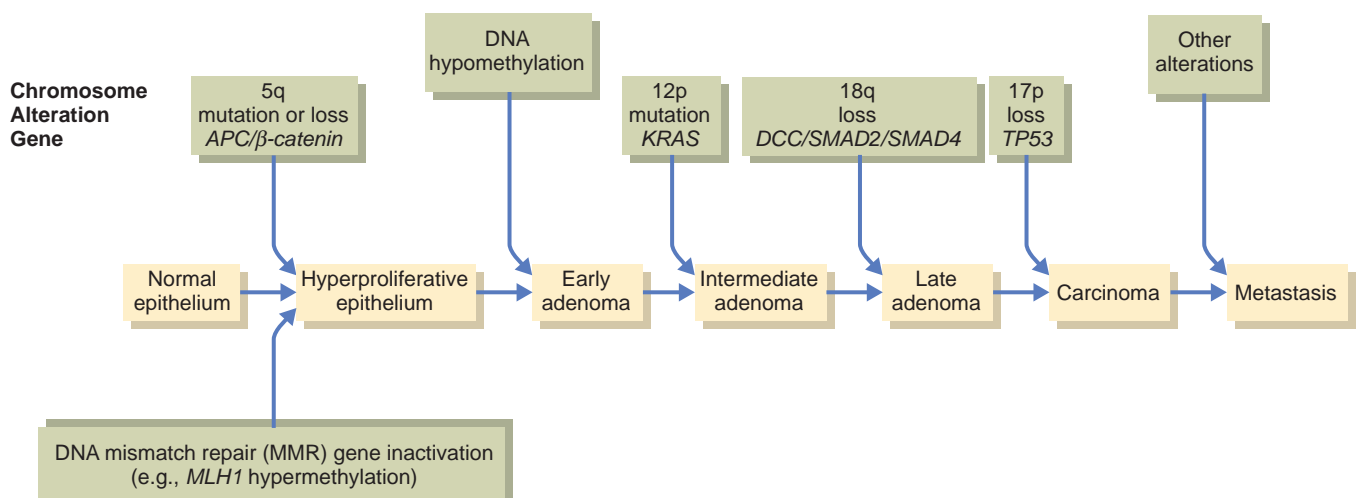

FIGURE 57-1 Model of colorectal carcinogenesis. Several genes are involved in the stepwise progression from normal colonic epithelium to adenocarcinoma.

in younger patients, are more common in women, are poorly differentiated, and are locally advanced but without significant lymph node spread.

Diagnosis

Screening for colorectal cancer is an important public health tool. Screening methods include fecal occult blood testing, imaging (barium enema, CT-guided colonography), and endoscopy (flexible sigmoidoscopy, colonoscopy). The resource setting, patient preference, and risk assessment (personal and family medical history) should guide the choice of screening method. Colonoscopy is the “gold standard” for visual confirmation and histologic diagnosis. In addition, colonoscopy aids in cancer prevention because it allows removal of adenomatous polyps that could progress to cancer if left untreated. Once a cancer diagnosis is established, staging is performed with the use of CT scans to evaluate for distant disease.

Treatment

For patients with resectable disease, surgical resection is the treatment of choice. Removal of the involved segment of the colon, along with the associated mesentery containing all draining lymph nodes, is recommended. Such procedures are being increasingly performed with the use of laparoscopic techniques, resulting in decreased perioperative morbidity. Decisions regarding chemotherapy after surgery (i.e., adjuvant chemotherapy) are based on the pathologic findings. For stage I disease (T1 or T2, N0), no chemotherapy is recommended. For stage III disease (any T, N+), chemotherapy is strongly recommended. A combination of a fluoropyrimidine (5-FU, capecitabine) with oxaliplatin, administered for 6 months, is the standard of care. For stage II disease (T3 or T4, N0), data are controversial. A careful risk-benefit evaluation for each patient is recommended to determine whether adjuvant chemotherapy is appropriate. Rectal cancer is associated with a high rate of local recurrence that can lead to significant morbidity. To improve outcomes, preoperative chemotherapy and radiation therapy are used, and surgery should include total mesorectal excision.

For metastatic colorectal cancer, treatment options include chemotherapy agents such as fluoropyrimidines, oxaliplatin, and irinotecan. The advent of targeted therapies has improved clinical outcomes. These therapies include anti-angiogenic agents (bevacizumab, ziv-aflibercept), anti-epidermal growth factor receptor antibodies (cetuximab, panitumumab), and multikinase inhibitors (regorafenib). Colon cancer is one of the few malignancies in which some cases of metastatic disease can also be cured with aggressive systemic therapy and surgery. Therefore, close surveillance after treatment of the initial cancer is recommended to detect recurrences early. Surveillance should include regular physical evaluation, CT scanning, and measurement of serum levels of carcinoembryonic antigen (CEA), a protein synthesized disproportionately by malignant epithelial cells. Increased physical activity and dietary modifications (reduced red meat and fat; increased fruits, vegetables, and fiber) have been associated with improved outcomes. Another important component of colorectal cancer care is family risk assessment, because this is a common disease, with up to 7500 cases each year in the United States being attributable to heritable

syndromes. Referral for genetic counseling should be made if such a syndrome is suspected.

Prognosis

Among gastrointestinal cancers, colorectal cancer has the best overall prognosis. For nonmetastatic disease, the 5-year survival rate ranges from 50% to 95%, depending on the extent of lymph node involvement. For metastatic disease, newer therapies, given in succession, can achieve a median overall survival time of more than 2 years. The key remains early detection by screening, which can improve population-level outcomes.

ANAL CANCER

Epidemiology

Anal cancer is an uncommon malignancy, with about 7000 cases reported annually in the United States. It is strongly associated with human papillomavirus (HPV) infection. It is also more common in patients with human immunodeficiency virus (HIV) infection and in those who engage in anal-receptive sexual intercourse, most likely because of poor host immunity and increased transmission of HPV, respectively. Condyloma acuminata are precursor lesions for this cancer.

Pathology

The histology is typical of a squamous cell carcinoma, with sheets of hyperproliferative keratinized cells. HPV, especially types 16 and 18, causes inactivation of the tumor suppressor genes *TP53* and *RBI* via the viral proteins E6 and E7, predisposing to eventual development of carcinoma. Chronic local inflammation due to inflammatory bowel disease or recurrent anal fissures and fistulas can also lead to anal cancer.

Clinical Presentation

Local symptoms, such as perianal pruritus or pain, bleeding, discharge, and a mass-like sensation, are common presentations. In cases of chronic underlying disease such as Crohn's disease, the presence of a nonhealing anal or perianal lesion despite good disease control elsewhere should raise suspicion for malignancy.

Diagnosis

Physical examination is adequate to identify suspicious lesions. A biopsy should be obtained to confirm the diagnosis. Evaluation for distant spread should include CT scans of the chest, abdomen, and pelvis. Special attention should be paid to examination of inguinal lymph nodes, because they are common sites of early spread.

Treatment

Anal cancer is one of the few solid tumor malignancies that are curable without surgical resection. For very small, early lesions, complete excision may suffice. However, for most cases, combined chemotherapy with 5-FU and mitomycin, together with radiation therapy, is the standard curative modality. This regimen has significant short-term toxicities that should be managed carefully. This treatment can obviate the need for a large operation that would result in a permanent colostomy.

Prognosis

More than 70% of cases can be cured with chemoradiation. Relapsed disease is usually treated with surgical excision (if local) or systemic chemotherapy (if distant). Widespread vaccination against HPV and better prevention and treatment of HIV infection should lower the incidence of anal cancer.

RENAL CELL CARCINOMA

Definition and Epidemiology

Renal cell carcinoma (RCC) represents 2% to 3% of all malignancies. It is the fifth most common cancer in men and the seventh most common cancer in women, with approximately 65,000 new cases diagnosed in the United States in 2013. Most patients do not have an identifiable risk factor. Smoking is an established risk factor for RCC, with a relative risk of two-fold greater than that of nonsmokers. Less certain risk factors include obesity and hypertension. RCC is also more common in patients with end-stage renal failure or polycystic kidney disease. A small number (3%) of cases of RCC are inherited.

The most recognized inherited RCC is von Hippel-Lindau (VHL) syndrome, an autosomal dominant disorder that is characterized by the development of multiple vascular tumors including clear cell RCC. The genetic event underlying VHL syndrome (inactivation of the *VHL* gene) also occurs in sporadic (noninherited) clear cell tumors, leading to RCC characterized by reliance on blood vessels for growth. Research into this syndrome has led to modified treatment options for advanced disease (see later discussion).

Pathology

The histologic subtypes of RCC are characterized by distinct genetic characteristics, histologic features, and clinical phenotypes. Clear cell RCC (75% of all RCCs) is the most common subtype and is characterized by *VHL* gene inactivation. Less common are the papillary, chromophobe, and unclassified subtypes and medullary RCC, which occurs almost exclusively in patients with sickle cell trait. Although these RCC subtypes are biologically distinct, the current surgical and medical approaches are uninfluenced by subtype.

Diagnosis and Differential Diagnosis

Masses in the kidney may be benign or malignant, with an increasing likelihood of malignancy with increasing size. Most clear cell RCC tumors are distinguishable based on their contrast enhancement. Other considerations for renal masses include benign tumors (e.g., oncocytoma), metastatic disease from another primary site (rare), angiomyolipoma, a lipid-containing benign tumor (most commonly occurring in young females), and infectious processes. The diagnosis is made on the basis of a biopsy or at the time of nephrectomy, although the radiographic appearance of each of the differential diagnoses is often characteristic.

Clinical Presentation

RCC is more common in males (2:1), and the median age at presentation is approximately 65 years. Most contemporary presentations are asymptomatic and incidental (identified on imaging studies ordered for other indications). Classic signs and symptoms include hematuria, flank pain, and a palpable abdominal mass. Systemic symptoms occur with metastatic disease or paraneoplastic syndromes. A renal mass is discovered, usually on computed tomography (CT) scanning, and has an appearance that is characteristic of RCC (i.e., highly vascular). Subsequently, a full staging work-up is performed, including CT scanning of the chest; CT head and bone scans are performed only as symptoms dictate. Diagnosis is usually made at the time of nephrectomy, although a biopsy of the renal mass may be indicated, such as in a patient with distant metastases in whom nephrectomy is not pursued or in a patient with a small renal mass that may be initially observed.

Treatment

Renal Masses

Some renal masses (approximately 20%) are not cancerous, so a diagnostic biopsy is indicated if the radiographic appearance is not classically consistent with RCC. One option for renal masses, even if proven to be RCC, is initial observation. Retrospective series have defined this approach in a select group of patients with renal masses smaller than 4 cm in diameter for whom surgery is not preferred. The growth rate is approximately 3 mm/year, and the reported incidence of development of metastases is very low. If surgery is pursued, then removal of either part of the kidney (partial nephrectomy) or the entire kidney (radical nephrectomy) is the standard of care, depending on factors such as the extent and anatomy of the tumor, native renal function, and surgical skill. Cancer outcomes are equivalent, although renal function is better preserved with partial nephrectomy. Another management option for renal masses is exposure to temperature extremes: freezing (cryotherapy) or burning (radiofrequency ablation). This approach is usually pursued in patients with contraindications to surgery. The long-term outcome awaits further data. To date no clinical trial evidence has demonstrated improvement in patient outcome, either before (neoadjuvant) or after (adjuvant) nephrectomy, regardless of risk of recurrence, despite clinical trials.

Surgery in Metastatic RCC

Removal of the primary renal tumor in the face of metastatic disease (i.e., debulking or cytoreductive nephrectomy) is pursued in patients with good performance status, limited extrarenal disease, and low comorbidities. Two randomized trials have shown an overall survival benefit in these circumstances. In addition, surgical removal of solitary metastatic sites is associated with disease control in up to 30% of highly selected patients.

Systemic Therapy for Metastatic RCC

The initial treatments for metastatic RCC—hormone therapy and chemotherapy—produced only minimal benefits (Table 58-1). Immunotherapy has yielded modest benefits, majority of benefit realized in highly selected patients who have a durable complete response to high-dose interleukin-2. The major treatment advance in metastatic RCC was the discovery of the reliance of the cancer on the vascular endothelial growth factor (VEGF) pathway, which results from *VHL* gene inactivation. This led to the clinical development of a number of VEGF pathway inhibitors, as outlined in Table 58-1. In general, 70% to 75% of patients who receive these drugs have some reduction or stabilization of tumor burden. Periods of disease control typically last for some months, although they can extend to several years in a small minority of patients. Combinations of existing agents are more toxic and no better than monotherapy. The current standard of care is a sequence of monotherapies with agents targeted to VEGF and/or mammalian target of rapamycin (mTOR).

Prognosis

The prognosis of localized kidney cancer is determined largely by the stage and grade of the primary tumor. Other systems have been based on other features, such as tumor necrosis, symptoms at presentation, or performance status. In metastatic disease, established schema associated with prognosis use performance status, time from diagnosis to metastatic disease, and laboratory values (lactate dehydrogenase [LDH], hemoglobin, calcium, neutrophils, and platelets).

BLADDER CANCER

Definition and Epidemiology

Urothelial carcinoma of the bladder (UCB) represents 4% of all malignancies and about 3% of cancer-related deaths in the United

States. It is more common in developed countries and is the fourth most common cancer among men and ninth among women in the Western world. Smoking is an established risk factor for bladder cancer; the incidence rate is four times higher for smokers than for nonsmokers. Occupational exposures from a range of agents that contain aromatic amines, as chlorinated hydrocarbons and polycyclic aromatic hydrocarbons, are believed to account for up to 20% of all bladder cancers. Genetic susceptibility is increasingly recognized as an important risk factor. The risk of bladder cancer is doubled in first-degree relatives of patients with bladder cancer. Inherited genetic factors, such as the slow acetylator *N*-acetyltransferase 2 (*NAT2*) variants and the glutathione *S*-transferase Mu 1 (*GSTM1*)-null genotypes, are established risk factors.

Pathology

Transitional cell carcinoma is the predominant histologic subtype in the United States and Europe, where it accounts for 90% of all bladder cancers. Adenocarcinoma, squamous cell carcinoma, and small cell cancers account for most of the remaining 10%, although there are parts of the world where nonurothelial carcinomas are more common. The bladder wall consists of four layers: urothelium (the innermost epithelial lining), lamina propria, muscularis propria (detrusor muscle), and adventitia (serosa).

Clinical Presentation

UCB is more common in males (4:1), and the median age at presentation is 73 years. Approximately 75% of newly diagnosed cases of UCB are not muscle invasive; the remaining 25% exhibit *de novo* invasion of the muscle wall of the bladder at presentation.

Patients with bladder cancer typically have painless hematuria at presentation, although irritative voiding symptoms (frequency, urgency, and dysuria) can be the initial manifestation. Patients with more advanced disease may have progressive flank or pelvic pain from direct extension of disease or as a consequence of ureteral obstruction.

Diagnosis and Differential Diagnosis

The initial evaluation typically involves an office-based cystoscopic evaluation, with the collection of urine for cytology. Subsequently, patients undergo a transurethral resection of bladder tumor (TURBT) under anesthesia to obtain tissue for histologic

TABLE 58-1 SUMMARY OF THERAPEUTIC APPROACHES IN METASTATIC RCC

AGENT	OBJECTIVE RESPONSE RATE	PFS (mo)	COMMENTS
Hormonal therapy	2%	N/A	Limited, palliative role in the treatment of metastatic RCC
Chemotherapy	5-6%	N/A	Not generally used
Interleukin-2	~20-25% (high dose)	3.1	Durable complete response rate of 7-8%
Interferon alfa	10-15%	4.7	Modest improvement in overall survival compared with inactive therapy
VEGF inhibitors [†]	Approximately 30%	9-11	Common toxicity includes fatigue, mucositis, hand-foot syndrome, diarrhea, hypertension, and hypothyroidism
mTOR inhibitors [‡]	2% (treatment refractory) to 9% (treatment naive)	4-7	Increased overall survival of temsirolimus monotherapy vs IFN monotherapy in poor-risk patients Toxicity includes fatigue, mucositis, rash and hypertriglyceridemia/hyperglycemia/hypercholesterolemia

IFN, Interferon; mTOR, mammalian target of rapamycin; N/A, not applicable; PFS, progression-free survival; RCC, renal cell carcinoma; VEGF, vascular endothelial growth factor.

[†]VEGF inhibitors: sorafenib, sunitinib, pazopanib, axitinib.

[‡]mTOR inhibitors: temsirolimus, everolimus.

diagnosis. Inclusion of muscle in the pathologic specimen is necessary to exclude muscle invasion. Additional evaluation includes CT scanning of the abdomen and pelvis (or CT urogram). For patients with muscle-invasive disease, CT imaging of the chest is indicated; and in patients with bone pain, bone scintigraphy. Most new cases of UCB are staged as Ta (involvement of epithelial lining), T1 (invasion of lamina propria), or carcinoma in situ (CIS); these are typically grouped and considered as non-muscle-invasive bladder cancer (NMIBC).

Patients with low-grade, low-stage bladder cancer remain at high risk for non-muscle-invasive recurrence, whereas patients with higher-grade, higher-stage disease are at increased risk for both recurrence and progression to muscle-invasive disease. Secondary involvement of the bladder with other cancers (e.g., lymphoma, sarcoma) is uncommon.

Treatment

Organ-Confined Disease

Low-grade, low-stage, non-muscle-invasive UCBs are typically managed with TURBT and intravesically administered cytotoxic agents. Multifocal, low-grade recurrent disease or high-risk NMIBC (high-grade T1 or CIS) is managed with intravesically administered bacillus Calmette-Guérin (BCG) or cystectomy.

Muscle-invasive bladder cancer is optimally managed with radical cystectomy and bilateral pelvic lymphadenectomy. For patients who are deemed poor surgical candidates or who refuse cystectomy, external beam radiotherapy and TURBT are alternative management options.

Cisplatin-based multiagent chemotherapy administered before cystectomy (i.e., neoadjuvant chemotherapy) has been shown by level I evidence to improve survival. Although it has not been prospectively evaluated in the neoadjuvant setting, the regimen of gemcitabine plus cisplatin (GC) is widely substituted for the older combination of methotrexate, vinblastine, doxorubicin, and cisplatin (M-VAC).

Metastatic Disease

Level I evidence from a series of phase III trials provides evidence that cisplatin-based chemotherapy (i.e., M-VAC or GC) in patients with de novo metastatic disease leads to median survival times in the range of 14 to 15 months, with 5% to 15% of patients likely to be cured. The latter group is made up primarily of patients with nodal metastatic disease.

Between 30% and 50% of patients with advanced UCB are ineligible for cisplatin because of concomitant renal insufficiency, typically as a consequence of age-related renal comorbidity or disease-related extrinsic obstruction. Although there have been no completed randomized phase III trials comparing cisplatin-based chemotherapy with carboplatin-based therapy in patients with advanced UCB, multiple randomized phase II trials have reported superior activity with cisplatin-based regimens.

The management of disease progression after front-line therapy (either perioperative or in the metastatic setting) is primarily palliative. Currently, there is no level I evidence that systemic therapy yields meaningful improvement in progression-free or overall survival. A large number of chemotherapeutic agents have been studied in the “salvage” setting, and there is no evidence that

multiagent therapy is more effective than single-agent therapy in palliating disease-related symptoms.

Prognosis

Patients with low-grade, low-stage NMIBC typically do not progress to muscle-invasive disease. Their disease does not alter life expectancy but is associated with morbidity and use of health care resources and requires long-term follow-up. Patients with muscle-invasive disease who undergo cystectomy are at risk for systemic failure based on the T stage and extent of nodal involvement. Patients with organ-confined disease without nodal involvement have cure rates greater than 50%. Patients with metastatic disease have median survival times in the range of 14 to 16 months with systemic therapy, and only a small subset (5% to 15%) are long-term survivors.

PROSTATE CANCER

Definition and Epidemiology

Prostate cancer is the most common malignancy among men in the United States; more than 239,000 cases were expected to be diagnosed in 2013. Biologically, prostate cancer is a heterogeneous disease with a diverse but often long natural history. Although the lifetime risk of developing prostate cancer is approximately 1 in 6, most men do not die of the disease. The promiscuous use of prostate-specific-antigen (PSA) measurement as a screening tool has affected the incidence of prostate cancer. Despite a recent transient decline, incidence rates remain high compared with the pre-PSA era.

Multiple risk factors, including age, race, dietary factors, and genetic factors, have been linked to prostate cancer. The median age at diagnosis is 65 years, and younger men (<40 years) rarely develop prostate cancer. African American men have a greater risk of developing prostate cancer compared with white or Hispanic men. Genetic mutations such as *BRCA1/2*, Lynch syndrome, and, more recently, abnormalities in homeobox B13 (*HOXB13*) have been linked to prostate cancer. A man with first-degree relatives affected by prostate cancer has a five-fold to ten-fold increased risk of prostate cancer. Whereas high animal fat intake has been linked to prostate cancer, no association between a diet rich in antioxidants, lycopene, fruit, or vegetables and prostate cancer has been identified.

Recently, a large chemoprevention trial (SELECT) demonstrated that intake of selenium and vitamin E does not reduce the risk of prostate cancer. Two studies evaluating the 5 α -reductase inhibitors, finasteride and dutasteride, demonstrated a 23% to 25% reduction in relative risk of prostate cancer. Despite these benefits, the use of these agents remains low, primarily because of side effects such as erectile dysfunction, lack of libido, and gynecomastia.

Pathology

Prostate cancer is typically diagnosed by transrectal ultrasound and biopsy, often performed after an abnormal PSA level or digital rectal examination result. In patients undergoing radical prostatectomy, the entire prostate, including seminal vesicles and lymph nodes (if present), is analyzed. Prognosis and treatment depend on tumor volume, the presence of perineural invasion,

extraprostatic extension, Gleason score, margin status, and involvement of seminal vesicles. Adenocarcinoma accounts for more than 95% of all prostate cancers. The remaining histologic subtypes include small cell carcinoma and sarcoma. Neuroendocrine differentiation and papillary features carry a poor prognosis.

The Gleason scoring system is pivotal in the management of prostate cancer, but its interpretation requires expertise in pathology. The score is based on growth pattern and degree of differentiation and ranges from 1 to 5 (5 being the least differentiated). The composite Gleason score is derived by adding together the numerical values for the two most prevalent differentiation patterns. For instance, if a specimen comprises primarily a grade 3 pattern and secondarily a grade 4 pattern, the score is reported as 7 (3 + 4). Scores of 8 to 10 represent poorly differentiated cancers, which are associated with poorer outcomes.

Diagnosis and Differential Diagnosis

With the exception of men with metastatic disease at presentation, most patients are diagnosed with the use of extended core biopsies (12 cores). A negative prostate biopsy result does not rule out prostate cancer. For men with metastatic disease, lymph node or bone biopsies can be performed. If the disease is confined to the prostate, imaging studies (bone scans and CT scans of the abdomen and pelvis) are obtained only in high-risk patients (i.e., high Gleason score, high PSA level). After diagnosis, risk stratification based on PSA level, Gleason score, and clinical stage becomes crucial to define management. Other important features determining treatment include age, comorbidities, patient preferences, and life expectancy.

Clinical Presentation

Because prostate cancer can be detected in small subsets even with very low PSA levels (i.e., <1 ng/mL) there is no “normal” PSA value. PSA values can be affected by rectal examination, ejaculation, infection, and urinary obstruction. PSA screening has been used extensively in the United States, but there is no evidence for a consequent reduction in mortality from prostate cancer.

Most men with early disease have no symptoms; however, urinary frequency, urgency, nocturia, and hesitancy do occur. The presence of hematuria or hematospermia should prompt consideration of prostate cancer. An abnormal rectal examination result (asymmetric mass/nodule) is also suggestive of cancer.

Treatment

Available treatment options for localized prostate cancer include radical prostatectomy, radiation therapy (either external beam radiation or brachytherapy), and active surveillance. For men with very-low-risk prostate cancer, active surveillance is appropriate. The selection between radical prostatectomy and radiation therapy is based on risk stratification and patient preferences. Surgery carries risks of urinary incontinence and erectile dysfunction. Radiation therapy has fewer local complications but can cause myelosuppression fatigue and a 3% to 5% lifetime risk of a secondary malignancy. Primary radiation therapy for intermediate- and high-risk patients is often given in combination with androgen deprivation therapy.

Once patients develop advanced disease, androgen deprivation therapy is widely used, although the appropriate timing remains unknown. For men with metastatic disease, continuous therapy with leutenizing hormone releasing hormone (LHRH) agonist with or without anti-androgen is the most common form of treatment, but intermittent androgen deprivation therapy is an effective alternative for patients whose only sign is a rising PSA level. In the setting of de novo metastatic disease, achievement of an undetectable PSA level at 6 months with androgen deprivation therapy predicts good outcome. Androgen deprivation therapy also has major side effects, including night sweats, hot flashes, erectile dysfunction, weight gain, loss of muscle mass, fatigue, bone loss, and metabolic syndrome.

Bone health is a significant problem in men with prostate cancer. Osteoporosis and skeletal-related events from metastases are both common. Two agents are available to prevent these complications: zoledronic acid, a bisphosphonate, and denosumab, a RANK-ligand inhibitor.

All patients with metastatic prostate cancer eventually develop castrate-resistant prostate cancer (CRPC), defined by serologic, clinical, or objective progression in the setting of a castrated testosterone level. Although the mechanism of CRPC is not well understood, several treatment options are now available. Sipuleucel-T, an autologous cell product capable of prolonging survival, and abiraterone acetate, a novel CYP17A1 (C17,20-lyase) inhibitor, are often used in the prechemotherapy setting. Two additional agents, cabazitaxel (a novel chemotherapy agent) and the androgen receptor inhibitor enzalutamide, have become a standard of care after docetaxel-based chemotherapy.

Prognosis

Many patients with favorable-risk, organ-confined disease are cured with surgery or radiotherapy. Most patients who have evidence of PSA recurrence after therapy will eventually manifest metastatic disease, but the natural history is variable. Patients with metastatic disease at presentation typically live for 3 to 5 additional years.

TESTICULAR CANCER

Definition and Epidemiology

The incidence of testis cancer varies widely among racial groups and geographic regions. In the United States, it is the most common cancer diagnosed in men aged 20 to 40 years of age, but it is rarely diagnosed before age 15 or after age 55. It is five times more common in whites than in blacks. The incidence has increased by more than 50% since 1975. Currently, a U.S. male faces a 0.37% lifetime risk of testis cancer and a 0.02% risk of dying from it. Risk factors include cryptorchidism and a personal or family history of testis cancer. Orchiopexy for cryptorchism before puberty reduces the risk of testis cancer.

Pathology

Approximately 95% of testis cancers are germ cell tumors; the others are mostly lymphomas, sex-cord stromal tumors, and adenocarcinomas of the rete testis. Germ cell tumors are divided into two broad categories: seminomas and nonseminomas (i.e., nonseminomatous germ cell tumors, or NSGCTs). Seminomas

by definition are 100% seminoma, whereas most NSGCTs are a mixture of two or more of the five types of germ cell tumors: seminoma, embryonal carcinoma, teratoma, yolk sac tumor, and choriocarcinoma. A tumor that contains any elements of embryonal carcinoma, teratoma, yolk sac tumor, or choriocarcinoma is considered to be an NSGCT even if most of the tumor is seminoma. Because seminomas do not produce α -fetoprotein (AFP), patients who have an elevated AFP level have a NSGCT by definition regardless of the histopathology.

Diagnosis and Differential Diagnosis

Whenever a testis tumor is suspected, transscrotal ultrasound should be performed; if a mass suspicious for cancer is seen, the standard diagnostic procedure is an inguinal orchiectomy. Transscrotal orchiectomy or biopsy is contraindicated because of the risk of seeding the tumor in the scrotum and altering the pattern of spread. Differential diagnosis includes testicular lymphoma, torsion, epididymo-orchitis and other benign scrotal lesions.

Clinical Presentation

Testis cancer most often manifests as testicular enlargement, mass, or induration. It may or may not be painful or tender, and the presence of pain does not exclude a diagnosis of cancer. Testicular atrophy, gynecomastia, back pain, and thromboembolic disease are less common presentations.

Staging the cancer requires measuring postorchiectomy levels of serum AFP, human chorionic gonadotropin (β -HCG), and LDH as well as assessing for nodal and organ metastases, which should be done with a CT scan of the abdomen and pelvis and either chest CT or a chest radiography. The testes drain to the retroperitoneal lymph nodes, and retroperitoneal nodal spread constitutes stage II disease. In practice, testis cancer is divided into three categories: stage I (localized), with no evidence of spread to lymph nodes or beyond; stage II (regional), with enlarged retroperitoneal lymph nodes but no distant metastases; and disseminated disease. Disseminated disease includes stage I or II disease in which serum AFP and/or β -HCG levels are persistently elevated after orchiectomy, bulky stage II disease, and all stage III disease. Metastases to other organs or to pelvic or other nonretroperitoneal lymph nodes represents stage III disease, as does spread to retroperitoneal nodes in the setting of highly elevated serum tumor markers. Disseminated disease is divided into three categories: good-risk, intermediate-risk, and poor-risk disease; treatment differs for the different risk groups.

Treatment

Stage I seminomas and NSGCTs are usually managed with surveillance after surgery. The risk of relapse is about 18% for seminomas and 30% for NSGCTs. Alternatives to surveillance are single-agent carboplatin chemotherapy or radiation therapy for seminomas and bleomycin and etoposide and cisplatin (BEP) chemotherapy or retroperitoneal lymph node dissection (RPLND) for NSGCTs. Long-term disease-specific survival for stage I disease is 99% regardless of which of these approaches is used.

Stage II seminomas are usually treated with radiation, but chemotherapy (with bleomycin, etoposide, and cisplatin [BEP]

or etoposide plus cisplatin [EP]) is used when the disease bulk is greater than 5 cm and sometimes for less bulky tumors. Management of stage II NSGCTs depends on the disease bulk and the levels of serum AFP and β -HCG. If either marker is elevated, then chemotherapy is preferred regardless of disease bulk. If no nodes are bigger than 2 cm and there are fewer than six enlarged nodes, then RPLND or close observation is appropriate. For bulkier disease, chemotherapy is administered, although RPLND may be used in carefully selected cases.

Treatment of stage III disease depends on the sites of metastases and the levels of serum tumor markers. For good-risk disease, the treatment is three cycles of BEP or four cycles of EP chemotherapy. For intermediate- and poor-risk disease, the treatment is four cycles of BEP chemotherapy (or etoposide, ifosfamide, and cisplatin [VIP] chemotherapy). In NSGCT, all residual masses should be resected after chemotherapy if feasible. In cases of seminoma, residual masses are typically observed unless they show increased uptake on 8-fluorodeoxyglucose (FDG) positron emission tomography (PET scan). Patients with pure seminomas and residual masses after chemotherapy are the only testis cancer patients who should be considered for PET scans.

Relapsed disease after chemotherapy is treated with salvage chemotherapy given either at standard doses or at high doses with hematopoietic stem cell support.

Prognosis

Overall, the long-term disease-specific survival rate for testis cancer is 95%. By stage, the survival rates are 99% for stage I, 96% for stage II, and 73% for stage III. By disseminated disease risk category, survival is about 90% for good-risk disease, about 80% for intermediate-risk disease, and about 50% for poor-risk disease.

Breast Cancer

Nicole M. Kuderer and Gary H. Lyman

EPIDEMIOLOGY

Breast cancer is the most common cancer in women other than skin cancer, and it represents the second leading cause of cancer death after lung cancer among women in the United States. An estimated 232,340 women will be diagnosed with invasive breast cancer, and almost 40,000 will die of the disease in 2013. Although breast cancer is far less common in males, more than 2000 men are diagnosed with breast cancer annually in the United States. Whereas reported breast cancer incidence rates have continued to rise, breast cancer mortality has declined by more than 2% annually since 1990 (Figs. 59-1 and 59-2).

Breast cancer is a disease of aging with an increasing incidence throughout most of adult life. Other risk factors for breast cancer include a family history of breast cancer, early menarche, late menopause, nulliparity or initial pregnancy after 25 years of age, prolonged use of exogenous estrogen, exposure to ionizing radiation, and obesity. Women with a history of breast cancer are also at increased risk for breast cancer in the contralateral breast. Although only 5% of patients with breast cancer have the breast cancer susceptibility genes, *BRCA1* and *BRCA2*, genetic counseling and possible testing for *BRCA1* and *BRCA2* should be offered, especially to patients with multiple affected family members and those with a personal or family history of male breast cancer, bilateral breast cancer, breast cancer at a young age (before age 45 to 50 years), ovarian cancer, or certain high-risk ethnicities (e.g., Ashkenazi Jewish).

FIGURE 59-1 Breast cancer incidence rates by race and ethnicity. (Modified from DeSantis C, Siegel R, Bandi P, et al: Breast cancer statistics, 2011, *CA Cancer J Clin* 61:409–418, 2011.)

SCREENING, INITIAL PRESENTATION, AND STAGING

Breast cancer is most often diagnosed through screening mammography or after a patient or her physician notices a palpable mass. Mammographic screening has been shown to reduce breast cancer mortality in both average- and high-risk populations. Although there is some variability among the major breast cancer screening guidelines, most recommend annual screening by mammography with or without physical examination between the ages of 50 to 74 years. Younger women might consider annual or biannual mammographic screening beginning at age 40. Screening with magnetic resonance imaging (MRI) of the breast is recommended in addition to mammography for women with a substantially increased predisposition, especially a strong family history or other genetic predisposition. A palpable breast mass warrants full evaluation even in the absence of diagnostic changes on mammography or breast MRI.

Breast cancer staging requires removal of the primary tumor and assessment of the ipsilateral axillary lymph nodes. Increasingly, lymphatic mapping with sentinel lymph node assessment is being used to evaluate the axilla, with complete lymph node dissection performed only for those with a positive sentinel node biopsy. A subset of women with a good prognosis and only a few positive lymph nodes may be able to forgo lymph node dissection altogether. Women with tumors larger than 5 cm and those with positive axillary lymph node involvement require additional staging imaging: a bone scan

FIGURE 59-2 Breast cancer mortality rates by race and ethnicity. (Modified from DeSantis C, Siegel R, Bandi P, et al: Breast cancer statistics, 2011, *CA Cancer J Clin* 61:409–418, 2011.)

and computed tomographic (CT) scanning of the chest and abdomen. In the absence of signs or symptoms suggestive of metastatic disease, patients with smaller tumors and negative lymph node involvement usually do not require further imaging. Fewer than 10% of women have metastatic breast cancer at diagnosis.

PATHOLOGY

Because of the increasing utilization and sophistication of breast cancer screening, ductal carcinoma in situ (DCIS) is being reported more frequently; however, it is infrequently invasive. Most invasive breast cancers are infiltrating ductal carcinomas, and a smaller proportion are infiltrating lobular carcinomas. Tubular and mucinous carcinomas, a subtype of infiltrating ductal cancers, are associated with a better prognosis. Inflammatory breast cancer is on the other end of the spectrum, frequently denoting a poor prognosis. Inflammatory breast cancer remains a clinical diagnosis: it is recognized by breast skin changes such as edema and erythema of the skin (peau d'orange), often in the absence of a palpable mass.

At the time of breast biopsy and definitive surgery, the estrogen and progesterone receptor status of the primary tumor should be routinely assessed. Overexpression of the human epidermal growth factor receptor *HER2/neu* or its gene amplification is critical for treatment selection and prognosis and should also be assessed. So-called triple-negative tumors—those that are negative for the estrogen and progesterone receptors and for amplification of the *HER2 [ERBB2]* oncogene—are associated with a poorer prognosis and offer fewer treatment options. Triple-negative tumors are more commonly found in women who have the *BRCA* breast cancer susceptibility gene. In women with hormone receptor-positive tumors, gene expression assays may provide additional prognostic information to guide treatment decision making.

TREATMENT

The appropriate care of patients with early-stage breast cancer is multidisciplinary, involving a radiologist, pathologist, surgeon, medical oncologist, radiation oncologist and often others. Breast-conserving therapy with lumpectomy followed by radiation therapy represents the current standard of care for most women with small invasive breast cancers. Women with large tumors may be considered for mastectomy with or without breast reconstruction. Currently, many such patients are considered for neoadjuvant (preoperative) chemotherapy; this may allow breast conservation in these women who would otherwise not be able to undergo a lumpectomy, and it also provides an objective assessment of tumor response to systemic therapy. Women who have had previous radiation to the breast for breast cancer or another malignancy, are usually treated with mastectomy. Frail patients with hormone receptor-positive tumors may be considered for primary hormonal therapy rather than radiation therapy; surgical treatment is usually indicated for these patients.

Adjuvant therapy with chemotherapy and hormonal therapy following definitive surgery improves relapse-free and overall survival rates in premenopausal and postmenopausal women. Subsequent adjuvant therapy for 1 year with the monoclonal antibody trastuzumab improves disease-free survival in patients

with tumors that demonstrate overexpression of the *HER2* oncoprotein or amplification of its *HER2 (ERBB2)* oncogene. DCIS is treated with either lumpectomy followed by radiation therapy or with mastectomy alone. Women with larger or multifocal DCIS should have assessment of their lymph node status to exclude lymph node involvement associated with occult invasive cancer. In the absence of invasive disease, adjuvant chemotherapy is not indicated for DCIS.

The risks and benefits associated with tamoxifen for chemoprevention in patients with higher risk features should be discussed. Women with the *BRCA1* or *BRCA2* breast cancer susceptibility genes should be offered prophylactic bilateral mastectomy and oophorectomy given their high risk for development of invasive breast cancer as well as ovarian cancer at a relatively young age. Close surveillance with breast clinical examinations as well as screening mammography and breast MRI should be offered to those patients with *BRCA* susceptibility genes who elect a nonsurgical approach. Oophorectomy or antiestrogen therapy can help decrease the risk of breast cancer in these women and others at high risk for the disease.

Breast cancer most commonly recurs with metastases in the bone, liver, lung, and central nervous system, but it can recur in any organ system. Rates of breast cancer recurrence and mortality are greater among African American women than white women; those of other ethnicities have lower mortality rates (see Fig. 59-2). Although women with metastatic breast cancer have an average life expectancy of years rather than months, the disease remains incurable. The decision to offer systemic therapy in women with metastatic breast cancer is based on extent and sites of disease, severity of symptoms, patient physical functioning, previous treatment, comorbid conditions, and especially the tumor molecular characteristics of hormone receptor and *HER2* status. Although tumor hormonal status and *HER2* status may change over the treatment course in a patient with metastatic breast cancer, life expectancy is typically longer in women with hormone-responsive (receptor-positive) disease and when the sites of metastases are lymph nodes or bone rather than liver, lung, or central nervous system. Patients with hormone-responsive metastatic breast cancer may live for many years, often responding to hormonal therapy for years before requiring chemotherapy for disease control.

In patients with *HER2*-positive tumors, trastuzumab may be used in combination with chemotherapy or hormonal therapy. Several novel anti-*HER2* therapies have been developed that are changing and expanding the therapeutic options and improving the prognostic outlook of these patients. Many chemotherapeutic agents (singly or in combination), including the anthracyclines, taxanes, alkylating agents, fluoropyrimidines, vinca alkaloids, gemcitabine, and epithilones, demonstrate activity against breast cancer. Bisphosphonates, such as zoledronate and pamidronate, are given intravenously to decrease the pain associated with bone metastases and the risk for fracture in women with skeletal metastases.

PROGNOSIS

Most women with early-stage breast cancer survive for many years after their initial diagnosis and treatment, and many enjoy

a normal life expectancy. The survival of patients with breast cancer has continued to improve over the last several decades because of improved early detection and more effective therapy (see Fig. 59-2). The rapidly increasing number of breast cancer survivors necessitates consideration of a number of important issues, including monitoring for cancer recurrence and management of the delayed and long-term physical and emotional effects of cancer and cancer treatment. Local disease recurrence should be detected early and treated with curative intent. Patients with a prior history of breast cancer are at increased risk for a second primary breast cancer in the ipsilateral or contralateral breast. However, there is no evidence that additional laboratory or imaging procedures (beyond a careful history and physical examination and appropriate screening imaging recommendations) provide further benefit in asymptomatic breast cancer survivors. Patients previously treated with chemotherapy, especially anthracyclines and alkylating agents, are at increased risk for acute myeloid leukemia or myelodysplastic syndrome, although these sequelae are uncommon. Anthracyclines and trastuzumab therapy also increase the risk for congestive heart failure.

The most common symptoms in longer-term breast cancer survivors are fatigue, depression, and sexual dysfunction. Fatigue appears to be the most common post-treatment symptom but is often underreported. Patients with fatigue should be evaluated for early signs of congestive heart failure due to prior therapy with anthracyclines or trastuzumab. Likewise, menopausal symptoms with hot flashes due to ovarian suppression from chemotherapy or the direct effects of endocrine therapy may contribute to fatigue.

Breast cancer survivors should be encouraged to follow a healthy lifestyle including an appropriate low fat diet, regular exercise, and limited alcohol consumption. Recently updated guidelines from the American Society of Clinical Oncology for breast cancer follow-up recommend regular history taking and physical examination every 3 to 6 months for 3 years after the initial diagnosis, followed by annual or biannual follow-up for 2

years and annual follow-up thereafter. It is also appropriate for many lower-risk patients to consider transitioning to a specialized survivorship program or primary care follow-up after the first year.

Improved understanding of the underlying biology of breast cancer along with the complexity of available diagnostic, prognostic, and therapeutic interventions has resulted in a compelling need for close coordination and integration of multiple specialty fields for the optimal care of patients with breast cancer. As efforts to detect breast cancer early and therapeutic interventions continue to improve, increasing importance must be placed on the most appropriate strategies for monitoring and managing the long-term consequences of breast cancer and its treatment in order to provide patients with the best chance for living a long and successful life as breast cancer survivors.

 For a deeper discussion on this topic, please see Chapter 198, "Breast Cancer and Benign Breast Disorders," in Goldman-Cecil Medicine, 25th Edition.

Other Solid Tumors

Michael J. McNamara

INTRODUCTION

Head and neck cancer, melanoma, sarcoma, and carcinoma of unknown primary site are distinct malignancies each with its own epidemiology, histopathology, treatment, and prognosis. Head and neck cancer and melanoma are relatively common, but sarcomas and unknown primary carcinoma are rare. Recent advances in understanding of the molecular biology of cancer and the interaction between the immune system and malignancy have improved therapeutic options for patients with these diseases.

HEAD AND NECK CANCER

Definition and Epidemiology

Head and neck cancers are squamous cell carcinomas that arise from the mucosal lining of the oral cavity, oropharynx, nasopharynx, hypopharynx, and larynx (Fig. 60-1). Other malignancies arising from structures within the head and neck, such as salivary gland tumors or thyroid cancers, differ in regard to biology, presentation, natural history, pathology, and response to therapy.

Head and neck cancer accounts for 3.2% of new cancer diagnoses in the United States. In 2013, there were expected to be 53,640 patients diagnosed with this disease and 11,520 deaths. Chronic exposure to tobacco smoke and alcohol have been considered the strongest risk factors for developing this disease, but in recent decades human papilloma virus (HPV) has been responsible for a dramatic increase in the incidence of oropharyngeal squamous cell carcinoma. Patients with HPV-associated oropharyngeal cancer are typically younger than patients with HPV-negative disease and often have minimal history of tobacco or alcohol use. Rather, these patients share a history of high-risk sexual behaviors, including earlier age at first intercourse and a large number of partners. Nasopharyngeal squamous cell carcinoma is relatively uncommon in the United States and is distinct from other head and neck cancers, given its association with Epstein-Barr virus (EBV) infection.

Pathology

Approximately 95% of all cancers arising from the squamous epithelium of the upper aerodigestive tract are squamous cell carcinomas. Mucosal melanomas, adenocarcinomas, and neuroendocrine tumors are also encountered. Squamous cell carcinomas are subdivided into well differentiated, moderately well differentiated, and poorly differentiated types based on their degree of resemblance to normal squamous epithelium. Poorly differentiated disease is more aggressive and has a worse prognosis. Nasopharyngeal carcinomas are also classified as either

keratinizing or nonkeratinizing, the latter strongly associated with EBV infection.

The increasingly common HPV-associated oropharyngeal cancer differs in molecular profile from alcohol- and smoking-related squamous cell carcinoma. For example, head and neck cancer related to alcohol and tobacco smoke is frequently associated with mutations in the tumor suppressor gene *TP53* and decreased expression of the cell cycle regulatory protein p16-INK4a. Conversely, HPV-associated oropharyngeal cancer displays wild-type *TP53* with increased expression of p16-INK4a. Immunohistochemistry results demonstrating p16-INK4a establishes a diagnosis of HPV-related disease.

Clinical Presentation

The presentation of patients with head and neck cancer depends on the location of the primary tumor and the extent of local disease. Disease dissemination to distant sites is uncommon at the time of diagnosis, so patients rarely have signs or symptoms of metastatic disease at presentation. Tumors of the nasopharynx often block the Eustachian tube or cause epistaxis. Oral cavity tumors may manifest with a painful, ulcerated lesion. HPV-associated oropharynx cancer usually manifests with cervical lymphadenopathy; the primary tumors are often small and asymptomatic. Cancer of the hypopharynx manifests with dysphagia and that of the larynx with hoarseness.

Metastases develop late in the course of this disease, commonly in lung or bone. Patients may also develop hypercalcemia as a paraneoplastic syndrome related to ectopic production of parathyroid hormone-related protein.

Diagnosis and Differential Diagnosis

The diagnosis of squamous cell carcinoma requires biopsy. Staging is accomplished by a combination of imaging and careful inspection of the upper aerodigestive tract. Second primary cancers are common in patients with a history of heavy alcohol and tobacco abuse. CT, MRI, and positron emission tomography (PET) can detect nodal involvement not appreciated on physical examination as well as distant metastases. Patients with squamous cell carcinoma who have cervical lymphadenopathy and no apparent primary site at presentation require random biopsies of the base of the tongue and surrounding tissues, in combination with an ipsilateral tonsillectomy, to identify the occult primary site.

Treatment and Prognosis

The prognosis of head and neck cancer depends on tumor stage. The American Joint Committee on Cancer (AJCC) TNM staging

FIGURE 60-1 Anatomic regions of the head and neck.

system is used. Patients with early-stage disease have an excellent prognosis, with 5-year survival rates approaching 90%. However, only a minority of patients are diagnosed with early-stage disease; cancer is usually locally advanced at the time of diagnosis, with large, invasive primary tumors or regional lymph node metastases. Cure is possible with multimodality therapies, but the aggregate outcome is less favorable.

The prognosis for patients with HPV-associated oropharyngeal cancer is better than for those whose cancer is related to tobacco smoke and alcohol abuse. Both the biology of the disease and medical comorbidities contribute to the poorer prognosis. Furthermore, these patients are at high risk for development of second primary cancers of the upper aerodigestive tract, including lung cancer and esophageal cancer—so-called *field cancerization*: the entire upper aerodigestive epithelium is at increased risk for malignant transformation.

Both surgery and radiotherapy are potentially curative in patients with head and neck cancer. Chemotherapy alone is not a curative treatment, but chemotherapy given simultaneously with radiotherapy, termed *chemoradiotherapy*, may enhance the cytotoxic effects of radiation. Chemoradiotherapy is more efficacious but more toxic than radiotherapy alone. The choice of treatment is based on the location of the primary tumor and the extent of disease. Surgery or radiotherapy alone can cure early-stage disease. Patients with locally advanced cancers require more aggressive management, either chemoradiotherapy or a combination of chemoradiotherapy and surgery.

Radiation-based treatment may be used instead of surgery for disease for which tumor resection could cause cosmetic deformity or loss of organ function. For example, chemoradiotherapy may be used to treat locally advanced laryngeal cancer without the

need to sacrifice the larynx. Although chemoradiotherapy may permit organ preservation, it has both acute and chronic toxicity.

Metastatic disease is incurable, and therapy is palliative. Chemotherapy may mitigate cancer-related symptoms and produce a modest improvement in the median survival time compared with supportive care alone.

MELANOMA

Definition and Epidemiology

Melanoma, a malignant disorder of melanocytes, differs from other common skin cancers by its aggressive behavior and proclivity for regional and distant metastasis. The incidence of melanoma is increasing; it is now the fifth most common cancer in the United States. There were expected to be 76,690 new diagnoses and 9,480 deaths from melanoma in 2013. Melanoma is more common in fair-skinned individuals who tend not to darken with sun exposure. Although there are multiple risk factors for melanoma, sun exposure is the most important. Intense and intermittent sun exposure, especially during childhood and early adulthood, is the strongest risk factor for development of this disease. Chronic or occupational sun exposure does not confer the same degree of risk but may contribute to the development of melanoma on sun-exposed areas such as the head and neck. Other risk factors for melanoma include a family or personal history of this disease, multiple typical nevi, and the presence of atypical nevi.

Pathology

Melanocytes are derived from neural crest cells that have migrated to the epidermis. They occupy the basal layer of the epidermis

and function in part to produce and transfer melanin to keratinocytes, thereby determining the color of skin and hair. There are also benign proliferative disorders of melanocytes, including the common acquired nevus (mole).

Melanoma has four major clinicopathologic subtypes. The most common subtype is superficial spreading melanoma, which can occur anywhere on the body but has a predilection for the torso and legs. Lentigo maligna melanoma manifests typically as a tan macule on chronically sun-exposed areas in older individuals. Nodular melanoma is associated with vertical growth into the dermis and manifests as a dark, nodular lesion. Acral lentiginous melanoma is an uncommon variant found on the palmar and plantar surfaces as well as subungual areas. This subtype is the most common form of melanoma in dark-skinned individuals. Other variants have also been described. Although this classification, which dates from the 1960s, captures the clinical heterogeneity of melanoma, it does not provide prognostic information or help determine clinical management.

Pathologic features that have prognostic relevance include the depth of invasion, the presence of ulceration, and the presence and number of mitotic figures. All of these features are incorporated into the AJCC TNM staging system of malignant melanoma. Increasing depth of invasion predicts a poor prognosis. The risk of lymph node metastasis, distant metastasis, and death, exists on a continuum with increasing tumor thickness. Therefore, patients with thin melanomas (≤ 1 mm thickness) generally have favorable outcomes, whereas patients with thick melanomas (>4 mm thickness), even in the absence of nodal disease, have a 5 year survival rate often less than 50% (Table 60-1).

Clinical Presentation

Most patients with cutaneous melanoma have early-stage disease at presentation. Approximately 15% of patients have clinically apparent regional adenopathy or radiographic evidence for metastatic disease at the time of diagnosis. A number of benign lesions share morphologic features with melanoma, making identification by physical examination challenging. Because survival for patients with limited disease is excellent, early detection is important.

TABLE 60-1 ESTIMATED OVERALL SURVIVAL FOR PATIENTS WITH MELANOMA BASED ON THE DEPTH OF INVASION AND NUMBER OF INVOLVED REGIONAL LYMPH NODES.

DEPTH OF PRIMARY TUMOR INVASION (mm)	AJCC T STAGE	5-YR OVERALL SURVIVAL (%)
≤ 1	T1	95
1.01-2.0	T2	85
2.01-4.0	T3	70
>4.0	T4	55
NUMBER OF INVOLVED REGIONAL LYMPH NODES	AJCC N STAGE	5-YR OVERALL SURVIVAL (%)
1	N1	65
2-3	N2	55
≥ 4	N3	35

Data from Edge S, Byrd DR, Compton CC, et al: AJCC Cancer Staging Manual, ed 7, New York, 2010, Springer.

AJCC, American Joint Committee on Cancer.

Features favoring malignancy are suggested by the ABCDE rule: *asymmetry*, *irregular borders*, *variable color*, *diameter* greater than 6 mm, and *evolving lesion*. A lesion that is changing in shape, size, or color should be considered suspicious.

Melanoma typically disseminates to regional lymph nodes. Regional lymph nodes should be examined. Metastatic disease also occurs in the liver, lung, skin, bone, and brain. Symptoms of advanced disease are highly variable.

In contrast to cutaneous melanoma, mucosal melanoma is often advanced at the time of diagnosis. This disease is rare, and the sites include the head and neck, anorectum, and vulvovaginal areas. Presenting symptoms are similar to those of the more common malignant diseases of these regions.

Diagnosis and Differential Diagnosis

The diagnosis of melanoma requires histologic evaluation of a biopsy specimen. In general, pigmented lesions suspicious for melanoma should undergo an excisional biopsy. This allows adequate assessment of tumor thickness, which informs decisions regarding the need for a sentinel lymph node biopsy and the width of subsequent local excision. If an excisional biopsy cannot be performed, a full-thickness punch biopsy is recommended. So-called shave biopsies of suspicious lesions make subsequent determination of tumor thickness difficult and may provide insufficient material for diagnosis. The histologic diagnosis is based on characteristic morphology and on immunohistochemical staining for markers such as S100, HMB45, and MART 1.

In general, imaging investigations for staging purposes are not required for patients with thin or intermediate-thickness melanoma. The likelihood of demonstrating metastatic disease is low. Patients with thick melanomas or lymph node metastasis detected on clinical examination or by sentinel lymph node biopsy are at high risk for disease dissemination and need radiographic staging by CT of the chest, abdomen, and pelvis. Further imaging depends on the clinical context. For example, patients with clinically advanced melanoma and new, diffuse bone pain should undergo a bone scan; those with neurologic symptoms should undergo brain imaging.

Treatment and Prognosis

The prognosis of melanoma can be accurately estimated using the AJCC TNM staging system. Overall survival depends on the thickness of the primary tumor and the presence and number of regional lymph node metastases. Tumor ulceration and high mitotic rate are associated with a poor prognosis. Metastatic disease is incurable, and the clinical course depends on the pattern and extent of dissemination. An elevated serum lactate dehydrogenase (LDH) level is an independent poor prognostic factor for patients with metastases.

Surgery with wide margins is the cornerstone of curative therapy for nonmetastatic disease. The optimal margin depends on the depth of invasion and the location of the primary lesion but is typically between 1 and 2 cm. Patients with tumors larger than 1 mm in thickness and a negative physical examination should also undergo regional lymph node biopsy to evaluate for metastasis. Patients with melanoma in the initial node or nodes merit lymph node dissection for more accurate staging and to remove any residual disease.

Adjuvant therapy with high-dose interferon may be considered for patients with a high risk of recurrence after complete resection—that is, those with a primary tumor larger than 4 mm or lymph node metastasis. Adjuvant interferon is administered over the course of 1 year; it has substantial morbidity. The improvement in outcome is modest, and the effect on overall survival remains unclear.

For patients with metastatic disease, new agents have been developed based on the molecular biology of the disease and the immune response to malignancy. Ipilimumab, for example, is a monoclonal antibody which targets cytotoxic T-lymphocyte antigen 4 (CTLA-4), an immune regulatory molecule that inhibits T cell activation. The immunomodulatory effects of ipilimumab result in an immune response against tumor antigens, improving the survival of patients with metastatic disease (level A evidence).

Approximately 45% of cutaneous melanomas have activating mutations of the proto-oncogene *BRAF*, a component of the mitogen-activated protein kinase (MAPK) signaling pathway. Vemurafenib and dabrafenib are oral *BRAF* inhibitors that improve the survival of patients with metastatic disease who harbor specific *BRAF* mutations (level A evidence). Trametinib is an orally active agent that targets MEK, another component of the MAPK pathway downstream of *BRAF*. This agent has also demonstrated activity in patients with *BRAF*-mutant metastatic melanoma.

SARCOMA

Definition and Epidemiology

Sarcomas are heterogeneous solid tumors of mesenchymal origin. These tumors are broadly categorized as sarcomas of bone or sarcomas of soft tissue, with several distinct clinicopathologic subtypes. There were expected to be 11,410 new diagnoses of soft tissue sarcoma and 3,010 new diagnoses of bone sarcoma in the United States in 2013. Overall, sarcomas account for fewer than 1% of all new cancer diagnoses.

Most sarcomas are sporadic, but risk factors include prior radiation exposure, chemical carcinogens, and genetic predisposition (familial adenomatous polyposis [FAP], Li-Fraumeni syndrome). Moreover, human herpesvirus 8 (HHV-8) infection is associated with the development of Kaposi's sarcoma.

Soft tissue sarcomas can be further classified by their anatomic site of origin: head and neck, visceral, retroperitoneal, intra-abdominal, and extremity. This categorization is useful for staging, assessing prognosis, and establishing a therapeutic approach. The most common soft tissue sarcomas are gastrointestinal stromal tumors (GISTs), pleomorphic sarcoma, liposarcoma, leiomyosarcoma, and synovial sarcoma. The most commonly encountered sarcomas of bone are the Ewing's family of sarcomas, chondrosarcomas, and osteosarcomas.

Clinical Presentation

Given the heterogeneity of this group of diseases, including differences in tumor biology and in anatomic site of origin, the clinical presentation is variable. Soft tissue sarcomas of the extremities and of the head and neck usually manifest as a progressively enlarging, often painless, mass. Visceral and

intra-abdominal sarcomas including GISTs are often found incidentally and are not symptomatic until they are locally advanced. Symptoms are often nonspecific but may include early satiety, abdominal fullness, bloating, or discomfort.

Bone sarcomas, such as Ewing's sarcoma and osteosarcoma, typically manifest with pain. The most frequently involved locations are the femur, tibia, and humerus. The physical examination may reveal a palpable mass, which is often tender to palpation. Symptoms may be present for several months before diagnosis. Most patients have locally confined disease at diagnosis; the lungs and bone are the most common sites of metastatic spread.

Diagnosis and Differential Diagnosis

The diagnosis of sarcoma can be established only by obtaining histologic confirmation, for which a biopsy is required. This disease must be distinguished from more common malignancies such as lymphoma, melanoma, and poorly differentiated carcinoma. The diagnosis of sarcoma is based on characteristic morphology but may be aided by the use of immunohistochemical and molecular studies. For example, Ewing's sarcoma is often associated with a characteristic reciprocal translocation between chromosomes 11 and 22, t(11:22). Several other molecular derangements have been identified and are helpful in establishing the specific diagnosis.

For bone sarcomas, plain films often demonstrate a mixture of lytic and blastic components with associated soft tissue edema. For osteosarcoma, the periosteal reaction produces a “sunburst” appearance as new bone forms at right angles to the tumor, as opposed to the “onion peel” appearance caused by layering of reactive bone, which is more commonly associated with Ewing's sarcoma.

Treatment and Prognosis

Surgery is the primary therapy for locally confined disease. Radiotherapy before or after surgery may decrease the likelihood of local recurrence. Chemotherapy patients with certain histologic subtypes of sarcoma (Ewing's sarcoma, osteosarcoma) may improve local control, decrease the risk of distant recurrences, and improve overall survival.

Patients with metastatic sarcoma may occasionally benefit from surgical extirpation of their disease. However, once metastatic dissemination has been detected, the intent of therapy is palliative. Chemotherapy can reduce the overall tumor burden and minimize cancer-related symptoms; doxorubicin, ifosfamide, and gemcitabine are used.

Targeted therapies have revolutionized the management of GISTs. The small-molecule tyrosine kinase inhibitor, imatinib, is highly active in patients with GISTs. It rapidly reduces tumor burden with sustained benefit. Imatinib is currently administered to patients with GISTs in the perioperative and advanced/metastatic settings (level A evidence).

CANCER OF UNKNOWN PRIMARY SITE

Definition and Epidemiology

Malignancies for which there is no apparent site of origin after a thorough history, physical examination, imaging investigations, and appropriate diagnostic procedures are referred to as *cancers*

of *unknown primary site* (CUP). CUP accounts for approximately 2% of all new cancer diagnoses in the United States, with 31,860 new cases anticipated in 2013. CUPs are heterogeneous with a highly variable clinical presentation and prognosis. Although the primary site rarely becomes evident during the course of the disease, molecular profiling suggests that CUP is frequently a result of occult lung, kidney, bladder, or pancreaticobiliary cancer.

Clinical Presentation

Most patients with CUP have nonspecific complaints. Constitutional symptoms such as anorexia, weight loss, and fatigue are typical of advanced disease and are commonly present at the time of diagnosis. Pain at the time of presentation is more variable but is frequently experienced by patients with bone metastasis. Less common presenting signs and symptoms include epidural spinal cord compression, hypercalcemia, isolated brain metastasis, ascites, and venous thromboembolic disease.

However, many patients have very few symptoms initially, such as progressive lymphadenopathy only. Occasionally, the diagnosis is arrived at incidentally, during evaluation for an unrelated condition.

Pathology

CUPs are categorized based on histologic evaluation. Most CUPs demonstrate adenocarcinoma histology. However, squamous cell carcinoma, neuroendocrine carcinoma, and poorly differentiated carcinoma are also commonly encountered. Poorly differentiated carcinoma must be distinguished from melanoma, lymphoma, and sarcoma, because the treatments differ by disease.

Immunohistochemistry may disclose the site of origin. For example, in the case of poorly differentiated tumors, the presence of S100 and HMB45 supports a diagnosis of melanoma, whereas CD45 supports a diagnosis of lymphoma. Chromogranin and synaptophysin suggest neuroendocrine differentiation. Cytokeratin 5 (CK5) and CK6 are strongly expressed by squamous cell carcinomas, whereas the expression pattern of CK7 and CK20 can limit the differential diagnosis of adenocarcinomas.

Molecular tumor profiling studies suggest that gene expression profiles can identify the primary site in 60% to 80% of patients. However, it remains unclear whether gene expression profiling improves patient outcomes.

Treatment and Prognosis

CUP confers a median survival time of 8 to 11 months. Therapy is almost always offered with palliative intent. Chemotherapy can

mitigate cancer-related symptoms and improve overall survival. However, there are several clinical presentations for which the prognosis is more favorable and therapy can be curative. For example, a woman presenting with adenocarcinoma isolated to unilateral axillary lymph nodes should be evaluated and treated as for a locally advanced breast cancer, regardless of whether imaging investigations demonstrate a primary breast malignancy. Likewise, a patient with squamous cell carcinoma isolated to cervical lymph nodes at presentation should receive therapy for locally advanced head and neck cancer, again regardless of whether a primary lesion can be identified. In both these circumstances, therapy may prove curative. Another clinical scenario for which specific therapy is beneficial is that of a young man with a poorly differentiated midline tumor: A favorable response to a chemotherapy regimen for germ cell cancers may be beneficial.

Assays that provide a molecular tumor profile, which may more accurately identify the primary site than standard clinicopathologic variables, are currently available.

Complications of Cancer and Cancer Treatment

Bassam Estfan and Alok A. Khorana

INTRODUCTION

Patients with cancer can experience various complications as a direct result of their disease or its treatment. Cancer complications can be localized or systemic (Table 61-1). Cancer treatments, especially chemotherapy and radiation therapy, have potentially significant side effects and complications; most are temporary, but some, such as peripheral neuropathy, can become permanent (Table 61-2). The significance of complications of cancer and its treatment goes beyond quality of life; cancer outcomes can be affected by resulting treatment delay or cessation, dose reduction, and hospitalization. Frequently, the management of cancer complications requires a multidisciplinary approach. This chapter highlights some important complications of cancer and its treatment.

CANCER-ASSOCIATED THROMBOSIS

Epidemiology

Patients with cancer are at increased risk for both venous and arterial thromboembolism; thromboembolic events are the second leading cause of death among patients with cancer.

TABLE 61-1 COMPLICATIONS OF CANCER

LOCALIZED	SYSTEMIC
Brain metastases	Anorexia/cachexia
Cancer-related pain	Cancer-associated thrombosis
Cord compression/cauda equina syndrome	Cancer-related anemia
Malignant effusions	Cancer-related fatigue
Pathologic fractures	Hypercalcemia
Superior vena cava syndrome	Paraneoplastic syndromes
Visceral obstruction	Tumor lysis syndrome

TABLE 61-2 COMPLICATIONS OF CANCER TREATMENT

Alopecia
Central line thrombosis/infections
Cytopenias
Febrile neutropenia
Hot flashes
Hypertension
Nausea and vomiting
Peripheral neuropathy
Secondary malignancies
Skin toxicity
Stomatitis
Tumor lysis syndrome

Pathology

The hypercoagulable state in patients with cancer is a result of activation of the coagulation system by neoplastic cells. Certain cancers such as pancreas, stomach, lung, lymphoma, and brain are particularly associated with venous thromboembolism. Cancer treatments including chemotherapy, anti-angiogenic agents, and hormonal therapy further increase the risk. Other risk factors include central venous catheters, obesity, and prior history of thrombosis and use of erythropoiesis-stimulating agents. Biomarkers, including elevated platelet and leukocyte counts, have also been shown to be predictive. However, risk cannot be determined on the basis of single risk factors alone, because the etiology is multifactorial. The Khorana Score is a validated risk that incorporates five simple clinical and laboratory variables has been endorsed by various guidelines for risk assessment.

Clinical Presentation

Clinical suspicion should be high in cancer patients whose presenting symptoms include dyspnea, cough, wheezing, chest pain, tachycardia, upper abdominal pain, or extremity swelling. Thrombosis remains a consideration even in ambulatory patients and those already receiving adequate anticoagulation. Incidental pulmonary embolisms may be identified on imaging studies conducted for staging of cancer; they are also associated with adverse outcomes and should be treated appropriately.

Treatment

Venous thromboembolism can be prevented with the use of prophylaxis in hospitalized cancer patients. Unfractionated heparin, low-molecular-weight heparins (LMWHs), and fondaparinux are safe and effective. Prophylaxis is being investigated in the ambulatory setting and appears to be beneficial in highly selected patients.

Established thrombosis should be treated with anticoagulation. Oral anticoagulation with warfarin is frequently complicated by interactions with chemotherapeutic agents, variable nutritional status, and relative resistance. In a randomized clinical trial, the LMWH dalteparin, given for up to 6 months, was more effective than warfarin in preventing recurrent thrombosis, and this class of anticoagulants is preferred for first-line therapy.

Vena caval interruption using filters should be considered only if anticoagulation is clearly contraindicated (e.g., in the presence

of active bleeding) or after failure of LMWHs. Novel oral anticoagulants have not yet been studied in the cancer setting.

SPINAL CORD COMPRESSION

Epidemiology

Spinal cord compression is the second most common neurologic complication of cancer after brain metastasis; it is estimated that 2.5% of cancer patients will suffer from cord compression. Breast, lung, and prostate cancers and multiple myeloma are the most common etiologies.

Pathology

Most cases (60% to 70%) occur at the level of the thoracic spine, followed by the lumbar and cervical spine. The conus medullaris terminates at the level of the L1 or L2 vertebral body; epidural disease below that level is associated instead with a cauda equina syndrome. Most spinal metastases affect the vertebral body; compression results from posterior extension of the tumor to the thecal sac. This leads to obstruction of the epidural venous circulation and vasogenic edema of the white and gray matter.

Clinical Presentation

Cord compression usually manifests with gradually worsening back pain around the level of involvement. Sudden positional back pain should raise the suspicion for vertebral compression fracture instead. Pain can become radicular and is usually worsened by the Valsalva maneuver. Sensorimotor neurologic deficit is a sign of advanced cord compression. Motor weakness is more common at presentation (up to 85% of patients); it is usually symmetric, but radicular motor weakness may be noticed with lateral vertebral metastases. Sensory deficit is less common and can manifest as paresthesia or lack of sensation. Bowel and bladder incontinence and urinary retention are usually late findings.

Diagnosis

Cord compression should be suspected clinically with any new back pain in the setting of cancer and rapidly investigated with spinal imaging. Plain radiographs of the vertebrae can reveal abnormalities such as lytic lesions or vertebral fractures, but magnetic resonance imaging (MRI) is the preferred diagnostic imaging modality. MRI of the full spine should be obtained even with localized symptoms, because multiple vertebral levels may be affected.

Treatment

The magnitude of the neurologic deficit before treatment is a good predictor of response and outcome. On diagnosis, pain management is important to allow better ambulation. Glucocorticoids have been used, while definitive therapy is awaited, at doses between 16 and 96 mg/day with both symptomatic and functional relief. There is no proven advantage to higher doses, which can be associated with more side effects. Surgical decompression and radiation are the two main treatment modalities.

In a phase III trial, 101 cancer patients with spinal cord compression were randomly assigned to receive radiation alone

(30 Gy in ten fractions) or surgical decompression followed by the same radiation regimen. More people in the surgical arm were ambulatory at interim analysis (84% versus 57%), and more people in that group regained the ability to walk (10/16 versus 3/16). Radiation therapy alone is useful for palliation of symptoms and local control; it is usually reserved for patients with spinal cord compromise without neurologic deficit or for those with an expected shorter survival time. Initial chemotherapy can be used in highly chemosensitive malignancies such as certain lymphomas or small cell lung carcinoma. Patient age, overall prognosis, and other comorbidities should be considered in treatment decision making.

SUPERIOR VENA CAVA SYNDROME

Definition

Superior vena cava syndrome in malignancy is the result of flow obstruction by either external compression or intravascular thrombosis. The superior vena cava is thin walled and therefore easily compressed. The most common malignant causes are lung cancer and lymphoma.

Clinical Presentation

Presentation depends on the rate of obstruction. Slow compression allows for the development of collaterals from the azygos, internal mammary, paraspinous, lateral thoracic, and esophageal venous systems. The azygos vein is the most important of these, and obstruction below its level is not well tolerated. Symptoms can be sudden or insidious. Most patients experience dyspnea (60% to 70%) and facial or neck swelling (50%). Cough, pain, arm swelling, and dysphagia are less common. Symptoms are frequently exacerbated by leaning forward or lying down. Physical findings may include venous distention of neck and chest wall, facial edema, plethora, cyanosis, and upper extremity edema.

Diagnosis

Plain chest radiographs are usually abnormal; mediastinal widening (64%) and pleural effusion (26%) are the most common findings. The diagnosis is best established with contrast-enhanced computed tomographic scanning of the chest. It demonstrates the location and size of masses, the presence of intravascular thrombosis, and collateral venous drainage. When superior vena cava syndrome is the initial manifestation of malignancy, pathologic diagnosis is the first step in establishing the proper initial treatment modality.

Treatment

The goals of treatment are to alleviate symptoms urgently and to treat the underlying malignancy. General supportive measures include head elevation and administration of glucocorticoids and diuretics. It is essential not to start radiation or glucocorticoids before obtaining a biopsy, because they could mask the diagnosis. Specific management depends on the underlying pathology. Chemotherapy is the preferred first line of therapy for chemosensitive malignancies such as lymphoma, small cell lung cancer, or germ cell tumors. For non-small cell lung cancers and other less chemosensitive tumors, initial radiation therapy may be preferred.

Symptomatic relief can occur within 2 weeks but is often temporary; therefore, systemic management should be initiated when indicated. Some tumors require surgical treatment. Persistent symptoms not relieved by chemotherapy or irradiation and those severe enough to warrant intervention before diagnosis can be successfully managed with endovascular stent placement with or without balloon angioplasty. For catheter-related thrombosis, anticoagulation is indicated; the decision regarding catheter removal should be individualized.

● HYPERCALCEMIA

Epidemiology

Hypercalcemia complicates cancer in up to 10% of cases, occurring in both hematologic and solid malignancies. The most common etiologies are multiple myeloma, breast cancer, and squamous cell carcinoma.

Pathology

Mechanisms leading to hypercalcemia include osteolysis due to bony involvement and tumor production of parathyroid hormone–related protein (PTHrP), calcitriol, or cytokines. Even in the presence of cancer, primary hyperparathyroidism should be ruled out. Many cancer patients have low albumin and calcium levels that should be corrected.

Clinical Presentation

Early symptoms of hypercalcemia include constipation, polydipsia, polyuria, nausea, vomiting, and bradycardia. Most patients have signs of dehydration. Altered mental status is often a presenting symptom. The severity of symptoms depends on the time course over which hypercalcemia has developed rather than the absolute calcium level.

Treatment

Calcium supplements, vitamin D, and diuretics should be stopped. Aggressive fluid resuscitation with normal saline at 200 to 300 mL/hour should be started to maintain a high urine output. This should be done carefully in patients with compromised cardiac or renal function. These measures may be adequate for mild hypercalcemia, but moderate and severe hypercalcemias require further interventions.

Bisphosphonates are the preferred agents for management. They inhibit osteoclasts and bone resorption. Intravenous pamidronate and zoledronic acid are the two most commonly used bisphosphonates. In a pooled analysis, zoledronic acid was associated with a higher rate of calcium normalization and longer control. Calcium response to bisphosphonates can take a few days; therefore, if a rapid reduction is required for acute hypercalcemia, subcutaneous calcitonin (4 units/kg) can be given 2 to 4 times daily. Calcitonin works by increasing calcium renal excretion and reducing bone resorption. Other agents less commonly used in the management of hypercalcemia include gallium nitrate and glucocorticoids. Management should eventually include control of the underlying disease. Frequently, new or recurring hypercalcemia indicates disease progression or treatment resistance, which should be addressed with systemic therapy.

● FEBRILE NEUTROPENIA

Definition

Febrile neutropenia is a common complication of chemotherapy. It is defined as a temperature of 100.4° F (38° C) in the setting of a neutrophil count lower than 500/ μ L (or lower than 1000/ μ L with a predicted decrease to less than 500/ μ L in the next 48 hours). The risk of febrile neutropenia increases with the intensity of the chemotherapy regimen and the severity and duration of neutropenia. It can lead to treatment delays or interruptions, prolonged hospitalizations, decreased quality of life, and increased morbidity and mortality.

Treatment

Although most cases are managed in the hospital, low-risk patients may occasionally be successfully managed as outpatients. The American Society of Clinical Oncology (ASCO) has published guidelines for outpatient management that are based on a risk-stratified scoring system. All patients should have a history and physical examination to identify possible focal sources of infection. Attention should be given to the presence of mucositis and to swelling or induration and erythema around indwelling catheters as possible sources of infection. The initial workup should include a full chemistry profile, complete blood count with differential, blood cultures with at least one from each existing catheter tip, urinalysis, and chest radiography.

Once the diagnosis is established and cultures have been obtained, empiric treatment with broad-spectrum antibiotics must be initiated. Frequently, organisms are not identified on cultures. Therapy is usually directed to coverage of gram-negative bacteria with cefepime or piperacillin-tazobactam. If line infection or mucosal or skin infection is suspected, vancomycin is indicated. Prolonged neutropenia increases the risk of fungal infections, and antifungal agents should be considered. The duration of antimicrobial treatment is determined on an individual basis, but it should continue at least until there is evidence of bone marrow recovery (usually a neutrophil count >500). Prophylaxis with myeloid growth factors such as filgrastim or pegfilgrastim can reduce the risk of febrile neutropenia from chemotherapy and is used in high-risk settings.

● CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

Definition

Nausea and vomiting are perhaps the most feared adverse effects of chemotherapy. Chemotherapy agents are stratified according to risk of emetogenicity (Table 61-3). Nausea and emesis are typically categorized as acute, delayed, or anticipatory. Acute nausea and vomiting occurs during the first 24 hours of treatment, whereas delayed nausea occurs 2 to 5 days after treatment initiation. Patients with high levels of anxiety or prior poor control of nausea may also suffer symptoms in anticipation of starting treatment. The risk of chemotherapy-induced nausea and vomiting is greater in younger patients and in women. A history of increased alcohol consumption is associated with lower risk.

TABLE 61-3 NAUSEA AND VOMITING RISK WITH CANCER THERAPY

EMETIC RISK	PERCENTAGE OF PATIENTS AFFECTED	REPRESENTATIVE AGENTS	RECOMMENDED PREVENTIVE ANTIEMETIC
High	>90	Cisplatin, high-dose cyclophosphamide	NK1 antagonist + dexamethasone + 5HT3 antagonist
Moderate	30-90	Oxaliplatin, doxorubicin, irinotecan	5HT3 antagonist + dexamethasone
Low	10-30	Paclitaxel, etoposide, gemcitabine	Dexamethasone or 5HT3 antagonist or dopamine antagonist
Minimal	<10	Vincristine, bleomycin	Not needed

5HT3, Serotonin receptor; NK1, neurokinin 1.

Pathology

The mechanism is not completely understood but involves an effect of chemotherapy on the gastrointestinal mucosa and central nervous system, such as the chemoreceptor trigger zone (area postrema). The neurotransmitters that are involved include dopamine, serotonin, and substance P.

Treatment

The best approach for treatment is prevention. The prophylactic antiemetic protocol depends on the chemotherapy regimen and emetic risk (see Table 61-3). Randomized clinical trials have established that the combination of a neurokinin 1 (NK1) receptor antagonist (aprepitant or fosaprepitant), a 5HT3 serotonin receptor antagonist, and dexamethasone is the regimen of choice for highly emetogenic chemotherapy. For moderately emetogenic chemotherapy, a 5HT3 antagonist with dexamethasone is usually adequate. All patients should be given a dopamine or 5HT3 receptor antagonist as rescue therapy for intermittent nausea.

Dexamethasone is the preferred treatment for delayed nausea and vomiting in highly and moderately emetogenic chemotherapy. Other agents with proven efficacy include olanzapine for the prevention of both acute and delayed nausea and vomiting. Anticipatory nausea or vomiting is best treated with proper control of symptoms in the initial cycles. When it occurs, it is best treated with a benzodiazepine before chemotherapy.

DERMATOLOGIC TOXICITY

Many chemotherapeutic and targeted agents are associated with dermatologic toxicity, which can lead to patient morbidity, alter quality of life, and affect therapeutic dosing.

Clinical Presentation

Acneiform eruptions are observed with agents targeted against epidermal growth factor receptor (EGFR) in 70% to 80% of patients. The rash is usually erythematous with pustulopapular eruptions over the face, scalp, and upper trunk.

Palmar-plantar erythema, or so-called hand-foot syndrome, is seen with chemotherapeutic agents such as 5-fluorouracil and capecitabine or with tyrosine kinase inhibitors such as sorafenib, sunitinib, and regorafenib. Manifestations can differ slightly between classes of drugs, but they usually involve symmetrical redness of the palms or soles. Tingling and pain may accompany erythema. With progression, painful blistering or skin peeling may occur. Symptoms are frequently observed at pressure areas, such as on the soles of the feet after prolonged standing or running.

Treatment

Treatment of skin rash associated with anti-EGFR therapies is tailored to the severity of the rash and may include topical steroids, oral antibiotics (minocycline or doxycycline), and dose modification or cessation. Sunscreens, reduced sun exposure, and lotions for dry skin should be used for prevention. For hand-foot syndrome, preventive measures such as sunscreens and routine application of lotion to hands and feet are helpful. The most effective treatment is a brief treatment break (typically for several days, until complete resolution occurs), followed by resumption but with a reduced dose of the inciting agent.

TUMOR LYSIS SYNDROME

Definition

Tumor lysis syndrome occurs in malignancies with a high proliferative rate (such as aggressive lymphoma or leukemia), usually after the initiation of cytotoxic chemotherapy. It is an oncologic emergency. Rarely, it can occur spontaneously.

Pathology

Massive tumor cell lysis causes the release of large amounts of potassium, phosphate, and nucleic acids into blood. This leads to rapidly increased production of uric acid, which can precipitate in the renal tubules, causing acute renal insufficiency.

Diagnosis

Tumor lysis syndrome should be suspected in the presence of hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia. Elevated creatinine can occur with renal damage from uric acid precipitation.

Treatment

In the appropriate clinical setting, tumor lysis syndrome should be anticipated and prevented. An international panel has developed a risk stratification scheme. Aggressive hydration is key to preventing this syndrome and should continue until the tumor burden is largely resolved. Allopurinol at a dose of 150 mg—or, in high-risk cases, rasburicase at a dose of 0.2 mg/kg—can be used for prophylaxis. Rasburicase may also be used to treat severe hyperuricemia and to prevent renal insufficiency.

For a deeper discussion on this topic, please see Chapters 176, "Hypercoagulable States," Chapter 179, "Tumor Lysis," Chapter 245, "Hypercalcemia," and Chapter 400, "Spinal Cord Compression" in Goldman-Cecil Medicine, 25th Edition.

Hypothalamic-Pituitary Axis

Kawaljeet Kaur and Diana Maas

ANATOMY AND PHYSIOLOGY

The pituitary gland sits in the skull base in a bony structure called the sella turcica. It weighs approximately 600 mg and is composed of three lobes, the adenohypophysis (anterior lobe), the neurohypophysis (posterior lobe), and the intermediate lobe. The infundibular stalk, which contains the portal plexus circulation, connects the hypothalamus to the pituitary gland. The pituitary gland is surrounded by important structures that can be compromised by its enlargement, including the optic chiasm, located superior to the gland, and the cavernous sinuses, located on both sides of the gland. The cavernous sinuses each contain the internal carotid artery and cranial nerves III, IV, V1, V2, and VI. (Fig. 62-1).

The anterior pituitary gland produces six hormones that are produced by specific cell types within the gland: adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), growth hormone (GH), prolactin, and thyroid-stimulating hormone (TSH or thyrotropin). These hormones are regulated by stimulatory and inhibitory peptides produced within the ventral hypothalamus and are transported to the anterior pituitary gland by the infundibular portal system. The posterior pituitary gland makes up about 20% of the total pituitary mass and stores and secretes two major peptide hormones: vasopressin (AVP or antidiuretic hormone) and oxytocin. These neurohypophyseal hormones are synthesized by the supraoptic and paraventricular nuclei of the hypothalamus and transported to the posterior lobe in neurosecretory granules along the supraopticohypophyseal tract. (Table 62-1) The intermediate lobe regresses in humans at about 15 weeks gestation and is absent in the adult normal pituitary gland.

On imaging studies, the normal adult pituitary gland has a flat superior border and a vertical height of approximately 8 to 10 mm. The anterior pituitary is homogeneous in signal on magnetic resonance imaging (MRI), the preferred imaging method, and enhances homogeneously after intravenous administration of a contrast agent (see Fig. 62-1). During periods of increased hormonal activity, most notably during pregnancy, the pituitary gland can increase in size and change shape. The posterior pituitary lobe is distinguished from the anterior lobe on T1-weighted MRI as a bright spot in the posterior aspect of the gland, best seen on a sagittal view. The bright appearance is thought to result from the presence of AVP and/or phospholipid vesicles within the normal neurohypophysial.

PITUITARY TUMORS

Pituitary tumors account for approximately 10% to 15% of intracranial tumors. They are the most common tumors in

FIGURE 62-1 Coronal section and corresponding magnetic resonance imaging scan of the pituitary gland and surrounding structures, including cranial nerves III (oculomotor), IV (trochlear), V1 (trigeminal, ophthalmic branch), V2 (trigeminal, maxillary branch), and VI (abducens). CC, Carotid artery (intracavernous); CS, cavernous sinus (left); IC, internal carotid artery; OC, optic chiasm; Pit, pituitary gland; SS, sphenoid sinus. (From Jesurasa A, Kailaya-Vasan A, Sinha S: Surgery for pituitary tumors, *Surgery* 29:428–433, 2011, Figure 1.)

the sella, accounting for more than 90% of masses that develop in that area, and they are usually benign. Their true incidence is difficult to determine because they are often asymptomatic, but the prevalence is about 10% to 20% in radiologic studies. Most pituitary tumors are slow growing, but some have higher growth rates and can be invasive. Pituitary carcinomas are very rare and are defined by the presence of a metastasis that is noncontiguous with the original tumor or cerebrospinal fluid dissemination.

TABLE 62-1 PITUITARY–TARGET ORGAN HORMONE AXIS

HYPOTHALAMIC HORMONE	PITUITARY TARGET CELL	PITUITARY HORMONE AFFECTED	PERIPHERAL TARGET GLAND	PERIPHERAL HORMONE AFFECTED
STIMULATORY				
Anterior Lobe of Pituitary Gland				
Thyrotropin-releasing hormone (TRH)	Thyrotroph	Thyroid-stimulating hormone (TSH)	Thyroid gland	Thyroxine (T ₄) Triiodothyronine (T ₃)
Growth hormone-releasing hormone (GHRH)	Somatotroph	Growth hormone (GH)	Liver	Insulin-like growth factor-I (IGF-I)
Gonadotropin-releasing hormone (GnRH)	Gonadotroph	Luteinizing hormone (LH)	Ovary Testis	Progesterone Testosterone
		Follicle-stimulating hormone (FSH)	Ovary Testis	Estradiol Inhibin
Corticotropin-releasing hormone	Corticotroph	Adrenocorticotrophic hormone (ACTH)	Adrenal gland	Cortisol
Posterior Lobe of Pituitary Gland				
Vasopressin (AVP)			Kidney	
Oxytocin			Uterus Breast	
INHIBITORY				
Somatostatin	Somatotroph	GH	Thyroid	
	Thyrotroph	TSH	Liver	
Dopamine	Lactotroph	Prolactin	Breast	

Pituitary tumors are classified by size and functionality or secretory capacity. Tumors that are smaller than 10 mm in diameter are called *microadenomas*, whereas lesions 10 mm or larger are called *macroadenomas*. Hormone-producing tumors are called *secretory adenomas*, and those that do not secrete a hormone are known as *nonsecretory adenomas*. Pituitary tumors may be composed of any of the anterior pituitary cell types, with multiple cell types forming plurihormonal tumors or nonsecretory tumors. Prolactin-secreting pituitary tumors are the most common type. [Table 62-2](#) reviews the prevalence of the various pituitary tumors, and [Table 62-3](#) describes the screening tests used to determine the secretory status of a new pituitary tumor.

The clinical manifestations of pituitary tumors are usually signs and symptoms caused by hormone overproduction or underproduction or mass effect. Common clinical features of pituitary mass effect include headaches, visual field defects, and cranial nerve palsies. Superior extension of a tumor compresses the optic chiasm, causing bitemporal hemianopsia; lateral

TABLE 62-2 PREVALENCE OF PITUITARY TUMORS

TUMOR	PREVALENCE (%)
Prolactinomas	40-45
Somatotroph adenomas	20
Corticotroph adenomas	10-12
Gonadotroph adenomas	15
Null cell adenomas	5-10
Thyrotroph adenomas	1-2

extension into the cavernous sinuses results in ophthalmoplegia, diplopia, or ptosis due to compression of cranial nerves III, IV, or VI or facial pain due to compression of V1 or V2. Compromise of normal pituitary tissue by a tumor can cause hormone loss or hypopituitarism. Screening tests for pituitary hormone deficiency are shown in [Table 62-3](#); typically, a destructive pituitary lesion causes loss of pituitary hormones in the following progression: first GH, then FSH and LH, then TSH, and finally ACTH.

Disorders of Anterior Pituitary Hormones

PROLACTIN

Definition and Epidemiology

The mature prolactin polypeptide contains 199 amino acids and is formed after a 28-amino acid signal peptide is proteolytically cleaved from the prolactin prohormone (preprolactin). Prolactin synthesis and secretion by pituitary lactotrophs is under tonic inhibitory control by hypothalamic-derived dopamine, which keeps prolactin at its basal levels. Factors stimulating prolactin synthesis and secretion, in addition to reduced dopamine availability to the lactotrophs, include

thyrotropin-releasing hormone (TRH), estrogen, vasoactive intestinal polypeptide (VIP), AVP, oxytocin, and epidermal growth factor.

Prolactin levels physiologically increase during pregnancy. After delivery, prolactin induces and maintains lactation of the primed breast. Once lactation has been initiated by these elevations in prolactin, prolactin falls to basal levels and lactation is maintained by the infant's suckling reflex. Hyperprolactinemia, regardless of the etiology, can cause hypogonadism through its inhibitory effect on gonadotropin release, infertility, galactorrhea, and/or bone loss from the hypogonadism.

TABLE 62-3 SCREENING TESTS FOR PITUITARY DISORDERS

DISORDER	TESTS	DISORDER	TESTS
PITUITARY TUMOR		HYPOPITUITARISM	
Acromegaly	IGF-I OGTT: measure blood sugar and GH (0, 60, 120 min)	GH deficiency	IGF-I GH provocative test: ITT Arginine-GHRH Glucagon stimulation test
Prolactinoma	Basal serum prolactin	Gonadotropin deficiency	Women: basal estradiol, LH, FSH Men: 8 AM fasting testosterone (total; free), LH, FSH
ACTH-secreting tumor	24-hr urine-free cortisol and creatinine level 1-mg overnight dexamethasone suppression test 11 PM salivary cortisol Serum ACTH Dexamethasone-CRH test Bilateral inferior petrosal sinus sampling	TSH deficiency	Serum TSH, free T ₄
TSH-secreting tumor	Serum TSH, FT ₄ , FT ₃	ACTH deficiency	ACTH Provocative test: ITT Metyrapone test Cosyntropin-stimulation test (1 µg and 250 µg)
Gonadotropin-secreting tumor	FSH, LH, alpha subunit		

ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF-I, insulin-like growth factor-I; ITT, insulin tolerance test; LH, luteinizing hormone; OGTT, oral glucose tolerance test; T₄, thyroxine; TSH, thyroid-stimulating hormone; TTT, thyroid function test.

Prolactinomas and hyperprolactinemia are more common in women, with a peak prevalence between 25 and 35 years of age. The mean prevalence of patients medically treated for hyperprolactinemia is approximately 20 per 100,000 in men and approximately 90 per 100,000 in women. Prolactinomas are rare in childhood or adolescence.

Clinical Presentation

The clinical presentation of a prolactinoma varies with the age and gender of the patient. Typically, the patient is a young woman with menstrual irregularities, galactorrhea, and infertility. Galactorrhea occurs in 50% to 80% of affected women. Men may report a decrease in libido and erectile dysfunction as result of hypogonadism caused by reduced secretion of LH and FSH. Typically, however, their tumors are diagnosed after symptoms of tumor compression appear, including headache, neurologic deficits, and vision changes. Galactorrhea and gynecomastia are rare in men. Because of the early presentation of menstrual irregularities in women, microprolactinomas are more common in women; macroprolactinomas are more frequent in men and in postmenopausal women.

Diagnosis and Differential Diagnosis

Hyperprolactinemia is diagnosed by a single measurement of serum prolactin; a level above the upper limit of normal confirms the diagnosis. For prolactinomas, serum prolactin levels typically parallel tumor size. A prolactin level greater than 250 ng/mL usually indicates the presence of a prolactinoma. Dynamic testing is not needed to diagnose hyperprolactinemia.

Two types of artifacts can occur during the standard measurement of prolactin: the presence of macroprolactin and the hook effect. When a patient with mild hyperprolactinemia does not have the expected clinical features of hyperprolactinemia (e.g., galactorrhea, menstrual disturbance, infertility), one should consider the presence of macroprolactin. Although 85% of circulating prolactin is monomeric, serum also contains the macroprolactin, a polymeric form of prolactin that is biologically inactive. Most commercially available prolactin assays do not detect macroprolactin, but it can be detected inexpensively in the serum by polyethylene glycol precipitation. The estimated incidence of macroprolactin accounting for a significant proportion of hyperprolactinemia is 10% to 20%. The hook effect should be

considered whenever a patient has a very large pituitary mass but only a mild elevation in prolactin. The hook effect is an assay artifact that occurs when very high serum prolactin concentrations saturate antibodies in the standard two-site immunoradiometric assay, resulting in falsely lower levels. This artifact can be overcome by repeating the prolactin measurement on a 1 : 100 serum sample dilution.

Physiologic increases in prolactin occur with pregnancy, physical or emotional stress, exercise, and chest wall stimulation. Other causes for hyperprolactinemia include some drugs, such as metoclopramide and risperidone, that can increase prolactin to greater than 200 ng/mL. Mild to moderate hyperprolactinemia (25 to 200 ng/mL) in the presence of a larger pituitary mass is more likely to be caused by a non-prolactin-secreting tumor with infundibular stalk compression and inhibition of dopamine transport to the lactotroph. Other causes include hypothalamic-pituitary disorders, systemic disorders, and neurogenic and idiopathic etiologies.

Treatment and Prognosis

Medical management with a dopamine agonist—bromocriptine or cabergoline—is the recommended treatment. The dopamine agonists normalize prolactin, decrease tumor size, and restore gonadal function in more than 80% of patients with prolactinomas. Because of the rapidity and efficacy of the dopamine agonists in treating these tumors, they are also the initial treatment for macroprolactinomas that have caused compromise in vision, neurologic deficits, or pituitary dysfunction.

Cabergoline, the newer agent, is preferred to other dopamine agonists because it has higher efficacy in normalizing prolactin levels and shrinking tumor size and has fewer side effects. The most common side effects seen with dopamine agonists are nausea, vomiting, orthostatic lightheadedness, dizziness, and nasal congestion. Because of the concern for cabergoline-related cardiac valvulopathy that was reported in patients who had Parkinson's disease treated with high doses of cabergoline and the possible long-term need for treatment, bromocriptine could be used in young patients if it is tolerated. Transsphenoidal resection of the tumor is indicated for patients who cannot tolerate the dopamine agonists or who do not respond to medical treatment. No treatment is required for patients who have microprolactinomas that are asymptomatic.

Recent studies have shown that dopamine agonists may be safely withdrawn in patients who have maintained normal prolactin levels for 2 years and who have no visible tumor remnant on tapering doses of dopamine agonist. Once the dopamine agonist is discontinued, prolactin levels should be checked every 3 months for 1 year and then annually. An MRI should be obtained only if the prolactin level becomes elevated again. Recurrence risk after drug withdrawal ranges from 26% to 69% and is predicted by the initial prolactin level and tumor size.

GROWTH HORMONE

Definition

GH is a single-chain polypeptide hormone consisting of 191 amino acids that is synthesized, stored, and secreted by the anterior pituitary somatotrophs. GH secretion is regulated by two factors derived from the hypothalamus: growth hormone-releasing hormone (GHRH) and somatostatin. GHRH stimulates somatotroph GH release, and somatostatin inhibits it. GH stimulates secretion of insulin-like growth factor-I (IGF-I) by the liver. IGF-I circulates in the blood attached to binding proteins; although there are six binding proteins in serum, more than 80% of IGF-I is bound to a protein called IGFBP3. Postnatally and through puberty, GH and IGF-I are critical in determining longitudinal skeletal growth, skeletal maturation, and acquisition of bone mass. In adulthood, they are instrumental in the maintenance of skeletal architecture and bone mass. GH also has effects on the metabolism of carbohydrates, lipids, and proteins by antagonizing insulin action, increasing lipolysis and free fatty acid production, and increasing protein synthesis.

Growth Hormone Deficiency

Epidemiology

Childhood-onset GH deficiency is most commonly idiopathic, but it may be genetic or associated with congenital anatomic malformations in the brain or sellar region. The most common cause of GH deficiency in adults is a pituitary macroadenoma and its treatment; deficiency of one or more pituitary hormones occurs in 30% to 60% of such cases. The incidence of hypopituitarism 10 years after irradiation of the sellar region is approximately 50%.

Clinical Presentation

Children with GH deficiency exhibit growth retardation, short stature, and fasting hypoglycemia. Manifestations of adult GH deficiency include reduced bone mineralization, decreased muscle strength and exercise performance, decreased lean body mass with increase in fat mass and abdominal adiposity, glucose intolerance and insulin resistance, abnormal lipid profile including elevated low-density lipoprotein and triglyceride levels with decreased high-density lipoprotein, depressed mood, and impaired psychosocial well-being.

Diagnosis and Differential Diagnosis

Because of the pulsatile nature of pituitary GH secretion, a single random measurement of serum GH is not helpful to diagnose GH deficiency. In adults with GH deficiency due to a pituitary tumor and concomitant hypopituitarism involving any three

other pituitary hormones, a low IGF-I level is sufficient to diagnose GH deficiency, and provocative testing is not warranted. Falsely low IGF-I levels are also seen in malnutrition, acute illness, celiac disease, poorly controlled diabetes mellitus, liver disease, and estrogen ingestion. In children, there tends to be greater variation in IGF-I levels that do not correspond to the true GH status, so provocative testing is required.

The historical “gold standard” stimulatory test is insulin-induced hypoglycemia (insulin tolerance test or ITT). Symptomatic hypoglycemia with a serum glucose level lower than 45 mg/dL is a potent stimulus for GH secretion; the normal GH response is greater than 10 ng/mL in children and greater than 5 ng/mL in adults. Because of the unavailability in the United States of GHRH, which is as sensitive and specific as the ITT in stimulating GH secretion, glucagon stimulation is being used, especially in adults with ischemic heart disease or seizures. A normal response with the glucagon stimulation test is defined as a GH peak greater than 3 ng/mL.

Treatment and Prognosis

Recombinant human growth hormone (hGH) is administered to promote linear growth in short children. The U.S. Food and Drug Administration (FDA) has approved GH treatment for conditions involving complete absence of GH associated with severe growth retardation or partial GH deficiency resulting in short stature. Short stature is defined as height more than 2.5 standard deviations below the mean for age-matched normal children, growth velocity less than the 25th percentile, delayed bone age, and predicted adult height less than the mean parental height. The conditions approved by the FDA to use GH include GH deficiency, idiopathic short stature, Turner’s syndrome, Prader-Willi syndrome, chronic kidney disease, AIDS-associated muscle wasting, *SHOX* gene deficiency, Noonan’s syndrome, and children born small for gestational age. Combined clinical evaluations, along with an inadequate pituitary GH response to provocative testing, are used in the assessment of childhood GH deficiency. Higher doses of GH are recommended for children without GH deficiency disorders or with partial GH deficiency.

In adults, GH is administered as a daily subcutaneous injection starting at 0.1 to 0.3 mg, with dose increases at 6-week intervals based on clinical response, side effects, and IGF-I levels. Absolute contraindications to GH therapy in adults include active neoplasm, intracranial hypertension, and proliferative diabetic retinopathy; uncontrolled diabetes and untreated thyroid disease are relative contraindications. Side effects of GH therapy are usually transient and include arthralgias, fluid retention, carpal tunnel syndrome, and glucose intolerance. Additional side effects in children include slipped capital femoral epiphysis and hydrocephalus.

Acromegaly or Growth Hormone Hypersecretion

Definition and Epidemiology

Acromegaly is literally translated as abnormal enlargement of the extremities of the skeleton. It is caused by hypersecretion of GH in adulthood. In children, excessive GH secretion before closure of the epiphyseal growth plate leads to gigantism. In both cases, the cause is almost always a GH-secreting pituitary tumor.

Approximately, 30% of GH-secreting pituitary adenomas are plurihormonal and also secrete prolactin. The incidence of acromegaly is about 2 to 4 per million population, and the mean age at diagnosis is 40 to 50 years.

Pathology

GH-secreting tumors are caused by a clonal expansion of pure somatotrophs or mixed somatomammotrophs. A variety of genetic abnormalities can be found in GH-secreting pituitary adenomas. GH hypersecretion due to somatotroph hyperplasia and adenomas is also seen in patients with McCune-Albright syndrome, which is caused by a G protein-activating mutation. There are also familial syndromes associated with GH-secreting pituitary adenomas, including multiple endocrine neoplasia type 1, Carney complex (myxomas, skin pigmentation, and testicular, adrenal, and pituitary tumors) and mutations in AIP (aryl hydrocarbon receptor interacting protein).

Clinical Presentation

Acromegaly is a rare disease, and the rate of change of symptoms and signs is slow and insidious. The usual period from earliest onset of symptoms and signs to diagnosis is 8 to 10 years, during which time many patients undergo medical and surgical treatments for many of the metabolic abnormalities and morbidities caused by GH excess. Characteristic clinical findings of this disease include physical changes of the bone and soft tissue and with multiple endocrine and metabolic abnormalities (Table 62-4).

Diagnosis and Differential Diagnosis

Measurement of serum IGF-I can be used to diagnose excess GH in most patients with acromegaly. An alternative is an oral glucose tolerance test using a 100-g glucose load. Normally, glucose suppresses GH levels to less than 1 ng/mL after 2 hours; in patients with acromegaly, GH levels may paradoxically increase, remain unchanged, or decrease but not below 1 ng/mL. Most acromegalic patients have GH-secreting pituitary tumors, and

approximately 70% of cases of acromegaly are caused by pituitary macroadenomas. Rarely, GH hypersecretion is caused by ectopic GHRH-secreting tumors, including hypothalamic hamartomas and gangliocytomas, pancreatic islet cell tumors, small cell carcinoma of the lung, carcinoid, adrenal adenomas, and pheochromocytomas. Ectopic GH secretion has also been reported in pancreatic, lung, and breast cancers.

Treatment and Prognosis

Treatment of acromegaly requires both treatment of the tumor and normalization of GH and IGF-I levels, along with management of the comorbidities and metabolic abnormalities caused by the excess GH. Treatment often requires the use of multiple modalities to achieve adequate control of the disease. Primary therapy is almost always transsphenoidal surgery, with the cure rate being directly proportional to tumor size. Patients with intrasellar microadenomas have a 75% to 95% cure rate with surgery. Even in patients with noninvasive macroadenomas, surgical removal results in normalization of IGF-I in 40% to 68% of patients.

Approximately 40% to 60% of tumors are not controlled with surgery alone because of cavernous sinus invasion or intracapsular intra-arachnoid invasion. Additional treatment options include primary medical therapy or primary surgical debulking of the tumor followed by medical therapy for hormonal control and/or radiation therapy for treatment of residual tumor. Conventional radiotherapy can normalize GH and IGF-I levels in more than 60% of patients, but the maximum response takes 10 to 15 years to achieve. Focused single-dose gamma knife radiotherapy has a 5-year remission rate of 29% to 60%. Hypopituitarism is seen in more than 50% of patients within 5 to 10 years after radiotherapy.

Currently, three drug classes are used to treat acromegaly: dopamine agonists, somatostatin receptor ligands (SRLs) such as octreotide and lanreotide, and GH receptor antagonists. SRLs work mainly through the somatostatin receptor subtypes 2 and 5, causing a decrease in tumor GH secretion. In acromegaly, SRLs are indicated for first-line treatment when there is low probability of surgical cure, after a failed surgical cure of GH hypersecretion, preoperatively to improve severe comorbidities that prevent or could complicate immediate surgery, and to provide GH and IGF-I control or partial control while waiting for radiotherapy to achieve its maximum effect. SRLs reduce GH and IGF-I levels to normal in 40% to 65% of patients and shrink tumor size in approximately 50% of cases. Side effects of SRLs include diarrhea, abdominal cramping, flatulence, and cholelithiasis (15%).

Pegvisomant is the only GH receptor antagonist available. It works by blocking the peripheral action of GH through blockade of the GH receptors located on the liver. Pegvisomant is indicated for patients who have persistent elevation in IGF-I even with maximum doses of SRLs. This drug is highly effective in the treatment of acromegaly and normalizes IGF-I levels in 97% of patients; transient elevation in liver function enzymes is seen in 25% of those treated, and tumor growth in fewer than 2%.

Cabergoline is the most efficacious of the dopamine agonists for treatment of acromegaly, but it is effective in fewer than 10% of patients.

TABLE 62-4 CLINICAL FEATURES OF ACROMEGALY

CHANGE	MANIFESTATIONS
SOMATIC CHANGES	
Acral changes	Enlarged hands and feet

Reproduction	Menstrual abnormalities Galactorrhea Decreased libido
Carbohydrate metabolism	Impaired glucose tolerance Diabetes mellitus
Lipids	Hypertriglyceridemia

Thyroid-Stimulating Hormone

TSH is a glycoprotein secreted from the thyrotroph cells of the anterior pituitary. It is composed of alpha and beta subunits. Its release is regulated by TRH (stimulatory) and somatostatin (inhibitory). In addition, it is subject to the negative feedback of thyroid hormones released from the thyroid gland.

Evaluation

Assessment of the pituitary-thyroid axis requires checking levels of TSH as well as thyroid hormones released by the thyroid gland (i.e., thyroxine [T_4] and triiodothyronine [T_3]). Dynamic testing using TRH is no longer available.

Deficiency of TSH

Definition and Epidemiology

Deficiency of TSH leads to secondary hypothyroidism: The diminished secretion of TSH from the pituitary provides inadequate stimulation to the thyroid gland for thyroid hormone release. The estimated prevalence of TSH deficiency is about 1 in 80,000 to 120,000 individuals.

Pathology

Hypopituitarism due to encroachment of a tumor on the normal pituitary can cause deficiency of one or more pituitary hormones. Radiation treatment of the pituitary gland can also cause hypopituitarism over time.

Clinical Presentation

The usual signs and symptoms of hypothyroidism are weight gain, fatigue, cold intolerance, and constipation. If the condition is caused by an underlying sellar tumor, symptoms of mass effect may also be present, depending on the size of the tumor.

Diagnosis and Differential Diagnosis

Secondary hypothyroidism is characterized by low levels of free T_4 along with low or inappropriately normal TSH. The differential diagnosis includes euthyroid sick syndrome, which is often seen in the setting of an acute illness. This syndrome does not require any intervention, and the laboratory results normalize on repeat testing after resolution of the acute illness.

Treatment and Prognosis

Management focuses on replacement of the thyroid hormones, as in primary hypothyroidism. However, measurement of free T_4 , rather than TSH, is used as a guide to adjust therapy. Underlying adrenal insufficiency should always be excluded and treated before treatment of secondary hypothyroidism to avoid precipitating an adrenal crisis.

TSH-Secreting Pituitary Tumors

Definition and Epidemiology

TSH-secreting pituitary tumors are rare and are characterized by inappropriate release of TSH that is refractory to the negative feedback mechanism of the thyroid hormones released by the

thyroid gland. The prevalence of TSH-secreting pituitary adenomas is 1 to 2 cases per million in the general population.

Pathology

The pathogenesis of TSH-secreting pituitary tumors is unknown.

Clinical Presentation

The most common age of presentation is in the early fifth decade, and there is no gender bias. Presenting symptoms can be the result of a mass effect of the tumor or, most commonly, there are symptoms and signs of hyperthyroidism, including weight loss, tremors, heat intolerance, and diarrhea. Diffuse goiter is observed in up to 80% of patients. Many times, these tumors are initially misdiagnosed as primary hyperthyroidism and patients are mistakenly treated with radioactive iodine. Sometimes, the TSH produced by these tumors is biologically inactive and the tumors are diagnosed as an incidental finding on imaging studies.

Diagnosis and Differential Diagnosis

The diagnosis is made in the setting of elevated or inappropriately normal TSH along with elevated levels of thyroid hormones (free and total T_4 and T_3). The differential diagnosis includes genetic resistance to thyroid hormone and euthyroid hyperthyroxinemia, which is characterized by normal TSH, high total T_4 , normal free T_4 , and elevated thyroxine-binding globulin levels. Imaging studies (MRI) should be done only after biochemical confirmation because of the high incidence of incidental pituitary tumors.

Treatment and Prognosis

Surgery (transsphenoidal resection) is the first-line treatment and should be performed by an experienced neurosurgeon. Radiotherapy can be used if surgery is declined or contraindicated. Medical therapy with somatostatin analogues (e.g., octreotide, lanreotide) may also be used for persistent hyperthyroidism after surgery. Most patients do well and achieve control of symptoms of thyrotoxicosis as well as reduction in tumor burden.

ADRENOCORTICOTROPIC HORMONE

ACTH is a 39-amino-acid peptide hormone that is formed from a precursor molecule, pro-opiomelanocortin (POMC) and is synthesized and secreted by corticotrophs in the anterior pituitary. It is stimulated by hypothalamic corticotropin-releasing hormone (CRH). ACTH, in turn, stimulates release of glucocorticoids and androgens from the adrenal cortex.

ACTH Deficiency

Definition and Pathology

ACTH deficiency causes secondary adrenal insufficiency leading to decreased cortisol and adrenal androgens. Aldosterone secretion from the adrenal glands is not impaired because it is maintained via the renin-angiotensin axis. ACTH deficiency can result from a large pituitary tumor impinging on the normal pituitary. Secondary or tertiary adrenal insufficiency is most commonly iatrogenic, caused by the use of steroids for other disease processes.

Clinical Presentation

Both primary and secondary adrenal insufficiency are characterized by weight loss, fatigue, muscle weakness, orthostatic symptoms, nausea, vomiting, diarrhea, and abdominal pain. Biochemical abnormalities include hyponatremia, azotemia, eosinophilia, and anemia. Importantly, hyperpigmentation of the skin and hyperkalemia are seen only with primary adrenal insufficiency, not with ACTH deficiency.

Diagnosis and Differential Diagnosis

The gold standard for diagnosis of secondary adrenal insufficiency has been an insulin tolerance test. The test is contraindicated in elderly patients and in those with a history of seizures, cardiovascular disease, or cerebrovascular disease. A safer test is an 8 AM fasting rapid ACTH stimulation test. This test measures the cortisol response to synthetic ACTH or cosyntropin. ACTH and cortisol levels are measured at baseline, followed by cortisol levels at 30 and 60 minutes. An 8 AM cortisol level of less than 5 µg/dL suggests adrenal insufficiency. A peak plasma cortisol level higher than 18 to 20 µg/dL is considered a normal response.

Treatment

Glucocorticoid replacement therapy in the form of hydrocortisone (10 mg in AM and 5 mg in PM) or prednisone (5 to 7.5 mg/

day) should be initiated. Patient education regarding stress dosing of steroids is important. Mineralocorticoids are usually not needed in patients with central adrenal insufficiency.

ACTH-Secreting Pituitary Tumors (Cushing's Disease)

Definition and Epidemiology

ACTH-secreting pituitary tumors (by definition, Cushing's disease) account for about 80% of the cases of Cushing's syndrome; they are usually microadenomas. There is a female preponderance (female-to-male ratio, about 3 : 1).

Pathology

The chronic stimulation by excessive ACTH causes simple diffuse hyperplasia of the bilateral adrenal glands or sometimes multinodular hyperplasia, both leading to excessive cortisol production.

Clinical Presentation

Signs and symptoms of Cushing's disease are related to the hypercortisolism and include central obesity, hirsutism, facial plethora, violaceous striae, supraclavicular and dorsocervical fat pads, and muscle weakness (Fig. 62-2). Additional manifestations of Cushing's disease are type 2 diabetes mellitus, hypertension, dyslipidemia, osteoporosis, and hypogonadism.

FIGURE 62-2 Clinical features of Cushing's syndrome. **A**, Centripetal and some generalized obesity and dorsal kyphosis in a 30-year-old woman with Cushing's disease. **B**, Moon facies, plethora, hirsutism, and enlarged supraclavicular fat pads in the same woman as in **A**. **C**, Facial rounding, hirsutism, and acne in a 14-year-old girl with Cushing's disease. **D**, Central and generalized obesity and moon facies in a 14-year-old boy with Cushing's disease. Typical centripetal obesity with livid abdominal striae in a 41-year-old woman (**E**) and a 40-year-old man (**F**) with Cushing's disease. **G**, Striae in a 24-year-old patient with congenital adrenal hyperplasia treated with excessive doses of dexamethasone as replacement therapy. **H**, Typical bruising and thin skin of a patient with Cushing's disease. In this case, the bruising has occurred without obvious injury. (From Larsen PR, Kronenberg H, Melmed S, et al: *Williams Textbook of Endocrinology*, ed 10, Philadelphia, 2003, Saunders.)

Diagnosis and Differential Diagnosis

Three different tests are performed in combination to assess for endogenous hypercortisolism. A 24-hour urine collection may show an elevated cortisol level, but this test is not reliable in patients with renal dysfunction. A second test, the 1-mg dexamethasone suppression test, measures an 8 AM fasting cortisol level after a dose of 1 mg dexamethasone given at 11 PM the night before. Cortisol suppression to less than 1.8 µg/dL is considered a normal response. Another diagnostic test is the late-night salivary cortisol measurement, using saliva collected at 11 PM on two consecutive nights. The test relies on a normal sleep cycle. Individuals who are using inhaled or topical steroids are not good candidates because of a high rate of false-positive results. A single positive finding is not sufficient to make this diagnosis and must be repeated and confirmed by doing additional tests. Because of the potential of cyclic ACTH overproduction by these tumors, repeat testing is recommended for individuals with high clinical suspicion but negative initial testing.

Pathologic hypercortisolism should be differentiated from physiologic activation of the hypothalamic-pituitary-adrenal axis, which can be observed in conditions such as critical illness, eating disorders, alcoholism, pregnancy, severe neuropsychiatric illness, and poorly controlled diabetes. Further, pathologic hypercortisolism can be ACTH dependent or independent. Once the diagnosis of ACTH-dependent hypercortisolism is established, a pituitary MRI should be performed, because most of these patients have a corticotroph adenoma; however, 40% to 45% of ACTH-secreting pituitary tumors are not seen even with MRI scanning. In those cases, patients with ACTH-dependent Cushing's syndrome should have inferior petrosal sinus sampling (IPSS) for ACTH with CRH stimulation; this differentiates between pituitary and ectopic ACTH overproduction by demonstrating a pituitary-to-peripheral ACTH gradient.

Treatment and Prognosis

The treatment involves removal of the pituitary tumor by an experienced neurosurgeon. Options after a failed resection include reoperation, bilateral adrenalectomy, radiotherapy, or pharmacotherapy. Pharmacotherapeutic agents include ketoconazole, metyrapone, mitotane, cabergoline, pasireotide, and mifepristone. In severe cases, intravenous etomidate may be used to stabilize patients for surgery. Long-term remission after resection of a pituitary microadenoma ranges from 69% to 98%, with a recurrence rate of 3% to 19%.

GONADOTROPINS

The two gonadotropins, LH and FSH, are glycoprotein hormones that are synthesized and secreted by gonadotrophs in anterior pituitary. They are both composed of an alpha and a beta subunit, the latter of which gives each its specific biologic function. These hormones bind to the receptors in the gonads (ovaries and testes) and modulate gonadal function. Secretion is regulated both by gonadotropin-releasing hormone (GnRH) from the hypothalamus and by feedback from circulating sex steroids (estrogen and testosterone).

Gonadotropin Deficiency (Hypogonadotropic Hypogonadism)

Definition

Hypogonadotropic hypogonadism is characterized by decreased or absent secretion of LH and FSH, which causes reduced secretion of the sex steroids (estrogen and testosterone).

Clinical Presentation

Signs and symptoms depend on the time of onset and the extent of gonadotropin deficiency. If deficiency occurs during fetal life, it can cause ambiguous genitalia. If deficiency occurs after birth but before puberty, it can cause delayed or absent sexual development. Onset after puberty often causes insidious changes and may remain undiagnosed for years, especially in men. The usual presentation after puberty includes symptoms of hypogonadism as well as infertility.

Diagnosis and Differential Diagnosis

The diagnosis is made by the presence of low or inappropriately normal FSH and LH levels along with low sex steroids (estrogen or testosterone). Causes of gonadotropin deficiency can be congenital (Kallman's syndrome, Prader-Willi syndrome, septo-optic dysplasia) or acquired, as in hemochromatosis, hyperprolactinemia, sellar tumors, cranial irradiation, and inflammatory and infiltrative disorders.

Treatment

For women, replacement therapy in the form of oral or transdermal estrogen should be continued until the age of natural menopause. Progesterone addition to induce withdrawal bleeding is essential in women with an intact uterus to prevent endometrial hyperplasia. For men, testosterone replacement is available in multiple forms, including an intramuscular injection product, several gels, and a patch. Fertility treatment requires additional therapy with recombinant FSH and LH in women or human chorionic gonadotropin (hCG) and FSH in men.

Gonadotropin-Secreting Pituitary Tumors

Definition and Epidemiology

Gonadotropin-secreting pituitary tumors are usually large and typically manifest with signs and symptoms of mass effect. Patients can also have symptoms of hypogonadism and other pituitary hormone deficiencies. These tumors can secrete FSH, LH, and/or alpha subunit.

Diagnosis and Differential Diagnosis

Hormonal evaluation reveals elevated FSH, LH, and/or alpha subunit in the absence of low estrogen or testosterone. Immunoperoxidase staining on surgical specimens is also needed to establish the diagnosis, especially in the case of postmenopausal women.

Treatment

Primary treatment is transsphenoidal surgical removal. Radiation therapy may be used as an adjunct treatment because of the size and more aggressive nature of these tumors, compared with true nonsecretory pituitary tumors.

Disorders of Posterior Pituitary Hormones

AVP and oxytocin are the two hormones that are produced in the hypothalamus and stored in and released from the posterior pituitary.

DIABETES INSIPIDUS

Definition

Diabetes insipidus (DI) is characterized by AVP deficiency and excretion of large volumes of dilute urine.

Pathology

Central DI can be familial due to an autosomal dominant mutation in the vasopressin gene that affects the functioning of the AVP-producing neurons. It can also be acquired secondary to intrasellar and suprasellar tumors, infiltration of the hypothalamus and posterior pituitary, infection, trauma or surgery, or as part of an autoimmune condition. [Table 62-5](#) gives a more extensive list of causes of diabetes insipidus.

Clinical Presentation

Polyuria (defined as excretion of more than 3 L of urine per day) and polydipsia are the clinical hallmarks of DI.

Diagnosis and Differential Diagnosis

DI can be central, caused by AVP deficiency, or nephrogenic, caused by resistance to AVP. As long as access to free water is maintained and the thirst mechanism is intact, patients with DI are usually able to maintain normal serum sodium levels

and osmolality. The water deprivation test is the primary test used to make the diagnosis and to differentiate the cause of DI. In patients with DI, the serum sodium level and osmolality increase in response to water deprivation. The response to a synthetic analogue of vasopressin is analyzed if the normal rise in urine osmolality and decrease in urine volume are not seen. Patients with central DI respond to the synthetic analogue by increasing urine osmolality and decreasing urine volume. In contrast, patients with nephrogenic DI do not respond to the synthetic vasopressin. Patients with partial central DI may have a limited response.

Primary polydipsia is characterized by increased water intake without a deficiency or resistance to AVP. Patients with primary polydipsia concentrate their urine without the need for synthetic vasopressin.

Treatment

Replacement therapy with desmopressin (DDAVP), an analogue of AVP, is available in oral, parenteral, and intranasal forms. Aqueous vasopressin is a shorter-acting analogue of AVP that can be given subcutaneously in the immediate postoperative period. Additional AVP analogues include DDAVP, which is available in subcutaneous, intranasal, and intravenous forms, and desmopressin, the only tablet form. Because of the transient nature of DI and a possible shift to a transient syndrome of inappropriate secretion of antidiuretic hormone (SIADH) phase in the patient who has undergone pituitary surgery, AVP is given cautiously and not as a scheduled medication to avoid hyponatremia.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIURETIC HORMONE

SIADH is covered in the discussion of hyponatremia in [Chapter 27](#).

TABLE 62-5 CAUSES OF DIABETES INSIPIDUS

CENTRAL DIABETES INSIPIDUS

- Idiopathic
- Familial
- Hypophysectomy
- Infiltration of hypothalamus and posterior pituitary
- Langerhans cell histiocytosis
- Granulomas
- Infection
- Tumors (intrasellar and suprasellar)
- Autoimmune

NEPHROGENIC DIABETES INSIPIDUS

- Idiopathic
- Familial
- V₂ receptor gene mutation
- Aquaporin-2 gene mutation
- Chronic renal disease (e.g., chronic pyelonephritis, polycystic kidney disease, or medullary cystic disease)
- Hypokalemia
- Hypercalcemia
- Sickle cell anemia
- Drugs
 - Lithium
 - Fluoride
 - Demeclocycline
 - Colchicine

Thyroid Gland

Theodore C. Friedman

INTRODUCTION

The thyroid gland secretes thyroxine (T_4) and triiodothyronine (T_3), both of which modulate energy utilization and heat production and facilitate growth. The gland consists of two lateral lobes joined by an isthmus (E-Fig. 63-1). The weight of the adult gland is 10 to 20 g. Microscopically, the thyroid is composed of several follicles that contain colloid surrounded by a single layer of thyroid epithelium. The follicular cells synthesize thyroglobulin, which is stored as colloid. Biosynthesis of T_4 and T_3 occurs by iodination of tyrosine molecules in thyroglobulin.

THYROID HORMONE PHYSIOLOGY

Thyroid Hormone Synthesis

Dietary iodine is essential for synthesis of thyroid hormones. Iodine, after conversion to iodide in the stomach, is rapidly absorbed from the gastrointestinal tract. After active transport from the bloodstream across the follicular cell basement membrane, iodide is enzymatically oxidized by thyroid peroxidase, which also mediates the iodination of the tyrosine residues in thyroglobulin, to form monoiodotyrosine and diiodotyrosine. The iodotyrosine molecules couple to form T_4 (3,5,3',5'-tetraiodothyronine) or T_3 (3,5,3'-triiodothyronine). Once iodinated, thyroglobulin containing newly formed T_4 and T_3 is stored in the follicles. Secretion of free T_4 and T_3 into the circulation occurs after proteolytic digestion of thyroglobulin, which is stimulated by thyroid-stimulating hormone (TSH). Deiodination of monoiodotyrosine and diiodotyrosine by iodotyrosine deiodinase releases iodine, which then re-enters the thyroid iodine pool

(E-Fig. 63-2).

Thyroid Hormone Transport

T_4 and T_3 are tightly bound to the serum carrier proteins thyroxine-binding globulin (TBG), thyroxine-binding prealbumin, and albumin. The unbound or free fractions are the biologically active fractions; they represent only 0.04% of the total T_4 and 0.4% of the total T_3 .

Peripheral Metabolism of Thyroid Hormones

The normal thyroid gland secretes T_4 , T_3 , and reverse T_3 , a biologically inactive form of T_3 . Most of the circulating T_3 is derived from deiodination of circulating T_4 in the peripheral tissues. Deiodination of T_4 can occur at the outer ring (5'-deiodination), producing T_3 (3,5,3'-triiodothyronine), or at the inner ring (5-deiodination), producing reverse T_3 (3,3,5'-triiodothyronine).

Control of Thyroid Function

Hypothalamic thyrotropin-releasing hormone (TRH) is transported through the hypothalamic-hypophyseal portal system to the thyrotrophs of the anterior pituitary gland, stimulating synthesis and release of TSH (Fig. 63-1). TSH, in turn, increases thyroidal iodide uptake and iodination of thyroglobulin, releases T_3 and T_4 from the thyroid gland by increasing hydrolysis of thyroglobulin, and stimulates thyroid cell growth. Hypersecretion of TSH results in thyroid enlargement (goiter). Circulating T_3 exerts negative feedback inhibition of TRH and TSH release.

Physiologic Effects of Thyroid Hormones

Thyroid hormones increase the basal metabolic rate by increasing oxygen consumption and heat production in several body tissues. Thyroid hormones also have specific effects on several organ systems (Table 63-1). These effects are exaggerated in hyperthyroidism and lacking in hypothyroidism, accounting for the well-recognized signs and symptoms of these two disorders.

THYROID EVALUATION

A careful thyroid examination is essential in evaluating a patient with thyroid disease (Video 63-1). Thyroid gland function and structure can be evaluated by (1) determining serum thyroid hormone levels, (2) imaging thyroid gland size and architecture, (3) measuring thyroid autoantibodies, and (4) performing a thyroid gland biopsy by fine-needle aspiration (FNA).

**TABLE 63-1** PHYSIOLOGIC EFFECTS OF THYROID HORMONE

SYSTEM	EFFECTS
Cardiovascular	Increased heart rate and cardiac output
Gastrointestinal	Increased gut motility
Skeletal	Increased bone turnover and resorption
Pulmonary	Maintenance of normal hypoxic and hypercapnic drive in the respiratory center
Neuromuscular	Increased muscle protein turnover and increased speed of muscle contraction and relaxation
Metabolism of lipids and carbohydrates	Increased hepatic gluconeogenesis and glycogenolysis, as well as intestinal glucose absorption Increased cholesterol synthesis and degradation Increased lipolysis
Sympathetic nervous system	Increased numbers of β -adrenergic receptors in the heart, skeletal muscle, lymphocytes, and adipose cells Decreased cardiac α -adrenergic receptors Increased catecholamine sensitivity
Hematopoietic	Increased red blood cell 2,3-diphosphoglycerate, facilitating oxygen dissociation from hemoglobin with increased oxygen available to tissues

Tests of Serum Thyroid Hormone Levels

Measurements of total serum T_4 and total T_3 indicate the total amount of hormone bound to thyroid-binding proteins by radioimmunoassay. Total T_4 and T_3 levels are elevated in hyperthyroidism and low in hypothyroidism. Increased production of TBG (as with pregnancy or estrogen therapy) increases the total T_4 and T_3 levels without actual hyperthyroidism. Similarly, total T_4 and T_3 are low despite euthyroidism in conditions associated with low levels of thyroid-binding proteins (e.g., congenital decrease, protein-losing enteropathy, cirrhosis, nephrotic syndrome). Therefore, further tests to assess the free hormone levels, which reflect biologic activity, must be performed. Free T_4 and free T_3 levels can be measured directly or by dialysis or ultrafiltration.

Serum TSH is measured by a third-generation immunometric assay that accurately discriminates between normal TSH levels and levels below the normal range. Thus, the TSH assay can diagnose clinical hyperthyroidism (elevated free T_4 and free T_3 and suppressed TSH) and subclinical hyperthyroidism (normal free T_4 and free T_3 and suppressed TSH). In hyperthyroidism, the free T_3 may be elevated in the presence of a normal free T_4 . In primary (thyroidal) hypothyroidism, serum TSH is supranormal because of diminished feedback inhibition. The TSH is usually low but may be normal in secondary (pituitary) or tertiary (hypothalamic) hypothyroidism.

Serum thyroglobulin measurements are useful in the follow-up of patients with papillary or follicular carcinoma. After thyroidectomy and iodine-131 (^{131}I) ablation therapy, thyroglobulin levels should be less than 0.5 $\mu\text{g/L}$ while the patient is on suppressive levothyroxine treatment. Levels in excess of this value indicate the possibility of persistent or metastatic disease.

Calcitonin is produced by the C cells of the thyroid and has a minor role in calcium homeostasis. Calcitonin measurements are invaluable in the diagnosis of medullary carcinoma of the thyroid and for monitoring the effects of therapy for this entity.

TABLE 63-2 HIGH-RISK FACTORS FOR MALIGNANCY IN A THYROID NODULE

HISTORY
Head and neck irradiation
Exposure to nuclear radiation
Rapid growth
Recent onset
Young age
Male sex
Familial incidence (medullary and about 5% of papillary carcinomas)
PHYSICAL EXAMINATION
Hard consistency of nodule
Fixation of nodule
Lymphadenopathy
Vocal cord paralysis
Distant metastasis
LABORATORY AND IMAGING STUDIES
Elevated serum calcitonin
Cold nodule on technetium scan
Ultrasonography:
Presence of microcalcifications
Presence of nodule hypoechogenicity compared with the normal thyroid parenchyma
Presence of increased nodular vascularity
Presence of irregular infiltrative margins
Nodule taller than wide on transverse view
Absent halo
Suspicious cervical lymphadenopathy
Partially cystic nodule
Spongiform appearance, defined as an aggregation of multiple microcystic components in >50% of the nodule volume

Thyroid Imaging

Technetium-99m ($^{99\text{m}}\text{Tc}$) pertechnetate is concentrated in the thyroid gland and can be scanned with a gamma camera, yielding information about the size and shape of the gland and the location of the functional activity in the gland (thyroid scan). The thyroid scan is often performed in conjunction with a quantitative assessment of radioactive iodine (^{123}I) uptake by the thyroid. Functioning thyroid nodules are called *warm* or *hot* nodules; *cold* nodules are nonfunctioning. Malignancy is usually associated with a cold nodule; 16% of surgically removed cold nodules are malignant.

Thyroid ultrasound evaluation is useful in the differentiation of solid nodules from cystic nodules. It also may be used to guide the clinician during FNA of a nodule (E-Fig. 63-3), and ultrasound characteristics of thyroid nodules may be helpful to distinguish those that are more likely to be malignant (Table 63-2).

Thyroid Antibodies

Autoantibodies to several different antigenic components in the thyroid gland, including thyroglobulin (TgAb), thyroid peroxidase (TPO Ab, formerly called *antimicrosomal antibodies*), and the TSH receptor, can be measured in the serum. A strongly positive test for TPO Ab indicates autoimmune thyroid disease. Elevated TSH receptor antibody occurs in Graves' disease (see later discussion).

Thyroid Biopsy

FNA of a nodule to obtain thyroid cells for cytologic evaluation is the best way to differentiate benign from malignant disease.

E-FIGURE 63-3 Ultrasound images of thyroid nodules. **A**, Transverse image of left thyroid lobe shows a complete thin rim of calcification encircling a thyroid nodule (eggshell calcification). **B**, Longitudinal image of a benign thyroid nodule in a different patient shows an incomplete, delicate thin rim of calcification at the inferior pole of a nodule proven to represent a benign hemorrhagic cyst. (From Desser TS, Kamaya A: Ultrasound of thyroid nodules, *Neuroimaging Clin N A* 18:463–478, 2008.)

FNA requires adequate tissue samples and interpretation by an experienced cytologist.

HYPERTHYROIDISM

Thyrotoxicosis is the clinical syndrome that results from elevated levels of circulating thyroid hormones. Clinical manifestations of thyrotoxicosis result from the direct physiologic effects of the thyroid hormones as well as the increased sensitivity to catecholamines. Tachycardia, tremor, stare, sweating, and lid lag are all caused by catecholamine hypersensitivity.

Signs and Symptoms

Table 63-3 lists the signs and symptoms of hyperthyroidism. Thyrotoxic crisis, or *thyroid storm*, is a life-threatening complication of hyperthyroidism that can be precipitated by surgery, radioactive iodine therapy, or severe stress (e.g., uncontrolled diabetes mellitus, myocardial infarction, acute infection). Patients develop fever, flushing, sweating, significant tachycardia, atrial fibrillation, and cardiac failure. Significant agitation, restlessness, delirium, and coma frequently occur. Gastrointestinal manifestations may include nausea, vomiting, and diarrhea. Hyperpyrexia out of proportion to other clinical findings is the hallmark of thyroid storm.

Differential Diagnosis

Thyrotoxicosis usually reflects excess secretion of thyroid hormones resulting from Graves' disease, toxic adenoma, multinodular goiter, or thyroiditis (Table 63-4 and Fig. 63-2). However, it may be the result of excessive ingestion of thyroid hormone or, rarely, thyroid hormone production from an ectopic site (as in struma ovarii).

Graves' Disease

Graves' disease, the most common cause of thyrotoxicosis, is an autoimmune disease that is more common in women, with a peak incidence between 20 and 40 years of age. One or more of the following features are present: (1) goiter; (2) thyrotoxicosis; (3) eye disease ranging from tearing to proptosis, extraocular muscle paralysis, and loss of sight as a result of optic nerve involvement; and (4) thyroid dermopathy, usually observed as significant skin thickening without pitting in a pretibial distribution (pretibial myxedema).

Pathogenesis

Thyrotoxicosis in Graves' disease is caused by overproduction of an antibody that binds to the TSH receptor. These thyroid-stimulating immunoglobulins increase thyroid cell growth and

thyroid hormone secretion. Ophthalmopathy results from inflammatory infiltration of the extraocular eye muscles by lymphocytes with mucopolysaccharide deposition. The inflammatory reaction that contributes to the eye signs in Graves' disease may be caused by sensitization of lymphocytes to antigens that are common to the orbital muscles and the thyroid.

Clinical Presentation

The common manifestations of thyrotoxicosis (see Table 63-3) are characteristic features of younger patients with Graves' disease. In addition, patients may exhibit a diffuse goiter or the eye signs characteristic of Graves' disease. Older patients often do not have the florid clinical features of thyrotoxicosis, and the condition termed *apathetic hyperthyroidism* is exhibited as flat affect, emotional lability, weight loss, muscle weakness,

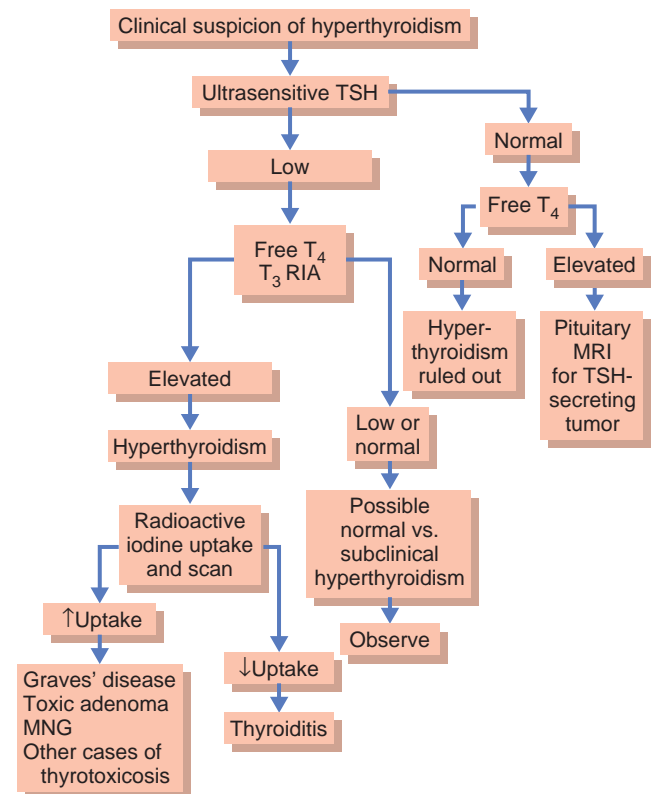

FIGURE 63-2 Algorithm for differential diagnosis of hyperthyroidism. MNG, Multinodular goiter; MRI, magnetic resonance imaging; RIA, radioimmunoassay; T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid-stimulating hormone.

TABLE 63-3 SIGNS AND SYMPTOMS OF HYPERTHYROIDISM

SYMPTOMS	SIGNS
Palpitations	Tachycardia
Nervousness	Atrial fibrillation
Shortness of breath	Wide pulse pressure
Heat intolerance	Brisk reflexes
Fatigue and weakness	Fine tremor
Increased appetite	Proximal limb-girdle myopathy
Weight loss	Chemosis (swelling of conjunctiva)
Oligomenorrhea	Thyroid bruit (Graves' disease)

TABLE 63-4 CAUSES OF THYROTOXICOSIS

COMMON CAUSES	THYROTOXICOSIS FACTITIA Postpartum thyroiditis (probably variant of silent thyroiditis)
Graves' disease	
Toxic adenoma (solitary)	
Toxic multinodular goiter	
LESS COMMON CAUSES	RARE CAUSES
Subacute thyroiditis (de Quervain's or granulomatous thyroiditis)	Struma ovarii
Hashimoto's thyroiditis with transient hyperthyroid phase	Metastatic thyroid carcinoma
	Hydatidiform mole
	TSH-secreting pituitary tumor

TSH, Thyroid-stimulating hormone.

congestive heart failure, and atrial fibrillation resistant to standard therapy.

Eye signs associated with Graves disease may also occur as a nonspecific manifestation of hyperthyroidism from any cause (e.g., thyroid stare). In Graves' disease, a specific inflammatory infiltrate of the orbital tissues leads to periorbital edema, conjunctival congestion and swelling, proptosis, extraocular muscle weakness, or optic nerve damage with visual impairment (E-Fig. 63-4).

Retibial myxedema (thyroid dermopathy) (E-Fig. 63-5) occurs in 2% to 3% of patients with Graves' disease and results in a thickening of the skin over the lower tibia without pitting. Onycholysis, characterized by separation of the fingernails from their beds, often occurs in patients with Graves' disease. Thyroid acropachy, or clubbing, may also occur.

Diagnosis

Elevated total or free T_4 or T_3 (or both) and a suppressed TSH confirm the clinical diagnosis of thyrotoxicosis. Thyroid-stimulating immunoglobulin is usually elevated, and its measurement may be useful in patients with eye signs who do not have other characteristic clinical features. Increased uptake of ^{123}I differentiates Graves' disease from early subacute or Hashimoto's thyroiditis, in which uptake is low in the presence of hyperthyroidism. Magnetic resonance imaging or ultrasonography of the orbit usually shows orbital muscle enlargement, whether or not clinical signs of ophthalmopathy are observed.

Treatment

Three treatment modalities are used to control the hyperthyroidism of Graves' disease: antithyroid drugs, radioactive iodine therapy, and surgery.

Antithyroid Drugs

The thiocarbamide drugs propylthiouracil, methimazole, and carbimazole block thyroid hormone synthesis by inhibiting thyroid peroxidase. Propylthiouracil also partially inhibits peripheral conversion of T_4 to T_3 . Medical therapy is usually administered for a prolonged period (1 to 3 years), with the dose gradually reduced until spontaneous remission occurs. One approach is to gradually decrease the dose while maintaining T_4 and T_3 in the normal range. After cessation of medication, 40% to 60% of patients remain in remission. Those who experience relapse can either resume therapy with thiocarbamide drugs or undergo definitive surgery or radioactive iodine treatment. Side effects of the thiocarbamide regimen include pruritus and rash (in about 5% of patients), elevated liver function enzymes, cholestatic jaundice, acute arthralgias, and, rarely, agranulocytosis (<0.5% of patients).

Methimazole is less toxic to the liver than propylthiouracil and has now become the preferred medical treatment for hyperthyroidism. Patients must be instructed to discontinue the medication and consult a physician if they develop fever or sore throat, because those symptoms may indicate agranulocytosis. At the onset of treatment during the acute phase of thyrotoxicosis, β -adrenergic receptor blockers are used to help alleviate tachycardia, hypertension, and atrial fibrillation. As the thyroid

hormone levels return to normal, the treatment with β -blockers is tapered.

Radioactive Iodine

In terms of cost, efficacy, ease, and short-term side effects, radioactive iodine has a better benefit profile than either surgery or antithyroid drugs; however, 80% to 90% of patients become hypothyroid after radiotherapy and require lifelong thyroid hormone replacement. ^{131}I is often the treatment of choice in adults with Graves' disease. It is contraindicated in women who are pregnant, but it does not increase the risk of birth defects in offspring conceived after ^{131}I therapy. Patients with severe thyrotoxicosis, very large glands, or underlying heart disease should be rendered euthyroid with antithyroid medication before receiving radioactive iodine, because ^{131}I treatment can cause a release of preformed thyroid hormone from the thyroid gland that could precipitate cardiac arrhythmias and exacerbate symptoms of thyrotoxicosis.

After administration of radioactive iodine, the thyroid gland shrinks; patients become euthyroid and later hypothyroid over a period of 6 weeks to 3 months. Serum free T_4 and TSH levels should be monitored, and replacement with levothyroxine should be instituted when hypothyroidism occurs. Hypothyroidism always occurs after surgical total thyroidectomy, frequently after subtotal thyroidectomy or administration of radioactive iodine, and in a smaller percentage of patients after antithyroid medication; therefore, lifelong monitoring of all patients with Graves' disease is mandated.

Surgery

Either subtotal or total thyroidectomy is the treatment of choice for patients with very large glands and obstructive symptoms, those with multinodular glands, and sometimes in those who desire pregnancy within the next year. It is essential that the surgeon be experienced in thyroid surgery. Preoperatively, patients receive 6 weeks of treatment with antithyroid drugs to ensure that they are euthyroid at the time of surgery. Two weeks before surgery, oral saturated solution of potassium iodide is administered daily to decrease the vascularity of the gland. Permanent hypoparathyroidism and recurrent laryngeal nerve palsy occur postoperatively in fewer than 2% of patients.

Graves' orbitopathy can be treated with glucocorticoids, orbital radiotherapy, or surgery. It was recently found that selenium is effective for Graves' orbitopathy.

Toxic Adenoma

Solitary toxic nodules, which are usually benign, occur more frequently in older patients. The clinical manifestations are those of thyrotoxicosis. Physical examination shows a distinct solitary nodule. Laboratory investigation shows suppressed TSH and significantly elevated T_3 levels, often with only moderately elevated T_4 . Thyroid scan shows a hot nodule in the affected lobe with partial or complete suppression of the unaffected lobe. Solitary toxic nodules are usually treated with radioactive iodine. Euthyroidism results if the unaffected lobe has suppressed uptake on a thyroid scan, and often hypothyroidism occurs if the unaffected lobe does not have suppressed uptake. For large nodules, unilateral lobectomy after the administration

E-FIGURE 63-4 Graves' ophthalmopathy. **A**, A 59-year-old woman with excess proptosis, moderate eyelid edema, and erythema with moderate eyelid retraction affecting all four eyelids. Conjunctival chemosis (edema) and erythema with bilateral edema of the caruncles and prolapse of the right caruncle are evident. **B**, A 40-year-old woman with excess proptosis, minimal bilateral injection, and chemosis with slight erythema of the eyelids. She also had evidence, on slit lamp examination, of moderate superior limbic keratoconjunctivitis. (From Bahn RS: Graves' ophthalmopathy, *N Engl J Med* 362:726–738, 2010.)

E-FIGURE 63-5 Thyroid dermopathy (localized myxedema) in five patients. **A**, Nonpitting edema form in pretibial area. **B**, Plaque form in pretibial area. **C**, Nodular form in ankle and foot. **D**, Elephantiasic form. **E**, Occurrence of thyroid dermopathy in scar tissue. (From Schwartz KM, Fatourechi V, Ahmed DD, Pond GR: Dermopathy of Graves' disease (pretibial myxedema): long-term outcome, *J Clin Endocrinol Metab* 87:438–446, 2002.)

of antithyroid drugs to render the patient euthyroid may be required.

Toxic Multinodular Goiter

Toxic multinodular goiter occurs in older patients with longstanding multinodular goiter, especially in patients from iodine-deficient regions when they are exposed to increased dietary iodine or receive iodine-containing radiocontrast dyes. The presenting clinical features are frequently tachycardia, heart failure, and arrhythmias. Physical examination shows a multinodular goiter. The diagnosis is confirmed by laboratory features of suppressed TSH, elevated T_3 and T_4 , and a thyroid scan showing multiple functioning nodules. The treatment of choice is often ^{131}I ablation. It is especially effective in patients with small glands and a high degree of radioactive uptake. Larger glands may require surgery.

Subclinical Hyperthyroidism

In subclinical hyperthyroidism, total or free T_4 and T_3 levels are normal and TSH is suppressed. The causes of this condition include early presentation of any form of hyperthyroidism (e.g., Graves' disease, toxic adenoma, toxic multinodular goiter). Because these patients, especially those who are older, are at an increased risk for cardiac dysrhythmias, many patients with a persistently suppressed TSH should be treated with thiocarbamide drugs or radioactive iodine. A decreased bone mineral density is another indication for treatment.

Thyroiditis

Thyroiditis may be classified as acute, subacute, or chronic. Although thyroiditis may eventually result in clinical hypothyroidism, the initial presentation is often that of hyperthyroidism as a result of acute release of T_4 and T_3 . Hyperthyroidism caused by thyroiditis can be readily differentiated from other causes of hyperthyroidism by suppressed uptake of radioactive iodine in the thyroid gland, reflecting decreased hormone production by damaged cells.

A rare disorder, acute suppurative thyroiditis, is caused by infection, usually bacterial. Patients exhibit high fever, redness of the overlying skin, and thyroid gland tenderness; the condition may be confused with subacute thyroiditis. If blood cultures are negative, FNA should identify the organism. Intensive antibiotic treatment and, occasionally, incision and drainage are required.

Subacute Thyroiditis

Subacute thyroiditis (also known as de Quervain's thyroiditis or granulomatous thyroiditis) is an acute inflammatory disorder of the thyroid gland that probably is caused by a viral infection and resolves completely in 90% of cases. Patients with subacute thyroiditis complain of fever and anterior neck pain. The patient may have symptoms and signs of hyperthyroidism. The classic feature on physical examination is an exquisitely tender thyroid gland. Laboratory findings vary with the course of the disease. Initially, the patient may be symptomatically thyrotoxic with elevated serum T_4 , depressed serum TSH, and low radioactive iodine uptake on the thyroid scan. Subsequently, the thyroid status fluctuates through euthyroid and hypothyroid

phases and may return to euthyroidism. An increase in radioactive iodine uptake on the scan reflects recovery of the gland. Treatment usually includes high-dose aspirin or other nonsteroidal anti-inflammatory drugs, but a short course of prednisone may be required if pain and fever are severe. During the hypothyroid phase, replacement therapy with levothyroxine may be indicated.

Postpartum thyroiditis resembles subacute thyroiditis in its clinical course. It usually occurs within the first 6 months after delivery and goes through the triphasic course of hyperthyroidism, hypothyroidism, and then euthyroidism, or it may develop with only hypothyroidism. Some patients have underlying chronic thyroiditis.

Chronic Thyroiditis

Chronic thyroiditis (Hashimoto's or lymphocytic thyroiditis), caused by destruction of the normal thyroidal architecture by lymphocytic infiltration, results in hypothyroidism and goiter. Riedel's struma is probably a variant of Hashimoto's thyroiditis; it is characterized by extensive thyroid fibrosis resulting in a rock-hard thyroid mass. Hashimoto's thyroiditis is more common in women and is the most common cause of goiter and hypothyroidism in the United States. Occasionally, patients with Hashimoto's thyroiditis have transient hyperthyroidism with low radioactive iodine uptake owing to the release of T_4 and T_3 into the circulation. Chronic thyroiditis can be differentiated from subacute thyroiditis in that, in the former, the gland is nontender to palpation and antithyroid antibodies are present in high titer. TPO Ab is usually present early and typically remains present for years. Presence of TgAb does not reflect Hashimoto's thyroiditis and does not provide additional information beyond the TPO Ab finding. Serum T_3 and T_4 levels are either normal or low; when they are low, the TSH is elevated. FNA of the thyroid shows lymphocytes and Hürthle cells (enlarged basophilic follicular cells). Hypothyroidism and significant glandular enlargement (goiter) are indications for levothyroxine therapy. Adequate doses of levothyroxine are administered to normalize TSH levels and shrink the goiter.

Thyrotoxicosis Factitia

Patients with thyrotoxicosis factitia ingest excessive amounts of thyroxine, often in an attempt to lose weight, and exhibit typical features of thyrotoxicosis. Serum T_3 and T_4 levels are elevated and TSH is suppressed, as is the serum thyroglobulin concentration. Radioactive iodine uptake is absent. Patients may require psychotherapy.

Rare Causes of Thyrotoxicosis

Struma ovarii occurs when an ovarian teratoma contains thyroid tissue that secretes thyroid hormone. A body scan confirms the diagnosis by demonstrating uptake of radioactive iodine in the pelvis.

Hydatidiform mole is caused by proliferation and swelling of the trophoblast during pregnancy, with excess production of chorionic gonadotropin, which has intrinsic TSH-like activity. The hyperthyroidism remits with surgical and medical treatment of the molar pregnancy.

HYPOTHYROIDISM

Hypothyroidism is a clinical syndrome caused by deficiency of thyroid hormones. In infants and children, hypothyroidism causes retardation of growth and development and may result in permanent motor and mental retardation. Congenital causes of hypothyroidism include agenesis (complete absence of thyroid tissue), dysgenesis (ectopic or lingual thyroid gland), hypoplastic thyroid, thyroid dysmorphogenesis, and congenital pituitary diseases. Adult-onset hypothyroidism results in a slowing of metabolic processes and is reversible with treatment. Hypothyroidism is usually primary (thyroid failure), but it may be secondary (hypothalamic or pituitary deficiency) or rarely the result of resistance at the thyroid hormone receptor (Table 63-5).

In adults, autoimmune thyroiditis (Hashimoto's thyroiditis) is the most common cause of hypothyroidism. This condition may be isolated, or it may be part of polyglandular failure syndrome type II (Schmidt's syndrome), which also includes insulin-dependent diabetes mellitus, adrenal insufficiency, pernicious anemia, vitiligo, gonadal failure, hypophysitis, celiac disease, myasthenia gravis, and primary biliary cirrhosis. Iatrogenic causes of hypothyroidism include ^{131}I therapy, thyroidectomy, and treatment with lithium or amiodarone. Iodine deficiency or excess can also cause hypothyroidism.

Clinical Presentation

The clinical presentation of hypothyroidism (Table 63-6) depends on the age at onset and the severity of the thyroid deficiency. Infants with congenital hypothyroidism (also called *cretinism*) may exhibit feeding problems, hypotonia, inactivity, an open posterior fontanelle, and edematous face and hands. Mental retardation, short stature, and delayed puberty occur if treatment is delayed.

Hypothyroidism in adults usually develops insidiously. Patients often complain of fatigue, lethargy, and gradual weight gain for years before the diagnosis is established. A delayed relaxation phase of deep tendon reflexes (*hung-up* reflexes) is a valuable clinical sign that is characteristic of severe hypothyroidism. Subcutaneous infiltration by mucopolysaccharides, which bind

water, causes the edema; this condition, termed *myxedema*, is responsible for the thickened features and puffy appearance of patients with severe hypothyroidism.

Severe untreated hypothyroidism can result in myxedema coma, which is characterized by hypothermia, extreme weakness, stupor, hypoventilation, hypoglycemia, and hyponatremia and is often precipitated by cold exposure, infection, or psychoactive drugs.

Diagnosis

Laboratory abnormalities in patients with primary hypothyroidism include elevated serum TSH and low total and free T_4 . A low or low-normal morning serum TSH level in the setting of hypothalamic or pituitary dysfunction characterizes secondary hypothyroidism. Often, the serum total and free T_4 levels are at the lower limits of normal.

Hypothyroidism is often associated with hypercholesterolemia and elevated creatine phosphokinase skeletal muscle (MM) fraction (the fraction representative of skeletal muscle). Anemia is usually normocytic and normochromic but may be macrocytic (with vitamin B_{12} deficiency resulting from associated pernicious anemia) or microcytic (caused by nutritional deficiencies or menstrual blood loss in women). Because TPO Ab is usually positive in Hashimoto's thyroiditis, the major cause of hypothyroidism in adults, its measurement is helpful in deciding whether levothyroxine treatment is appropriate in patients with subclinical hypothyroidism (discussed later).

Differential Diagnosis

Because the initial manifestations of hypothyroidism are subtle, early diagnosis demands a high index of suspicion in patients with one or more of the signs and symptoms (see Table 63-6). Early symptoms that are often overlooked include menstrual irregularities (usually menorrhagia), arthralgias, and myalgias.

Laboratory diagnosis may be complicated by the finding of a low total T_4 level in euthyroid states associated with low TBG, such as nephrotic syndrome, cirrhosis, or TBG deficiency. TSH and free T_4 levels are normal in these instances. A low total T_4 level may also be found with nonthyroidal illness (*euthyroid sick syndrome*), a condition occurring in acutely ill patients. In such patients, total and occasionally free T_4 levels are low; the serum TSH level is usually normal but may be mildly elevated. This condition can be differentiated from primary hypothyroidism by absence of a goiter, negative antithyroid antibodies, and elevated serum reverse T_3 levels as well as by the clinical presentation.

TABLE 63-5 CAUSES OF HYPOTHYROIDISM

PRIMARY HYPOTHYROIDISM	Hypoplastic thyroid Biosynthetic defects

CHILDREN	Weight gain Constipation Menstrual irregularities Dry, coarse, cold skin Periorbital and peripheral edema Delayed reflexes Bradycardia
Learning disabilities Mental retardation Short stature Delayed bone age Delayed puberty	ADULTS
ADULTS	Arthralgias, myalgias
Fatigue Cold intolerance	

The thyroid hormone levels return to normal with resolution of the acute illness, and patients do not require levothyroxine therapy.

Treatment

Hypothyroidism should be treated initially with synthetic levothyroxine. Administration of levothyroxine results in physiologic levels of bioavailable T_3 and T_4 . Levothyroxine has a half-life of 8 days; consequently, it needs to be given only once a day. The average replacement dose of levothyroxine for adults is 75 to 150 $\mu\text{g}/\text{day}$. In healthy adults, 1.6 $\mu\text{g}/\text{kg}/\text{day}$ is an appropriate starting dose. In some older patients and patients with cardiac disease, levothyroxine should be increased gradually, starting at 25 $\mu\text{g}/\text{day}$ and increasing the dose by 25 μg every 2 weeks; however, most patients can safely be started on a full replacement dose. The therapeutic response to levothyroxine therapy should be monitored clinically and with measurement of serum TSH levels 6 weeks after a dose adjustment. TSH levels between 0.5 and 2 mU/L are optimal. Because TSH measurements are not a useful guide in patients with secondary hypothyroidism (pituitary or hypothalamic dysfunction), these patients should be given levothyroxine until their free T_4 is in the mid-normal range.

Recent studies have suggested that a percentage of patients treated with levothyroxine for hypothyroidism continue to have hypothyroid symptoms despite normalization of TSH. Furthermore, a large study found that more than 20% of athyreotic patients treated with levothyroxine replacement did not maintain free T_3 or free T_4 values in the normal range despite normal TSH levels. This reflects the inadequacy of peripheral deiodination to compensate for the absent T_3 secretion. Because of these studies, there is renewed interest (accompanied by a large amount of controversy) in treating hypothyroid patients who have not had an adequate clinical response to levothyroxine replacement with a combination of levothyroxine and liothyronine, or with desiccated thyroid preparations that contain levothyroxine and liothyronine.

In patients with myxedema coma, 500 to 800 μg of levothyroxine is administered intravenously as a loading dose, followed by 100 $\mu\text{g}/\text{day}$ of levothyroxine, hydrocortisone (100 mg IV intravenously three times daily), and intravenous fluids. Steroids should be given before thyroxine in autoimmune conditions. The underlying precipitating event should be corrected. Respiratory assistance and treatment of hypothermia with warming blankets may be required. Although myxedema coma carries a high mortality rate despite appropriate treatment, many patients improve in 1 to 3 days.

Subclinical Hypothyroidism

In subclinical hypothyroidism, T_4 and T_3 levels are normal or low-normal, and TSH is mildly elevated. Some of these patients develop overt hypothyroidism. The decision as to when to treat patients who have a mildly elevated TSH level is controversial. It is frequently recommended that patients should be treated with levothyroxine if they have a TSH level greater than 5 mU/L on two occasions and either positive anti-TPO Ab test results or a goiter. If the patient does not have an appreciable goiter and has negative anti-TPO Ab test results, many experts suggest that levothyroxine should be given only if the TSH level is greater

than 10 mU/L on two occasions. Other experts suggest treatment at lower TSH levels depending on the presence of TPO antibody.

GOITER

Enlargement of the thyroid gland is called a *goiter*. Patients with goiters may be euthyroid (simple goiter), hyperthyroid (toxic nodular goiter or Graves' disease), or hypothyroid (nontoxic goiter or Hashimoto's thyroiditis). Thyroid enlargement (often focal) may also be the result of a thyroid adenoma or carcinoma. In nontoxic goiter, inadequate thyroid hormone synthesis leads to TSH stimulation with resultant enlargement of the thyroid gland. Iodine deficiency (endemic goiter) was once the most common cause of nontoxic goiter. Since the widespread availability of iodized salt, endemic goiter is less common in North America.

Goitrogens are agents that can cause a goiter, and iodine and lithium are the two chemicals or drugs that frequently cause a goiter. Natural goitrogens include thioglucosides found in vegetables such as cabbage, broccoli, brussel sprouts, turnips, cauliflower, kale, and other greens. Other foods that are goitrogens include soybeans and soybean products, peanuts, spinach, sweet potatoes, and fruits (e.g., strawberries, pears, and peaches). Thyroid hormone biosynthetic defects can cause goiter associated with hypothyroidism (or, with adequate compensation, euthyroidism).

A careful thyroid examination coupled with thyroid hormone tests can reveal the cause of the goiter. A smooth, symmetrical gland, often with a bruit, and hyperthyroidism are suggestive of Graves' disease. A nodular thyroid gland with hypothyroidism and positive antithyroid antibodies is consistent with Hashimoto's thyroiditis. A diffuse, smooth goiter with hypothyroidism and negative antithyroid antibodies may be indicative of iodine deficiency or a biosynthetic defect. Goiters can become very large, extending substernally and causing dysphagia, respiratory distress, or hoarseness. An ultrasound evaluation or radioactive iodine scan delineates the thyroid gland, and measurement of the TSH level determines the functional activity of the goiter.

Hypothyroid goiters are treated with thyroid hormone at a dose that normalizes TSH. Previously, euthyroid goiters were treated with levothyroxine therapy; however, regression with levothyroxine therapy is unlikely and is no longer recommended. Surgery is indicated for nontoxic goiter only if obstructive symptoms develop or substantial substernal extension is present.

SOLITARY THYROID NODULES

Thyroid nodules are common. They can be detected clinically in about 4% of the population and are found in about 50% of the population at autopsy. Benign thyroid nodules are usually follicular adenomas, colloid nodules, benign cysts, or nodular thyroiditis. Patients may have one prominent nodule on clinical examination, but thyroid ultrasound evaluation may reveal multiple nodules. Although most nodules are benign, a small percentage are malignant. Fortunately, most thyroid cancers are low-grade malignancies. History, physical examination, and laboratory tests can be helpful in differentiating benign from malignant lesions (see Table 63-2). For example, lymph node involvement or hoarseness is strongly suggestive of a malignant tumor.

The major etiologic factor for thyroid cancer is childhood or adolescent exposure to head and neck radiation. Previously, radiation was used to treat an enlarged thymus, tonsillar disease, hemangioma, or acne. More recently, exposure to radiation from nuclear plants (e.g., Chernobyl, Ukraine) contributed to an increased incidence of thyroid cancer. Patients with a history of irradiation should have a baseline thyroid ultrasound study, and careful palpation of their thyroid every 1 to 2 years.

A dominant nodule (>1 to 1.5 cm) or nodules with ultrasound features compatible with neoplasia should undergo FNA, which is a safe procedure that has reduced the need for surgical excision. An expert cytologist can identify most benign lesions (75% of all biopsies). In addition, malignant lesions (5% of biopsies), such as papillary, anaplastic, and medullary carcinomas, can be specifically identified. Follicular neoplasms, however, cannot be diagnosed as benign or malignant by FNA; a cytology report of follicular neoplasia, along with “suspicious” cytology, requires surgical excision. Molecular testing can now be performed on FNA specimens to help determine whether follicular lesions have molecular characteristics of malignancy and should be removed. If the patient has a follicular lesion and a suppressed TSH level, a thyroid scan should be performed, because hot nodules are rarely malignant.

Although in the past benign thyroid nodules were treated with levothyroxine suppression, this is no longer recommended because it is uncommon for thyroid nodules to shrink substantially with levothyroxine.

THYROID CARCINOMA

The types and characteristics of thyroid carcinomas are presented in Table 63-7. Papillary carcinoma is associated with local invasion and lymph node spread. Indicators of poor prognosis include thyroid capsule invasion, size greater than 2.5 cm, age at onset older than 45 years, tall cell or Hürthle cell variant, and lymph node involvement. Follicular carcinoma is slightly more aggressive than papillary carcinoma and can spread by local invasion of lymph nodes or hematogenously to bone, brain, or lung. Many tumors show both papillary and follicular cell types. Patients may exhibit metastases before diagnosis of the primary thyroid lesion. Anaplastic carcinoma tends to occur in older individuals, is very aggressive, and rapidly causes pain, dysphagia, and hoarseness.

Medullary thyroid carcinoma is derived from calcitonin-producing parafollicular cells and is more malignant than papillary or follicular carcinoma. It is multifocal and spreads both locally and distally. It may be either sporadic or familial. When

familial, it is inherited in an autosomal dominant pattern and is part of multiple endocrine neoplasia type IIA (medullary carcinoma of the thyroid, pheochromocytoma, and hyperparathyroidism) or multiple endocrine neoplasia type IIB (medullary carcinoma of the thyroid, mucosal neuromas, intestinal gangliogliomas, marfanoid habitus, and pheochromocytoma). Elevated basal serum calcitonin levels confirm the diagnosis. Evaluation for *RET* proto-oncogene mutations should be performed in patients with medullary carcinoma; if mutations are present, all first-degree relatives should be examined.

Treatment

Lobectomy may be performed for isolated papillary microcarcinoma. However, larger papillary tumors and most follicular tumors require thyroidectomy with a central compartment lymph node dissection, as well as a modified neck dissection if evidence of lateral lymph node metastases is found. After surgery, patients with low-risk, small carcinomas may be administered doses of levothyroxine sufficient to keep the TSH level in the low-normal or slightly suppressed range and monitored with serum thyroglobulin determinations and neck ultrasound examinations. Patients with large lesions and those at high risk for persistence or metastatic disease should be treated with radioactive iodine. Sufficient levothyroxine is then administered to suppress serum TSH to subnormal levels. Frequent clinical and ultrasound neck examinations for masses should be accompanied by measurement of serum thyroglobulin levels.

Thyroid cancer patients are considered to have no residual disease if neck ultrasound imaging studies are negative and serum thyroglobulin is suppressed after recombinant TSH stimulation. Recurrence and metastases are also evaluated by ¹³¹I whole body scans carried out under conditions of TSH stimulation, which increase ¹³¹I uptake by the thyroid tissue. Elevated TSH levels can be achieved by withdrawal of thyroxine supplementation for 6 weeks or by treatment with recombinant human TSH administered while the patient maintains therapy with thyroid hormone replacement. The latter avoids symptomatic hypothyroidism. A rise in serum thyroglobulin levels suggests recurrence of thyroid cancer. Local or metastatic lesions that take up ¹³¹I on whole body scanning can be treated with radioactive iodine after the patient has stopped thyroid hormone replacement, whereas those that do not take up ¹³¹I can be treated with surgical excision or local x-ray therapy. Conventional chemotherapy has limited efficacy in the treatment of differentiated thyroid cancer, but newer biologic agents targeting the molecular pathogenesis of these tumors appear promising.

TABLE 63-7 CHARACTERISTICS OF THYROID CANCERS

TYPE OF CANCER	PERCENTAGE OF THYROID CANCERS	AGE AT ONSET (YR)	TREATMENT	PROGNOSIS
Papillary	80	40-80	Thyroidectomy, followed by radioactive iodine ablation	Good
Follicular	15	45-80	Thyroidectomy, followed by radioactive iodine ablation	Fair to good
Medullary	3	20-50	Thyroidectomy and central compartment lymph node dissection	Fair
Anaplastic	1	50-80	Isthmusectomy followed by palliative x-ray treatment	Poor
Lymphoma	1	25-70	X-ray therapy or chemotherapy or both	Fair

Medullary carcinoma of the thyroid requires total thyroidectomy with removal of the central lymph nodes in the neck. Completeness of the procedure and monitoring for recurrence are determined by measurements of serum calcitonin.

Anaplastic carcinoma is treated with isthmusectomy to confirm the diagnosis and to prevent tracheal compression, followed by palliative x-ray treatment. Thyroid lymphomas are also treated with x-ray therapy or chemotherapy or both.

The prognosis for well-differentiated thyroid carcinomas is good. The patient's age at the time of diagnosis and sex are the most important prognostic factors. Men older than 40 years of age and women older than 50 years of age have higher recurrence and death rates than do younger patients. The 5-year survival rate for invasive medullary carcinoma is 50%, whereas the mean survival time for anaplastic carcinoma is 6 months.

 For a deeper discussion on this topic, please see Chapter 226, "Thyroid," in Goldman-Cecil Medicine, 25th Edition.

Adrenal Gland

Theodore C. Friedman

PHYSIOLOGY

The adrenal glands (Fig. 64-1) lie at the superior pole of each kidney and are composed of two distinct regions: the cortex and the medulla. The adrenal cortex comprises three anatomic zones: the outer *zona glomerulosa*, which secretes the mineralocorticoid aldosterone; the intermediate *zona fasciculata*, which secretes cortisol; and the inner *zona reticularis*, which secretes adrenal androgens. The adrenal medulla, lying in the center of the adrenal gland, is functionally related to the sympathetic nervous system and secretes the catecholamines epinephrine and norepinephrine in response to stress.

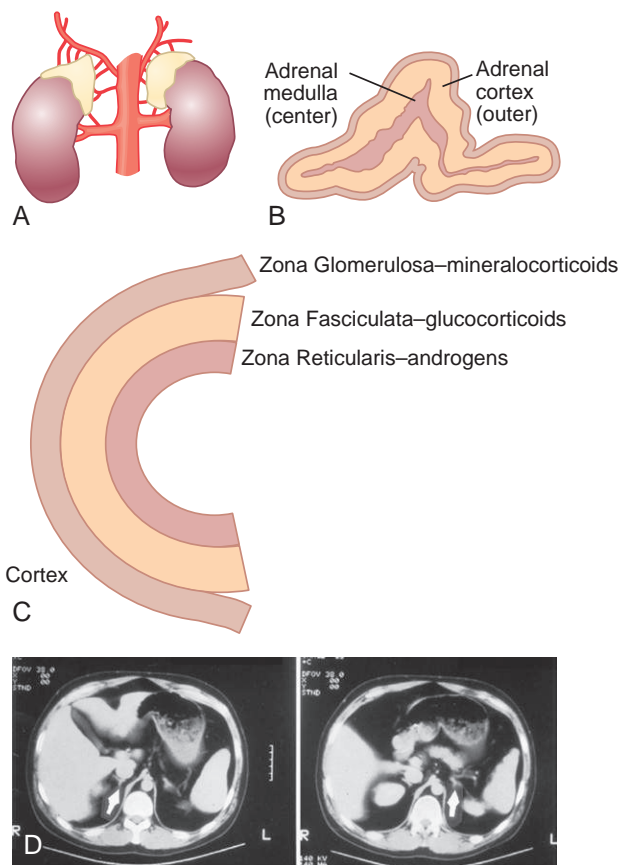

FIGURE 64-1 **A**, Anatomic location of the adrenal glands. **B**, Distribution of adrenal cortex and medulla. **C**, Zones of the adrenal cortex. **D**, Magnetic resonance images of the abdomen showing the position and relative size of the normal adrenal glands (arrows). (**D**, From Nieman LK: Adrenal cortex. In Goldman L, Schafer AI, editors: Cecil-Goldman medicine, ed 24, Philadelphia, 2012, Saunders, Figure 234-1.)

The synthesis of all steroid hormones begins with cholesterol and is catalyzed by a series of regulated, enzyme-mediated reactions (Fig. 64-2). Glucocorticoids affect metabolism, cardiovascular function, behavior, and the inflammatory and immune responses (Table 64-1). Cortisol, the natural human glucocorticoid, is secreted by the adrenal glands in response to adrenocorticotropic hormone (ACTH), a 39-amino-acid neuropeptide that is regulated by corticotropin-releasing hormone (CRH) and vasopressin (AVP) produced in the hypothalamus (see Chapter 62). Glucocorticoids exert negative feedback on CRH and ACTH secretion. The brain hypothalamic-pituitary-adrenal (HPA) axis (Fig. 64-3) interacts with and influences the functions of the reproductive, growth, and thyroid axes at many levels, with major participation of glucocorticoids at all levels.

The renin-angiotensin-aldosterone system (Fig. 64-4) is the major regulator of aldosterone secretion. Renal juxtaglomerular cells secrete renin in response to a decrease in circulating volume or a reduction in renal perfusion pressure or both. Renin is the rate-limiting enzyme that cleaves the 60-kD angiotensinogen molecule, synthesized by the liver, to produce the bioinactive decapeptide angiotensin I. Angiotensin I is rapidly converted to the octapeptide angiotensin II by angiotensin-converting enzyme in the lungs and other tissues. Angiotensin II is a potent vasopressor; it stimulates aldosterone production but does not stimulate cortisol production. Angiotensin II is the predominant regulator of aldosterone secretion, but plasma potassium concentration, plasma volume, and ACTH level also influence aldosterone secretion. ACTH also mediates the circadian rhythm of aldosterone, and as a result, the plasma concentration of aldosterone is highest in the morning. Aldosterone binds to the type I mineralocorticoid receptor. In contrast, cortisol binds to both the type I mineralocorticoid receptor and type II glucocorticoid receptors. The intracellular enzyme 11β -hydroxysteroid dehydrogenase (11β -HSD) type II, which catabolizes cortisol to inactive cortisone, limits the functional binding to the former receptor. The availability of cortisol to bind to the glucocorticoid receptor is modulated by 11β -HSD type I, which interconverts cortisol and cortisone. Binding of aldosterone to the cytosol mineralocorticoid receptor leads to sodium (Na^+) absorption and potassium (K^+) and hydrogen (H^+) secretion by the renal tubules. The resultant increase in plasma Na^+ and decrease in plasma K^+ provide a feedback mechanism for suppressing renin and, subsequently, aldosterone secretion.

Adrenal androgen precursors include dehydroepiandrosterone (DHEA) and its sulfate and androstenedione. These are synthesized in the zona reticularis under the influence of ACTH and other adrenal androgen-stimulating factors. Although they

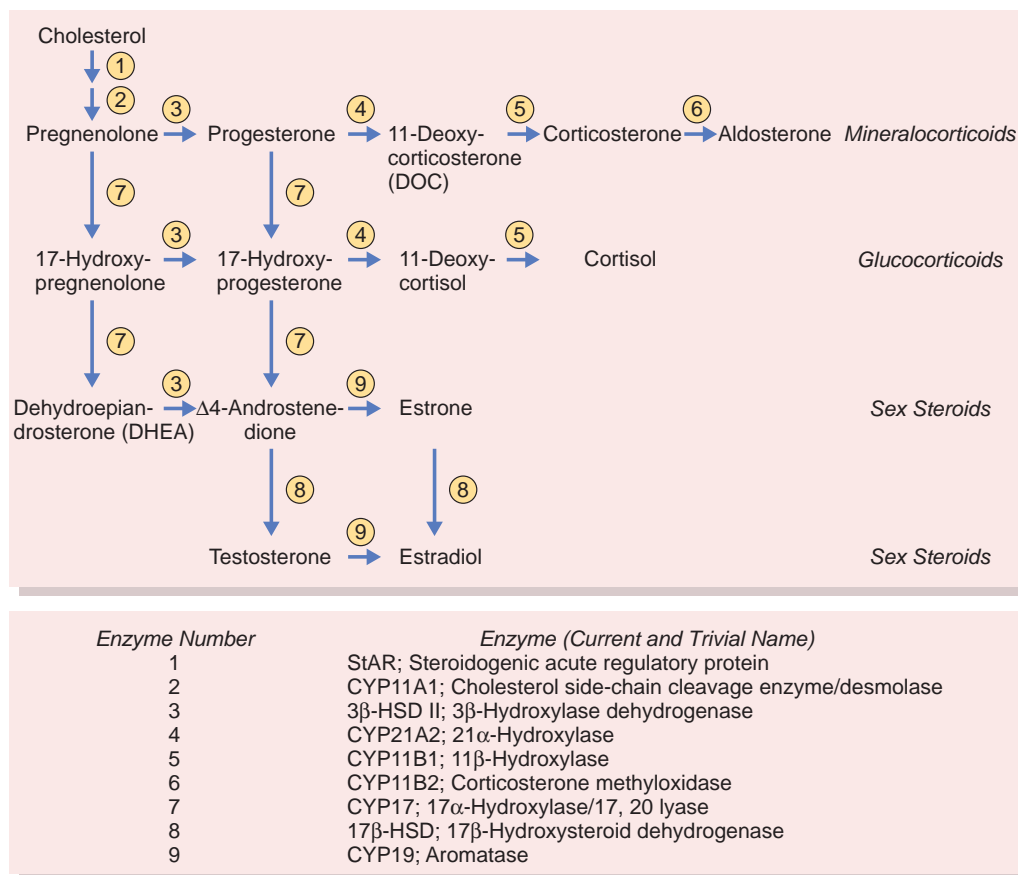

FIGURE 64-2 Pathways of steroid biosynthesis.

have minimal intrinsic androgenic activity, they contribute to androgenicity by their peripheral conversion to testosterone and dihydrotestosterone. In men, excessive levels of adrenal androgens have no clinical consequences, but in women they result in acne, hirsutism, and virilization. Because of gonadal production of androgens and estrogens and the secretion of norepinephrine by sympathetic ganglia, deficiencies of adrenal androgens and catecholamines are not clinically recognized.

SYNDROMES OF ADRENOCORTICAL HYPOFUNCTION

Adrenal Insufficiency

Glucocorticoid insufficiency can be primary, resulting from destruction or dysfunction of the adrenal cortex, or secondary, resulting from ACTH hyposecretion (Table 64-2). Autoimmune destruction of the adrenal glands (Addison's disease) is the most common cause of primary adrenal insufficiency in the industrialized world, accounting for about 65% of cases. Usually, both glucocorticoid and mineralocorticoid secretions are diminished in this condition which, if left untreated, can be fatal. Isolated glucocorticoid or mineralocorticoid deficiency may also occur, and it is becoming apparent that mild adrenal insufficiency (similar to subclinical hypothyroidism, discussed in Chapter 63) should also be diagnosed and, in some cases, treated. Adrenal medulla function is usually spared. About 70% of patients with Addison's disease have antiadrenal antibodies.

Tuberculosis used to be the most common cause of adrenal insufficiency. However, its incidence in the industrialized world

has decreased since the 1960s, and it now accounts for only 15% to 20% of patients with adrenal insufficiency; calcified adrenal glands can be observed in 50% of these patients. Rare causes of adrenal insufficiency are listed in Table 64-2. Many patients with human immunodeficiency virus (HIV) infection have decreased adrenal reserve without overt adrenal insufficiency.

Addison's disease may be part of two distinct autoimmune polyglandular syndromes. The triad of hypoparathyroidism, adrenal insufficiency, and mucocutaneous candidiasis characterizes type I polyglandular autoimmune syndrome, which usually manifests in childhood. Other, less common manifestations include hypothyroidism, gonadal failure, gastrointestinal malabsorption, insulin-dependent diabetes mellitus, alopecia areata and totalis, pernicious anemia, vitiligo, chronic active hepatitis, keratopathy, hypoplasia of dental enamel and nails, hypophysitis, asplenism, and cholelithiasis. Type II polyglandular autoimmune syndrome, also called *Schmidt's syndrome*, is characterized by Addison's disease, autoimmune thyroid disease (Graves' disease or Hashimoto's thyroiditis), and insulin-dependent diabetes mellitus. Other associated diseases include pernicious anemia, vitiligo, gonadal failure, hypophysitis, celiac disease, myasthenia gravis, primary biliary cirrhosis, Sjögren's syndrome, lupus erythematosus, and Parkinson's disease. This syndrome usually develops in adults.

Common manifestations of adrenal insufficiency are anorexia, weight loss, increasing fatigue, occasional vomiting, diarrhea, and salt craving. Muscle and joint pain, abdominal pain, and postural dizziness may also occur. Signs of increased pigmentation

FIGURE 64-3 Brain hypothalamic-pituitary-adrenal axis. Minus signs indicate negative feedback. ACTH, Adrenocorticotropic hormone; AVP, arginine vasopressin; CRH, corticotropin-releasing hormone.

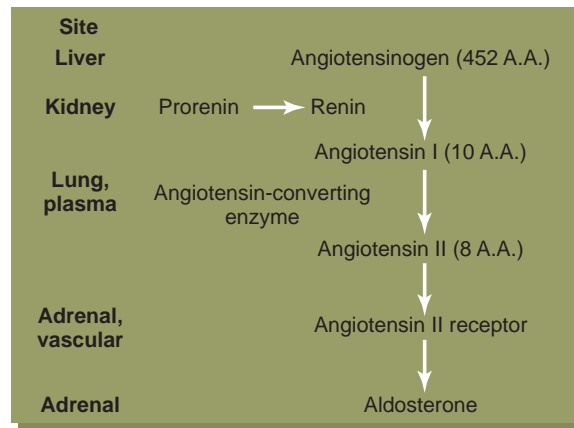

FIGURE 64-4 Renin-angiotensin-aldosterone axis. A.A., Amino acids.

TABLE 64-1 ACTIONS OF GLUCOCORTICOIDS

METABOLIC HOMEOSTASIS

Regulate blood glucose level (permissive effects on gluconeogenesis)
 Increase glycogen synthesis
 Raise insulin levels (permissive effects on lipolytic hormones)
 Increase catabolism, decrease anabolism (except fat), inhibit growth hormone axis
 Inhibit reproductive axis
 Stimulate mineralocorticoid receptor by cortisol

CONNECTIVE TISSUES

Cause loss of collagen and connective tissue

CALCIUM HOMEOSTASIS

Stimulate osteoclasts, inhibit osteoblasts
 Reduce intestinal calcium absorption, stimulate parathyroid hormone release, increase urinary calcium excretion, decrease reabsorption of phosphate

CARDIOVASCULAR FUNCTION

Increase cardiac output
 Increase vascular tone (permissive effects on pressor hormones)
 Increase sodium retention

BEHAVIOR AND COGNITIVE FUNCTION

Daytime fatigue
 Nocturnal hyperarousal
 Decreased short-term memory
 Decreased cognition

EUPHORIA OR DEPRESSION

IMMUNE SYSTEM

Increase intravascular leukocyte concentration
 Decrease migration of inflammatory cells to sites of injury
 Suppress immune system (thymolysis; suppression of cytokines, prostanoids, kinins, serotonin, histamine, collagenase, and plasminogen activator)

(initially most significant on the extensor surfaces, palmar creases, and buccal mucosa) often occur secondary to the increased production of ACTH and other related peptides by the pituitary gland (E-Fig. 64-1). Laboratory abnormalities may include hyponatremia, hyperkalemia, mild metabolic acidosis, azotemia, hypercalcemia, anemia, lymphocytosis, and eosinophilia. Hypoglycemia may also occur, especially in children.

Acute adrenal insufficiency is a medical emergency, and treatment should not be delayed pending laboratory results. In a critically ill patient with hypovolemia, a plasma sample for cortisol,

ACTH, aldosterone, and renin should be obtained, and then treatment with hydrocortisone (100 mg IV bolus) and parenteral saline administration should be initiated. Sepsis-induced adrenal insufficiency is recognized by a basal cortisol level lower than 10 $\mu\text{g}/\text{dL}$ or a change in cortisol of less than 9 $\mu\text{g}/\text{dL}$ after administration of 0.25 mg ACTH (1-24) (cosyntropin). In severe illness, albumin and cortisol-binding globulin (CBG) are low, resulting in a low level of total cortisol but not free cortisol; therefore, a low total cortisol level may not be diagnostic of adrenal insufficiency in this setting.

In a patient with chronic symptoms suggestive of adrenal insufficiency, a basal morning plasma cortisol measurement or a 1-hour cosyntropin test, or both, should be performed. In the latter test, 0.25 mg of cosyntropin is given intravenously or intramuscularly, and plasma cortisol is measured after 0, 30, and 60 minutes. A normal response is a plasma cortisol concentration higher than 20 $\mu\text{g}/\text{dL}$ at any time during the test. A patient with a basal morning plasma cortisol concentration lower than 5 $\mu\text{g}/\text{dL}$ and a stimulated cortisol concentration lower than 18 $\mu\text{g}/\text{dL}$ probably has adrenal insufficiency and should receive treatment. A basal plasma morning cortisol concentration between 10 and 18 $\mu\text{g}/\text{dL}$ in association with a stimulated cortisol concentration lower than 18 $\mu\text{g}/\text{dL}$ probably indicates impaired adrenal reserve and a requirement for receiving cortisol replacement under stress conditions (see later discussion).

Once the diagnosis of adrenal insufficiency is made, the distinction between primary and secondary adrenal insufficiency needs to be established. Secondary adrenal insufficiency results from inadequate stimulation of the adrenal cortex by ACTH (see Chapter 62). Hyperpigmentation does not occur. In addition, because mineralocorticoid levels are normal in secondary adrenal insufficiency, symptoms of salt craving, as well as the laboratory abnormalities of hyperkalemia and metabolic acidosis, are not present, although hyponatremia may be observed. Hypothyroidism, hypogonadism, and growth hormone deficiency may also be present. To distinguish primary from secondary adrenal insufficiency, a basal morning plasma ACTH value should be obtained, along with a standing (upright for at least 2 hours) serum aldosterone level and a measurement of plasma renin activity (PRA). A plasma ACTH value greater than 20 pg/mL (normal, 5 to 30 pg/mL) is consistent with primary adrenal insufficiency, whereas a value lower than 20 pg/mL probably represents

TABLE 64-2 SYNDROMES OF ADRENOCORTICAL HYPOFUNCTION**PRIMARY ADRENAL DISORDERS****Combined Glucocorticoid and Mineralocorticoid Deficiency**

Autoimmune

- Isolated autoimmune disease (Addison's disease)
- Polyglandular autoimmune syndrome, type I
- Polyglandular autoimmune syndrome, type II

Infectious

- Tuberculosis
- Fungal
- Cytomegalovirus
- Human immunodeficiency virus

Vascular

- Bilateral adrenal hemorrhage
- Sepsis
- Coagulopathy
- Thrombosis, embolism
- Adrenal infarction

Infiltration

- Metastatic carcinoma and lymphoma
- Sarcoidosis
- Amyloidosis
- Hemochromatosis

Congenital

- Congenital adrenal hyperplasia
- 21-Hydroxylase deficiency
- 3 β -ol Dehydrogenase deficiency
- 20,22-Desmolase deficiency
- Adrenal unresponsiveness to ACTH
- Congenital adrenal hypoplasia
- Adrenoleukodystrophy
- Adrenomyeloneuropathy

Iatrogenic

- Bilateral adrenalectomy
- Drugs: metyrapone, aminoglutethimide, trilostane, ketoconazole, *o,p'*-DDD, mifepristone, pasireotide

Mineralocorticoid Deficiency without Glucocorticoid Deficiency

- Corticosterone methyl oxidase deficiency
- Isolated zona glomerulosa defect
- Heparin therapy
- Critical illness
- Angiotensin-converting enzyme inhibitors

SECONDARY ADRENAL DISORDERS**Secondary Adrenal Insufficiency**

- Hypothalamic-pituitary dysfunction
- Exogenous glucocorticoids
- After removal of an ACTH-secreting tumor

Hyporeninemic Hypoaldosteronism

- Diabetic nephropathy
- Tubulointerstitial diseases
- Obstructive uropathy
- Autonomic neuropathy
- Nonsteroidal anti-inflammatory drugs
- β -Adrenergic drugs

ACTH, Adrenocorticotropic hormone; *o,p'*-DDD, *o,p'*-dichlorodiphenyldichloroethane (mitotane).

secondary adrenal insufficiency. An upright PRA value greater than 3 ng/mL/hour in the setting of a suppressed aldosterone level is consistent with primary adrenal insufficiency, whereas a value lower than 3 ng/mL/hour probably represents secondary adrenal insufficiency. The 1-hour cosyntropin test is suppressed in both primary and secondary adrenal insufficiency.

Secondary adrenal insufficiency occurs commonly after the discontinuation of glucocorticoids. Alternate-day glucocorticoid

treatment, if feasible, results in less suppression of the HPA axis than does daily glucocorticoid therapy. Complete recovery of the HPA axis can take 1 year or more, and the rate-limiting step appears to be recovery of the CRH-producing neurons.

Under stress, cortisol secretion is increased. Therefore, the concept of adrenal fatigue, proposed by some alternative providers, has no biologic validity.

After stabilization of acute adrenal insufficiency, patients with Addison's disease require lifelong replacement therapy with both glucocorticoids and mineralocorticoids. Many patients are overtreated with glucocorticoids and undertreated with mineralocorticoids. Because overtreatment with glucocorticoids results in insidious weight gain and osteoporosis, the minimal cortisol dose that can be tolerated without symptoms of glucocorticoid insufficiency (usually joint pain, abdominal pain, or diarrhea) is recommended. An initial regimen of 15 to 20 mg hydrocortisone first thing in the morning plus 5 mg hydrocortisone at about 3:00 PM mimics the physiologic dose and is recommended; a third dose is occasionally needed. Whereas glucocorticoid replacement is fairly uniform in most patients, the requirement for mineralocorticoid replacement varies greatly. The initial dose of the synthetic mineralocorticoid fludrocortisone should be 100 μ g/day (often in divided doses), and the dosage should be adjusted to keep the standing PRA value between 1 and 3 ng/mL/hour.

Under the stress of a minor illness (e.g., nausea, vomiting, fever $>100.5^{\circ}$ F), the hydrocortisone dose should be doubled for as short a period as possible. An inability to ingest hydrocortisone pills may necessitate parenteral hydrocortisone administration. Patients undergoing a major stressful event (e.g., surgery necessitating general anesthesia, major trauma) should receive 150 to 300 mg parenteral hydrocortisone daily (in three divided doses) with a rapid taper to normal replacement during recovery. All patients should wear a medical information bracelet and should be instructed in the use of intramuscular emergency hydrocortisone injections.

Hyporeninemic Hypoaldosteronism

Mineralocorticoid deficiency can result from decreased renin secretion by the kidneys. Resultant hypoangiotensinemia leads to hypoaldosteronism with hyperkalemia and hyperchloremic metabolic acidosis. The plasma sodium concentration is usually normal, but total plasma volume is often deficient. PRA and aldosterone levels are low and unresponsive to stimuli, including hypokalemia. Diabetes mellitus and chronic tubulointerstitial diseases of the kidney are the most common underlying conditions leading to impairment of the juxtaglomerular apparatus. A subset of hyporeninemic hypoaldosteronism is caused by autonomic insufficiency and is a frequent cause of orthostatic hypotension. Stimuli such as upright posture or volume depletion, mediated by baroreceptors, do not cause a normal renin response. Administration of pharmacologic agents such as nonsteroidal anti-inflammatory agents, angiotensin-converting enzyme inhibitors, and β -adrenergic antagonists can also produce conditions of hypoaldosteronism. Salt administration often with fludrocortisone and the α_1 -receptor agonist midodrine are effective in correcting the orthostatic hypotension and electrolyte abnormalities caused by hypoaldosteronism.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) refers to autosomal recessive disorders of adrenal steroid biosynthesis that result in glucocorticoid and mineralocorticoid deficiencies and compensatory increase in ACTH secretion (see Fig. 64-2). Five major types of CAH exist, and the clinical manifestations of each type depend on which steroids are in excess and which are deficient. 21 α -Hydroxylase (CYP21) deficiency is the most common of these disorders and accounts for about 95% of patients with CAH. In this condition, there is a failure of 21-hydroxylation of 17-hydroxyprogesterone and progesterone to 11-deoxycortisol and 11-deoxycorticosterone, respectively, with deficient cortisol and aldosterone production. Cortisol deficiency leads to increased ACTH release, resulting in adrenal hyperplasia and overproduction of 17-hydroxyprogesterone and progesterone. Increased ACTH production also leads to increased biosynthesis of androstenedione and DHEA, which can be converted to testosterone. Patients with 21-hydroxylase deficiencies can be divided into two clinical phenotypes: classic 21-hydroxylase deficiency, which usually is diagnosed at birth or during childhood, and late-onset 21-hydroxylase deficiency, which develops during or after puberty. Two thirds of patients with classic 21-hydroxylase deficiency have various degrees of mineralocorticoid deficiency (salt-losing form); the remaining one third have the non-salt-losing type (simple virilizing form). Both decreased aldosterone production and increased concentrations of precursors that are mineralocorticoid antagonists (progesterone and 17-hydroxyprogesterone) contribute to salt loss.

Late-onset 21-hydroxylase deficiency represents an allelic variant of classic 21-hydroxylase deficiency and is characterized by a mild enzymatic defect. This deficiency is the most common autosomal recessive disorder in humans and is present at high frequency in Ashkenazi Jews. The syndrome usually develops at the time of puberty with signs of virilization (hirsutism and acne) and amenorrhea or oligomenorrhea. This diagnosis should be considered in women who have unexplained hirsutism and menstrual abnormalities or infertility.

The most useful initial measurement for the diagnosis of classic 21-hydroxylase deficiency is that of plasma 17-hydroxyprogesterone. A value greater than 200 ng/dL is consistent with the diagnosis. The diagnosis of late-onset 21-hydroxylase deficiency is based on the finding of an elevated level of plasma 17-hydroxyprogesterone (>1500 ng/dL) 30 minutes after administration of 0.25 mg of synthetic ACTH (1-24).

The aim of treatment for classic 21-hydroxylase deficiency is to replace glucocorticoids and mineralocorticoids, suppress ACTH and androgen overproduction, and allow for normal growth and sexual maturation in children. A proposed approach to treating classic 21-hydroxylase deficiency recommends physiologic replacement with hydrocortisone and fludrocortisone in all affected patients. Virilizing effects can be prevented by the use of an antiandrogen (flutamide) and an aromatase inhibitor (testolactone). Although the traditional treatment for late-onset 21-hydroxylase deficiency is dexamethasone (0.5 mg/day), the use of an antiandrogen such as spironolactone (100 to 200 mg/day) or flutamide (125 mg/day) is probably equally effective and

has fewer side effects. Mineralocorticoid replacement is not needed in late-onset 21-hydroxylase deficiency.

11 β -Hydroxylase (CYP11B1) deficiency accounts for about 5% of patients with CAH. In this syndrome, the conversions of 11-deoxycortisol to cortisol and 11-deoxycorticosterone to corticosterone (the precursor to aldosterone) are blocked. Affected patients usually have hypertension and hypokalemia because of increased amounts of precursors with mineralocorticoid activity. Virilization occurs, as with 21-hydroxylase deficiency, and a late-onset form manifesting as androgen excess also occurs. The diagnosis is made from the finding of elevated plasma 11-deoxycortisol levels, either basally or after ACTH stimulation.

Rare forms of CAH are 3 β -HSD type II deficiency, 17 α -hydroxylase (CYP17) deficiency, and steroidogenic acute regulatory protein (StAR) deficiency.

SYNDROMES OF ADRENOCORTICAL HYPERFUNCTION

Hypersecretion of the glucocorticoid hormone cortisol results in Cushing's syndrome, a metabolic disorder that affects carbohydrate, protein, and lipid metabolism. Hypersecretion of mineralocorticoids such as aldosterone results in a syndrome of hypertension and electrolyte disturbances.

Cushing's Syndrome

Pathophysiology

Increased production of cortisol is seen in both physiologic and pathologic states (Table 64-3). Physiologic hypercortisolism occurs with stress, during the last trimester of pregnancy, and in persons who regularly perform strenuous exercise. Pathologic conditions of elevated cortisol levels include exogenous or endogenous Cushing's syndrome and several psychiatric states, such as depression, alcoholism, anorexia nervosa, panic disorder, and alcohol or narcotic withdrawal.

Cushing's syndrome may be caused by exogenous administration of ACTH or glucocorticoid or by endogenous overproduction of these hormones. Endogenous Cushing's syndrome is either ACTH dependent or ACTH independent. ACTH dependency accounts for 85% of patients and includes pituitary sources of ACTH (Cushing's disease) and ectopic sources of ACTH. Pituitary Cushing's disease accounts for 90% of patients with ACTH-dependent Cushing's syndrome. Ectopic secretion of ACTH occurs most commonly in patients with small cell lung carcinoma. These patients are older, usually have a history of smoking, and primarily exhibit signs and symptoms of lung cancer rather than those of Cushing's syndrome. Patients with the clinically apparent ectopic ACTH syndrome, in contrast, have mostly intrathoracic (lung and thymic) carcinoids. ACTH-independent causes account for 15% of patients with Cushing's syndrome and include adrenal adenomas, adrenal carcinomas, micronodular adrenal disease, and autonomous macronodular adrenal disease. The female-to-male ratio for noncancerous forms of Cushing's syndrome is 4:1.

Clinical Presentation

The clinical signs, symptoms, and common laboratory findings of hypercortisolism observed in patients with Cushing's syndrome are listed in Table 64-4 (see also Fig. 64-2). Patients with

TABLE 64-3 SYNDROMES OF ADRENOCORTICAL HYPERFUNCTION

STATES OF GLUCOCORTICOID EXCESS	STATES OF MINERALOCORTICOID EXCESS
Physiologic States	Primary Aldosteronism
Stress	Aldosterone-secreting adenoma
Strenuous exercise	Bilateral adrenal hyperplasia
Last trimester of pregnancy	Aldosterone-secreting carcinoma
Pathologic States	Glucocorticoid-suppressible hyperaldosteronism
Psychiatric conditions (pseudo-Cushing's disorders)	Adrenal Enzyme Deficiencies
Depression	11 β -Hydroxylase deficiency
Alcoholism	17 α -Hydroxylase deficiency
Anorexia nervosa	11 β -Hydroxysteroid dehydrogenase type II deficiency
Panic disorders	Exogenous Mineralocorticoids
Alcohol and drug withdrawal	Licorice
ACTH-dependent states	Carbenoxolone
Pituitary adenoma (Cushing's disease)	Fludrocortisone
Ectopic ACTH syndrome	Secondary Hyperaldosteronism
Bronchial carcinoid	Associated with hypertension
Thymic carcinoid	Accelerated hypertension
Islet cell tumor	Renovascular hypertension
Small cell lung carcinoma	Estrogen administration
Ectopic CRH secretion	Renin-secreting tumors
ACTH-independent states	Without hypertension
Adrenal adenoma	Bartter's syndrome
Adrenal carcinoma	Sodium-wasting nephropathy
Micronodular adrenal disease	Renal tubular acidosis
Exogenous Sources	Diuretic and laxative abuse
Glucocorticoid intake	Edematous states (cirrhosis, nephrosis, congestive heart failure)
ACTH intake	

ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

Cushing's syndrome often have some, but not all, of the signs and symptoms discussed here. Typically, the obesity is centripetal, with a wasting of the arms and legs, which is distinct from the generalized weight gain observed in idiopathic obesity. Rounding of the face (called *moon facies*) and a dorsocervical fat pad (*buffalo hump*) may occur in obesity not related to Cushing's syndrome, whereas facial plethora and supraclavicular filling are more specific for Cushing's syndrome. Patients with Cushing's syndrome may have proximal muscle weakness; consequently, the inability to stand up from a squat or to comb one's hair can be revealing. Sleep disturbances and insomnia, hyperarousal in the evening and night, mood swings, and other psychological abnormalities are frequently seen. Cognitive dysfunction and severe fatigue are often present. Menstrual irregularities often precede other cushingoid symptoms in affected women. Patients of both sexes complain of a loss of libido, and affected men frequently complain of erectile dysfunction. Adult-onset acne or hirsutism in women could also suggest Cushing's syndrome. The skin striae observed in patients with Cushing's syndrome are violaceous (i.e., purple or dark red) with a width of at least 1 cm. Thinning of the skin on the top of the hands is a specific sign in younger adults with Cushing's syndrome. Old pictures of patients are extremely helpful for evaluating the progression of the physical stigmata of Cushing's syndrome.

Associated laboratory findings in Cushing's syndrome include elevated plasma alkaline phosphatase levels, granulocytosis,

TABLE 64-4 SIGNS, SYMPTOMS, AND LABORATORY ABNORMALITIES OF HYPERCORTISOLISM

FEATURE	PERCENTAGE OF PATIENTS
Fat redistribution (dorsocervical and supraclavicular fat pads, temporal wasting, centripetal obesity, weight gain)	95
Menstrual irregularities	80 (of affected women)
Thin skin and plethora	80
Moon facies	75
Increased appetite	75
Sleep disturbances	75
Nocturnal hyperarousal	75
Hypertension	75
Hypercholesterolemia and hypertriglyceridemia	70
Altered mentation (poor concentration, decreased memory, euphoria)	70
Diabetes mellitus and glucose intolerance	65
Striae	65
Hirsutism	65 (of affected women)
Proximal muscle weakness	60
Psychological disturbances (emotional lability, depression, mania, psychosis)	50
Decreased libido and erectile dysfunction	50 (of affected men)
Acne	45
Osteoporosis and pathologic fractures	40

Poor wound healing	40
Virilization	20 (of affected women)
Edema	20
Increased infections	10
Cataracts	5

thrombocytosis, hypercholesterolemia, hypertriglyceridemia, and glucose intolerance and/or diabetes mellitus. Hypokalemia or alkalosis usually occurs in patients with severe hypercortisolism as a result of the ectopic ACTH syndrome.

Diagnosis

If the history and physical examination findings are suggestive of hypercortisolism, then the diagnosis of Cushing's syndrome can usually be established by collecting urine for 24 hours and measuring the urinary free cortisol (UFC). This test is extremely sensitive for diagnosis of Cushing's syndrome because in 90% of affected patients, the initial UFC level is greater than 50 $\mu\text{g}/24$ hours (Fig. 64-5).

The overnight dexamethasone suppression test has been widely used as a screening tool to evaluate patients who may have hypercortisolism. Dexamethasone, 1 mg, is given orally at 11:00 PM or midnight, and plasma cortisol is measured the following morning at 8:00 AM. A morning plasma cortisol level greater than 1.8 $\mu\text{g}/\text{dL}$ suggests hypercortisolism. This test produces a significant number of both false-positive and false-negative results, but it is still recommended in the 2008 Endocrine Society consensus guidelines.

Cortisol is normally secreted in a diurnal manner: The plasma concentration is highest in the early morning (between 6:00 and 8:00 AM) and lowest around midnight. Most patients with Cushing's syndrome have blunted diurnal variation. Nighttime plasma cortisol values greater than 50% of the morning values are

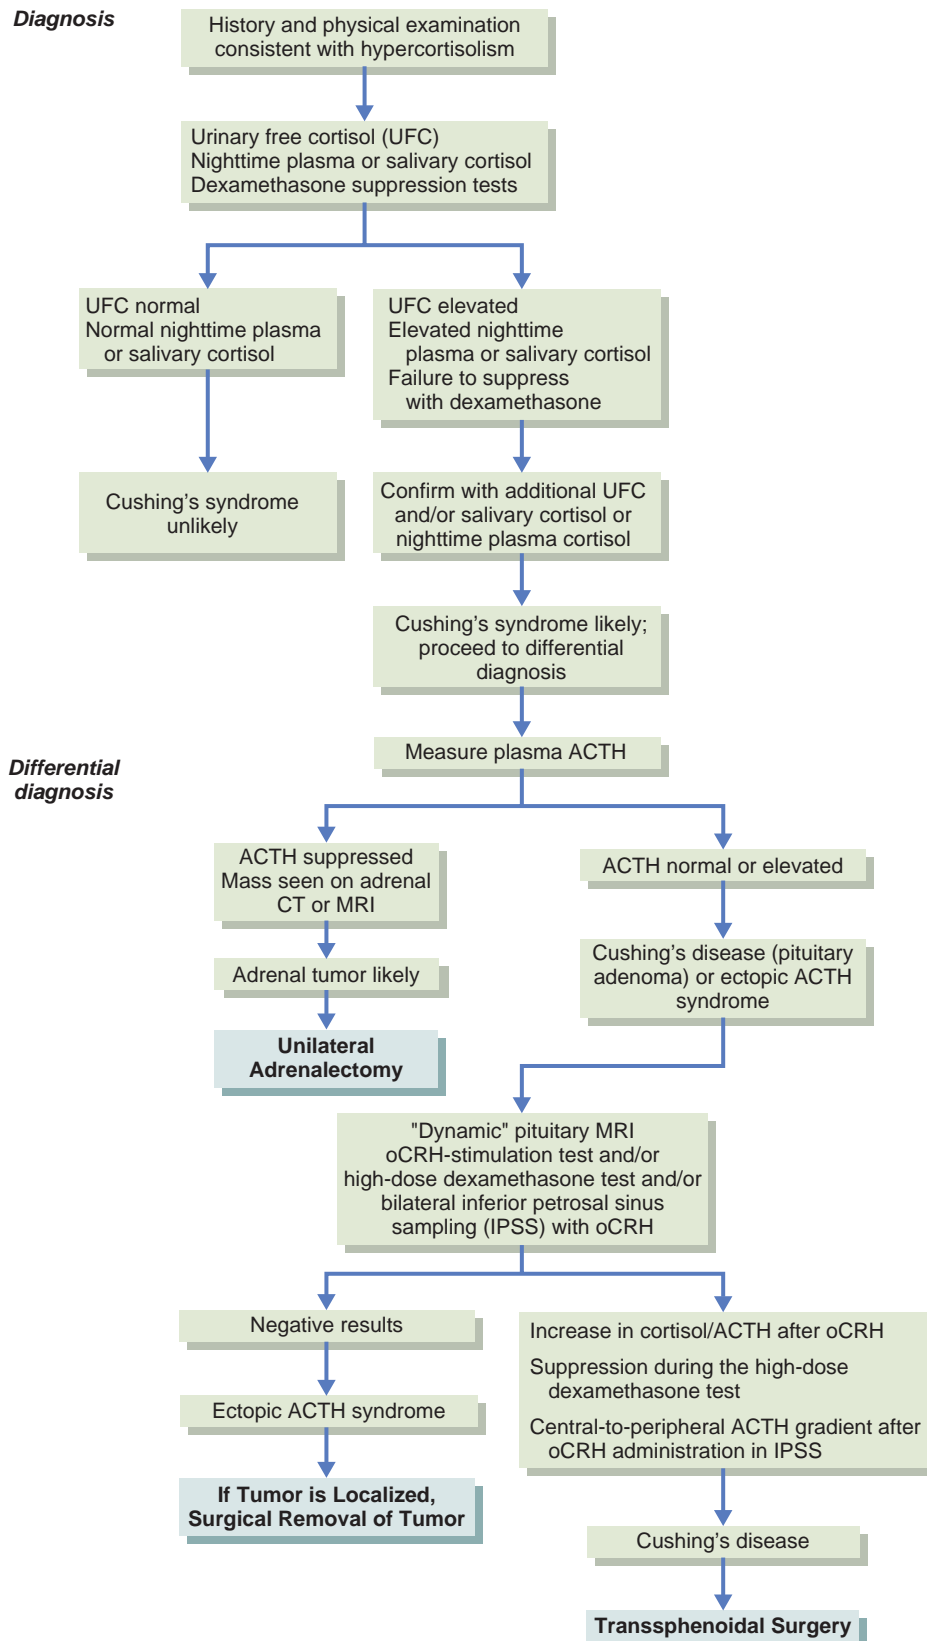

FIGURE 64-5 Flowchart for evaluation of a patient with possible Cushing's syndrome. ACTH, Adrenocorticotropic hormone; CT, computed tomography; MRI, magnetic resonance imaging; oCRH, ovine corticotropin-releasing hormone.

considered to be consistent with Cushing's syndrome. Because of the difficulty of obtaining nighttime plasma cortisol levels, measurement of late-night salivary cortisol has been developed to assess hypercortisolism. This test appears to have a high degree of sensitivity and specificity for diagnosis of Cushing's syndrome. Multiple measurements of UFC or salivary cortisol may be needed either to diagnose or exclude Cushing's syndrome, especially in subjects with suggestive signs and symptoms of hypercortisolism.

Differential Diagnosis

Once the diagnosis of Cushing's syndrome is established, the cause of the hypercortisolism needs to be ascertained by biochemical studies that evaluate the feedback regulation of the HPA axis; this can be accomplished by venous sampling and imaging procedures. The initial approach is to measure basal ACTH levels, which are normal or elevated in Cushing's disease and the ectopic ACTH syndrome but are suppressed in primary adrenal Cushing's syndrome. Patients with a suppressed ACTH level can proceed to adrenal imaging studies. To distinguish between Cushing's disease and the ectopic ACTH syndrome, the high-dose or 8-mg overnight dexamethasone suppression test, the ovine CRH (oCRH) test, and bilateral simultaneous inferior petrosal sinus sampling (IPSS) are used.

In the dexamethasone suppression test (Liddle test), 0.5 mg of dexamethasone is given orally every 6 hours for 2 days (low dose), followed by 2 mg of dexamethasone every 6 hours for another 2 days (high dose). On the second day of high-dose dexamethasone, the UFC level will be suppressed to less than 10% of the baseline collection value in patients with pituitary adenomas but not in patients with the ectopic ACTH syndrome or adrenal cortisol-secreting tumors. The Liddle test has some methodologic drawbacks, and results should be interpreted cautiously; other confirmatory tests should be performed before surgery is recommended.

An overnight high-dose dexamethasone suppression test is helpful in establishing the cause of Cushing's syndrome. In this test, a baseline cortisol level is measured at 8:00 AM, and then 8 mg of dexamethasone is given orally at 11:00 PM. At 8:00 AM the following morning, a plasma cortisol measurement is obtained. Suppression, which occurs in patients with pituitary Cushing's disease, is defined as a decrease in plasma cortisol to less than 50% of the baseline level.

The oCRH test can also be used to establish the cause of Cushing's syndrome, but this test was not available in the United States in 2014.

Bilateral IPSS is an accurate and safe procedure for distinguishing pituitary Cushing's disease from the ectopic ACTH syndrome. Venous blood from the anterior lobe of the pituitary gland empties into the cavernous sinuses and then into the superior and inferior petrosal sinuses. Venous plasma samples for ACTH determination are obtained from both inferior petrosal sinuses, along with a simultaneous peripheral sample, both before and after intravenous bolus administration of oCRH. Significant gradients at baseline and after oCRH stimulation between petrosal sinus and peripheral samples suggest pituitary Cushing's disease. In baseline measurements, an ACTH concentration gradient of 1.6 or more between a sample from either of the petrosal sinuses and the peripheral sample is strongly suggestive of

pituitary Cushing's disease, whereas patients with the ectopic ACTH syndrome or adrenal adenomas have no ACTH gradient between their petrosal and peripheral samples. After oCRH administration, a central-to-peripheral gradient of more than 3.2 is consistent with pituitary Cushing's disease. The use of oCRH has enabled complete distinction of pituitary from nonpituitary Cushing's syndrome. An ACTH gradient ipsilateral to the side of the tumor is found in 70% to 80% of pituitary Cushing's disease patients sampled. Although this procedure requires a radiologist who is experienced in IPSS, it is available at many tertiary care facilities.

Magnetic resonance imaging (MRI) with gadolinium is the preferred procedure for localizing a pituitary adenoma. In many centers, a *dynamic* MRI is performed; the pituitary is visualized as the gadolinium enters and leaves the gland. Because about 10% of normal individuals are found to have a nonfunctioning pituitary adenoma on pituitary MRI, pituitary imaging should not be the sole criterion for the diagnosis of pituitary Cushing's disease.

Treatment

The preferred treatment for all forms of Cushing's syndrome is appropriate surgery or, in some cases, radiation therapy (see [Chapter 62](#)). A more appealing option for patients with Cushing's disease who remain hypercortisolemic after pituitary surgery is bilateral adrenalectomy followed by lifelong glucocorticoid and mineralocorticoid replacement therapy.

In patients with the ectopic ACTH syndrome, the goal is to localize the tumor by appropriate scans so it can be removed surgically. A unilateral adrenalectomy is the treatment of choice in patients with a cortisol-secreting adrenal adenoma. Cortisol-secreting adrenal carcinomas initially should also be managed surgically; however, the prognosis is poor, with only 20% of patients surviving more than 1 year after diagnosis.

Medical treatment for hypercortisolism may be needed to prepare patients who are undergoing or have undergone pituitary irradiation and are awaiting its effects before surgery as well as those who are not surgical candidates or elect not to have surgery. Ketoconazole, *o,p'*-DDD (mitotane), metyrapone, aminoglutethimide, mifepristone, and trilostane are the most commonly used agents for adrenal blockade and can be used alone or in combination. The somatostatin analogue, pasireotide, which decreases ACTH and may decrease tumor size, is a recently FDA-approved drug for treating Cushing's disease.

Primary Mineralocorticoid Excess

Pathophysiology

The causes of primary aldosteronism (see [Table 64-3](#)) are aldosterone-producing adenoma (75%), bilateral adrenal hyperplasia (25%), adrenal carcinoma (1%), and glucocorticoid-remediable hyperaldosteronism (<1%). Adrenal enzyme defects (11 β -HSD type II, 11 β -hydroxylase, and 17 α -hydroxylase deficiencies) and apparent mineralocorticoid excess (from ingestion of licorice or carbenoxolone, which inhibit 11 β -HSD type II, or from a congenital defect in this enzyme) are also states of functional mineralocorticoid overactivity. Secondary aldosteronism (see [Table 64-3](#)) results from an overactive renin-angiotensin system.

Primary aldosteronism is usually recognized during evaluation of hypertension or hypokalemia and represents a potentially curable form of hypertension. Up to 5% of patients with hypertension have primary aldosteronism. These patients are usually between the ages of 30 and 50 years, and the female-to-male ratio is 2 : 1.

Clinical Presentation

Hypertension, hypokalemia, and metabolic alkalosis are the main clinical manifestations of hyperaldosteronism; most of the presenting symptoms are related to hypokalemia. Symptoms in patients with mild hypokalemia are fatigue, muscle weakness, nocturia, lassitude, and headaches. If more severe hypokalemia exists, polydipsia, polyuria, paresthesias, and even intermittent paralysis and tetany can occur. Blood pressure can range from minimally elevated to very high. A positive Trousseau or Chvostek sign may occur as a result of metabolic alkalosis.

Diagnosis and Treatment

Initially, hypokalemia in the presence of hypertension must be documented (Fig. 64-6). The patient must have adequate salt intake and discontinue diuretics before potassium measurement. A morning plasma aldosterone level (measured in ng/dL) and a

PRA value (in ng/mL/hour) should be obtained. A ratio of serum aldosterone to PRA greater than 20 with a serum aldosterone level greater than 15 ng/dL suggests the diagnosis of hyperaldosteronism. Confirmatory tests for hyperaldosteronism should be performed, such as oral sodium loading, saline infusion, fludrocortisone suppression, or captopril challenge.

Once the diagnosis of primary aldosteronism has been demonstrated, it is important to distinguish between an aldosterone-producing adenoma and bilateral hyperplasia, because the former is treated with surgery and the latter is treated medically. A computed tomography (CT) scan of the adrenal glands should be performed to localize the tumor. The patient should undergo unilateral adrenalectomy if a discrete adenoma is observed in one adrenal gland and the contralateral gland is normal. Patients in whom biochemical and localization study findings are consistent with bilateral hyperplasia should be treated medically with a potassium-sparing diuretic, usually eplerenone or spironolactone. Hyperaldosteronism and hypertension secondary to activation of the renin-angiotensin system can occur in patients with accelerated hypertension, in those with renovascular hypertension, in those receiving estrogen therapies, and, rarely, in patients with renin-secreting tumors. Hyperaldosteronism without hypertension occurs in patients with Bartter's syndrome, sodium-wasting nephropathy, or renal tubular acidosis, as well as those who abuse diuretics or laxatives.

ADRENAL MEDULLARY HYPERFUNCTION

The adrenal medulla synthesizes the catecholamines norepinephrine, epinephrine, and dopamine from the amino acid tyrosine. Norepinephrine, the major catecholamine produced by the adrenal medulla, has predominantly α -agonist actions, causing vasoconstriction. Epinephrine acts primarily on the β -receptors, having positive inotropic and chronotropic effects on the heart and causing peripheral vasodilation and increasing plasma glucose concentrations in response to hypoglycemia. The action of circulating dopamine is unclear. Whereas norepinephrine is synthesized in the central nervous system and sympathetic post-ganglionic neurons, epinephrine is synthesized almost entirely in the adrenal medulla. The adrenal medullary contribution to total body norepinephrine secretion is relatively small. Hypofunction of the adrenal medulla has little physiologic effect, whereas hypersecretion of catecholamines produces the clinical syndrome of pheochromocytoma.

Pheochromocytoma

Pathophysiology

Although pheochromocytomas can occur in any sympathetic ganglion in the body, more than 90% arise from the adrenal medulla. Most extra-adrenal tumors occur in the mediastinum or abdomen. Bilateral adrenal pheochromocytomas are present in about 5% of the cases and may occur as part of familial syndromes. Pheochromocytoma occurs as part of multiple endocrine neoplasia type IIA or IIB. The former (Sipple's syndrome) is marked by medullary carcinoma of the thyroid, hyperparathyroidism, and pheochromocytoma; the latter is characterized by medullary carcinoma of the thyroid, mucosal neuromas, intestinal ganglioneuromas, marfanoid habitus, and pheochromocytoma. Pheochromocytomas are also associated with

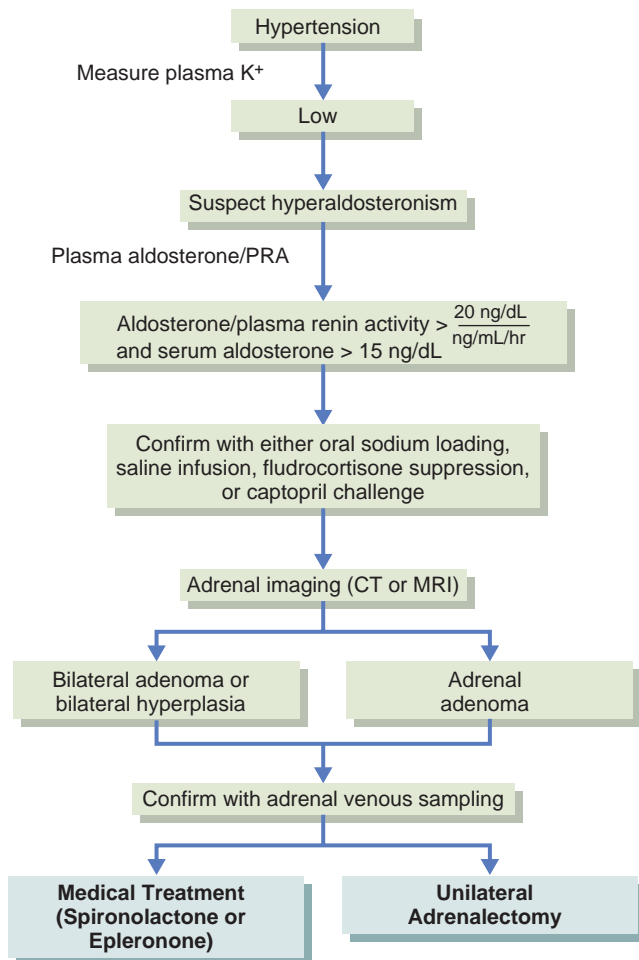

FIGURE 64-6 Flowchart for evaluation of a patient with probable primary hyperaldosteronism. Plasma aldosterone is measured in ng/dL, and plasma renin activity (PRA) is measured in ng/mL/hour. CT, Computed tomography; MRI, magnetic resonance imaging.

neurofibromatosis, cerebelloretinal hemangioblastosis (von Hippel–Lindau disease), and tuberous sclerosis.

Clinical Presentation

Because most pheochromocytomas secrete norepinephrine as the principal catecholamine, hypertension (often paroxysmal) is the most common finding. Other symptoms include the triad of headache, palpitations, and sweating as well as skin blanching, diarrhea, anxiety, nausea, fatigue, weight loss, and abdominal and chest pain. Emotional stress, exercise, anesthesia, abdominal pressure, or intake of tyramine-containing foods may precipitate these symptoms. Orthostatic hypotension can also occur. Wide fluctuations in blood pressure are characteristic, and the hypertension associated with pheochromocytoma usually does not respond to standard antihypertensive medicines. Cardiac abnormalities, as well as idiosyncratic reactions to medications, may also occur.

Diagnosis and Treatment

Although measurements of fractionated catecholamine and metanephrine levels in the urine are often used as screening tests, plasma free metanephrine and normetanephrine levels are the best tests for confirming or excluding pheochromocytoma. A plasma free metanephrine level greater than 0.61 nmol/L and a plasma free normetanephrine level greater than 0.31 nmol/L are consistent with the diagnosis of a pheochromocytoma. If these levels are only mildly elevated, a clonidine suppression test can be performed. In patients with pheochromocytoma, levels are unchanged or increased. Once the diagnosis of pheochromocytoma is made, a CT scan of the adrenal glands should be performed. Most intra-adrenal pheochromocytomas are readily visible on this scan and enhance with contrast. If the CT scan is negative, then extra-adrenal pheochromocytomas can often be localized by iodine 131–labeled metaiodobenzylguanidine (¹³¹I-MIBG), positron emission tomography, octreotide scan, or abdominal MRI. Pheochromocytomas show high signal intensity on T2-weighted images.

The treatment of pheochromocytoma is surgical if the lesion can be localized. Patients should undergo preoperative α -blockade with phenoxybenzamine 1 to 2 weeks before surgery. β -Adrenergic antagonists should be used before or during surgery. About 5% to 10% of pheochromocytomas are malignant. ¹³¹I-MIBG or chemotherapy may be useful, but the prognosis is poor. α -Methyl-*p*-tyrosine, an inhibitor of tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis, may be used to decrease catecholamine secretion from the tumor.

Incidental Adrenal Mass

Clinically inapparent adrenal masses may be discovered inadvertently in the course of diagnostic testing or treatment for other clinical conditions not related to the signs and symptoms of adrenal disease; they are commonly known as *incidentalomas*

 (E-Fig. 64-2). Some of these tumors secrete a small amount of

excess cortisol, leading to a condition called *subclinical Cushing's syndrome*. A morning plasma ACTH level and an overnight 1-mg dexamethasone test are recommended for patients with an adrenal incidentaloma. Patients with hypertension should also undergo measurement of serum potassium, plasma aldosterone concentration, PRA, and urine or plasma free metanephrines. Surgery should be considered for all patients with functional adrenal cortical tumors that are hormonally active or larger than 4 cm. Tumors not associated with hormonal secretion that are smaller than 4 cm can be monitored with repeated imaging and hormonal assessment.

Primary Adrenal Cancer

Primary adrenal carcinomas are rare, with an incidence of 1 to 5 per 1 million persons. The female-to-male ratio is 2.5:1, and the mean age at onset is 40 to 50 years. About 25% of patients have symptoms, including abdominal pain, weight loss, anorexia, and fever. Eighty percent of primary adrenal carcinomas are functional, with secretion of glucocorticoid alone (45%) or glucocorticoid plus androgens (45%) being most common.

At presentation, metastatic spread is evident in 75% of cases. An incidentally discovered adrenal mass that is large is more likely to be malignant. Resection is recommended for tumors larger than 6 cm and often for those larger than 4 cm. In patients who do not have a known cancer, most adrenal masses that turn out to be malignant are primary adrenocortical carcinomas, whereas in patients with a known malignancy, an adrenal mass is likely to be a metastasis in about 75% of cases.

The treatment of adrenocortical carcinomas is surgery. These cancers are usually resistant to radiation and chemotherapy, but the adrenolytic compound mitotane has been shown to improve survival. Adrenocortical carcinomas carry a poor prognosis, with overall 5-year survival rates of less than 20%.

 For a deeper discussion on this topic, please see Chapter 227, "Adrenal Cortex," in Goldman-Cecil Medicine, 25th Edition.

Male Reproductive Endocrinology

Glenn D. Braunstein

INTRODUCTION

The testes are composed of Leydig (interstitial) cells, which secrete testosterone and estradiol, and the seminiferous tubules, which produce sperm. They are regulated by the luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are secreted by the anterior pituitary under the influence of the hypothalamic decapeptide gonadotropin-releasing hormone (GnRH) (Fig. 65-1). LH stimulates the Leydig cells to secrete testosterone, which feeds back in a negative fashion at the level of the pituitary and hypothalamus to inhibit further LH production. FSH stimulates sperm production through interaction with the Sertoli cells in the seminiferous tubules. Feedback inhibition of FSH is through gonadal steroids, as well as through inhibin, a glycoprotein produced by Sertoli cells.

FIGURE 65-1 Regulation of the hypothalamic-pituitary-testicular axis. The plus (+) and minus (-) symbols indicate positive and negative feedback, respectively. FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Biochemical evaluation of the hypothalamic-pituitary-Leydig axis is carried out by measurement of serum LH and testosterone concentrations, whereas a semen analysis and serum FSH determination provide an assessment of the hypothalamic-pituitary-seminiferous tubular axis. The ability of the pituitary to release gonadotropins can be tested dynamically through GnRH stimulation, and the ability of the testes to secrete testosterone can be evaluated through injections of human chorionic gonadotropin (HCG), a glycoprotein hormone that has biologic activity similar to that of LH.

HYPOGONADISM

Either testosterone deficiency or defective spermatogenesis constitutes *hypogonadism*. Often both disorders coexist. The clinical manifestations of androgen deficiency depend on the time of onset and the degree of deficiency. Testosterone is required for development of the wolffian duct into the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts, as well as for virilization of the external genitalia through the major intracellular testosterone metabolite, dihydrotestosterone (DHT). Consequently, early prenatal androgen deficiency leads to the formation of ambiguous genitalia and to male pseudohermaphroditism. Androgen deficiency occurring later during gestation may result in micropenis or *cryptorchidism*, the unilateral or bilateral absence of testes in the scrotum resulting from the failure of normal testicular descent.

During puberty, androgens are responsible for male sexual differentiation, which includes growth of the scrotum, epididymis, vas deferens, seminal vesicles, prostate, penis, skeletal muscle, and larynx. Additionally, androgens stimulate the growth of axillary, pubic, facial, and body hair and increase sebaceous gland activity. They are also responsible through conversion to estrogens for the growth and fusion of the epiphyseal cartilaginous plates, clinically seen as the *pubertal growth spurt*. Prepubertal androgen deficiency leads to poor muscle development, decreased strength and endurance, a high-pitched voice, sparse axillary and pubic hair, and the absence of facial and body hair. The long bones of the lower extremities and arms may continue to grow under the influence of growth hormone; this condition leads to eunuchoid proportions (i.e., arm span exceeding total height by ≥ 5 cm) and greater growth of the lower extremities relative to total height. Postpubertal androgen deficiency may result in a decrease in libido, impotence, low energy, fine wrinkling around the corners of the eyes and mouth, and diminished facial and body hair.

Male hypogonadism may be classified into three categories according to the level of the defect (Table 65-1). Diseases directly affecting the testes result in *primary* or *hypogonadotropic hypogonadism*, which is characterized by oligospermia or azoospermia and low testosterone levels but exhibits elevations of LH and FSH because of a decrease in the negative feedback regulation on the pituitary and hypothalamus by androgens, estrogens, and inhibin. In contrast, hypogonadism from lesions in the hypothalamus or pituitary gives rise to *secondary* or *hypogonadotropic hypogonadism*; the low testosterone level or ineffective spermatogenesis results from inadequate concentrations of the gonadotropins. The third category of hypogonadism is the result of defects in androgen action.

Hypothalamic-Pituitary Disorders

Panhypopituitarism occurs congenitally from structural defects or from inadequate production or release of the hypothalamic-releasing factors. The condition may also be acquired through replacement by tumors, infarction from vascular insufficiency, infiltrative disorders, autoimmune diseases, trauma, and infections.

Kallmann syndrome is a form of hypogonadotropic hypogonadism that is associated with problems in the ability to discriminate odors, either incompletely (*hyposmia*) or completely (*anosmia*). This syndrome results from a defect in the migration of the GnRH neurons from the olfactory placode into the hypothalamus. Therefore, it represents a GnRH deficiency. Patients remain prepubertal, with small, rubbery testes, and they develop eunuchoidism (E-Fig. 65-1).

Hyperprolactinemia may result in hypogonadotropic hypogonadism because prolactin elevation inhibits normal release of GnRH, decreases the effectiveness of LH at the Leydig cell level, and also inhibits some of the actions of testosterone at the level of the target organ. Normalization of prolactin levels through withdrawal of an offending drug, by surgical removal of the pituitary adenoma, or with the use of dopamine agonists reverses this form of hypogonadism.

TABLE 65-1 CLASSIFICATION OF MALE HYPOGONADISM

HYPOTHALAMIC-PITUITARY DISORDERS (SECONDARY HYPOGONADISM)

Panhypopituitarism
Isolated gonadotropin deficiency
Complex congenital syndromes
Hyperprolactinemia
Hypothalamic dysfunction

GONADAL DISORDERS (PRIMARY HYPOGONADISM)

Klinefelter's syndrome and associated chromosomal defects
Myotonic dystrophy
Cryptorchidism
Bilateral anorchia
Seminiferous tubular failure
Adult Leydig cell failure
Androgen biosynthesis enzyme deficiency

DEFECTS IN ANDROGEN ACTION

Testicular feminization (complete androgen insensitivity)
Incomplete androgen insensitivity
5 α -Reductase deficiency

Weight loss or systemic illness in male patients can cause another form of secondary hypogonadism, *hypothalamic dysfunction*. Weight loss or illness induces a defect in the hypothalamic release of GnRH and results in low levels of gonadotropin and testosterone. This condition is commonly observed in patients with cancer, AIDS, or chronic inflammatory processes.

Primary Gonadal Abnormalities

The most common congenital cause of primary testicular failure is *Klinefelter's syndrome*, which occurs in about 1 of every 600 live male births and is usually caused by a maternal meiotic chromosomal nondisjunction that results in an XXY genotype. At puberty, clinical findings include the following: a variable degree of hypogonadism; gynecomastia; small, firm testes measuring less than 2 cm in the longest axis (normal testes, 3.5 cm or greater); azoospermia; eunuchoid skeletal proportions; and elevations of FSH and LH (E-Fig. 65-2). Primary gonadal failure is also found in patients with another congenital condition, *myotonic dystrophy*, which is characterized by progressive weakness; atrophy of the facial, neck, hand, and lower extremity muscles; frontal baldness; and myotonia.

About 3% of full-term male infants have *cryptorchidism*, which spontaneously corrects during the first year of life in most cases; consequently, by 1 year of age, the incidence of this condition is about 0.75%. When the testes are maintained in the intra-abdominal position, the increased temperature leads to defective spermatogenesis and oligospermia. Leydig cell function usually remains normal, resulting in normal levels of adult testosterone.

Bilateral anorchia, also known as the vanishing testicle syndrome, is a rare condition in which the external genitalia are fully formed, indicating that ample quantities of testosterone and DHT were produced during early embryogenesis. However, the testicular tissue disappears before or shortly after birth, and the result is an empty scrotum. This condition is differentiated from cryptorchidism by an HCG stimulation test. Patients with cryptorchidism have an increase in serum testosterone level after an injection of HCG, whereas patients with bilateral anorchia do not.

Acquired gonadal failure has numerous causes. The adult seminiferous tubules are susceptible to a variety of injuries, and seminiferous tubular failure is found after infections such as mumps, gonococcal or lepromatous orchitis, irradiation, vascular injury, trauma, alcohol ingestion, and use of chemotherapeutic drugs, especially alkylating agents. The serum FSH concentration may be normal or elevated, depending on the degree of damage to the seminiferous tubules. The Leydig cell compartment may also be damaged by these same conditions. In addition, some men experience a gradual decline in testicular function as they age, possibly because of microvascular insufficiency. Patients with decreased testosterone production may clinically exhibit lowered libido and potency, emotional lability, fatigue, and vasomotor symptoms such as hot flushes. The serum LH concentration is usually elevated in this situation.

Defects in Androgen Action

When either testosterone or its metabolite, DHT, binds to the androgen receptor in target cells, the receptor is activated and binds DNA; the resulting stimulation of transcription, protein synthesis, and cell growth collectively constitutes androgen

E-FIGURE 65-1 A boy aged 15 years, 10 months, with isolated gonadotropin deficiency and anosmia (Kallmann syndrome). He had undescended testes, but after administration of 10,000 U of human chorionic gonadotropin (HCG), the testes descended and were palpable in the scrotum. Height was 163.9 cm (−1.5 standard deviation); the upper-to-lower body ratio was 0.86, which is eunuchoid. The phallus measured 6.3 × 1.8 cm, and the testes were 1.2 × 0.8 cm. The concentration of plasma luteinizing hormone (FSH) was 1.2 ng/mL, and that of testosterone was 16 ng/mL. After administration of 100 μg of LH-releasing hormone (LHRH), the plasma LH (LER-960) was 0.7 ng/mL, and the FSH (LER-869) was 2.4 ng/mL. (From Styne DM, Grumbach MM: Puberty in the male and female: its physiology and disorders. In Yen SCC, Jaffee RB, editors: Reproductive endocrinology, ed 2, Philadelphia, 1986, Saunders, p. 313–384.)

E-FIGURE 65-2 **A**, A 19-year-old phenotypic male with chromatin-positive seminiferous tubule dysgenesis (Klinefelter's syndrome). The karyotype was 47,XXY, gonadotropin levels were elevated, and testosterone levels were low-normal. Notice normal virilization with long legs and gynecomastia (**B**). **C**, The testes were small and firm and measured 1.8×0.9 cm. Testicular biopsy revealed a severe degree of hyalinization of the seminiferous tubules and clumping of Leydig cells. **D**, A 48-year-old male with 47,XXY Klinefelter's syndrome with severe leg varicosities. (From Larsen PR, Kronenberg HM, Melred S, et al, editors: Williams textbook of endocrinology, ed 10, Philadelphia, 2002, Saunders.)

action. An absence of androgen receptors causes the syndrome of *testicular feminization*, a form of male pseudohermaphroditism. These genetic males have cryptorchid testes but appear to be phenotypic females. Because androgens are inactive during embryogenesis, the labial-scrotal folds fail to fuse, and a short vagina results. The fallopian tubes, uterus, and upper portion of the vagina are absent because the testes secrete müllerian duct inhibitory factor during early fetal development. At puberty, these patients have breast enlargement because the testes secrete a small amount of estradiol and the peripheral tissues convert testosterone and adrenal androgens to estrogens. Axillary and pubic hair does not grow because androgen action is required for their development. The serum testosterone concentrations are elevated as a result of continuous stimulation by elevated concentrations of LH. LH is high because of the inability of the testosterone to act in a negative feedback fashion at the hypothalamus. Patients may have incomplete forms of androgen insensitivity caused by point mutations affecting the androgen receptor gene, and clinically these patients show varying degrees of male pseudohermaphroditism.

Patients who lack the 5α -reductase enzyme that is required to convert testosterone to DHT are born with a *bifid scrotum*, which reflects abnormal fusion of the labial-scrotal folds, and

hypospadias, in which the urethral opening is in the perineal area or in the shaft of the penis. At puberty, androgen production is sufficient to partially overcome the defect; the scrotum, phallus, and muscle mass enlarge, and these patients appear to develop into physiologically normal men.

Diagnosis

Figure 65-2 illustrates an algorithm for the laboratory evaluation of hypogonadism in a phenotypic man. Serum concentrations of LH, FSH, and testosterone should be obtained, and a semen analysis should be performed. A low testosterone level with low concentrations of gonadotropins indicates a hypothalamic-pituitary abnormality, which needs to be evaluated with serum prolactin determination and radiographic examination. Elevated concentrations of gonadotropins with a normal or low testosterone level reflect a primary testicular abnormality. If no testes are palpable in the scrotum and careful *milking* of the patient's lower abdomen does not bring retractile testes into the scrotum, an HCG stimulation test should be performed. A rise in serum testosterone concentrations indicates the presence of functional testicular tissue, and a diagnosis of cryptorchidism can be made. Absence of a rise in testosterone suggests bilateral anorchia. Small, firm testes in the scrotum are highly suggestive of

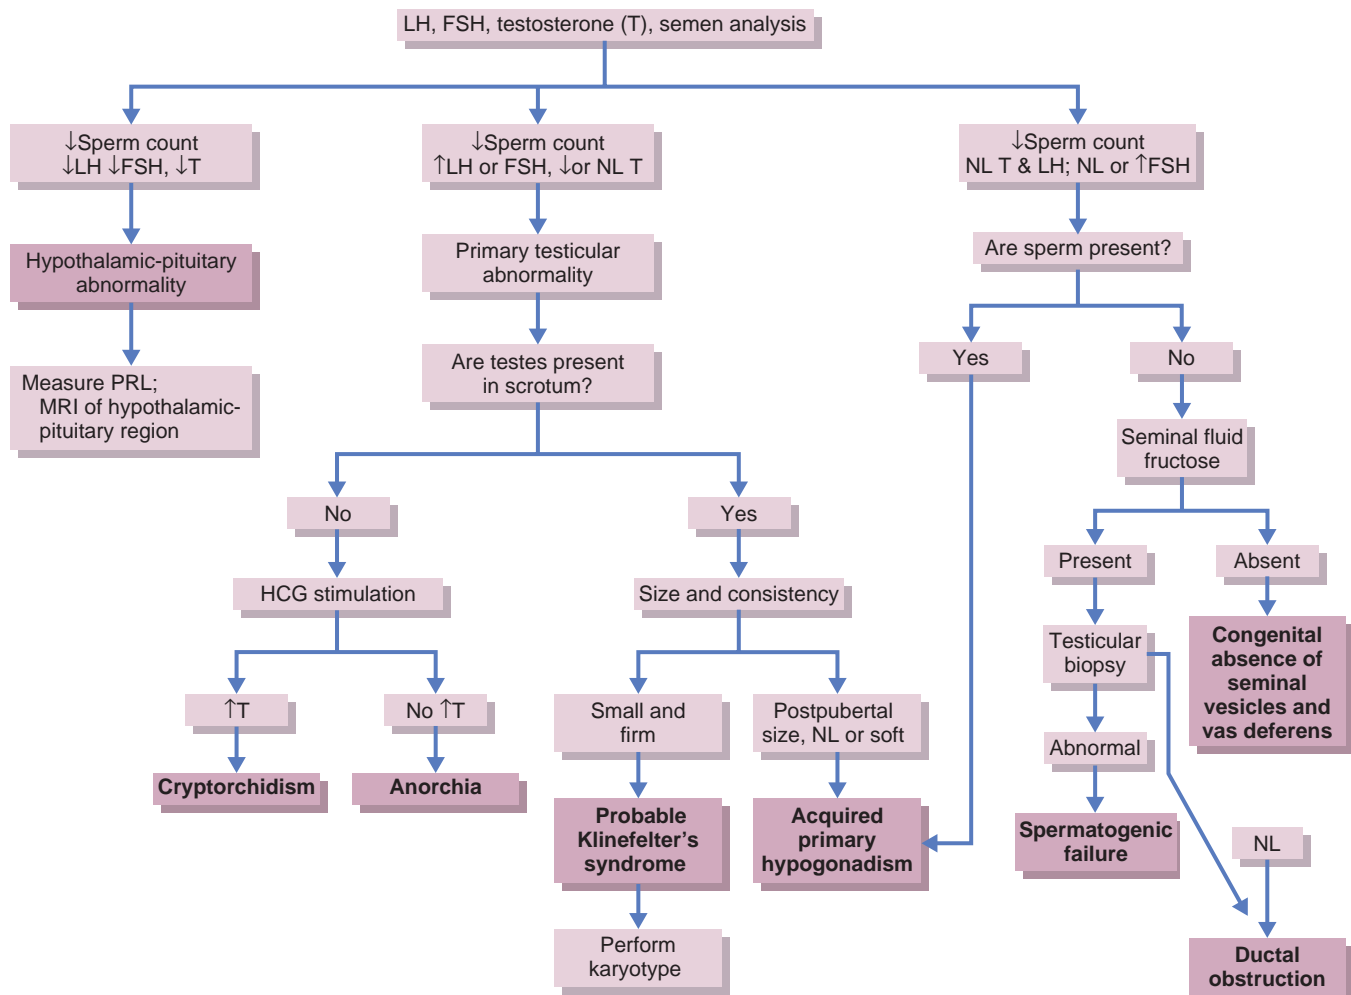

FIGURE 65-2 Laboratory evaluation of hypogonadism. ↑, Elevated; ↓, decreased or low; FSH, follicle-stimulating hormone; HCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; NL, normal; PRL, prolactin.

Klinefelter's syndrome; this diagnosis needs to be confirmed with a chromosomal karyotype. Testes that are more than 3.5 cm in longest diameter and that are either of normal consistency or are soft indicate postpubertal acquired primary hypogonadism.

If the major abnormality is a deficient sperm count with or without an elevation of FSH, differentiation between a ductal problem and acquired primary hypogonadism must be made. If spermatozoa are present, at least the ducts emanating from one testicle are patent; this condition indicates an acquired testicular defect. If the patient has no sperm in the ejaculate, a primary testicular or ductal problem may be responsible. The seminal vesicles secrete fructose into the seminal fluid. Therefore, the presence of fructose in the ejaculate should be followed by a testicular biopsy to determine whether the defect results from spermatogenic failure or from an obstruction of the ducts leading from the testes to the seminal vesicles. Absence of seminal fluid fructose indicates a congenital absence of the seminal vesicles and vas deferens.

Male Infertility

Infertility affects about 15% of couples, and male factors appear to be responsible in about 40% of cases. Female factors account for another 40%, and a couple factor is present in about 20% of cases. In addition to the defects in spermatogenesis that occur in patients with hypothalamic, pituitary, testicular, or androgen action disorders, hyperthyroidism, hypothyroidism, adrenal abnormalities, and systemic illnesses can result in defective spermatogenesis, as can microdeletions of genetic material on the Y chromosome. Disorders of the vas deferens, seminal vesicles, and prostate may also lead to infertility, as may diseases affecting the bladder sphincter that result in *retrograde ejaculation*, in which the sperm passes into the bladder rather than through the penis. Anatomic defects of the penis (as observed in patients with hypospadias), poor coital technique, and the presence of antisperm antibodies in the male or female genital tract also are associated with infertility.

Therapy for Hypogonadism and Infertility

Treatment of androgen deficiency in patients who have hypothalamic-pituitary or primary testicular abnormalities is best accomplished with exogenous testosterone administration—either intramuscular injection of intermediate-acting testosterone esters or transdermal testosterone patches or gel. Testosterone therapy increases libido, potency, muscle mass, strength, athletic endurance, and hair growth on the face and body. Side effects include acne, fluid retention, erythrocytosis, benign prostate hyperplasia, and, rarely, sleep apnea. This therapy is contraindicated in patients with cancer of the prostate.

If fertility is desired, patients with hypothalamic abnormalities may develop virilization and spermatogenesis with the use of GnRH delivered in a pulsatile fashion subcutaneously by an external pump. Direct stimulation of the testes in patients with hypothalamic or pituitary abnormalities may be accomplished with the use of exogenous gonadotropins, which increase testosterone and sperm production. If primary testicular failure is present and the patient has oligospermia, an attempt can be made to concentrate the sperm for intrauterine insemination or in vitro fertilization. If the azoospermia is caused by ductal obstruction,

repair of the obstruction may be undertaken or aspiration of sperm from the epididymis may be accomplished for in vitro fertilization.

GYNECOMASTIA

Gynecomastia refers to a benign enlargement of the male breast that results from proliferation of the glandular component. This common condition is found in as many as 70% of pubertal boys and in about one third of adults 50 to 80 years old. Estrogens stimulate and androgens inhibit breast glandular development; gynecomastia results from an imbalance between estrogen and androgen actions at the breast tissue level. This condition may result from an absolute increase in free estrogens, a decrease in endogenous free androgens, androgen insensitivity of the tissues, or enhanced sensitivity of the breast tissue to estrogens. [Table 65-2](#) lists the common conditions associated with gynecomastia.

Gynecomastia must be differentiated from fatty enlargement of the breasts without glandular proliferation and from other disorders of the breasts, especially breast carcinoma. *Male breast cancer* usually manifests as a unilateral, eccentric, hard or firm mass that is fixed to the underlying tissues. It may be associated with skin dimpling or retraction or with crusting of the nipple or nipple discharge. In contrast, gynecomastia occurs concentrically around the nipple and is not fixed to the underlying structures. Although physical examination is usually sufficient to differentiate gynecomastia from breast carcinoma, mammography may be required.

Painful and tender gynecomastia in a pubertal adolescent should be monitored with periodic examinations because, in most patients, pubertal gynecomastia disappears within 1 year. Incidentally discovered, asymptomatic gynecomastia in an adult requires a careful assessment for alcohol, drug, or medication

TABLE 65-2 CONDITIONS ASSOCIATED WITH GYNECOMASTIA

Cytotoxic agents
Efavirenz
Alcohol
Human immunodeficiency virus infection
Idiopathic

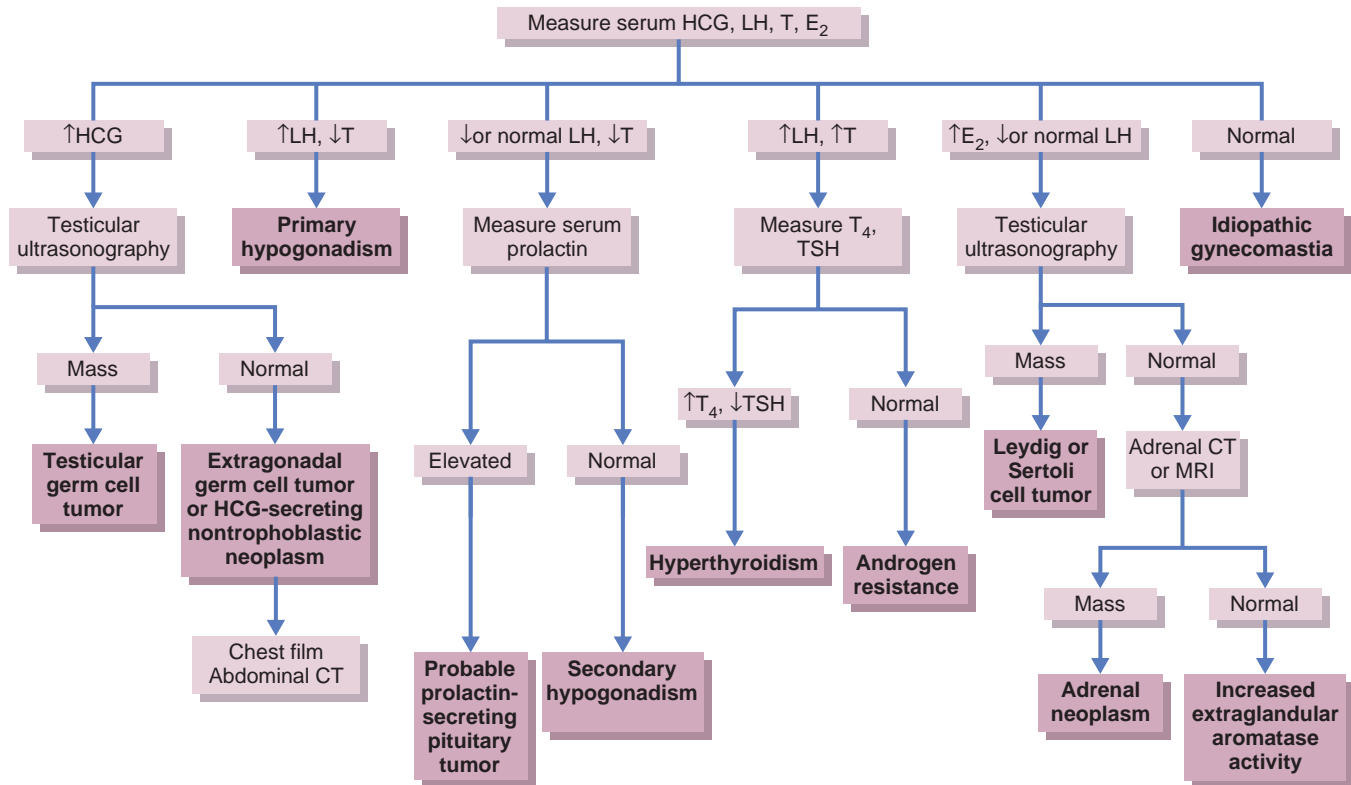

FIGURE 65-3 Diagnostic evaluation for causes of gynecomastia based on measurements of serum human chorionic gonadotropin (HCG), luteinizing hormone (LH), testosterone (T), and estradiol (E_2). ↑, Increased; ↓, decreased; CT, computed tomography; MRI, magnetic resonance imaging; T_4 , thyroxine; TSH, thyroid-stimulating hormone. (From Braunstein GD: Gynecomastia, *N Engl J Med* 328:490–495, 1993.)

use; liver, lung, or kidney dysfunction; and signs and symptoms of hypogonadism or hyperthyroidism. If these conditions are not present, only follow-up is required. In contrast, in an adult with recent onset of progressive painful gynecomastia, thyroid, liver, and renal function should be determined. If test results are normal, serum concentrations of HCG, LH, testosterone, and estradiol should be measured. Further evaluation should be carried out according to the schema outlined in [Figure 65-3](#).

Removal of the offending drug or correction of the underlying condition causing the gynecomastia may result in regression of the breast glandular tissue. If the gynecomastia persists, a trial of antiestrogens (e.g., tamoxifen) may be given for 3 months to see whether regression occurs. Gynecomastia that has been present for longer than 1 year usually contains a fibrotic component that does not respond to medications. In these cases, correction usually requires surgical removal of the tissue.

For a deeper discussion on this topic, please see [Chapter 236, "Reproductive Endocrinology and Infertility,"](#) in *Goldman-Cecil Medicine, 25th Edition*.

Diabetes Mellitus, Hypoglycemia

Robert J. Smith

DIABETES MELLITUS

Definition and Diagnostic Criteria

Diabetes mellitus is not a single disease but a group of disorders that develop as a consequence of absolute or relative deficiency of the hormone insulin. Inadequate actions of insulin in stimulating the uptake of glucose by body tissues and regulating the metabolism of carbohydrate, fat, and protein result in *hyperglycemia*. Other metabolic disturbances in addition to hyperglycemia typically occur in uncontrolled diabetes, including altered lipoprotein dynamics and elevated free fatty acid levels. These abnormalities contribute to the acute and chronic clinical consequences of diabetes.

The criteria used to diagnose diabetes mellitus in nonpregnant individuals are summarized in [Table 66-1](#). The diagnosis can be made on the basis of a fasting blood glucose level of 126 mg/dL or higher, a random blood glucose concentration (i.e., determined at any time in association with meals or fasting) of 200 mg/dL or higher, or a 2-hour glucose level of 200 mg/dL or higher as part of a 75-g oral glucose tolerance test. Alternatively, diabetes can be diagnosed if the hemoglobin A_{1c} (HbA_{1c}) level is 6.5% or higher. HbA_{1c}, a measure of the percentage of hemoglobin in circulating erythrocytes that is glycosylated, correlates with mean circulating glucose levels. HbA_{1c} provides an index of the average blood glucose level over the preceding 2 to 3 months. Because HbA_{1c} accumulates progressively throughout the lifespan of an erythrocyte, spurious values may occur in states of altered erythrocyte turnover (e.g., with various anemias) or with certain hemoglobinopathies that increase or decrease the susceptibility of hemoglobin to glycosylation. In patients with marked elevations in blood glucose or HbA_{1c} and coincident symptoms typical for hyperglycemia (e.g., polyuria and polydipsia), the

diagnosis can be made based on a single test result. With less marked glucose elevations in the absence of symptoms, the diagnosis should be confirmed by repeat testing on a separate day.

Patients who have mild elevations in plasma glucose levels that do not reach the threshold for diagnosis of diabetes (e.g., HbA_{1c} levels between 5.7% and 6.4%) are at increased risk for progression to diabetes and therefore are considered to have *prediabetes*. Prediabetes patients with fasting blood glucose levels between 100 and 125 mg/dL are more specifically labeled as having *impaired fasting glucose*, and those with 2-hour postprandial plasma glucose levels between 140 and 199 mg/dL (most reliably measured after a standardized 75-g oral glucose load) have *impaired glucose tolerance* (see [Table 66-1](#)). Although not all individuals with prediabetes will become diabetic, the mean progression rate to overt diabetes is approximately 6% per year. There also is evidence from observational studies that the prediabetic state is associated with an increased risk of cardiovascular disease.

Gestational diabetes mellitus (GDM) is a term applied to diabetes first recognized during pregnancy. The most widely accepted thresholds for diagnosis of GDM are a fasting plasma glucose level of 92 mg/dL or higher at any gestational stage and values on a 75-g oral glucose tolerance test at 24 to 28 weeks' gestation of 92 mg/dL or higher fasting, 180 mg/dL or higher at 1 hour, or 153 mg/dL or higher at 2 hours after glucose loading ([Table 66-2](#)). Untreated diabetes in pregnancy is associated with increased fetal malformations, problems in delivery, and possibly more frequent diabetes complications in the mother.

Etiologic Classification

Once the diagnosis is made based on elevated blood glucose or HbA_{1c} values, it is important to establish the specific subtype of diabetes based on a combination of clinical and molecular pathophysiological features [Table 66-3](#).

TABLE 66-1 CRITERIA FOR THE DIAGNOSIS OF DIABETES MELLITUS

MEASUREMENT	NORMAL	PREDIABETES	DIABETES MELLITUS
Plasma glucose (mg/dL)			
Fasting*	<100	100-125 [†]	≥126

*Fasting: no caloric intake for ≥8 hr.

TABLE 66-3 ETIOLOGIC CLASSIFICATION OF DIABETES MELLITUS**TYPE 1 DIABETES MELLITUS**

Immune-mediated (type 1a)
Idiopathic (type 1b)

TYPE 2 DIABETES MELLITUS**OTHER SPECIFIC TYPES**

Genetic defects of beta-cell function
 Maturity-onset diabetes of the young (MODY) and other disorders
Genetic defects in insulin action
 Insulin receptor mutations and other disorders
Diseases of the exocrine pancreas
Endocrinopathies
 Cushing's syndrome, acromegaly, and other disorders
Drug- or chemical-induced
 Glucocorticoids most common
Infections
Uncommon forms of immune-mediated diabetes
 Insulin receptor–blocking antibodies and other disorders
Other genetic syndromes sometimes associated with diabetes

GESTATIONAL DIABETES MELLITUS

Data from the American Diabetes Association clinical practice recommendations 2013, *Diabetes Care* 36(Suppl 1):S67–S74, 2013.

Type 1 diabetes (T1DM) is characterized by extensive destruction of the insulin-producing beta cells within the islets of Langerhans in the pancreas and dependence on insulin therapy for survival. In previous medical literature, the terms *juvenile-onset diabetes* or *insulin-dependent diabetes* were used for T1DM. This terminology is no longer used, because T1DM not uncommonly has its onset in adulthood, and multiple other forms of diabetes often require treatment with insulin. T1DM accounts for 5% to 10% of all diabetes in the United States. In most patients, it involves autoimmune mechanisms leading to beta cell destruction (the *type 1A* form). Rare individuals have no markers for autoimmunity and are classified as having *type 1B (idiopathic) diabetes*. Most patients with T1DM progress to marked insulin deficiency over a period of several weeks to months after initial presentation. A smaller number of individuals with evidence of beta cell autoimmunity but much slower disease progression have a variant form of T1DM that is designated *latent autoimmune diabetes of adulthood (LADA)*.

In patients with marked elevations in glucose and accompanying ketoacidosis, particularly if they are young and nonobese, the diagnosis of T1DM is highly probable. This can be confirmed by measuring autoantibodies, often as a panel including insulin, anti-IA2 (anti-tyrosine phosphatase), anti-insulin, and glutamic acid

decarboxylase (GAD or GAD65) antibodies, and also by a clinical course demonstrating an ongoing need for insulin to control hyperglycemia. A fasting C-peptide level can be measured later in the disease to confirm marked deficiency in insulin secretion. C-peptide is a fragment of the insulin precursor proinsulin, which is cleaved during the synthesis of insulin. It is secreted and circulates in proportion to endogenous insulin production but is absent from injected exogenous insulin preparations.

Type 2 diabetes (T2DM) is a heterogeneous, clinically defined subtype that accounts for more than 90% of all diabetes in the United States. It typically has a gradual onset with progression over multiple years or even decades. There is often prolonged preservation of at least partial insulin secretory capacity together with evidence of insulin resistance. Most patients have associated obesity (80% to 90%), although a subset of patients with a clinical picture otherwise typical for T2DM are nonobese. T2DM usually can be presumptively distinguished from T1DM by its indolent course in the presence of risk factors such as obesity and by the milder hyperglycemia and absence of ketoacidosis due to residual insulin secretion. If there is clinical suspicion of T1DM based on earlier age at onset, degree of hyperglycemia, absence of obesity, or presence of ketoacidosis, an autoantibody panel (which should be negative) and a C-peptide level (which should be positive) can be measured.

An expanding number of diabetes etiologies distinct from T1DM and T2DM are classified under a broad category designated *other specific types*. Although these forms of diabetes are uncommon (1% to 2% of all diabetes), it is important to recognize them in clinical practice. They include a group of inherited, autosomal dominant disorders historically designated *maturity-onset diabetes of the young (MODY)*; many of these patients have clinical features similar to those of T2DM but onset typically before 25 years of age. Patients with MODY3 (hepatocyte nuclear factor-1alpha mutations) are particularly sensitive to sulfonylureas, whereas those with MODY2 (glucokinase mutations) have mild, nonprogressive blood glucose elevations and often require no treatment except during pregnancy. For this reason, patients with early-onset diabetes, lack of autoimmune markers, and family histories suggestive of autosomal dominant inheritance should be considered for MODY gene sequencing.

Much less common genetic defects include mutations in insulin receptors or various other genes involved in insulin action. Exocrine pancreatic disease from causes such as chronic pancreatitis or surgery results in loss of the glucagon-producing islet alpha-cells as well as the insulin-producing beta cells. These patients often exhibit greater sensitivity to insulin and more of a propensity for hypoglycemia than T1DM patients because of the absent insulin counter-regulatory effects of glucagon. Endocrine disorders with excess production of hormones that counteract insulin, such as growth hormone in acromegaly or glucocorticoids in Cushing's syndrome, are important to recognize as causes of diabetes because removal of the source of excess hormone can lead to resolution of the diabetic state. Many drugs have been associated with diabetes, most notably glucocorticoids.

The category GDM includes any woman in whom diabetes is first recognized during pregnancy and usually represents T2DM.

Type 1 Diabetes

Epidemiology and Pathology

The principal features of T1DM, contrasted with T2DM, are summarized in Table 66-4. The peak incidence occurs between the ages of 6 and 14 years, but onset in approximately half of patients with T1DM occurs after the age of 20. The role of genetic factors in T1DM risk is supported by an observed increased incidence of T1DM among family members of affected patients: approximately 5% in siblings, 6% in offspring of a diabetic father, and 2% in offspring of a diabetic mother. On a background of genetic risk factors, it is hypothesized that the immune destruction of beta cells is precipitated by environmental factors that still are not well understood but may include microbial, chemical, or dietary triggers (Fig. 66-1). The operation of a combination of genetic and environmental factors is thought to explain the high but not absolute concordance observed in monozygotic twins (30% to 50%).

The prevalence of T1DM varies substantially in different populations; for example, it is relatively high in northwestern Europe and much lower in parts of Asia. The overall prevalence in the United States is approximately 2.4 cases per 1000 population. The frequent onset before age 20 makes T1DM one of the most common chronic, serious childhood diseases. It is the most common subtype of diabetes in childhood, accounting for approximately 70% of all cases, with T2DM accounting for most of the remainder. LADA, a variant form of autoimmune T1DM, is characterized by onset in adulthood and a more prolonged waxing and waning course than is typical for T1DM.

The onset of overt T1DM follows a preclinical phase of variable duration (typically extending from months to years) during which there is specific destruction of beta cells resulting predominantly from cell-mediated immune mechanisms (mononuclear cells; mainly CD8+ T lymphocytes). It is believed that the autoantibodies (to islet cells, insulin, GAD, and tyrosine

phosphatases) are generated for the most part in response to exposure of beta cells and islets and are not themselves mediators of the destructive process. Demonstration of one or more autoantibodies also represents the most sensitive and useful way to establish preclinical disease in patients at risk (e.g., first-degree relatives of patients with T1DM).

The complement of islets in a healthy individual normally provides enough excess beta cell secretory capacity to maintain blood glucose levels until 80% to 90% of beta cells have been lost. In some patients, the subclinical loss of beta cells may be unmasked, resulting in hyperglycemia during the course of an intercurrent illness such as an incidental upper respiratory tract infection. Hyperglycemia and even ketogenesis can result from a lack of adequate insulin, decreased glucose excretion due to hypovolemia, accelerated gluconeogenesis, increased insulin resistance, and hepatic ketogenesis. After diagnosis and institution of insulin and other therapy, stress-induced insulin resistance resolves, and there may be some degree of recovery of beta cell function. Some patients revert to a state in which no insulin is required. This phenomenon, designated the *honeymoon* period, lasts for several weeks to as long as 1 year. Patients generally should continue insulin administration at doses low enough to be tolerated during this interval, because progressive beta cell function can be expected eventually to result in recurrent hyperglycemia and, potentially, diabetic ketoacidosis (DKA).

Screening for T1DM is not a part of standard medical care. Screening for autoantibody determinations in individuals at risk is not clinically useful.

Clinical Presentation

T1DM most often manifests clinically with symptoms resulting from hyperglycemia and consequent osmotic diuresis. Patients typically have a history extending over days to weeks of worsening polyuria, plus polydipsia (as a compensatory response to

TABLE 66-4 GENERAL COMPARISON OF THE TWO MOST COMMON TYPES OF DIABETES MELLITUS

	TYPE 1	TYPE 2
Previous terminology	Insulin-dependent diabetes mellitus, type I; juvenile-onset diabetes	Non-insulin-dependent diabetes mellitus, type II; adult-onset diabetes
Age at onset	Usually <30 yr, particularly childhood and adolescence, but any age	Usually >40 yr, but increasingly at younger ages
Genetic predisposition	Moderate; environmental factors required for expression; 35-50% concordance in monozygotic twins; multiple candidate genes proposed	Strong; 60-90% concordance in monozygotic twins; many candidate genes proposed
Human leukocyte antigen associations	Linkage to DQA and DQB, influenced by DRB3 and DRB4 (DR2 protective)	None known
Other associations	Autoimmune; Graves' disease, Hashimoto's thyroiditis, vitiligo, Addison's disease, pernicious anemia	Heterogeneous group, ongoing subclassification based on identification of specific pathogenic processes and genetic defects
Precipitating and risk factors	Largely unknown; microbial, chemical, dietary, other	Age, obesity (central), sedentary lifestyle, previous gestational diabetes
Findings at diagnosis	85-90% of patients have one and usually more autoantibodies to ICA512, IA-2, IA-2 β , GAD ₆₅ , IAA	Possibly complications (microvascular and macrovascular) caused by significant hyperglycemia in the preceding asymptomatic period
Endogenous insulin levels	Low or absent	Usually present (relative deficiency), early hyperinsulinemia
Insulin resistance	Only with hyperglycemia	Mostly present
Prolonged fast	Hyperglycemia, ketoacidosis	Euglycemia
Stress, withdrawal of insulin	Ketoacidosis	Nonketotic hyperglycemia, occasionally ketoacidosis

GAD, Glutamic acid decarboxylase; IA-2, IA-2 β , insulinoma-associated protein 2 and 2 β (tyrosine phosphatases); IAA, insulin autoantibodies; ICA, islet cell antibody; ICA512, islet cell autoantigen 512 (fragment of IA-2).

FIGURE 66-1 Natural history of type 1 diabetes mellitus. The honeymoon period with temporary improvement in beta-cell function occurs with the initiation of insulin therapy at the time of clinical diagnosis. GAD, Glutamic acid decarboxylase; HLA, human leukocyte antigen; IA-2, IA-2 β , tyrosine phosphatases; ICA, islet cell antibody; ICA512, islet cell autoantigen 512 (fragment of IA-2); IL-1, interleukin-1; NK, natural killer; Th1, subset of CD4+ helper T cells responsible for cell-mediated immunity; Th2, subset of CD4+ helper T cells responsible for humoral immunity; TNF- α , tumor necrosis factor- α .

hypovolemia and increased serum osmolality). The polyuria may be evident as bed wetting or daytime incontinence in children and as nocturia in adults. There typically also is weight loss, and patients often describe low energy and lethargy. Approximately 25% of patients with T1DM have progressed to DKA by the time of clinical presentation.

Treatment

The management of T1DM involves immediate treatment at the outset to correct hyperglycemia, fluid deficits, and DKA, if present, plus attention to possible precipitating or complicating factors such as infection. The initial treatment of T1DM should be coupled with education of patients and their family members (appropriate to the patient's age) concerning the needed skills to manage insulin administration, blood glucose testing, nutrition, and exercise. This often is best accomplished by a team involving the physician, educators (typically specially trained nurses or pharmacists), and a dietician. Medical advice, patient education, and psychological support should be provided on an ongoing, long-term, individualized basis. The primary goal of glucose management is to minimize the degree of hyperglycemia, and its attendant risks of long-term complications of diabetes, while avoiding the acute and chronic risks of hypoglycemia. Medical care also should include attention to control of lipid levels, blood pressure, and other factors that affect the risks of long-term diabetes complications. Routine assessments of foot care, peripheral nerve function, retinal status, and renal function should be used to detect incipient diabetes complications and enable early treatment interventions. Other sources should be consulted for

information on specific issues related to T1DM management in children and adolescents.

Blood Glucose Control

Patients with T1DM have an absolute requirement for exogenous insulin. The Diabetes Control and Complications Trial (DCCT) and other studies have established that improved glycemic control in patients with T1DM decreases long-term microvascular complications (retinopathy, nephropathy, and neuropathy). A follow-up study of the same patients (the Epidemiology of Diabetes Interventions and Complications [EDIC] study) further demonstrated lower cardiovascular morbidity and mortality with intensive insulin management. Based on these and other studies, the most generally accepted target goal for HbA_{1c} in T1DM is 7.0%. For patients who have difficulty sensing hypoglycemia or who have other factors complicating blood glucose management (e.g., renal failure), it is appropriate to set an individualized HbA_{1c} goal of 8.0% or even higher.

Many preparations of insulin are available. They differ in rapidity of onset, degree of peaking of blood levels, and duration of action after subcutaneous injection (Table 66-5). The different kinetics of recombinant human insulin preparations derive from their specific complexing with proteins and zinc. Additionally, multiple analogues of human insulin are available that have rapid or slow kinetics as a consequence of altered solubility at subcutaneous injection sites. Most insulin preparations are provided at a concentration of 100 U/mL (U-100). Self-monitoring of blood glucose (SMBG) by patients using glucose meters is critical to the implementation of an effective insulin regimen. Ideally,

TABLE 66-5 TYPES OF INSULIN*

INSULIN TYPE	GENERIC NAME	PREPRANDIAL INJECTION TIMING (HR)	ONSET (HR)	PEAK (HR)	DURATION (HR)	BG NADIR (HR)
Rapid-acting	Lispro [†]	0-0.2	0.1-0.5	0.5-2	<5	2-4

BG, Blood glucose; NPA, neutral protamine aspart; NPH, neutral protamine Hagedorn; NPL, neutral protamine lispro.

*Time profiles depend on several factors, including dose, anatomic site of injection, method (profiles in this table are for subcutaneous injections), duration of diabetes, type of diabetes, degree of insulin resistance, level of physical activity, presence of obesity, and body temperature. Some time ranges are wide to include data from several separate studies. Preprandial injection timing depends on premeal BG values and insulin type. If BG is low, it may be necessary to inject insulin and eat immediately (carbohydrate portion of meal first). If BG is high, it may be necessary to delay the meal after insulin injection and then eat the carbohydrate portion last.

[†]Insulin analogue with reversal of lysine and proline at positions 28 and 29 on the B chain of the insulin molecule.

[‡]Insulin analogue with substitution of aspartic acid for proline at position 28 on the B chain of the insulin molecule.

[§]Insulin analogue with substitution of lysine for asparagine at position 3 on the B chain and glutamic acid for lysine at position 29 on the B chain of the insulin molecule.

^{||}Insulin analogue with substitution of glycine for asparagine at position 21 on the A chain and addition of two arginines to the carboxyl terminus of the B chain of the insulin molecule.

^{**}Administer at same time each day, unrelated to meals. Morning administration may result in greater glucose lowering and less nocturnal hypoglycemia.

**Do not mix glargine or detemir with other insulins.

SMBG should be performed as frequently as practicable: fasting, preprandial, 2 hours postprandial, at bedtime, and occasionally at 2:00 to 3:00 AM. Values and times are saved in most meters for subsequent review. It is helpful for patients to manually record these data on a flow chart, and it is also possible to download meter data to a computer. SMBG records are most useful when annotated with relevant details on food intake, exercise, or the occurrence of symptoms. HbA_{1c} determinations should be obtained every 3 months.

Most cases of T1DM should be managed with an *intensive insulin therapy regimen* involving multiple (three or more) daily subcutaneous injections or continuous subcutaneous insulin infusion (CSII) using an insulin pump. Multiple-injection regimens, also termed *basal-bolus therapy*, typically involve injections of a long-acting insulin analogue (such as glargine or detemir) once or twice daily to establish a stable basal insulin level. Regular insulin or a rapid-acting insulin analogue is additionally injected three or more times daily (before each meal and sometimes before snacks) to provide appropriate post-meal peaks in insulin levels. Usually, once glucose levels are stabilized on a regimen, the doses of long-acting insulin are kept constant from day to day. The rapid-acting insulin doses can be kept constant with efforts to ingest a fixed amount of carbohydrate and total calories at each meal. Alternatively, better control and greater flexibility can be achieved if rapid-acting insulin doses are adjusted according to the blood glucose level (measured before each meal) and the carbohydrate calories ingested with the meal. The long-acting insulin glargine and detemir analogues cannot be mixed in a single syringe with other insulins; for

this reason, basal-bolus regimens often require four or more daily injections.

For patients newly diagnosed with T1DM, a typical starting dose of insulin is a total of 0.2 to 0.4 U/kg/day, with the expectation that this will be increased to 0.6 to 0.7 U/kg/day over time. Approximately half of the total dose should be given as basal insulin. Depending on individual patient blood glucose responses, the basal glargine or detemir insulin may be administered as a single daily dose (in the morning or at bedtime), or two equally divided doses may be required. For a neutral protamine Hagedorn (NPH) basal regimen, two thirds of the dose should be given in the morning and one third at bedtime. This decreases the risk of nocturnal hypoglycemia and times the maximum NPH peak to approximately match the midday meal. The rapid-acting component of the daily insulin dose is distributed before meals according to meal size and content.

An insulin pump (CSII) represents the preferred method of insulin administration for many T1DM patients. These small, wearable devices contain a reservoir of rapid-acting insulin that is infused via an easily placed subcutaneous catheter. A microprocessor-controlled pump provides the basal insulin infusion and can be programmed to adjust basal rates at multiple points during the day according to predetermined patient needs. The patient further instructs the pump to make bolus insulin injections to cover meals, snacks, or needed corrections in hyperglycemia. Controlled studies have shown that modestly better blood glucose control can be achieved with CSII, compared to basal-bolus regimens with multiple daily injections. When used appropriately, CSII represents the most flexible means of

managing insulin doses, with options for dose adjustments and supplementation that do not require separate injections. Limitations include need for greater patient involvement, lack of a long-acting pool, and pump failure. Newly diagnosed T1DM should be managed for a period of time (at least 6 to 12 months) with intermittently injected insulin before transition to a pump is considered. During the transition from intermittent insulin injections to CSII in a patient with well-controlled blood glucose levels ($\text{HbA}_{1c} \leq 7.0\%$), the total daily insulin dose typically is decreased by 10% to 20% initially.

Many CSII patients require a slightly higher basal infusion rate in the early morning hours to accommodate the *dawn phenomenon*, a period of decreased insulin sensitivity secondary to circadian changes in secretion of insulin counter-regulatory hormones such as growth hormone. Adjustments in the basal rate may also be needed at other times of day because of changes in insulin sensitivity that may occur (e.g., after exercise). Premeal insulin boluses are calculated to include a correction dose if needed, based on the premeal blood glucose level, plus a meal coverage dose calculated from the patient's predetermined individual carbohydrate/insulin ratio. It often is most effective for a patient to be seen in a specialty setting during transition to CSII, so that an experienced educator (often a specially trained RN) can assist with needed patient education. Devices are available that provide continuous glucose monitoring (CGM), either as a separate device or integrated with an insulin pump. Because of concern about their consistent accuracy, insulin infusion rates are not adjusted automatically in response to the measured glucose levels by current devices; rather, patient intervention is required to make changes.

Intensive insulin therapy is not appropriate for all T1DM patients. Some patients are unwilling or unable to manage the required frequent glucose monitoring, diet adherence, and multiple insulin boluses. In other patients, the tight blood glucose control and low HbA_{1c} targets that are the goals of intensive insulin therapy may not be feasible. For example, there may be an increased risk of hypoglycemia because of autonomic neuropathy and inability to sense hypoglycemia, or gastrointestinal neuropathy may cause gastroparesis resulting in unpredictable variations in nutrient digestion and absorption. Under such circumstances, simpler approaches to insulin therapy and blood glucose management, previously termed *conventional insulin therapy*, may be appropriate. Such a regimen may be based, for example, on two injections per day of intermediate-acting insulin with or without short- or rapid-acting insulin. As one example, a *split-mixed regimen* uses NPH/regular or NPH/lispro (or aspart or glulisine) formulations twice daily. Initially, two thirds of the estimated total daily dose is given before breakfast and one third before dinner; at each of these times, two thirds of the insulin is given as NPH and one third as regular or a rapid-acting insulin. The amount of each insulin type at each of the injection times is then adjusted according to measured blood glucose levels, with the expectation that the peak of the morning NPH will cover lunch, the rapid-acting insulins will cover the other meals, and the NPH will otherwise ensure adequate basal blood glucose control. Two daily injections are made possible by mixing the intermediate- and rapid-acting insulins in a single syringe. Premixed insulin

preparations, such as 70% NPH plus 30% rapid-acting insulin or 50% NPH plus 50% regular insulin, also are available for injection with syringes or with preloaded insulin pens. Premixed insulins provide greater ease of use but are less likely to achieve good glycemic control.

Hypoglycemia Management

Irrespective of the specific treatment regimen, patients with T1DM need to learn how to manage hypoglycemia. Patients usually experience adrenergic symptoms (e.g., sweating, anxiety, tremulousness) as blood glucose levels decrease below the normal range (<50 to 70 mg/dL). If glucose levels decrease markedly enough, patients may experience central nervous system (CNS) symptoms ranging from difficulty thinking clearly to confusion, obtundation, and loss of consciousness. If low blood glucose is confirmed (e.g., <70 mg/dL), 10 to 15 g of rapidly absorbed carbohydrate should be ingested. For a glucose level lower than 50 mg/dL, 20 to 30 g of carbohydrate is advisable. This can be provided as orange juice or crackers, or patients can carry glucose tablets or squeeze tubes of glucose solution (obtainable over-the-counter from pharmacies) for use in treating hypoglycemia. The blood glucose level should be retested after 15 minutes, and the treatment should be repeated as needed until hypoglycemia is resolved. An alternative is to inject glucagon. For patients who have a history of hypoglycemia severe enough (including loss of consciousness) to require assistance from others, it often is helpful for a family member to be trained in glucagon injection. With severe hypoglycemia, there is a risk of injury, such as from a fall or automobile accident, as well as neurologic damage if hypoglycemia is sustained.

Nutritional Management

Appropriate nutritional management is an essential component of an effective T1DM treatment program. This ideally should be individualized to the patient's lifestyle, exercise regimen, eating habits, culture, and financial resources. Many expert panel recommendations allow individualized decisions regarding the relative amounts of carbohydrate, fat, and protein consumed within a general set of guidelines. For example, the American Diabetes Association (ADA) recommends the following:

- Fat intake, less than 7% of total calories with minimal amounts of trans-fats
- Total cholesterol intake, less than 200 mg/day
- Dietary protein intake, 15% to 20% of total calories in the absence of renal failure
- Fiber intake, at least 14 g per 1000 total calories
- Reduced sodium intake (1500 mg/day), especially in the context of even mild hypertension.

Patients should work with a medical professional who is trained in diabetes care to establish nutritional goals.

Most diets focus on measuring and controlling the amounts rather than the sources of carbohydrates. Patients can be taught to estimate the grams of carbohydrate in a meal (*carbohydrate counting*) as a means of ensuring that a consistent amount of carbohydrate is ingested. Alternatively, they can use carbohydrate

counting with each meal as part of a strategy that enables day-to-day variations in consumption with adjustments of mealtime insulin doses according to a predetermined, patient-specific *insulin/carbohydrate ratio*. It is advisable to avoid foods that contain supplemental fructose as a sweetener because of the potential adverse effects of fructose on lipid metabolism. Alcohol consumption in moderation is acceptable (one drink or less for women and two drinks or less for men per day).

Because of the contribution of excess body weight to increased cardiovascular risk, a fundamental goal of nutritional management should be to maintain normal body weight or to achieve weight reduction in overweight or obese patients. Eating disorders including binge eating, anorexia nervosa, and bulimia are relatively common in T1DM, especially among younger female patients.

Exercise

Regular physical exercise should be encouraged for its beneficial effects on weight control, risks of long-term complications, and overall quality of life. The general recommendation of several expert panels is 30 minutes or more of moderate-intensity physical exercise on at least 5 days per week. Physical exercise burns calories in proportion to its duration and intensity and also may result in increased insulin sensitivity after exercise (sometimes lasting for many hours). It often is most effective for patients to schedule regular exercise periods with a consistent temporal relationship to meals and insulin injections. Blood glucose should be tested before and after exercise, and exercise should not be undertaken if the initial blood glucose level is low (because of increased risk of hypoglycemia) or if it is higher than 250 mg/dL (because of risk of inducing further blood glucose elevation and development of ketosis). Patients with T1DM should be encouraged to pursue age- and overall health-appropriate athletic interests, including competitive sports, but this should be done only with careful attention to blood glucose monitoring and appropriate adjustments in insulin regimen and diet.

Type 2 Diabetes

Epidemiology and Pathology

T2DM is an extraordinarily common disorder, affecting 8% to 10% of the population in the United States and with a similar prevalence in most other developed or developing countries. Many patients with T2DM are undiagnosed, and many additional individuals (approximately 6% of the U.S. population) have a prediabetic state. T2DM is characterized by varying degrees of insulin resistance and insulin deficiency, which are believed to result from the impact of environmental factors on a background of genetic risk. The principal features of T2DM, contrasted with T1DM, are summarized in Table 66-4. The prevalence of T2DM has increased more than 10-fold over the past 50 years, driven primarily by increased calorie intake, decreased exercise, and resulting obesity. More than 80% of patients with T2DM are obese. The peak incidence of T2DM occurs in the fifth and sixth decades; however, T2DM now accounts for up to 30% of childhood diabetes in some populations. The lifetime risk of developing T2DM is approximately 40% among the offspring of a single

affected parent, and approximately 70% if both parents are affected. The incidence of T2DM in the United States is higher in Hispanic/Latino populations, among African Americans, and in some east Asian populations, compared to populations of northern and western European ancestry. This is thought to result in part from effects of socioeconomic and cultural factors (e.g., differences in consumption of low-cost, calorie-dense foods) but also from genetic differences among these populations. The genetic predisposition in all populations that have been studied is thought to reflect the combined influence of more than 40 genes. No single gene or small group of genes with dominant influence on diabetes risk in any population has been identified.

T2DM is typically preceded by a prolonged preclinical or prediabetic phase during which there is a gradual deterioration in glucose tolerance (Fig. 66-2). This process occurs over a decade or more on average, with marked individual variation in the rate of progression. Most patients are insulin resistant during the preclinical phase but are able to compensate by producing more insulin (hyperinsulinemia) to maintain euglycemia. With time, there is progressive deterioration in the capacity to compensate for the insulin resistance. This is associated with a decrease in beta cell mass during the preclinical phase of T2DM, but substantial residual beta cells (typically 40% to 50% of the normal complement) are still present at the time that overt hyperglycemia develops. Therefore, there is compromised function as well as a reduced number of beta cells in T2DM. As blood glucose levels rise, the hyperglycemia itself may contribute to progression of the diabetic state by further decreasing insulin secretion and insulin resistance through mechanisms that are not well understood (referred to as *glucotoxicity*).

Screening of certain high-risk populations for T2DM and prediabetes by determination of a fasting or random plasma glucose measurement is considered cost-effective. More than 30% of people with T2DM and an even higher percentage of those with prediabetes are undiagnosed. Expert panel recommendations from the ADA for screening based on age, lifestyle factors, family history, and ethnicity are summarized in Table 66-6. Because of the insidious nature of T2DM, patients have a high risk for development of complications by the time of clinical diagnosis (see later discussion).

Clinical Presentation

Many patients are asymptomatic and are diagnosed on routine blood glucose testing. Blood glucose levels that rise high enough to exceed the renal threshold for glucose reabsorption (>170 mg/dL) induce an osmotic diuresis, resulting in the typical presenting symptoms of polyuria and polydipsia, as well as blurred vision secondary to osmotic shifts in the lens. Patients may also have weight loss or bacterial urinary tract or cutaneous fungal infections at presentation. Osmotic diuresis secondary to hyperglycemia may lead to electrolyte abnormalities and even occasionally to a severe hyperosmolar state associated with clinical symptoms and signs including fatigue, weakness, and ultimately compromised mental status that can range from confusion to coma (see later discussion). This most frequently occurs in elderly patients who may have compromised baseline renal function. In contrast to patients with T1DM, those with T2DM usually have enough

FIGURE 66-2 Natural history of type 2 diabetes mellitus. The numbers for time/age markers in years for the different phases of beta-cell decompensation toward overt diabetes and an insulin-requiring state are approximate guides. Certain groups are more insulin sensitive and require a greater loss of beta-cell function to precipitate diabetes, compared with obese insulin-resistant people, who develop diabetes after small declines in beta-cell function. Use of insulin in patients with type 2 diabetes varies considerably and is not age dependent. HGP, Hepatic glucose production; IR, insulin resistance.

residual insulin activity to partially suppress lipolysis, and this protects them from developing DKA. In a subset of T2DM patients, DKA can develop, possibly reflecting individual variations in the degree of suppression of insulin secretion by glucotoxicity.

As a consequence of prolonged exposure to hyperglycemia and associated metabolic disturbances, patients with T2DM may already have developed long-term microvascular or macrovascular complications of diabetes by the time of diagnosis. Therefore, patients may experience a cardiovascular event, such as acute myocardial infarction, and then incidentally be found to have T2DM.

The Metabolic Syndrome

Susceptibility to cardiovascular disease is further increased by the frequent association of insulin resistance, prediabetes, and T2DM with other cardiac risk factors, including abdominal or visceral obesity, dyslipidemia, and hypertension. The term *metabolic syndrome* has been applied to patients who have a combination of these cardiovascular risk factors. Different but overlapping diagnostic criteria for the metabolic syndrome have been proposed by various expert panels. The National Cholesterol Education Program Adult Treatment Panel III (ATP III) defines this syndrome as the presence of any three of the following five characteristics:

1. Fasting blood glucose level ≥ 100 mg/dL or drug treatment for elevated blood glucose
2. High-density lipoprotein (HDL)-cholesterol < 40 mg/dL in men or < 50 mg/dL in women or drug treatment for low HDL-cholesterol
3. Plasma triglycerides ≥ 150 mg/dL or drug treatment for elevated triglycerides
4. Abdominal obesity (waist ≥ 102 cm in men or ≥ 88 cm in women)
5. Blood pressure $\geq 130/85$ mm Hg or drug treatment for hypertension.

There is debate about whether the metabolic syndrome represents a discrete pathologic entity, but its recognition does draw attention to the frequent clustering of cardiovascular risk factors.

Treatment

Patients with T2DM should receive nutrition counseling starting at the time of diagnosis. This should include efforts at weight loss in overweight or obese patients. Adjustments in diet, especially reductions in calorie intake, can rapidly improve blood glucose levels in many patients independent of other interventions. Weight reduction by as little as 10% to 20% of body weight can have marked beneficial effects on insulin resistance and glycemia in some patients.

TABLE 66-6 SCREENING CRITERIA FOR DIABETES IN ASYMPTOMATIC ADULTS

1. Testing for diabetes should be considered in all persons ≥ 45 yr of age; if normal, the test should be repeated at 3-yr intervals.
2. Testing should be considered at a younger age (< 30 yr) or performed more frequently in individuals who
 - a. Are overweight (BMI ≥ 25) or who have central obesity with normal BMI (18.5-24.9)
 - b. Have an habitually sedentary lifestyle
 - c. Have a first-degree relative with diabetes (i.e., parent or sibling)
 - d. Are members of a high-risk ethnic population (e.g., African American, Latino/Hispanic American, Native American, Asian American, Pacific Islander)
 - e. Have delivered a baby weighing > 9 lb (4 kg), have experienced unexplained perinatal death of a child, or have been diagnosed with gestational diabetes
 - f. Are hypertensive ($\geq 140/90$ mm Hg)
 - g. Have an HDL cholesterol level < 35 mg/dL (0.9 mmol/L) and/or a triglyceride level > 250 mg/dL (2.82 mmol/L)
 - h. Had, on previous testing, impaired glucose tolerance (plasma glucose ≥ 140 mg/dL [7.8 mmol/L] but < 200 mg/dL [11.1 mmol/L] 2 hr after 75-g oral glucose tolerance test), impaired fasting glucose (plasma glucose 100-125 mg/dL [5.6-6.9 mmol/L]), or HbA_{1c} $\geq 5.7\%$
 - i. Have other clinical conditions associated with insulin resistance (e.g., PCOS, acanthosis nigricans)
 - j. Have a history of cardiovascular disease

Modified from the American Diabetes Association Clinical Practice Recommendations 2013, *Diabetes Care* 36(Suppl 1):S11-S66, 2013.

BMI, Body mass index (weight [kg]/height [m²]); HbA_{1c}, glycosylated hemoglobin; HDL, high-density lipoprotein; PCOS, polycystic ovary syndrome; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

Depending on initial blood glucose levels, the presence or absence of symptoms related to hyperglycemia, and the presence of other complicating medical conditions, a decision can be made on whether to treat the patient initially with diet alone or to also start medication. Patients with marked hyperglycemia, fluid deficits, altered mental status related to hyperosmolar state, and DKA should be hospitalized for acute treatment (see later discussion).

For most patients, treatment of T2DM can be conducted on an outpatient basis. Useful and frequently updated guidelines are available on line from the ADA and the European Association for the Study of Diabetes. Most expert panels recommend starting with one or two oral glucose-lowering medications (depending on the degree of hyperglycemia) with progression to a third oral agent or insulin if this proves ineffective. In patients with marked hyperglycemia (> 300 mg/dL or HbA_{1c} $> 9.0\%$ to 9.5%), consideration should be given to starting insulin from the outset. There typically is gradually progressive loss of beta cell function in T2DM, extending sometimes over many years, and this results in a need over time for increased doses or additional glucose-lowering agents and often, ultimately, the use of insulin. As for T1DM, the overall management of T2DM should include not only the treatment of hyperglycemia but also interventions that assess, decrease the risks for, and treat long-term microvascular and macrovascular complications.

Blood Glucose Control

The United Kingdom Prevention of Diabetes Study (UKPDS) and other randomized, controlled trials have established that improved blood glucose control lowers the risk of microvascular

long-term complications (retinopathy, nephropathy, and neuropathy) in T2DM. The risk appears to increase progressively, starting with any increment above normoglycemia. Randomized clinical trial data have not convincingly demonstrated improved macrovascular (i.e., cardiovascular disease) outcomes in T2DM. HbA_{1c} goals therefore should be developed on an individualized basis, such that the benefits of improving microvascular complications are balanced against the risks of hypoglycemia. T2DM patients, particularly those who are older or have complicating comorbid conditions, may have limited capacity to manage a tight blood glucose control regimen and also increased susceptibility to adverse effects of hypoglycemia. Whereas an HbA_{1c} of 7.0% or less is an appropriate target for younger T2DM patients, 8.0% or less may be an acceptable and safer target for older patients with complicating medical conditions and limited life expectancy. Patients or their caregivers should perform regular glucose monitoring (SMBG) to assess ongoing blood glucose control, identify potential hypoglycemia, and detect marked increases in blood glucose that may occur during an intercurrent illness. HbA_{1c} determinations provide important supplemental information about blood glucose control and should be performed at intervals of 3 to 6 months.

Non-Insulin Pharmacologic (Antidiabetic) Agents in T2DM

Non-insulin pharmacological agents from many different drug classes are available for treatment of T2DM, some taken orally and others by injection (Table 66-7). When non-insulin pharmacologic agents are appropriate, metformin is first-line therapy because of its glucose-lowering efficacy, absence of weight gain and hypoglycemia, favorable safety and tolerability profile based on many years of clinical experience, and low cost. For patients who are unable to tolerate metformin, a sulfonylurea is a reasonable choice, again based on efficacy, tolerability, and low cost. Sulfonylureas have the disadvantages of inducing modest weight gain in many patients, and they carry a risk of causing hypoglycemia. Agents in other drug classes can be considered for first-line therapy, but there is less knowledge or more concern about their long-term safety profiles, and they have higher cost.

If a single drug is tolerated but does not adequately control blood glucose levels, the usual practice is to continue that drug and add a second. Drug combinations often are selected from classes with complementary mechanisms of actions. For example, the combination of an insulin sensitizer such as metformin and an insulin secretagogue such as a sulfonylurea has theoretical appeal in providing greater potential for additive or synergistic actions. Patients with marked hyperglycemia that is not judged severe enough to merit insulin treatment may be started on two agents from the outset. This has the potential advantage of more rapidly achieving blood glucose control but the disadvantage of exposing patients to the potential side effects of taking two drugs simultaneously. Many combination preparations are available for administration of more than one drug; these are more convenient for patients and sometimes less expensive than taking the multiple drugs separately.

Available non-insulin antidiabetic agents are summarized here and in Table 66-7. Current manufacturer information should be

TABLE 66-7 NON-INSULIN ANTIDIABETIC AGENTS BY DRUG CLASS*

DRUG CLASS	AVAILABLE AGENTS (GENERIC NAME)	ROUTE OF ADMINISTRATION	MODE OF ACTION
Biguanides	Metformin	Oral	Insulin sensitizer
Sulfonylureas	Glipizide, glyburide, glimeperide, gliclazide, chlorpropamide, tolazamide	Oral	Insulin secretagogue
Meglitinides	Repaglinide, nateglinide	Oral	Insulin secretagogue
Thiazolidinediones	Pioglitazone, rosiglitazone	Oral	Insulin sensitizer
GLP-1 analogues	Exenatide, liraglutide, albiglutide	Subcutaneous injection	Incretin mimetic
DPP-4 inhibitors	Sitagliptin, saxagliptin, linagliptin, alogliptin	Oral	Incretin amplifier
α -Glucosidase inhibitors	Acarbose, miglitol	Oral	Delay carbohydrate digestion/absorption
Amylin mimetics	Pramlintide	Subcutaneous injection	Delay gastric emptying, suppress glucagon
SGLT2 inhibitors	Canagliflozin, dapagliflozin, empagliflozin	Oral	Increase urinary glucose excretion

DPP-4, Dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; SGLT2, sodium glucose transport protein subtype 2.

*Consult current manufacturer information for details on available combinations, prescribing, and safety.

consulted before prescribing these drugs to ensure updated and adequately detailed information on available single and combination agents and their effective and safe use.

Metformin

Metformin is an oral agent in the biguanide class that produces its most prominent effects by decreasing gluconeogenesis and thus reducing hepatic glucose production. This insulin-sensitizing effect is associated with a low risk of hypoglycemia. It has been in use for more than 30 years and is available in inexpensive generic form. The usual starting dose is 500 mg once or twice daily with incremental advancement at several-week intervals to a usual maximum of 2000 mg daily in two or three divided doses. Metformin typically decreases HbA_{1c} by about 1.5%. Further benefits include modest weight loss (approximately 3 kg on average) and a small improvement in plasma lipid profile (decrease in low-density lipoprotein [LDL]-cholesterol and triglycerides and increase in HDL). Adverse reactions include gastrointestinal effects and, rarely, lactic acidosis. The drug should be avoided in patients with renal insufficiency.

Sulfonylureas

Sulfonylureas stimulate endogenous insulin secretion by binding and activating potassium channels in beta cells. In patients with adequate residual beta cell function, they can lower HbA_{1c} levels by 1% to 2%. Drugs in this class have been in clinical use for more than 40 years, and many inexpensive, generic sulfonylureas are available that differ in duration of action, metabolism, and mode of clearance. Because they can increase insulin secretion even in the absence of hyperglycemia, they have significant potential to cause hypoglycemia. Patients need to be instructed how to recognize and treat hypoglycemia before starting a sulfonylurea. Factors that increase the risk for hypoglycemia with sulfonylureas include advanced age, poor nutrition, alcohol ingestion, and hepatic and renal insufficiency. Other disadvantages of this drug class are a tendency to cause weight gain and a loss of effectiveness over time.

Meglitinides

Repaglinide and nateglinide activate beta cell potassium channels and thus stimulate endogenous insulin secretion through a mechanism similar to that of sulfonylureas, although they generally result in less reduction in blood glucose than sulfonylureas. They have rapid action and have less tendency to cause hypoglycemia

than sulfonylureas. Their use has been limited by high cost and lack of advantage over the sulfonylureas.

Thiazolidinediones

The thiazolidinediones (TZDs) activate the nuclear peroxisome proliferator-activated receptor- γ (PPAR- γ), which leads to changes in transcription rates of multiple genes. The net effect is reduced insulin resistance, and the resulting augmented actions of insulin lead to increased glucose uptake in peripheral tissues and reduced hepatic glucose production. Pioglitazone typically lowers HbA_{1c} by 0.5% to 1.4% and carries a low risk of hypoglycemia. Potential side effects include weight gain and hepatotoxicity.

Glucagon-Like Peptide-1 Analogues

Glucagon-like peptide-1 (GLP-1) is one of several hormones produced in the small intestine (designated *incretins*) that modify gastrointestinal motility and insulin secretion. The GLP-1 analogues, exenatide, liraglutide, and albiglutide, bind to GLP-1 receptors and improve blood glucose control by enhancing insulin-dependent insulin secretion, slowing gastric emptying, suppressing postprandial glucagon production, and decreasing food intake through enhanced satiety. This results in decreases in HbA_{1c} by 0.5% to 1.5% and modest weight loss (in the range of 3 kg). They are administered via injection with prefilled pens—exenatide twice daily or once weekly in long-acting form, liraglutide once daily, and albiglutide once weekly. The most common side effects are nausea and sometimes diarrhea, likely related to the drugs' effects on gastrointestinal motility. GLP-1 analogue use is tempered by the inconvenience of injection, relatively high cost, and a lack of long-term data on durability of weight loss or other outcome benefits. They most often are used as second-line agents in conjunction with other glucose-lowering drugs or insulin.

Dipeptidyl Peptidase-4 Inhibitors

The dipeptidyl peptidase-4 (DPP-4) inhibitors—sitagliptin, saxagliptin, linagliptin, and alogliptin—block the deactivation of GLP-1 (described in the previous section) and glucose-dependent insulinotropic peptide (GIP), peptide hormones that are important in the regulation of glucose homeostasis. Some of the effects of DPP-4 inhibitors may overlap with those of administered GLP-1 analogues, but they likely have additional actions by increasing levels of hormones other than GLP-1. DPP-4

inhibitors are taken orally and result in decreased HbA_{1c} in the range of 0.5% to 1.0%. They can be used as monotherapy or in combination with one or more other agents and have favorable side effect profiles.

α-Glucosidase Inhibitors

The α -glucosidase inhibitors, acarbose and miglitol, are oral agents that improve glycemia by inhibiting the enzymatic breakdown of complex carbohydrates within the lumen of the small intestine. They have modest glucose-lowering effects, decreasing HbA_{1c} in the range of 0.5% to 0.8%. Their use is limited by the frequent occurrence of flatulence and diarrhea as a consequence of undigested carbohydrates reaching lower intestinal regions.

Pramlintide

Pramlintide is a stable analogue of the beta cell peptide, amylin, which has actions that include slowing of gastric emptying, satiety effects that decrease food intake, and decrease in postmeal glucagon. It is not widely used because of required multiple injections and limited efficacy in lowering HbA_{1c}.

SGLT2 Inhibitors

Canagliflozin, dapagliflozin, and empagliflozin are recently approved oral agents that function by inhibiting the subtype 2 sodium glucose transport protein (SGLT2). SGLT2 mediates more than 90% of glucose reabsorption in the renal tubules, and the drug lowers blood glucose levels by promoting excretion of glucose in the urine. This results in a decrease in HbA_{1c} in the range of 0.5% to 1.0% and modest weight loss. Concerns about potential side effects of increased cardiovascular events, increased LDL-cholesterol, urinary and genital infections, hypotension, and hypoglycemia are under investigation.

Insulin Treatment in T2DM

For patients who have inadequate glycemic control with oral agents, insulin may be started as a basal supplement to the oral regimen. Frequently used choices include glargine (once daily), detemir (once or twice daily), or NPH (once daily at bedtime) (see later discussion and [Table 66-5](#) for more details on different types of insulin). Starting doses are typically in the range of 10 U (or can be more specifically calculated as 0.2 U/kg), with increases of 2 to 4 U at intervals of 3 days or longer. Oral agent regimens commonly are simplified at the time of starting insulin (e.g., shifting from multiple agents to a single oral agent). For patients who do not achieve adequate control with basal insulin, mealtime coverage is provided by a rapid-acting insulin. Often, under this circumstance, all oral agents are discontinued, and blood glucose control is achieved with the use of exogenous insulin alone. Compared to patients with T1DM, those with T2DM may not require as tight a match of carbohydrate to insulin doses at meals, perhaps because of some residual insulin secretion. For this reason, insulin pumps are only rarely used in T2DM.

Nutritional and Weight Management

Patients should receive counseling from a dietician and be assisted in developing a nutritional plan that is individualized to their lifestyle, exercise, culture, and financial resources.

Guidelines from many current expert panels allow flexibility in the relative amounts of carbohydrate, fat, and protein. Nutritional management in T2DM often has a major focus on achieving reductions in calorie intake and weight loss. Achieving weight loss may be made more difficult by a tendency of some oral antidiabetic agents and also insulin to induce a degree of weight gain.

An important goal of nutritional management should be to balance the timing and quantities of ingested macronutrients with medications and exercise to help achieve targets for blood glucose control without periods of hypoglycemia.

For overweight or obese patients, it often is practical to set an initial goal of losing 5% to 10% of body weight. This may significantly improve diabetes control and increase the patient's motivation to then set goals for further weight loss (see [Chapter 67](#)).

Bariatric surgical procedures represent a method for achieving weight loss and potentially dramatic improvements in glycemia and risk factors for long-term complications in T2DM. Patients typically have improvements in glycemic control and lower requirements for antidiabetic medications within days after undergoing the Roux-en-Y gastric bypass procedure. This is thought to reflect changes in gut hormones and metabolic factors independent of weight loss. Beneficial effects on glucose control develop more gradually after the placement of an adjustable gastric band or sleeve gastrectomy. Randomized trials comparing bariatric surgery with medical nutrition therapy alone for weight loss have shown greater efficacy in achieving HbA_{1c} goals with surgery, and some studies have shown dramatic rates of remission, with 75% of patients or more becoming normoglycemic off all antidiabetic agents (see [Chapter 67](#)).

Exercise

Physical exercise should be encouraged in T2DM as an important component of weight loss regimens and also for its beneficial effects in decreasing the risks of long-term complications. The general recommendation of several expert panels is 30 minutes or more of moderate-intensity physical exercise on at least 5 days per week, but the regimen needs to be highly individualized according to a patient's capabilities and limitations imposed by other medical conditions such as cardiovascular disease. Patients who are unwilling or unable to undertake significant aerobic exercise should be encouraged to do daily walking or other physical activities within their limitations.

Standards of Care in T1DM and T2DM in Addition to Blood Glucose Control

A number of assessments and interventions should be performed at intervals in patients with T1DM or T2DM. These include blood pressure measurement and examination of the feet at each physician visit. Patients who smoke should receive counseling at each visit about the importance of and strategies for discontinuing. A dilated eye examination should be performed annually, or more often in patients with diabetic eye disease. A dental examination also should be performed at least annually. Starting 5 years after disease onset in T1DM and at the time of diagnosis in T2DM, patients should have annual measurement of their urinary albumin/creatinine ratio with confirmation if elevated (>30 mg albumin per gram of creatinine). A fasting lipid profile should be obtained annually. Aspirin (75 to 162 mg daily) is

usually recommended for secondary prevention of cardiovascular disease (supported by clinical trial evidence) or for primary prevention in patients with a 10-year cardiovascular risk greater than 10% (based on expert opinion). Influenza vaccination should be provided yearly; pneumococcal immunization should be given once and then repeated after age 65.

Management of Diabetes during Intercurrent Illness

Diabetes often requires changes in the blood glucose management regimen during an intercurrent illness to accommodate potential decreases in nutrient intake and increases in insulin resistance secondary to disease-related release of stress hormones. Patients with T1DM require exogenous insulin administration at all times to prevent marked hyperglycemia and DKA, even if they are unable to consume nutrients during an illness (e.g., with gastroenteritis). Depending on the degree and duration of interruption of food intake, they may require a transient, partial reduction in insulin dosage as well as more frequent glucose monitoring. Alternatively, if they are consuming a normal diet, they may require a modest increase in insulin dose because of insulin resistance related to the stress of illness. T2DM patients taking oral agents who are undergoing surgical procedures or are hospitalized for serious illness often require discontinuation of the oral agents and use of insulin to control blood glucose until normal eating patterns are resumed.

For hospitalized patients, blood glucose target goals are adjusted to prevent marked hyperglycemia and at the same time protect against hypoglycemia. For noncritical illness, typical blood glucose targets include lowest levels of 90 to 100 mg/dL, premeal levels lower than 140 mg/dL, and random levels lower than 180 mg/dL. For critically ill patients, intravenous insulin infusion may be needed to allow for rapid adjustments in dosage, and the blood glucose range recommended by most expert panels is 140 to 180 mg/dL.

Gestational Diabetes

The hormonal environment of pregnancy results in insulin resistance and therefore predisposes to the development or unmasking of diabetes during pregnancy. GDM occurs in 2% to 5% of all pregnancies and is associated with consequences for both mother and fetus if untreated. For this reason, screening for GDM is routinely performed between 24 and 28 weeks of gestation in women older than 25 years of age and in younger women who fulfill one or more of the risk criteria in Table 66-6 (2a through 2d and 2g). Women who are at high risk (i.e., those who are obese, have a personal history of GDM, glycosuria, or have a first-degree relative with diabetes) should be screened earlier, at their initial obstetric or prenatal visit. A broadly accepted approach to screening is a 2-hour 75-g oral glucose tolerance test with cutoff values as specified in Table 66-2.

A detailed discussion of the approach to managing GDM and also preexisting diabetes during pregnancy is beyond the scope of this chapter. The fundamental principles include diet, exercise, and glucose-lowering oral agents or insulin as needed. Blood glucose goals are set lower than in nonpregnant individuals because of the importance of minimizing exposure of the fetus to hyperglycemia: fasting, 95 mg/dL (5.3 mmol/L) or lower;

1-hour postprandial, 140 mg/dL (7.8 mmol/L) or lower; and 2-hours postprandial, 120 mg/dL (6.7 mmol/L) or lower. HbA_{1c} levels may be useful in establishing the presence of hyperglycemia before its discovery during pregnancy, but they have limited value in managing GDM. Women with GDM should be reevaluated with a 75-g glucose tolerance test 6 to 12 weeks after delivery, at which point approximately 10% will still have overt diabetes. Up to 40% of women with GDM go on to develop diabetes in the subsequent 20 years, with this risk varying substantially depending on ethnic background and obesity. Pregnancy serves as a provocative test and not as a risk factor for the future development of diabetes.

Management of Severe Metabolic Decompensation in Diabetes

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) develops most commonly in patients with T1DM (approximately 2.5 cases per 100 T1DM patients per year). It also can occur in those with T2DM, especially during acute illness (severe infection, medical illness, or trauma), and in a subset of *ketosis-prone* T2DM patients. DKA is present in approximately 25% of T1DM patients at diagnosis and otherwise most often develops when patients with known T1DM stop taking prescribed insulin. It is a potentially life-threatening condition that has an overall mortality rate of approximately 2.5%, with most deaths resulting from complicating or precipitating medical conditions rather than the metabolic disturbances of DKA itself.

The pathophysiology of DKA results from the combined effects of insulin deficiency and increased levels of *insulin counter-regulatory (stress) hormones*. With insulin deficiency, glucose levels rise as a consequence of decreased uptake and metabolism by body tissues, the breakdown of hepatic glycogen stores (*glycogenolysis*), and net glucose production by the liver and kidney (*gluconeogenesis*). Catabolism of muscle proteins as a result of low insulin levels leads to the release of amino acids, which provide substrate that further drives gluconeogenesis. Because glucose is being synthesized endogenously, blood glucose levels rise markedly, even in the fasted state. Blood glucose levels greater than 170 mg/dL result in glycosuria. Excretion of glucose in the urine necessitates the co-excretion of large amounts of water and electrolytes (Na⁺ and K⁺). Patients experience polyuria but cannot compensate adequately and become progressively more fluid and electrolyte depleted. The osmotic diuresis is characterized by greater losses of water than electrolytes, and this leads to progressively increasing hyperosmolality. Because of insulin deficiency, there is decreased *lipogenesis* and accelerated *lipolysis* leading to increased levels of circulating free fatty acids, which serve as a substrate for the hepatic synthesis of ketone bodies (β -hydroxybutyrate, acetoacetate, and acetone). β -Hydroxybutyrate and acetoacetate are acids, and their rising plasma levels contribute to the development of a metabolic acidosis.

These processes can result from simple insulin deficiency, but often they are exacerbated by an underlying or precipitating illness, such as an infection. Infection results in insulin resistance secondary to increased levels of *stress hormones* (cortisol,

catecholamines, glucagon, and growth hormone). A series of positive feedback loops are thus generated and lead to ever-accelerating hyperglycemia, fluid and electrolyte depletion, ketosis, and metabolic acidosis. More than simple restoration of insulin dosing is required, and patients usually need hospital admission and multicomponent interventions.

Common presenting symptoms in DKA include polyuria, thirst and polydipsia, recent weight loss (especially in new-onset diabetes), blurred vision, weakness, anorexia, nausea and vomiting, abdominal pain (which can mimic acute abdomen), and mental status changes varying from somnolence to coma. DKA and these associated symptoms usually evolve over 2 to 4 days but can have an onset of less than 12 hours in patients using insulin pumps. On physical examination, patients typically have evidence of dehydration including decreased skin turgor, hypotension, and tachycardia. The skin may be warm and dry from the vasodilating effects of acidosis, and marked hypotension should generate concern for impending vascular collapse. Patients often have deep, rapid respirations (Kussmaul breathing) as respiratory compensation for the metabolic acidosis, together with a characteristic fruity odor on their breath from exhaled acetone. The diagnosis is made in patients who have (1) a high blood glucose concentration (>250 mg/dL), (2) moderate to severe ketonemia (β -hydroxybutyrate >5 mmol/L or positive ketone levels by Ketostix at a serum dilution of 1:2 or higher), and (3) acidosis (pH <7.3 or plasma bicarbonate ≤ 15 mEq/L). Measurements of urine ketones may be misleading, because urinary ketones can be positive during fasting in the absence of DKA.

Additional evaluation besides the diagnostic tests already mentioned should include electrolytes, blood urea nitrogen, creatinine, phosphate, liver function tests, and amylase; arterial or mixed venous blood gases (including pH); complete blood count; urinalysis; electrocardiogram; and chest radiographs. The serum anion gap, which is usually greater than 12 mEq/L in DKA, should be calculated (anion gap = $[\text{Na}^+] - [\text{Cl}^- + \text{HCO}_3^-]$). Serum osmolality should be measured directly or calculated: estimated osmolality = $(2 \times [\text{Na}^+]) + ([\text{glucose in mg/dL}] / 18)$.

Precipitating causes of DKA include infection (most common), myocardial infarction (including silent infarction), inflammatory processes (appendicitis, pancreatitis), and medications (especially glucocorticoids).

Treatment of DKA should start promptly with institution of measures to correct life-threatening abnormalities, including insulin deficiency, fluid and electrolyte depletion, potassium (K^+) depletion, and metabolic acidosis. In a typical regimen, insulin is administered as a regular insulin bolus (0.1 U/kg) followed by a continuous intravenous infusion at 0.1 U/kg/hour. Plasma glucose is monitored hourly until it is less than 250 mg/dL, and the rate of insulin infusion is adjusted as needed to target a rate of blood glucose decline of 75 to 100 mg/dL/hour to avoid potential complications of rapid shifts in osmolality.

At the time of starting insulin, it is essential to begin fluid and electrolyte replacement. The initial fluid deficit should be estimated based on the magnitude of weight loss (if known), mucous membrane dryness, skin turgor, and whether or not there is postural hypotension, with the knowledge that losses in DKA usually range from 3 to 8 L. A typical program for intravenous fluid replacement starts with 1 L of normal saline in the first hour.

Normal saline may then be continued at 15 mL/minute for a second hour depending on the estimated severity of initial fluid depletion. This then may be changed to 0.45% (half-normal) saline at 7.5 mL/minute for the next 2 hours and gradually tapered thereafter to achieve full replacement of the estimated fluid deficit in approximately 8 hours. During that time, there should be frequent monitoring for jugular venous distention and chest auscultation to ensure early detection of fluid overload. Central venous pressure should be monitored in patients who are at risk for congestive heart failure.

Potassium repletion is needed in all patients, and there should be careful monitoring and replacement to ensure that patients do not develop potentially harmful hypokalemia or hyperkalemia. Urine output should be verified with the use of a Foley catheter if necessary before K^+ replacement is started. Unless patients are anuric, K^+ replacement should be initiated within 1 to 2 hours after starting insulin. A key goal is to maintain serum K^+ at all times higher than 3.5 mEq/L, and it is especially important to administer K^+ early in the course of treatment if there is initial hypokalemia or if bicarbonate is administered to correct acidosis, because the latter action promotes a shift of extracellular K^+ into cells. Potassium typically is withheld if the serum K^+ is 5 mEq/L or higher; otherwise, it is administered as part of the intravenous fluid regimen at 10 to 40 mEq/hour depending on the measured serum level. Serum K^+ should be monitored every 2 hours if it is less than 4 or greater than 5 mEq/L.

Bicarbonate infusion in general should be avoided but needs to be considered for patients who have a pH lower than 7, a serum bicarbonate level lower than 5.0 mEq/L, a K^+ concentration greater than 6.5 mEq/L, hypotension unresponsive to fluid replacement, severe left ventricular failure, or respiratory depression. Under these circumstances, 50 to 100 mEq (1 to 2 ampules) of bicarbonate may be infused intravenously over 2 hours.

As DKA resolves, it is important to continue providing adequate insulin to effectively resolve the ketosis, which may correct more slowly than the other abnormalities. This can be accomplished by adding glucose to the intravenous regimen (e.g., 5% glucose in half-normal saline) when blood glucose levels decrease to less than 200 to 250 mg/dL and continuing insulin infusion at 1 to 2 U/hour.

In patients with resolved DKA, transition to subcutaneous insulin can be made when the patient is clinically stable with normal vital signs, the acidosis is fully corrected, the patient is able to take fluids orally without nausea or vomiting, and any precipitating conditions (e.g., infection) are controlled.

Hyperglycemic Hyperosmolar State

A hyperglycemic hyperosmolar state (HHS) occurs almost exclusively in patients with T2DM, one third of whom have not been previously diagnosed. Patients often are elderly and frequently have compromised renal function. Insulin deficiency, often exacerbated by insulin resistance resulting from the stress, leads to hyperglycemia, glucosuria, and an osmotic diuresis. However, the presence of some endogenous insulin secretion suppresses lipolysis and ketogenesis enough to prevent ketoacidosis. Patients with HHS typically develop more marked hyperglycemia, fluid and electrolyte deficits, and hyperosmolality compared to those with DKA. HHS usually develops insidiously over days to weeks,

and patients may be vulnerable to development of more severe hyperglycemia and volume deficits over this extended period.

HHS is associated with infections (40%), diuretic use (35% to 40%), and residency in nursing homes (25% to 30%). Other precipitating and complicating factors may include intestinal obstruction, mesenteric thrombosis, pulmonary embolism, peritoneal dialysis, subdural hematoma, and an extensive list of medications. The overall mortality rate exceeds that of DKA (10% to 40%), with higher mortality rates associated with age older than 70 years, nursing home residency, and higher osmolality or serum Na^+ concentration. Clinically, patients have evidence of the marked fluid and electrolyte deficits and tend to have more prominent neurologic abnormalities than those with DKA, including confusion, obtundation, and coma.

Therapy for HHS follows the same general principles as that for DKA, with a greater volume replacement required (typically 8 to 12 L in fully developed HHS). Restoration of the fluid and electrolyte deficits should proceed more slowly than in DKA, ideally over 36 to 72 hours. Insulin therapy should be started only after rehydration is in progress. There is a need for K^+ replacement, but less than in DKA. Patients with HHS may be more sensitive to insulin than those with DKA and may require lower insulin doses. In view of the severe dehydration and predisposition to vascular thrombosis, heparin prophylaxis usually should be provided. Despite the very marked hyperglycemia of HHS, patients may be able to return to oral treatment eventually.

Chronic Complications of Diabetes

Chronic complications of T1DM and T2DM are similar and include microvascular complications (nephropathy, retinopathy, and neuropathy) and macrovascular or cardiovascular complications (coronary artery disease, peripheral vascular disease, and cerebrovascular disease). The long-term complications of diabetes result in substantial morbidity and shorten the average lifespan by 10 years. Candidate mechanisms for microvascular and macrovascular complications include activation of the polyol pathway (with accumulation of sorbitol), formation of glycated proteins and advanced glycation end products (cross-linked glycated proteins), abnormalities in lipid metabolism, increased oxidative damage, hyperinsulinemia, hyperperfusion of certain tissues, hyperviscosity, platelet dysfunction (increased aggregation), endothelial dysfunction, and activation of various growth factors.

Microvascular Complications

Retinopathy

Diabetic retinopathy affects almost all patients with T1DM and 60% to 80% of those with T2DM by 20 years after the diagnosis of diabetes. It is the most common cause of blindness in persons between the ages of 20 and 74 years in the developed world. The incidence and progression of diabetic retinopathy increase with duration of diabetes, poor glycemic control, the type of diabetes (T1DM more than T2DM), and the presence of hypertension, smoking, dyslipidemia, nephropathy, and pregnancy.

Early interventions often are beneficial in slowing or sometimes reversing diabetic retinopathy, but most patients have no symptoms until the lesions are advanced. Therefore, annual

ophthalmologic screening is recommended starting at 5 years after diagnosis in T1DM and at the time of diagnosis in T2DM.

In nonproliferative retinopathy, the progression to visual loss in patients with clinically significant macular edema is improved by focal laser photocoagulation. Panretinal photocoagulation improves outcomes in patients with proliferative retinopathy and also in the subset of T2DM patients with severe nonproliferative diabetic retinopathy. Patients who have had vitreous hemorrhage and resulting visual loss may have significant restoration of vision with vitrectomy. In addition to diabetic retinopathy, patients with diabetes are at increased risk for development of cataracts.

Nephropathy

Diabetic nephropathy is the most common cause of end-stage renal disease (ESRD) in developed countries (about 30% of cases). However, the risk of progression to ESRD has been markedly decreasing over the last several decades. ESRD now appears to affect fewer than 10% of patients. The risk of developing advanced renal disease in diabetes is increased by poor glycemic control, hypertension, smoking, and possibly use of oral contraceptives, obesity, and more advanced age.

Diabetic nephropathy is primarily a glomerulopathy, with pathologic features that include mesangial expansion, glomerular basement membrane thickening, and glomerular sclerosis. Many but not all patients develop albuminuria early in the course, and the level of albumin correlates with the rate of progression and the degree of renal injury. For this reason, patients should be monitored annually for albuminuria starting 5 years after diagnosis in T1DM and at the time of diagnosis in T2DM. Measurement of the ratio of microalbumin to creatinine in a random urine sample is adequate, because this ratio correlates well with results from 24-hour collections. Albumin excretion of 30 to 300 mg per gram of creatinine is designated *moderately increased albuminuria* (previously called “microalbuminuria”) and indicates probable diabetic nephropathy. Albumin excretion of greater than 300 mg per gram of creatinine is designated *severely increased albuminuria* (formerly “macroalbuminuria”); these patients are at high risk for progression to nephrotic-range proteinuria and ESRD.

Efforts to achieve blood glucose targets and rigorously control blood pressure (appropriate to age and overall risk profile) should be part of the strategy for primary prevention of nephropathy in all patients with diabetes. Blood pressure should be maintained lower than 130/80 mm Hg unless otherwise contraindicated. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) are preferable first-line agents. The calcium channel blockers diltiazem and verapamil can be used as alternatives in patients who are unable to tolerate ACE inhibitors or ARBs, or as additive therapy in patients who need multiple drugs to control blood pressure. Diuretics and moderate Na^+ restriction also frequently are needed to reach blood pressure goals.

Neuropathy

The likelihood of development of diabetic neuropathy increases with duration of disease and is influenced by the degree of glycemic control (occurring overall in up to 70% of people with diabetes). Any part of the peripheral or autonomic nervous system may be affected. *Peripheral polyneuropathy* occurs most

commonly, usually manifesting as a bilaterally symmetrical, distal, primarily sensory polyneuropathy (with or without motor involvement) in a *glove-and-stocking* distribution. Pain, numbness, hyperesthesias, and paresthesias progress to sensory loss. This condition, together with loss of proprioception, can lead to an abnormal gait with repeated trauma and potential for fractures of the tarsal bones, sometimes resulting in the development of Charcot joints. These changes lead to abnormal pressures in the feet that, together with the soft tissue atrophy related to peripheral arterial insufficiency, result in foot ulcers that may progress to osteomyelitis and gangrene. Detailed, regular neurologic examination of all patients is essential to elicit the early loss of light touch (using a size 5.07/10-g monofilament), reflexes, and vibratory sensation.

A second common form of diabetic neuropathy is autonomic neuropathy, which may develop in concert with or separate from distal polyneuropathy. Resulting symptoms can be debilitating, including postural hypotension leading to falls or syncope, gastroparesis, enteropathy with constipation or diarrhea, and bladder outflow obstruction with urinary retention. Diabetic autonomic neuropathy together with vascular disease is a contributor to erectile dysfunction in males. Gastrointestinal dysfunction with autonomic neuropathy can complicate efforts to achieve blood glucose control by causing variable absorption of food. A suspected diagnosis of autonomic neuropathy can be strengthened by demonstrating loss of normal variability in heart rate with deep respirations or the Valsalva maneuver.

Other, less common manifestations of diabetic neuropathy include thoracic and lumbar nerve root *polyradiculopathies*, individual peripheral and cranial nerve *mononeuropathies*, and asymmetrical neuropathies of multiple peripheral nerves (mononeuropathy multiplex). Diabetic amyotrophy causing muscle atrophy and weakness most often involving the anterior thigh muscles and pelvic girdle is an uncommon form of diabetic neuropathy that often resolves after several months.

The primary approach to all diabetic neuropathies consists of efforts to improve blood glucose control. Clinical trials have shown decreased development of distal polyneuropathy with improved glycemia in T1DM. It also is particularly important for patients with neuropathies to receive regular foot care, including daily self-inspection of the feet, regular physician examinations, and early interventions for developing callouses, infections, or other foot lesions. Painful polyneuropathies cause substantial morbidity and are difficult to treat. First-line drugs include amitriptyline, venlafaxine, duloxetine, and pregabalin. For patients who do not respond adequately to one drug, combination therapy with two drugs of different classes can be tested. Alternative treatments that may be effective in some patients include topical capsaicin cream, lidocaine patch, α -lipoic acid, isosorbide dinitrate topical spray, and transcutaneous electrical nerve stimulation (TENS). *Gastroparesis* secondary to autonomic neuropathy may improve symptomatically with metoclopramide or domperidone (dopamine D2 antagonists), erythromycin (motilin agonist) for bacterial overgrowth, cisapride (cholinergic agonist), or mosapride (selective serotonin 5-HT₄ receptor agonist). Diarrhea may respond to loperamide or diphenoxylate and atropine. Orthostatic hypotension can be treated by attention to mechanical factors such as elevation of

the head of the bed, gradual rising from a lying to standing position, use of support stockings, and sometimes use of the mineralocorticoid fludrocortisone.

Macrovascular Complications

The risk of macrovascular disease including cardiovascular disease, transient ischemic attacks and strokes, and peripheral vascular disease is increased twofold to fourfold and accounts for 70% to 80% of deaths in patients with diabetes. This increased risk is believed to result from the altered metabolism in diabetes and also from the frequent occurrence of associated risk factors in diabetic patients, including hypertension and dyslipidemia. Screening for macrovascular disease and predisposing factors were discussed earlier. Approaches to decreasing the risk of macrovascular disease should include optimization of blood glucose control, weight loss for overweight and obese patients, smoking cessation, control of blood pressure, and treatment of dyslipidemia. (See Chapter 69 for details on the management of dyslipidemia.)

HYPOGLYCEMIA

Definition

Hypoglycemia most often occurs in patients with T1DM or T2DM under circumstances in which insulin or other antidiabetic therapies result in blood glucose levels' decreasing below the lower limit of normal (<50 to 60 mg/dL for most laboratories). This may be caused by overtreatment with glucose-lowering agents, failure to take in anticipated calories, or the combination of increased glucose utilization and increased insulin sensitivity induced by exercise.

Hypoglycemia much less commonly occurs as a primary disorder in patients who do not have drug-treated diabetes. Under these circumstances, clinically significant hypoglycemia can be difficult to identify based on blood glucose measurements alone, because the normal lower limit of blood glucose varies in individuals and is influenced by duration of fasting and gender. Plasma glucose levels during a fast in men decrease to approximately 55 mg/dL at 24 hours and 50 mg/dL at 48 and 72 hours, whereas in premenopausal women they may be as low as 35 mg/dL at 24 hours without symptoms of hypoglycemia. In evaluating glucose determinations, it is important to recognize that plasma levels are approximately 15% higher than glucose levels in whole blood. Clinically significant hypoglycemia can be most readily established if patients manifest *Whipple's triad*, which refers to the combination of: (1) symptoms suggestive of hypoglycemia, (2) documented low plasma glucose levels (<50 to 60 mg/dL), and (3) prompt resolution of symptoms when the low blood glucose is corrected.

Signs and Symptoms

Typical signs and symptoms of hypoglycemia are listed in Table 66-8. *Autonomic* symptoms result from sympathetic neural outflow that occurs as part of the counter-regulatory response to hypoglycemia. Although most patients appear to fully recover CNS function after a neuroglycopenic episode, there is a risk of irreversible brain damage or death with sustained or repeated episodes of severe neuroglycopenia.

TABLE 66-8 SIGNS AND SYMPTOMS OF HYPOGLYCEMIA

AUTONOMIC		
Sweating	Palpitations	Hunger
Pallor	Tachycardia	Nausea
Anxiety	Hypertension	Vomiting
Tremor	Irritability	Paresthesias
NEUROGLYCOPENIC		
Difficulty thinking	Dizziness	Seizures
Fatigue, weakness	Visual blurring	Loss of consciousness
Somnolence	Confusion	Coma
Headache	Abnormal behavior	Death

Pathology

Hypoglycemic disorders can result when there is overproduction of hormones that lower glucose concentrations, underproduction of hormones that serve to elevate glucose levels, deficiency of substrates for endogenous glucose synthesis, or changes in cells and tissues that result in their increased consumption of glucose.

Etiologic Classification

Causes of hypoglycemia by etiologic categories are listed in [Table 66-9](#).

Drug-Induced

The most common causes of hypoglycemia are excess insulin or insulin secretagogues (especially sulfonylureas) administered in the treatment of diabetes. Ethanol is another commonly used drug that can cause hypoglycemia. This most often occurs in the context of chronic alcoholism in an individual who is nutritionally depleted, often after binge drinking for several days or longer. Under these circumstances, hepatic glycogen stores become depleted, and the process of alcohol metabolism blocks gluconeogenesis by depriving the liver of nicotinamide adenine dinucleotide (NAD⁺). Commonly used pharmacologic agents that have been associated with hypoglycemia include β -blockers (especially nonselective β_2 -adrenergic antagonists), ACE inhibitors, pentamidine (through toxic effects on beta cells), quinine, and quinolones.

Excess Endogenous Insulin or Insulin-like Hormones

Alimentary hypoglycemia is a disorder in which low blood glucose levels occur typically 90 to 180 minutes after meals in patients who have undergone gastric outlet surgery with resulting accelerated gastric emptying. This is distinct from the more common *dumping syndrome*, which results from rapid entry of an osmotic load into the small intestine and associated fluid shifts and autonomic responses and is not associated with hypoglycemia. “Reactive hypoglycemia” is a now outmoded term that previously was applied to adrenergic symptoms occurring 2 to 4 hours after a meal in patients who are not hypoglycemic; these individuals may experience decreased symptoms with frequent feedings and avoidance of high-carbohydrate meals.

Tumors of islet beta cells (*insulinomas*) can cause hypoglycemia by producing excess insulin in an unregulated manner. They are uncommon (1 in 250,000 patient-years), but it is important

TABLE 66-9 ETIOLOGIC CLASSIFICATION OF HYPOGLYCEMIC DISORDERS MANIFESTING IN ADULTS

DRUG-INDUCED
Antidiabetic agents (insulin, sulfonylureas, meglitinides)
Alcohol
Other pharmacologic agents (β -blockers, ACE inhibitors, pentamidine, quinine, quinolones and many others)
ALTERED GASTROINTESTINAL FUNCTION
Alimentary hypoglycemia
BETA-CELL INSULIN OVERSECRETION
Insulinoma
Non-insulinoma pancreatogenous hypoglycemia (without or with bariatric surgery)
NON-ISLET CELL NEOPLASMS
Tumor insulin-like growth factor-II secretion
Tumor glucose consumption
AUTOIMMUNE
Circulating insulin antibodies
Insulin receptor activating antibodies
ENDOCRINE DEFICIENCIES
Glucocorticoids (adrenal insufficiency), growth hormone, catecholamines, glucagon
SEVERE ILLNESS
Sepsis
Hepatic failure
Renal failure
MALNUTRITION
Anorexia nervosa

ACE, Angiotensin-converting enzyme.

to recognize them when they do occur. Insulinomas usually are small (1 to 2 cm), benign (>90%), solitary (>90%), and confined to the endocrine pancreas (99%). Some patients have an indolent course extending over many years before diagnosis, but insulinomas can produce profound hypoglycemia. There is a tendency for adrenergic symptoms to become suppressed as a consequence of repeated exposures to hypoglycemia, and neuroglycopenic symptoms may predominate, including sometimes bizarre behavioral abnormalities. Patients may eat frequently in response to the hypoglycemia and exhibit moderate weight gain.

Non-insulinoma pancreatogenous hypoglycemia is a disorder that may manifest with symptoms similar to those of insulinomas, but the pathology involves beta-cell hypertrophy and hyperplasia rather than the presence of a discrete tumor. More recently, the development of hypoglycemia with similar beta-cell hyperplasia has been described in a small number of patients, more often in females, months to years after Roux-en-Y gastric bypass surgery.

Non-islet cell neoplasms are a rare cause of hypoglycemia; they produce an insulin-like growth factor (IGF), usually a partially processed form of IGF-II designated *big IGF-II*, that can have insulin-like effects. The tumors typically are large and malignant and are most often located in the retroperitoneal space, abdomen, or thoracic cavity. Tumor types include hemangiopericytomas, hepatocellular carcinomas, lymphomas, adrenocortical carcinomas, gastrointestinal carcinoids, and mesenchymal tumors. Some large tumors cause hypoglycemia in the absence of detectable insulin-like factors.

Hormone Deficiencies

Deficiencies of insulin counter-regulatory hormones, which normally function to raise glucose levels, can result in or contribute to hypoglycemia. An example is low levels of corticosteroids caused by primary or secondary adrenocorticoid insufficiency. Deficiencies of other hormones, including catecholamines, glucagon, and growth hormone, also can cause hypoglycemia.

Severe Illness

Hypoglycemia can occur during severe illness through a number of different mechanisms in association with sepsis, hepatic insufficiency, and renal failure. Patients with severe illness appear to be particularly vulnerable to hypoglycemia when they are poorly nourished, although malnutrition alone is rarely associated with hypoglycemia.

Approach to the Diagnosis

For patients who have well-documented hypoglycemia, the diagnosis often is evident or strongly suggested by the clinical setting, history, and physical examination findings. Hypoglycemia induced by insulin or other glucose-lowering agents in diabetic patients often is immediately apparent from the medical history. Alcohol-induced hypoglycemia may be suspected in a patient with a known or suspected history of alcohol abuse and binge drinking. Identification of other candidate drugs as a cause of hypoglycemia requires a thorough medical history, and the condition can be expected to resolve if the suspect medication is stopped. The patient may have a known diagnosis of adrenal insufficiency, or this may be suggested by other clinical findings (e.g., orthostatic hypotension, increased skin pigmentation) or the development of markedly increased insulin sensitivity in a patient with T1DM. The patient may have a known tumor suggesting the possibility of a non- β -cell neoplasm as a cause of hypoglycemia. There may be a history of Roux-en-Y bypass surgery, raising the possibility of beta-cell hyperplasia. The co-occurrence of sepsis, hepatic failure, renal failure, profound malnutrition, or a known diagnosis of anorexia nervosa may suggest one of these potential underlying causes.

A number of algorithms have been developed to guide the evaluation of documented or potential hypoglycemia, including a recommended approach from an expert panel published by the Endocrine Society. If there is an opportunity to observe the patient during a symptomatic episode of presumed hypoglycemia, plasma should be obtained, if possible before treatment, for measurement of glucose, insulin, proinsulin, C-peptide, β -hydroxybutyrate, and screening for sulfonylureas and meglitinides. Hypoglycemia can be rapidly, provisionally confirmed with a test meter. After blood samples have been obtained for the tests described, glucose should be administered orally (15 to 30 g) or intravenously (25 g, or 1 ampule of 50% dextrose), and recovery of glucose levels and symptoms should be observed.

For patients with suspected or confirmed hypoglycemia developing specifically in the fasted state, it may be possible to replicate the condition by observing during several hours of daytime fasting, with or without a preceding overnight fast. The same laboratory testing panel as described earlier then can be obtained

if symptoms suggestive of hypoglycemia occur. For patients who describe postprandial hypoglycemic symptoms (within 5 hours after a meal), a mixed meal (not a pure glucose load) should be provided, with blood sampling at baseline and every 30 minutes thereafter for 5 hours

For patients who do not manifest hypoglycemia with the testing procedures described despite a strong suspicion of hypoglycemia, the most frequently utilized approach is a 72-hour fast according to a protocol developed at the Mayo Clinic. Blood is obtained every 6 hours and at test termination. The test is ended at 72 hours or at an earlier time point if the plasma glucose level decreases (by glucose meter testing) with associated symptoms to 45 mg/dL (2.5 mmol/L) or lower or to less than 55 mg/dL (3 mmol/L) in a patient with prior documentation of Whipple's triad. At the end of the 72-hour test period, the patient is given 1 mg of glucagon intravenously, and blood is obtained at 10, 20, and 30 minutes, after which the patient is given a meal. The final blood sample obtained at the end of the fast (before glucagon administration) is analyzed additionally for β -hydroxybutyrate and a sulfonylurea/meglitinide panel.

For any of these test protocols, elevations of insulin, proinsulin, and C-peptide associated with hypoglycemia at the same time point are consistent with an insulinoma, beta-cell hyperplasia, the effects of an insulin secretagogue (sulfonylurea or meglitinide), or the presence of insulin antibodies. An elevation in these three hormones during a meal test in a patient who has had gastric surgery is suggestive of alimentary hypoglycemia. Plasma insulin, proinsulin, and C-peptide are not elevated in patients with hypoglycemia secondary to extrapancreatic neoplasms. This diagnosis usually can be further confirmed by evidence of a large tumor with various imaging techniques. High insulin levels, together with low proinsulin and C-peptide concentrations in the presence of hypoglycemia, is indicative of exogenous insulin administration. Factitious hypoglycemia secondary to insulin or insulin secretagogue administration is uncommon and has been observed in individuals with or without diabetes.

Treatment

The most important therapeutic step in hypoglycemia is to identify and treat the underlying causes, including drugs, alcohol, serious infection, tumors, and hypoadrenalism. The occurrence of hypoglycemia usually can be substantially improved in patients with alimentary hypoglycemia by a modified feeding regimen with frequent, small meals and avoidance of concentrated sources of rapidly digested and absorbed carbohydrate.

Non- β -cell tumor hypoglycemia is treated by tumor resection if possible. For nonresectable tumors, a debulking procedure may be effective in reducing hypoglycemia. Hypoglycemia in patients with insulinomas can be cured by resection. Persistent hypoglycemia secondary to nonresectable insulinoma can sometimes be treated effectively with diazoxide, long-acting somatostatin analogues (octreotide or lanreotide), verapamil, or phenytoin. For patients with beta-cell hyperplasia after bariatric surgery, first-line treatment includes diet modifications with more frequent, small meals and avoidance of concentrated sources of carbohydrate to decrease meal-induced insulin secretion.

For a deeper discussion of this topic, please see Chapter 229, "Diabetes Mellitus," and Chapter 230, "Hypoglycemia/Pancreatic Islet Cell Disorders," in Goldman-Cecil Medicine, 25th Edition.

Obesity

Osama Hamdy

DEFINITION AND EPIDEMIOLOGY

Obesity is a disease that is usually defined as a body mass index (BMI) greater than or equal to 30 kg/m^2 (weight [kg]/(height [m])²). A BMI of 30 to 34.9 is considered class 1 obesity, 35 to 39.9 is class 2 obesity, and 40 or higher is class 3 or severe obesity. The term “morbid obesity” previously was applied to individuals weighing at least 45 kg (100 lb) more than, or typically about 60% more than, desirable body weight; the term also has been applied to any individual with a BMI greater than or equal to 40 kg/m^2 .

There is increasing recognition of limitations to defining obesity based on BMI resulting from the variable correlation between BMI and amount of body fat in different ethnic (genetic) populations or in individuals with different degrees of muscularity. Many investigators and clinicians are moving toward a definition that defines obesity as an excess of body fat sufficient to confer risk. Linking obesity to cardiometabolic risk, body fat distribution, and waist circumference is more important than measuring percentage body fat or BMI alone. People who accumulate visceral fat and clinically have higher waist circumference (metabolic obesity) are at much higher risk for cardiovascular disease and diabetes than those with the same BMI or the same percentage of body fat but a lower waist circumference. The National Cholesterol Education Program Adult Treatment Panel III (ATP III) considered a waist circumference greater than 40 inches (102 cm) in American men or 35 inches (88 cm) in American women to be among the five criteria that define the cardiometabolic syndrome. In spite of its limitations, BMI remains a simple measurement with utility in estimating a person’s health risks and comparing outcomes between trials.

During the last 30 years, there has been a dramatic increase in the percentage of both adults and children in the United States who are overweight (defined as BMI of 25 to 30) or obese. According to the 2009-2010 National Health and Nutrition Examination Survey (NHANES) conducted by the Centers for Disease Control and Prevention (CDC), more than one third of U.S. adults (35.7%) were obese. This was more than double the prevalence in the 1976-1980 NHANES data (15.0%). Non-Hispanic blacks had the highest age-adjusted rates of obesity (49.5%), followed by Mexican Americans (40.4%), all Hispanics (39.1%), and non-Hispanic whites (34.3%). More recently, there appears to have been a slowing of the rate of increase or even a leveling off. Obesity prevalence varies significantly across states, from a low of 20.5% in Colorado to a high of 34.7% in Louisiana in 2012. In general, higher prevalence of adult obesity was found in the midwest (29.5%) and the

south (29.4%) and lower prevalence in the northeast (25.3%) and the west (25.1%).

The percentage of children and adolescents who are overweight or obese has almost tripled since 1980. Currently, 17% of children and adolescents aged 2 to 19 years (12.5 million individuals) are obese. NHANES data from 1976-1980 and from 2009-2010 show the prevalence of obesity increasing from 5.0% to 12.1%, respectively, for children aged 2 to 5 years and from 5.0% to 18.4% for those aged 12 to 19 years. Among low-income preschool children, the prevalence of obesity increased between 1998 and 2003 from 13.0% to 15.2%, and severe obesity from 1.8% to 2.2%. These rates decreased slightly between 2003 and 2010: obesity from 15.2% to 14.9%, and severe obesity from 2.2% to 2.1%.

Overweight and obesity and their associated health problems have a significant economic impact on the U.S. health care system through direct medical expenses and indirect costs (e.g., loss of work time and productivity). Medical costs of obesity account for an estimated 10% of total U.S. medical expenditures. The estimated total annual medical costs of obesity in the United States was \$147 billion in 2008, with medical costs on average \$1429 higher per year for obese compared with normal-weight individuals. Approximately half of these costs were paid by Medicaid and Medicare.

PATHOLOGY OF OBESITY

Obesity develops as a consequence of genetic-environmental interactions, such that genetically prone individuals who lead a sedentary lifestyle and consume larger amounts of dietary calories are at higher risk. Children of obese parents are 80% more likely to become obese, and it is believed that this results from a combination of genetic and environmental influences.

The genetic contributions to obesity are most commonly considered to reflect the combined effects of variations in multiple genes and only rarely appear to result from a defect in a single powerful gene. Single-gene defects identified in experimental animals have been useful to demonstrate appetite and satiety mechanisms, and mutations in some of these same genes have subsequently been identified in rare human forms of genetic obesity. For example, loss-of-function mutations in the leptin gene and in the cellular receptor for leptin were first identified as a cause of obesity in laboratory mice (*ob/ob* and *db/db* mice, respectively). Leptin is a hormone that is produced in fat cells, mostly in subcutaneous fat. It is a potent satiety factor that acts in the arcuate nucleus of the hypothalamus to reduce the production of neuropeptide Y, a stimulator of food intake. After its discovery in mice, leptin gene mutations were identified as a cause

of a rare form of heritable human obesity. Affected individuals develop marked obesity in childhood as a consequence of increased food intake. Leptin secretion normally follows a circadian pattern, with higher levels during evening and night hours. Loss of leptin secretion has particularly marked effects during these hours, resulting in a phenomenon known as night-eating syndrome, in which patients tend to consume large amounts of food during the night.

Other single-gene defects identified as rare causes of human obesity include loss-of-function mutations in genes encoding carboxypeptidase E, melanocortin-4 or melanocortin-3 receptors, and serotonin-2C or serotonin-1B receptors. Obesity is also a feature of many other genetic disorders in which the specific mechanisms of the obesity are less well understood. These different syndromes may have autosomal dominant, autosomal recessive, or X-linked inheritance patterns, consistent with multiple different genetic causes. Among the best known of these disorders, the Bardet-Biedl syndrome, is an autosomal recessive disorder characterized by obesity and other abnormalities, including hypogonadism in men, mental retardation, retinal dystrophy, polydactyly, and renal malformations. In Prader-Willi syndrome, loss of portions of the long arm of chromosome 15 (q11-13) is associated with obesity, poor muscle tone in infancy, defects in cognition, behavioral abnormalities (irritability), short stature, and hypogonadotropic hypogonadism.

Although known single-gene mutations account for only a small percentage of human obesity, there is evidence for widespread heritable influences in more common forms of human obesity. For example, in twin and adoptee studies, both members of identical twin pairs tend to become obese in concordance with the same weight pattern as their biologic parents, even when raised apart. Metabolic rate, spontaneous physical activity, and thermic response to food seem to be heritable to a variable extent, but the specific genes that contribute to prevalent forms of human obesity have not yet been defined. Genomic analyses in large populations have identified multiple genes or genetic regions in which polymorphisms are associated with obesity risk. These include polymorphisms in or near genes for the melanocortin-4 receptor (a protein involved in appetite suppression pathways in the hypothalamus), brain-derived neurotrophic factor (role in energy balance); the β_3 -adrenergic receptor (role in visceral fat accumulation), and peroxisome proliferator-activated receptor- γ 2 (PPAR- γ 2, a transcription factor involved in adipocyte differentiation. Multiple other sites of genetic variation associated with increased obesity risk have been identified for which potential mechanistic links to obesity are not yet apparent. It is hypothesized that the heritable component of common forms of human obesity derives from the effects of variations in these and many yet unidentified genes acting both additively and synergistically.

Important environmental factors driving the recent increased prevalence of obesity include increased caloric intake (reflecting greater availability of high-calorie, low-cost foods) and decreased energy expenditure (as a consequence of decreased physical activity). Lower socioeconomic status, lower education level, cessation of smoking, and consumption of carbohydrates with a high glycemic index have been identified as specific confounders of obesity. Additional factors that may influence obesity risk include intrauterine growth and nutritional history, levels of

reproductive and other hormones, and factors that may alter the feedback between energy intake and expenditure. Ultimately, an increase in total body fat results from energy intake that exceeds energy expenditure. This occurs through the operation of genetic and environmental influences, together with individual behavioral characteristics.

PATHOLOGY OF OBESITY-ASSOCIATED HEALTH RISKS

Adipose tissue is not just a passive depot for lipids. Adipocytes also function as a complex and active endocrine organ with metabolic and secretory products (hormones, prohormones, cytokines, and enzymes) that play a major role in whole-body metabolism. Relationships between obesity and both insulin resistance and endothelial dysfunction (the early stage of atherosclerosis) are mediated through the release of several hormones from adipose tissue. These hormones, designated adipocytokines or adipokines, comprise a group of pharmacologically active low- and medium-molecular-weight proteins that possess autocrine and paracrine effects and are known products of the inflammatory and immune systems. They play an important role in adipose tissue physiology and in initiating metabolic and cardiovascular abnormalities, not only in overweight and obese individuals but also in lean persons with higher visceral fat mass. Adipokines include adiponectin, leptin, tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), resistin, plasminogen activator inhibitor-1 (PAI-1), angiotensinogen, and monocyte chemoattractant protein-1 (MCP-1). An increased amount of adipose tissue or its disproportionate distribution between central and peripheral body regions is related to altered serum levels of these factors. With the exceptions of leptin and adiponectin, the adipokines are produced both from fat cells and from adipose tissue-resident macrophages in the stromal tissues surrounding fat cells. For unknown reasons, an increase in the amount of body fat is associated with increases in the number of adipose tissue macrophages and their production of cytokines.

Human adiponectin is a relatively abundant, 244-amino-acid polypeptide in plasma, accounting for 0.01% of total plasma proteins. Adiponectin gene expression in adipose tissue is associated with obesity, insulin resistance, and type 2 diabetes (T2DM). Hypoadiponectinemia is more strongly related to the degree of insulin resistance than to the degree of adiposity or glucose intolerance. Genetic polymorphisms may influence the regulation of adiponectin and lead to variations in its levels among different individuals. Several human studies have shown that high adiponectin levels protect against development of T2DM and point to the possible future use of adiponectin as an indicator of diabetes risk. Low plasma concentrations of adiponectin are observed in patients with coronary artery disease (CAD), and lower adiponectin levels have been found in diabetic patients with CAD than in those without CAD. In obesity, a 10% reduction in body weight leads to a significant increase in adiponectin (40% to 60%) in both diabetic and nondiabetic patients. Adiponectin is also involved in the modulation of inflammatory responses through attenuation of TNF- α -mediated inflammatory effects, regulation of endothelial function, and inhibition of growth factor-induced proliferation of vascular smooth muscle cells.

Leptin is a 167-amino-acid adipocyte-derived hormone that circulates in the plasma in free and bound forms. It affects energy balance by activating specific centers in the hypothalamus to

decrease food intake, increase energy expenditure, modulate glucose and fat metabolism, and alter neuroendocrine function. Leptin plasma levels increase exponentially with increased fat mass (fourfold higher in obese compared with lean individuals in one study), and this is thought to reflect resistance to leptin in obesity. Leptin therapy in lipodystrophic patients has been shown to lower blood glucose, improve insulin-stimulated hepatic and peripheral glucose metabolism, and reduce hepatic and muscle triglyceride content, suggesting that leptin acts as a signal that contributes to regulation of total body sensitivity to insulin. It has also been found that leptin is independently associated with cardiovascular mortality. Although both adiponectin and leptin are integrally related to insulin resistance, adiponectin is more strongly related to visceral abdominal fat stores, whereas leptin is more closely related to subcutaneous fat.

Adipose tissue serves as a major source of TNF- α and substantial amounts of IL-6. Levels of these two proinflammatory cytokines correlate with obesity and are strongly related to insulin resistance. Several studies have demonstrated a strong link between TNF- α and cardiovascular disease. Plasma levels of TNF- α are increased in individuals with premature cardiovascular disease independent of insulin sensitivity. Conversely, circulating levels of TNF- α decrease after weight reduction in parallel with improvements in endothelial function.

Resistin is an adipocyte-derived, cysteine-rich signaling protein that is expressed predominantly in white adipose tissue and is also detectable in serum. Resistin is thought to act at sites remote from adipose tissue, similar to other adipokines, and to contribute to insulin resistance in obesity. PAI-1 is another bioactive peptide produced by subcutaneous and visceral fat. Its circulating levels correlate better with visceral than with subcutaneous adiposity and are a strong predictor of CAD. High PAI-1 levels are associated with increased blood coagulability. Improvement in insulin sensitivity by either weight reduction or medication lowers circulating levels of PAI-1. This decrease in PAI-1 correlates with the amount of weight loss and the decline in serum triglycerides.

Visceral and subcutaneous fat differ in their production of specific adipokines, pointing to differences in endocrine function between these two adipose depots. Removal of a significant amount of only subcutaneous fat by liposuction in obese individuals with and without diabetes resulted in reduction in serum leptin but did not change the serum levels of other cytokines or any other metabolic parameters. It also did not improve insulin sensitivity or decrease the high serum insulin level observed initially in those individuals. In animal models, removal of subcutaneous fat resulted in an increase in mesenteric fat volume and increased production of TNF- α by visceral fat. Although surgical removal of visceral fat has not been attempted in humans, two studies of aging in rodent models showed that removal of visceral fat reduces the production of inflammatory adipokines and improves glucose tolerance and insulin sensitivity.

Risks Associated with Obesity

Overweight and obese individuals are at increased risk for the following health conditions:

- Cardiometabolic syndrome
- Type 2 diabetes (T2DM)

- Hypertension
- Dyslipidemia
- Coronary heart disease
- Congestive heart failure
- Atrial fibrillation
- Osteoarthritis
- Stroke
- Gall bladder disease
- Fatty liver and nonalcoholic steatohepatitis
- Sleep apnea
- Asthma
- Gastroesophageal reflux (GERD)
- Some cancers (endometrial, breast, and colon)
- Gynecologic disorders (abnormal menses, infertility, polycystic ovarian syndrome)

Weight loss of 7%-10% is associated with reduced risk for many if not all of these disorders. Recent studies have shown that significant weight reduction (15% to 25% of initial body weight) after gastric bypass surgery in class 2 and class 3 obese patients with T2DM results in transient remission of diabetes for 2 to 10 years. The relative importance of the weight loss itself and the hormonal changes associated with gastric bypass surgery to terms of diabetes remission is not yet understood.

DIAGNOSIS AND ASSESSMENT OF OBESITY

The form of obesity that characteristically occurs in men—android or abdominal obesity (apple-shaped body configuration)—is closely associated with metabolic complications such as insulin resistance, hypertension, dyslipidemia, and hyperuricemia. By contrast, the typical female or gynecoid obesity (pear-shaped body configuration), in which fat accumulates in the hips and gluteal and femoral regions, has milder metabolic complications. The waist-to-hip circumference ratio (WHR) has been used to distinguish these forms of obesity. A ratio greater than 1.0 in men or greater than 0.8 in women, indicative of visceral fat deposition and abdominal obesity, correlates with increased health risks.

Previously, the “gold standard” technique for measuring total body fat was hydrodensitometry (underwater weighing). This is based on the principle that fatty tissue is less dense than muscle. Currently, dual-energy x-ray absorptiometry (DEXA) scanning is used to accurately measure body composition, particularly fat mass and fat-free mass. It has an additional advantage of measuring regional fat distribution. DEXA is more accurate than anthropometric measures and is more cost-effective than computerized tomography (CT) or magnetic resonance imaging (MRI) scans. However, DEXA cannot distinguish between subcutaneous and visceral abdominal fat depots, nor between subcutaneous and intramuscular peripheral fat depots. Bioelectric impedance is a simpler and less expensive method for measuring total body fat, but it is greatly affected by the hydration state of the body and is less accurate overall than DEXA.

BMI is widely used as measure of obesity. It is calculated by dividing a person's body weight in kilograms by the square of the person's height in meters; alternatively, weight in pounds \times 703 is divided by the square of the height in inches). A BMI between 19 and 27 has little association with cardiometabolic risk in whites. Adverse health consequences occur with a BMI

of 27 or more and increase with increasing levels of BMI. Risks associated with increased BMI are more pronounced in older patients.

Waist circumference or WHR or both are often used to indirectly estimate intra-abdominal fat volume in epidemiologic studies. Although these measures show good correlation with intra-abdominal fat volume as measured by CT, they are less accurate than CT. At present, waist circumference is the easiest anthropometric measurement for routine use by health care professionals to estimate visceral adiposity and monitor changes in visceral fat volume.

The current gold standard techniques for measuring visceral fat volume are abdominal CT (at the L4-L5 vertebral level) and MRI. These methods are not widely used because of high cost and radiation exposure. In contrast to CT, MRI requires additional definition of adipose tissue by adjusting settings on the MRI scanner. Several commercial software packages are available for calculation of visceral fat volume, and it is possible to further subdivide body fat into at least three separate and measurable compartments: subcutaneous, intramuscular, and visceral fat.

Visceral fat volume determination by abdominal ultrasonography has been investigated for use in research and clinical settings. Several studies found good correlation between intra-abdominal fat volume measured by abdominal ultrasound and that measured by abdominal CT scanning. Measurements should be performed with the patient in the supine position at the end of a quiet inspiration with compression of the transducer against the abdomen. Intra-abdominal fat is quantified based on the distance between the peritoneum and the lumbar spine. Studies have shown that intra-abdominal fat measured by ultrasound has a stronger association with metabolic risk factors for CAD than does waist circumference or WHR. Recently, visceral fat has been measured using bioelectric impedance, but this technique is less accurate than CT.

TREATMENT OF OBESITY

Current guidelines for treatment of obesity are summarized in Table 67-1. The preferred intervention varies with the obesity level based on five BMI categories. The major four therapeutic options are lifestyle modification (diet and exercise), behavior modification, pharmacologic intervention, and bariatric surgery. In general, better results are obtained with a combination of different interventions rather than a single modality.

Lifestyle Modification

Key components of effective lifestyle modification most often include structured dietary interventions and individualized

physical activity programs. Behavior modification strategies and patient education are also critical for achievement and maintenance of target weight loss. Evidence-based dietary guidelines should be used to design individualized patient plans in consultation with a registered dietitian or qualified health care provider. First, daily caloric intake should be reduced by a modest 250 to 500 calories. Reasonable and paced reductions can help patients continue on the recommended dietary plan for a longer time. Daily calories from carbohydrate should be reduced to approximately 40% to 45% of intake, with a total daily carbohydrate intake of no less than 130 g/day. Except in patients with renal impairment (creatinine clearance <60 mL/min) or significant microalbuminuria, protein intake should not be less than 1.2 g/kg of adjusted body weight (adjusted body weight = ideal body weight + 0.25 [current weight – ideal body weight]). This typically accounts for 20% to 30% of total calorie intake and is intended to minimize loss of lean body mass during weight reduction. The remaining 30% to 35% of calorie intake should come from fat. *Trans*-fats should be eliminated, and saturated fat should be reduced to less than 7% of total calorie intake. Meal plans should also include substantial soluble fiber (e.g., from fresh fruits and vegetables) and consumption of healthy carbohydrates, especially foods that are high in fiber and have a low glycemic index. Approximately 14 g of fiber per 1000 calories (20 to 35 g of fiber) per day is recommended.

Caloric intake should be adjusted downward over time until weight loss is achieved. Underlying all of these steps should be the goal of designing an individualized plan that can be maintained over the long term. Many patients find it helpful to receive a structured dietary intervention that includes specific suggestions for daily meals. Such structured diets may increase adherence and can be easier to follow than a list of general guidelines. Nutritionally complete meal replacement (e.g., in the form of shakes or bars) can be useful for some patients, especially at the start of a weight reduction program. If meal replacement is used, 100- to 200-calorie snacks (e.g., fruits and nuts) may be added at breakfast, lunch, or between meals.

Each patient should meet with an exercise physiologist to construct an individualized plan that is responsive to his or her lifestyles, capabilities, and potential cardiovascular risks. Because obese individuals frequently have difficulty exercising, this process requires careful attention. A balanced exercise plan incorporates a mix of cardiovascular, stretching, and strength exercises and should be graded to increase gradually in both duration and intensity. Patients can start with 10 to 20 minutes of daily stretching and aerobic exercise (e.g., moderate-intensity walking) with subsequent progressive increases. Any exercise

TABLE 67-1 GUIDE TO SELECTING TREATMENT BASED ON BMI CATEGORY*

Pharmacotherapy		Yes with comorbidities	Yes	Yes	Yes
Weight-loss surgery			Yes with comorbidities	Yes with comorbidities	Yes with comorbidities

From National Institutes of Health (NIH), National Heart, Lung, and Blood Institute (NHLBI), North American Association for the Study of Obesity (NAASO): The practical guide to the identification, evaluation, and treatment of overweight and obesity in adults. NIH Publication No. 00-4084, Bethesda, Md., October 2000, NIH. http://www.nhlbi.nih.gov/files/docs/guidelines/prctgd_c.pdf. Accessed November 2014.

*“Yes” indicates that the treatment is indicated regardless of comorbidities.

should be preceded by a warm-up period to minimize injuries.

Long-term lifestyle modification trials, such as the Diabetes Prevention Program, have targeted 150 minutes of exercise per week. Newer guidelines recommend 60 to 90 minutes of daily exercise, with a minimum of 150 to 175 minutes per week needed to obtain weight loss benefit. Emphasis should be placed on moderate-intensity exercise, such as walking 20-minute miles, rather than strenuous exercise. Because patients who are not used to exercising may find it difficult to incorporate physical activity into daily practice, it is also important to use a variety of exercises to maintain interest. Increasing exercise duration to 300 minutes/week was found to help in long-term maintenance of weight reduction. Frequent short bouts of exercise as brief as 10 minutes each can increase adherence to a regimen.

Behavior Modification and Patient Education

Cognitive-behavioral intervention and patient education are important components of successful weight loss programs. Whenever possible, cognitive-behavioral intervention should be conducted by an experienced psychologist. The fundamental principles of intervention typically include behavioral goal setting, stimulus control techniques, cognitive restructuring, assertive communication skills, stress management, and relapse prevention. Cognitive-behavioral support conducted in a group setting with weekly meetings is frequently successful. Patients should learn how to set *SMART* goals (*s*pecific, *m*easurable, *a*ction-oriented, *r*ealistic, *t*ime-limited). It can be helpful to emphasize real-life examples (e.g., success stories, logbook learning, recommitting to progress). The behavioral modification strategy should assist patients in identifying precipitants for deviations from a diet (e.g., timing, types of food or exercise, situations, feelings), overcoming challenges (planning ahead, delay and distraction, problem solving), managing automatic negative thinking (“detour thoughts”), coping with cravings through mindful strategic eating, preventing relapses using logbook learning, navigating social eating, and setting personal weight maintenance plans.

Pharmacologic Options

The four anti-obesity drugs currently licensed for use in the United States are orlistat, phentermine, lorcaserin, and the combination of phentermine and long-acting topiramate. Except for phentermine by itself, the three other medications are approved for long-term management of obesity.

Orlistat

Orlistat limits caloric intake through inhibition of the lipase-mediated breakdown of fat in the gastrointestinal tract. This mechanism results in an approximately 30% reduction of fat absorption and an increase in fecal fat content. In addition to weight loss, orlistat use has been associated with decreased incidence of diabetes, improved concentrations of total cholesterol and low-density lipoprotein (LDL)-cholesterol, and improved blood pressure and glycemic control in patients with diabetes. However, high-density lipoprotein (HDL)-cholesterol has been found to be slightly lowered. Most people develop side effects with variable degrees of diarrhea, flatulence, oily stools, fecal

urgency, and, rarely, fecal incontinence. There also is an increased risk of cholelithiasis. Gastrointestinal side events are usually proportional to the amount of fat intake. Supplemental fat-soluble vitamins A, D, E, and K must be taken to prevent possible deficiencies. The usual dose of orlistat is 120 mg before each meal. A 60 mg dose formulation is currently available over the counter; it is less effective but is also associated with fewer side effects.

Phentermine

Phentermine is approved for short-term treatment of obesity (up to 6 months). Because phentermine has actions similar to amphetamines, it can elevate blood pressure, increase heart rate, and stimulate the central nervous system (frequently causing insomnia), in addition to suppressing the appetite. The recommended phentermine dose is 30 mg once daily. Combining phentermine with tricyclic antidepressants or monoamine oxidase inhibitors may result in substantial increases in blood pressure and other serious reactions because of elevated serotonin levels in the blood.

Lorcaserin

Lorcaserin is a selective serotonin (5-hydroxytryptamine) receptor agonist with specificity for the 5-HT_{2C} receptor subtype. The activation of these receptors in the hypothalamus is thought to activate production of proopiomelanocortin (POMC) and, consequently, to promote weight loss through satiety signals. Lorcaserin has 100-fold higher selectivity for 5-HT_{2C} versus the closely related 5-HT_{2B} receptor. Activation of the 5-HT_{2B} receptor by the less selective agents fenfluramine and dexfenfluramine previously was linked to serious cardiac valvulopathy, but there is no evidence for this adverse effect with lorcaserin. Clinical trials showed that 47.5% of patients treated with lorcaserin lost at least 5% of their initial body weight, and 22.6% lost at least 10%, in 1 year. Lorcaserin treatment also resulted in significantly lower glycosylated hemoglobin (HbA_{1c}) values in patients with T2DM and improved lipid profile and decreased blood pressure in clinical studies.

Lorcaserin is approved for use as an adjunct to a reduced-calorie diet and exercise for chronic weight management in patients with initial BMI values of 30 kg/m² or higher and in those with BMI values of 27 kg/m² or higher with at least one weight-related comorbid condition (e.g., hypertension, dyslipidemia, T2DM). It is given in a dose of 10 mg twice daily. Side effects usually are mild to moderate, with the most common being headache, upper respiratory tract infection, nasopharyngitis, sinusitis, dizziness, nausea, and fatigue. The U.S. Drug Enforcement Administration has classified lorcaserin as a schedule IV drug because it has hallucinogenic properties that could lead to psychiatric complications.

Phentermine and Long-Acting Topiramate

Phentermine is an appetite suppressant and stimulant of the amphetamine and phenethylamine class (see earlier discussion for details on the use of phentermine alone for weight reduction). Topiramate is an anticonvulsant that was found to have weight loss side effects. The combination of phentermine plus low doses of topiramate has been shown to have synergistic effects on weight loss. As with lorcaserin, this combination tablet is

indicated as an adjunct to a reduced-calorie diet and exercise for chronic weight management. Clinical trials showed that average weight loss after 1 year of 10.9% for patients receiving the maximum dose (phentermine/topiramate, 15 mg/92 mg) and 5.1% for those taking the recommended starting dose (3.75 mg/23 mg). The drug is taken once daily in the morning to avoid insomnia caused by the phentermine component. The initial dose of 3.75 mg/23 mg is given for 2 weeks before titration to 7.5 mg/46 mg for another 12 weeks. If a patient has not lost at least 3% of baseline body weight on the higher dosage, the drug may be discontinued or the dose may be escalated to 11.25 mg/69 mg for an additional 2 weeks before a further increase to the maximum dose of 15 mg/92 mg. If a patient has not lost at least 5% of baseline body weight after 12 weeks, the drug is discontinued gradually. Side effects include paresthesias, dry mouth, constipation, metabolic acidosis, nasopharyngitis, upper respiratory infection, and headache.

Data indicate that fetuses exposed during the first trimester to topiramate (when used alone as an anticonvulsant) have an increased risk (9.6%) of cleft lip with or without cleft palate. Therefore, the drug should not be given to women of child-bearing age unless an effective method of contraception is used and a pregnancy test is conducted monthly during use. Phentermine/topiramate may increase resting heart rate up to 20 beats/minute, so the drug should be used cautiously in patients with a history of cardiac or cerebrovascular disease. Topiramate also increases the risk of suicidal thoughts or behaviors and mood disorders including depression, anxiety, and insomnia. It can also cause cognitive dysfunction, including impairment of concentration or attention, difficulty with memory, and speech or language problems, particularly word-finding difficulties. It is contraindicated in patients with closed-angle glaucoma because it increases intraocular pressure and the risk of permanent loss of vision.

Contrave is a combination of Bupropion and Naltrexone just approved by the FDA for weight loss (Medical Letter November 10, 2014).

Bariatric Surgery

At present, there are three broad categories of bariatric surgical procedures: (1) pure gastric restriction; (2) gastric restriction with some malabsorption, as represented by the Roux-en-Y gastric bypass (RYGB) procedure; and (3) gastric restriction with significant intestinal malabsorption (discussed later). The

number of bariatric procedures performed in the United States increased from an estimated 13,365 in 1998 to almost 220,000 in 2008. Bariatric surgery is considered to be indicated for adults with class 3 obesity (BMI ≥ 40 kg/m²). In patients with less severe obesity (BMI 35 to 40 kg/m²), bariatric surgery can be considered if there are one or more high-risk comorbid conditions present, such as life-threatening cardiopulmonary disease (e.g., severe sleep apnea, obesity-related cardiomyopathy) or uncontrolled T2DM. Bariatric surgery is sometimes performed for patients with diabetes or metabolic syndrome and a BMI of 30 to 35 kg/m², although current evidence on benefit is limited. For teenagers younger than 17 years old who have attained skeletal maturity (usually by 13 years for girls and 15 years for boys), bariatric surgery has been recommended with different guidelines: BMI 35 to 40 kg/m² with at least one serious comorbid condition (e.g., T2DM, obstructive sleep apnea, pseudotumor cerebri) or BMI 50 kg/m² or higher with less serious comorbidities. Contraindications for bariatric surgery include high operative risk (e.g., congestive heart failure, unstable angina), active substance abuse, and significant psychopathology.

Different types of commonly used bariatric procedures are shown in Figure 67-1. Gastric restriction procedures induce weight loss by producing early satiety and limiting food intake. Gastric restriction by vertical banded gastroplasty (VBG) typically limits the volume of the upper gastric pouch into which the esophagus empties to 15 to 45 mL and restricts the pouch outlet to the remaining stomach to 10 to 11 mL. Currently, the laparoscopic adjustable gastric band (LAGB) has almost completely replaced the VBG procedure, because it is less invasive, adjustable, and reversible and has better outcomes.

LAGB is associated with substantially better maintenance of weight loss than lifestyle intervention alone, and it carries a very low operative mortality rate (0.1%). However, it is associated with significantly lower loss of excess weight at 5 years and 10 years and with smaller reductions in fat-free mass compared with RYGB. LAGB has been demonstrated to be safe in patients older than 55 years of age. Complications associated with the LAGB procedure include band slippage, band erosion, balloon failure, injection port malposition, band and port infections, and esophageal dilatation. Some of these problems have been decreased by use of a different method of band insertion and revision of the port connection. Overall, complication and

FIGURE 67-1 Common bariatric procedures. BPD, Biliopancreatic diversion; VBG, Vertical banded gastroplasty; LAGB, laparoscopic adjustable gastric band; RYGB, Roux-en-Y gastric bypass; SLG, sleeve gastrectomy; BPD, biliopancreatic diversion; BPD/DS, BPD with duodenal switch.

mortality rates are much lower for LAGB than for RYGB. Nevertheless, RYGB is currently the most commonly performed bariatric procedure in the United States because it achieves greater weight loss.

In RYGB, the upper stomach is transected, thereby creating a very small proximal gastric pouch measuring 10 to 30 mL. The gastric pouch is anastomosed to a Roux-en-Y proximal jejunal segment, bypassing the remaining stomach, duodenum, and a small portion of jejunum. The standard Roux (alimentary) limb length is about 50 to 100 cm, and the biliopancreatic limb is 15 to 50 cm. As a result, the RYGB serves to limit food intake and induces some nutrient malabsorption.

Sleeve gastrectomy (SLG) is another restrictive surgery in which the stomach is reduced to about 25% of its original size by surgical removal of a large portion of the stomach fundus, resulting in a tube-like structure. Although the procedure permanently reduces stomach size, some dilatation of the stomach may occur later. The procedure is frequently performed by a laparoscopic technique. Because it has low operative risk, the use of sleeve gastrectomy currently is increasing more rapidly than other types of bariatric surgery. Other procedures, including biliopancreatic diversion (BPD), biliopancreatic diversion with duodenal switch (BPD/DS), and staged bariatric surgical procedures, are less commonly performed.

There is a need for more data to guide the choice of bariatric procedures for individual patients. Most procedures currently are being performed laparoscopically. This approach has the advantages of fewer wound complications, less postoperative pain, a shorter hospital stay, and more rapid postoperative recovery with comparable efficacy. However, these advantages may be offset by more frequent complications associated with techniques used for laparoscopic gastrojejunostomy creation, anastomotic strictures, and higher rates of postoperative bowel obstructions.

The Agency for Healthcare Research and Quality (AHRQ) identified a 0.19% in-hospital mortality rate for all bariatric discharges in the United States. A recent meta-analysis showed that mortality rate from bariatric surgery within 30 days was 0.08% and the mortality rate after 30 days was 0.31%. Bariatric surgery is not uniformly a “low-risk” procedure, and judicious patient selection and diligent perioperative care are mandatory. Preoperative patient selection and education as well as careful postsurgical follow-up are important for successful outcomes.

The benefits of bariatric surgery extend beyond calorie restriction and weight loss. Foregut bypass leads to improvement in the physiologic responses of gut hormones involved in glucose regulation and appetite control, including ghrelin, glucagon-like peptide-1 (GLP-1) and peptide YY³⁻³⁶ (PYY). Mechanical improvements include less weight-bearing burden on joints, improved lung compliance, and reduced fatty tissue around the neck, which can relieve obstruction to breathing and sleep apnea.

In an extensive meta-analysis of 22,000 bariatric surgeries, patients lost on average 61% of excess body weight and exhibited improvements in T2DM, hypertension, sleep apnea, and dyslipidemia. The beneficial effect of obesity surgery on T2DM is one of the most important outcomes observed, with gastric bypass and malabsorptive procedures having the greatest impact. A shorter duration of diabetes and greater weight loss are independent predictors of diabetes remission after bariatric surgery.

Improvements in fasting blood glucose levels occur before significant weight loss is achieved. Insulin-treated patients experience significant decreases in insulin requirements, and most T2DM patients are able to discontinue insulin therapy by 6 weeks after surgery. Euglycemia is maintained in some patients for up to 14 years after RYGB. Two recent randomized controlled studies compared RYGB to intensive lifestyle intervention in moderately obese patients with T2DM and found RYGB to be superior in inducing diabetes remission and reducing use of antihyperglycemic medications.

Weight loss after malabsorptive bariatric surgery usually reaches a nadir after 12 to 18 months. Over the following decade, there is weight regain of approximately 10% of body weight. Weight loss is more gradual for the restrictive LAGB procedure and may continue for several years. In purely restrictive procedures, failure to experience optimal weight loss has been associated with consumption of calorically dense liquids that can pass through the stoma without producing satiety.

PROGNOSIS

Although recent clinical data show that patients on average can maintain a 4% to 5% weight loss for 10 years with ongoing medically supervised intensive lifestyle intervention, many patients are subjected to less intensive intervention and regain their initial weight loss over months or years. Weight regain even after bariatric surgery is not uncommon and most often occurs after 2 years of peak weight loss. Loss of 10% to 20% of the initial body weight is associated with a decrease in total and resting energy expenditure, a change that retards further weight loss. Similarly, weight gain is associated with an increase in energy expenditure, which retards further weight gain. These observations suggest that the human body adopts a biologic set point or mechanism that tends to maintain body weight, and they lend support to the theory that behavior is not the sole determinant of obesity. Although long-term intensive lifestyle intervention in obese patients with T2DM resulting in approximately 5% body weight loss can significantly decrease the risks of chronic kidney disease and depression and further improve glucose control, blood pressure, physical fitness, and some lipid parameters, it has not been shown to reduce cardiovascular events or mortality. Further understanding of genetic and hormonal regulation of obesity may help researchers create more effective and long-lasting interventional tools.

Malnutrition, Nutritional Assessment, and Nutritional Support in Hospitalized Adults

Thomas R. Ziegler

MALNUTRITION IN HOSPITALIZED PATIENTS

Numerous surveys conducted in developed countries in the 21st century continue to demonstrate the frequent rate of protein-energy malnutrition as well as depletion of specific micronutrients in patients with chronic illnesses and those requiring elective or emergent hospital admission. Hospitalized patients commonly receive inadequate amounts of calories, protein, vitamins, and minerals during their stay, and ad libitum intake of prescribed diets is typically inadequate. Studies have shown that worsening of malnutrition during hospitalization is common. This is problematic, because adequate intake of essential macronutrients (energy, carbohydrate, protein/amino acids, and fats) and micronutrients (vitamins, minerals, and electrolytes) is critical for optimal cellular and organ structure and function, muscle mass, tissue repair, immune function, ambulatory capacity, and patient recovery. Significant erosion of lean body mass (predominately derived from skeletal muscle) and deficiencies of specific vitamins and minerals are variously associated with weakness and fatigue, increased rates of infection, impaired wound healing, and delayed convalescence. This relationship is especially apparent in patients with chronic protein-energy malnutrition and body weight loss associated with illness.

Patients with acute or chronic illnesses typically have experienced several days to several months of continuous or intermittent decreased food intake due to anorexia, gastrointestinal symptoms, depression and anxiety, and other medical factors. They may also have had food intake restricted by surgical operations or diagnostic or therapeutic procedures and recovery from these. Some patients have abnormal nutrient losses due to diarrhea (e.g., with chronic malabsorptive and maldigestive disorders or infectious diarrhea), vomiting, polyuria (as in uncontrolled diabetes mellitus), wound drainage, dialysis, or other causes. Certain drugs, including corticosteroids, chemotherapeutic agents, antirejection drugs, and diuretics, are associated with skeletal muscle breakdown, gastrointestinal injury, or loss of electrolytes or water-soluble vitamins. Bedrest or markedly decreased ambulation are common in outpatient and inpatient settings and are associated with skeletal muscle wasting and impaired protein synthesis.

Catabolic and critical illnesses are associated with concomitantly increased blood concentrations of “counterregulatory” hormones derived from the adrenal glands and pancreas (e.g., cortisol, catecholamines, glucagon); release of pro-inflammatory cytokines from stimulated immune, endothelial, and epithelial cells, such as interleukins (e.g., IL-1, IL-6, IL-8) and tumor necrosis factor- α (TNF- α); and peripheral tissue resistance to anabolic hormones such as insulin and insulin-like growth factor-I (IGF-I). These hormonal and cytokine alterations increase the availability of endogenous metabolic substrates that are critical for cellular and organ function, wound healing, and host survival (e.g., glucose via glycogenolysis and gluconeogenesis, amino acids via skeletal muscle breakdown, and free fatty acids via lipolysis). This combination of decreased nutrient intake and increased tissue nutrient losses (from the actions of these hormones and cytokines), coupled with increased energy (calorie), protein, and micronutrient needs due to inflammation, infection, and cytokinemia, is responsible for the wasting and micronutrient depletion commonly observed in medical patients with acute and chronic illnesses. Common causes of protein-energy malnutrition and micronutrient depletion in medical patients are shown in [Table 68-1](#). Obesity has become a widespread medical problem and is also a form of malnutrition; it is considered in detail in [Chapter 67](#).

NUTRITIONAL ASSESSMENT

Serial assessment of nutritional status is a critically important component of routine medical care. The major objectives are to detect preexisting depletion of body protein, energy reserves, and micronutrients; to identify risk factors for malnutrition (see [Table 68-1](#)); and to take steps to prevent nutrient deficiencies, depletion of lean body mass, and loss of skeletal muscle. There are still no practical “gold standard” tests that can provide an index of general nutritional status. Blood concentrations of specific micronutrients (e.g., copper, zinc, thiamine, 25-hydroxyvitamin D, vitamin B₆, folate, vitamin B₁₂) and electrolytes (e.g., magnesium, potassium, phosphorus) are important to guide needs and repletion responses. Nutritional assessment involves an integration of multiple factors, including the patient’s medical and surgical history, type and severity of the acute or chronic underlying illness and its anticipated

TABLE 68-1 COMMON CAUSES OF PROTEIN-ENERGY MALNUTRITION AND MICRONUTRIENT DEPLETION IN MEDICAL PATIENTS WITH ACUTE OR CHRONIC ILLNESSES

- Decreased spontaneous food intake due to anorexia from chronic or acute illness, gastrointestinal symptoms (e.g., nausea, vomiting, abdominal pain), or depression and anxiety
- Restricted food intake required for surgical operations or diagnostic or therapeutic procedures and gastrointestinal dysfunction after these procedures
- Abnormal macronutrient and micronutrient losses from the body due to malabsorption (e.g., celiac sprue, short gut syndrome, inflammatory bowel disease, cystic fibrosis, diarrhea), maldigestion (e.g., pancreatitis), emesis, polyuria (e.g., in diabetes), wound drainage, or renal replacement therapy
- Periods of increased energy expenditure (caloric needs), protein requirements, and micronutrient needs (e.g., critical illness, increased inflammation)
- Catabolic effects of counterregulatory hormones (e.g., cortisol, catecholamines, glucagon), release of pro-inflammatory cytokines from stimulated immune cells and endothelial and epithelial cells such as interleukins (e.g., IL-1, IL-6, IL-8) and tumor necrosis factor- α (TNF- α), and peripheral tissue resistance to the anabolic hormones insulin and insulin-like growth factor-I (IGF-I).
- Bedrest, decreased ambulation, and chemical paralysis during mechanical ventilation (skeletal muscle wasting due to impaired protein synthesis)
- Administration of drugs that induce skeletal muscle breakdown, gastrointestinal injury, or loss of electrolytes and water-soluble vitamins (e.g., corticosteroids, chemotherapeutic agents, diuretics, antirejection regimens)
- Socioeconomic deprivation, inadequate caregivers, ambulation difficulties in the home setting
- Inadequate provision of calories, protein, and essential micronutrients (vitamins, minerals, trace elements) during hospitalization

medical and surgical course, fluid drainage sites and amounts, physical examination findings, history of body weight change (degree and temporal aspects), dietary intake pattern, use of nutritional supplements including prior administration of specialized enteral nutrition (EN) or parenteral nutrition (PN), evaluation of current organ function and fluid status, and determination of selected vitamin, mineral, and electrolyte concentrations in blood (E-Table 68-1). In the intensive care unit (ICU) setting, measured body weight typically reflects recent intravenous fluid administration and is typically much higher than recent “dry” or preoperative body weight, which is the best parameter to use.

Integration of the factors outlined in E-Table 68-1 provides important information on whether patients are likely to be adequately nourished; to have mild, moderate, or severe protein-energy malnutrition; or to have depletion or deficiency of specific vitamins, minerals, or electrolytes. Patients who have experienced an involuntary body weight loss of 5% to 10% or more of their usual body weight in the previous few weeks or months, those who weigh less than 90% of their ideal body weight (IBW), and those who have a body mass index (BMI) lower than 18.5 kg/m² should be carefully evaluated, because these individuals are likely to be malnourished.

Among hospitalized patients, especially those in the ICU, circulating concentrations of proteins (e.g., albumin, prealbumin) are often quite low and not useful as protein nutritional status biomarkers given their lack of specificity. Plasma concentrations of albumin and prealbumin typically fall during active inflammation or infection, in critical illness, and after traumatic injury (due to decreased synthesis by the liver and catabolism of blood proteins). They are markedly affected by non-nutritional factors,

including fluid status, capillary leak, decreased hepatic synthesis, and increased clearance from blood. Because of the long circulating half-life of albumin (18 to 21 days), concentrations in blood remain low despite adequate feeding and are slow to respond to nutritional repletion, irrespective of other confounding factors. Prealbumin has a much shorter circulating half-life (several days), and serial blood levels can be used as a general indicator of protein status in clinically stable outpatients. E-Table 68-2 illustrates physical examination findings that may be observed in associated with depletion of specific nutrients.

Energy requirements can be estimated with the use of standard equations, such as the Harris-Benedict equation, which incorporate the patient’s age, gender, weight, and height to determine basal energy expenditure (BEE) (see E-Table 68-1). Physical activity and the thermic effect of macronutrient administration can be added to the BEE to arrive at the energy prescription to maintain current body weight; for most hospitalized patients and outpatients, this is estimated as 1.2 to 1.3 times the BEE, unless energy needs are decreased because the patient is sedated or on bedrest (common in the ICU). The estimated maintenance energy requirement is approximately 1.3 times BEE in ambulatory subjects. Typically, lower amounts of calories are now given in ICU patients (as discussed later). Use of data obtained from a bedside metabolic cart machine (indirect calorimeter), which measures expired breath to determine oxygen consumption and carbon dioxide production, provides accurate actual energy expenditure in most settings and can be very useful (see E-Table 68-1).

A simple and relatively accurate method to estimate energy needs is simply to use 20 to 25 kcal/day per kilogram of actual weight, dry weight, or IBW in most patients. Values for IBW are obtained from standard tables or equations. This estimation assumes that the body weight used does not reflect intravenous fluid administration or capillary leak syndromes (discussed earlier). In ICU patients, even lower caloric doses (equivalent to 15-20 kcal/kg dry weight/day) have been advocated by some, based on known complications of overfeeding (see later discussion) and limited data on clinical outcome as a function of energy dose. In clinically stable, malnourished, non-ICU patients who require nutritional repletion, higher doses of calories (up to 35 kcal/kg/day) appear to be generally well tolerated if refeeding syndrome is avoided (see later discussion). In obese subjects (defined for these calculations as patients with body weight >20% to 25% greater than ideal), an adjusted body weight value should be used for calculation of energy and protein needs, as determined by the following equation:

$$\text{Adjusted body weight} = (\text{current weight} - \text{IBW}) \times 0.25 + \text{IBW}$$

Guidelines for protein or amino acid administration are given in E-Table 68-3. Studies in nonburned ICU patients indicate that protein loads of more than 2.0 g/kg/day are not efficiently utilized for protein synthesis, and the excess may be oxidized, contributing to azotemia. In most catabolic patients requiring specialized feeding, a recommended protein dose is 1.5 g/kg/day for individuals with normal renal function. This is about twice the recommended dietary allowance (RDA) for healthy adults of 0.8 g/kg/day. The administered protein dose should be adjusted downward as a function of the degree and tempo of azotemia (in the absence of dialysis therapy) and of hyperbilirubinemia (see

E-TABLE 68-1 COMPREHENSIVE NUTRITIONAL ASSESSMENT OF MEDICAL AND SURGICAL PATIENTS

1. Review past medical and surgical history and current illness
 - a. Degree of catabolic stress (e.g., fever, infections, sepsis, surgeries, lung failure)
 - b. Organ function (e.g., liver, kidneys, lung, heart/vascular, GI)
 - c. Use of medications that may decrease nutrient absorption (e.g., phenytoin, sulfasalazine, elixir-based medications), alter metabolism or utilization (e.g., warfarin, isoniazid, methotrexate), or increase excretion (e.g., gentamicin, loop diuretics)
 - d. Recent intravenous fluid and electrolyte therapy
 - e. Medical and surgical procedures that are likely in the near term
 - f. Hemodynamic status and requirements for pressor agents to maintain blood pressure
2. Obtain body weight history
 - a. Current body weight (dry weight if available preoperatively or from a recent clinic visit) + usual body weight when healthy or clinically stable; calculate % body weight loss from usual body weight over the last several weeks or months
 - b. Calculate current weight as % of ideal body weight*
 - c. Determine BMI (weight in kg divided by square of height in m); BMI <18.5 is considered underweight
3. Determine dietary intake pattern in relation to nutrient needs
 - a. General food and beverage intake pattern, % of usual dietary intake consumed in recent weeks and months, unusual or excessive consumption of specific foods or beverages (including alcoholic beverages)
 - b. Previous use and type of enteral tube feedings or parenteral nutritional support
 - c. Previous use of liquid or solid nutritional supplements, multivitamin-multimineral preparations, specific vitamins or minerals
 - d. Consult registered dietitian for more detailed nutrient intake assessment
4. Perform detailed physical examination
 - a. Skeletal muscle wasting (cannot be assessed accurately in overweight or obese patients)
 - b. Loss of body fat stores
 - c. Presence and qualities of wounds
 - d. Skin, hair, tongue, and conjunctival lesions suggestive of micronutrient deficiency (see E-Table 68-2)
 - e. Evidence of organ dysfunction (GI, liver, renal, cardiopulmonary)
 - f. Fluid status (e.g., normal, dehydrated, fluid overload, capillary leak); daily fluid requirements are typically 30-40 mL/kg body weight
5. Evaluate GI tract function
 - a. Swallowing or chewing difficulties, nausea, emesis, abdominal pain
 - b. Intestinal ileus, motility disorders, partial or complete obstruction
 - c. Diarrhea history (frequency, amount, other characteristics)
 - d. Acute or chronic GI bleeding
 - e. Presence of fistulas; history of recent abdominal surgery
 - f. Drainage tube losses (e.g., gastric, biliary, intestinal, peritoneal)
6. Determine functional status
 - a. Ability to perform daily activities, ambulatory capacity, bedrest, chemical paralysis
 - b. History or physical examination evidence of muscle weakness and fatigue
 - c. Mental capacity, history of psychiatric disorders that may preclude oral food intake
7. Serial evaluation of selected biochemical tests
 - a. Standard blood measures of organ function
 - b. Electrolyte concentrations (e.g., calcium, magnesium, phosphorus, potassium)
 - c. Blood pH (in ICU patients on mechanical ventilation)
 - d. Blood triglyceride concentrations (in patients receiving intravenous lipid emulsion)
 - e. Blood concentrations of selected vitamins and minerals if suggested by medical or dietary history, physical examination, or underlying illness (e.g., zinc, selenium, copper, thiamine, vitamin B₆, vitamin B₁₂, folate, 25-hydroxyvitamin D, iron, ferritin)
 - f. Serum prealbumin (in stable outpatients)[†]
8. Estimate caloric (kcal), protein and micronutrient needs
 - a. Caloric needs are based on the Harris-Benedict equation[‡], guidelines on kcal/kg body weight[§], or indirect calorimetry results (use serially in ICU patients and in the initial assessment of very underweight or obese hospital patients requiring prolonged nutritional support)
 - b. Protein needs vary as a function of recognized clinical situations (see E-Table 68-3)
 - c. Vitamin and mineral needs are based on conventional requirements, serial blood levels, and clinical judgment regarding intake and estimated losses from comprehensive nutritional assessment
 - d. Nitrogen balance studies are not useful in nonresearch settings because of their variability and inaccuracy
 - e. Serial body composition measurements for lean body mass and body fat estimates may be useful in the outpatient setting (by BIA or DEXA) but are not practical or reliable in inpatient nonresearch settings because of fluid shifts and other factors
9. Evaluate enteral and parenteral access for nutrient delivery
 - a. Ability to take oral diet and/or liquid supplements
 - b. Central venous or PICC line access; peripheral line access
 - c. Nasogastric, nasoenteric, or percutaneous feeding tube availability or feasibility
10. Consultation with multidisciplinary nutrition support team

BIA, Bioelectrical impedance analysis; BMI, body mass index; DEXA, dual energy x-ray absorptiometry; GI, gastrointestinal; ICU, intensive care unit; PICC, peripherally inserted central venous catheter.

*Ideal body weight can be estimated in men as 48 kg (106 lb) per 5 ft of height + 2.7 kg (6 lb) for each inch of height above 5 ft and in women as 45 kg (100 lb) per 5 ft of height + 2.3 kg (5 lb) for each inch of height above 5 ft.

[†]Blood concentrations of albumin and prealbumin in hospitalized patients, especially in the ICU setting, are markedly affected by non-nutritional factors (e.g., inflammation, infection, fluid status, capillary leak, decreased hepatic synthesis, increased clearance from blood).

[‡]Harris-Benedict equation to estimate basal energy expenditure (BEE) in kcal/24 hr: for males, BEE = 66.5 + (13.8 × kg body weight) + (5.0 × height in cm) - (6.8 × age in years); for females, BEE = 655 + (9.6 × kg body weight) + (1.8 × height in cm) - (4.7 × age in years).

[§]Caloric needs can also be estimated as follows (using dry weight or ideal body weight in ICU patients with fluid overload): in ICU settings, 20-25 kcal/kg/day (some studies suggest that 15-20 kcal/kg/day or lower may be appropriate); in non-ICU settings, 25-35 kcal/kg/day.

E-TABLE 68-2 CLINICAL MANIFESTATIONS OF SPECIFIC NUTRIENT DEFICIENCIES

SIGN OR SYMPTOM OF NUTRIENT DEPLETION*	SPECIFIC NUTRIENTS DEPLETED
Muscle and fat wasting, weakness	Calories, protein, combined calories + protein
Anorexia	Calories, protein
Glossitis (discolored, smooth, painful tongue)	Folate, vitamin B ₁₂ , niacin, riboflavin, thiamine, iron
Cheliosis, angular stomatitis	Riboflavin, niacin, folate, vitamin B ₁₂
Symmetrical motor/sensory dysfunction, ataxia, nystagmus, heart failure, mental status changes or confusion	Thiamine (beriberi)
Peripheral edema	Thiamine (heart failure), protein (low oncotic pressure)
Loss of vibratory or position sense, fatigue	Vitamin B ₁₂
Dermatitis (sun-exposed skin), diarrhea, dementia	Niacin (pellagra)
Bleeding gums, petechiae, ecchymosis	Vitamins C and K
Poor wound healing	Calories, protein, calories + protein, vitamin C, vitamin A, zinc, others
Bone pain	Vitamin D (osteomalacia)
Follicular hyperkeratosis, night blindness, Bitot's spots	Vitamin A
Flaky, whitish dermatitis	Essential fatty acid (linoleic, α -linolenic)
Hair sparse or easily pluckable	Zinc, protein
Pale skin, nail spooning (koilonychia)	Iron
Loss of taste; reddish dermatitis around nose, mouth, groin; hair loss	Zinc
Peripheral neuropathies, gait abnormalities, weakness, fatigue	Copper
Muscle pain, heart failure, Paresthesias, carpal pedal spasm	Selenium Calcium, magnesium, phosphorus, or potassium

*Typically, severe deficiency of specific nutrients (with depletion initially in tissue and later in blood) has occurred before physical manifestations of deficiency are evident.

E-TABLE 68-3 ESTIMATION OF PROTEIN OR AMINO ACID REQUIREMENTS IN ADULT PATIENTS

CLINICAL CONDITION	PROTEIN OR AMINO ACID DOSE (g/kg/day)*
Well-nourished with acute illness	1.2-1.5
Malnourished and/or severe catabolic stress	1.5-1.8
Postoperative	1.2-1.5
Hepatic failure	0.6-1.2
Encephalopathy	0-0.6
Acute renal failure, not on renal replacement therapy	0.6-0.8
Renal failure, on renal replacement therapy	1.2-2.5

*Oral/enteral nutrient supplements and tube feedings contain either intact or partially hydrolyzed high-quality protein (typically casein, soy, and/or whey). Parenteral nutrition solutions for peripheral or central vein administration provide known essential L-amino acids combined with several nonessential amino acids. These may be limiting in certain conditionally essential amino acids (e.g., cysteine, taurine) in some clinical conditions.

E-Table 68-3). These strategies take into account the relative inability of catabolic patients to efficiently utilize exogenous nutrients and knowledge that most protein and lean tissue repletion occurs over a period of several weeks to months during post-hospital convalescence. Adequate nonprotein energy is essential to allow amino acids to be effectively used for protein synthesis and not oxidized for production of energy (adenosine triphosphate, or ATP). The ratio of nonprotein calories to nitrogen used in most centers typically ranges from 75:1 to 125:1. Because nitrogen = protein/6.25, this equates to 75 to 125 nonprotein kilocalories for each 6.25 g of protein or amino acid administered.

NUTRITIONAL SUPPORT

Table 68-2 lists common clinical scenarios in which specialized oral/EN or PN support may be indicated. In these settings, consultation with a multidisciplinary nutrition support team, if available, has been shown to reduce complications and costs and to increase the appropriate use of EN and PN in both academic and community medical centers.

Oral Nutrition Support

Oral nutrition supplementation includes provision of balanced oral diets of usual foods supplemented with complete liquid (or solid) nutrient products, protein supplements (e.g., hydrolyzed whey or casein powder that can be mixed with dietary beverages), high-potency multivitamin-multimineral supplements, and/or specific micronutrients required to treat a diagnosed deficiency (e.g., zinc, copper, vitamin B₆, vitamin B₁₂, vitamin D). Special supplements designed for patients with chronic renal failure (featuring concentrated calories and low amounts of protein and electrolytes) are available, as are a variety of formulations designed for other specific disease categories (see later discussion). Several studies have shown that convalescence after stresses such as total hip replacement or gastrointestinal surgery

is enhanced with the addition of one or two containers per day of complete liquid nutrient supplements. These provide calories, carbohydrate, high-quality protein, fat, and micronutrients; are lactose and gluten free; and may contain small peptides and medium-chain triglycerides to facilitate absorption of amino acid and fat, respectively. Some formulations also contain soluble fiber or prebiotics (e.g., fructo-oligosaccharides) designed to decrease diarrhea. It is probably prudent to place outpatients who exhibit or are at risk for undernutrition (see E-Tables 68-1 and 68-2) and can tolerate oral medications on a potent oral multivitamin-multimineral preparation, at least for several months.

Administration of Enteral Tube Feeding

Patients with conditions outlined in Table 68-2 may have a functional gastrointestinal tract and yet be unable to consume adequate diet orally due to medical or surgical conditions (e.g., mechanically ventilation, pancreatitis, dementia, dysphagia, trauma or burns). Although PN is commonly administered in these settings, this practice is not evidence based; academic guidelines strongly suggest that oral nutritional supplements or enteral tube feedings should be used if specialized nutrition support is indicated in patients with a functional gastrointestinal tract ("if the gut works, use it"). E-Table 68-4 shows major characteristics of common complete liquid tube feeding formulations and the types of patients for which these are typically prescribed. These products can be used for oral nutrient supplementation as tolerated. When delivered in appropriate amounts, the liquid diets provide complete nutrition for most patients, although some ICU patients and patients with malabsorption or other conditions may have special needs (see later discussion).

The feedings can be delivered by conventional nasogastric tubes into the stomach or by small-bore nasogastric or nasojejunal tubes, percutaneous gastrostomy or jejunostomy tubes, or percutaneous gastrojejunostomy tubes (in which the gastric port may be used for suction and the jejunal port for feeding). Gastric feedings can be administered by either continuous or bolus feeds, whereas small bowel feeds must employ a continuous slow infusion using an infusion pump to avoid diarrhea. Tube feedings should be initiated at a slow rate (e.g., 10 to 20 mL/hour) for 8 to 24 hours and slowly advanced to the goal rate in 8- to 24-hour increments to deliver the calculated caloric and protein needs over the next 24 to 48 hours, depending on clinical tolerance and clinical conditions. Recent guidelines emphasize placing tube-fed patients in the semirecumbent position (e.g., increase head of bed), advancing feedings cautiously (with serial evaluations for diarrhea, nausea, emesis, abdominal distention, and significant gastric residuals), and using prokinetic agents and/or postpyloric feedings if gastric feedings are not well tolerated. Recent data suggest that higher volumes of gastric residuals (e.g., >250 mL) are usually well tolerated in patients being tube fed.

Primarily based on results of animal studies, EN is associated with improved gut barrier function, decreased infectious complications, less hypermetabolism, and decreased morbidity and mortality in catabolic models, compared with PN. Salutory clinical outcomes have been shown in randomized clinical trials in patients with pancreatitis receiving EN into the jejunum, compared with PN. Based on available data, recent guidelines for ICU patients by international expert panels and academic societies suggest that enteral tube feeds should be started within 1 to 3

TABLE 68-2 SOME CLINICAL INDICATIONS FOR SPECIALIZED ORAL/ENTERAL OR PARENTERAL NUTRITION SUPPORT

Patient currently exhibits moderate to severe protein or protein-energy malnutrition or has evidence of specific deficiency of one or more essential micronutrients
Patient with involuntary body weight loss of 5-10% or more of their usual body weight in the previous few weeks or months, weighs less than 90% of ideal body weight, or has a BMI lower than 18.5 kg/m ² .
Dietary food intake in a hospital or outpatient setting likely to be <50% of needs for more than 5-10 days due to underlying illness
Patient with severe catabolic stress (e.g., ICU care, serious infection) and adequate nutrient intake unlikely for >3-5 days.
After major gastrointestinal surgery or other major operation (e.g., hip replacement, partial organ resection)
Medical illness associated with prolonged (>5-10 days) GI dysfunction (diarrhea, nausea and vomiting, GI bleeding, severe ileus, partial obstruction) and/or short bowel syndrome, chronic or severe diarrhea, or other malabsorptive disorders
Clinical settings in which adequate oral food intake may be contraindicated or otherwise significantly decreased, such as respiratory or other acute or severe organ failure, dementia, dysphagia, chemotherapy or irradiation, inflammatory bowel disease, pancreatitis, high-output enterocutaneous fistula, alcoholism, drug addiction
Chronic obstructive lung disease, chronic infection, or other chronic inflammatory or catabolic disorders with documented poor nutrient intake and/or recent weight loss

BMI, Body mass index; GI, gastrointestinal; ICU, intensive care unit; PN, parenteral nutrition.

E-TABLE 68-4 COMPLETE ENTERAL NUTRIENT FORMULAS AND CLINICAL INDICATIONS

FORMULA TYPE AND CHARACTERISTICS*	CLINICAL INDICATION
Intact protein, complex ¹	Normal intestinal function
Hydrolyzed protein/peptides, semi-elemental ¹	Gut mucosal disease, injury
High calories, lower protein, lower electrolytes ²	Renal failure
High calories, complex ²	Fluid restriction (e.g., cardiac failure)
“Immune-modulating” enriched in arginine, glutamine, nucleotides, omega-3 fatty acids, and/or antioxidants ^{3,5}	Postoperative, immunosuppressed, severe stress, injury, gut mucosal disease
EPA, γ -linolenic acid, and antioxidants ⁷	ARDS

ARDS, Acute respiratory distress syndrome; EPA, eicosapentanoic acid; MCT, medium-chain triglycerides.

*All formulations are lactose and gluten free, are relatively low in sodium, and provide adequate vitamins and minerals with daily volumes of 1-1.5 L.

¹Least expensive; protein sources are intact casein, whey, and/or soy; fat sources are corn, safflower, or soy oils and MCT; carbohydrate sources are maltodextrin, corn syrup, hydrolyzed corn starch, sucrose; caloric density varies from 1 to 2.0 kcal/mL (primarily by increasing fat content); may feature high-protein composition and soluble fiber or prebiotics; osmolality 350-550 mOsm/kg.

²Protein sources are hydrolyzed casein, soy, and/or whey; may feature more MCT, hydrolyzed corn starch, and sucrose for enhanced digestion and absorption; caloric density is 1 to 1.5 kcal/mL.

³Calorically dense (2.0 kcal/mL); low to moderate protein; low potassium, magnesium, phosphorus, and vitamin A content; higher calcium content.

⁴Use in septic or hemodynamically compromised patients is currently controversial.

⁵Glutamine is supplied as L-glutamine or glutamine peptides; several randomized, controlled clinical trials show conflicting results regarding decrease in infections with enteral glutamine supplementation; some formulas combine glutamine and other supplements (e.g., enriched in antioxidants, omega-3 fatty acids).

⁷Several, but not all, randomized, controlled clinical trials show clinical efficacy with this formulation in patients who require mechanical ventilation due to ARDS; formula is not enriched in arginine, glutamine, or nucleotides.

days after ICU admission if adequate caloric needs (e.g., >60%) cannot be achieved with oral diet and supplements alone, especially for patients with existing malnutrition. Many studies have shown that ICU patients actually receive only 60% to 75% of the amount of tube feeding ordered by physicians. This can occur because of tube feeding intolerance (e.g., high gastric residuals, emesis, diarrhea, tube dislodgement) or discontinuation of feeding for diagnostic tests or therapeutic interventions. Although supplemental PN (see later discussion) is commonly ordered in patients who are not able to achieve tube feeding rates adequate for their needs, this practice remains controversial because of the limited number of good clinical trials. Rigorous studies are now in progress to address the efficacy of this approach, motivated by data suggesting that an increase in net caloric deficit (i.e., the difference between daily caloric requirements and daily actual calories delivered, summed over time) is associated with worse clinical outcomes in medical and surgical ICU patients.

Most outpatients and hospitalized ICU and non-ICU patients tolerate standard, inexpensive enteral formulas delivered via gastric or intestinal routes that provide between 1.0 and 1.5 kcal/mL. A large variety of enteral tube feeding products is available for clinical use. The specific product chosen should be based both on clinical conditions and underlying organ function, as outlined in [E-Table 68-4](#). Because EN products can be marketed without efficacy data from randomized, controlled clinical trials, there remains a clear need for such trials to determine optimal EN formulations for different clinical conditions.

Complications of enteral feeding include diarrhea. Diarrhea is common in hospital patients receiving tube feedings but is typically caused by factors independent of the feeding, including administration of antibiotics, sorbitol-containing or hypertonic medications (e.g., acetaminophen elixir), and infections. Diarrhea caused by tube feeding itself does occur with rapid formula administration, in patients with underlying gut mucosal disease, and in those with severe hypoalbuminemia, which causes bowel wall edema. A fiber-containing enteral formula is sometimes useful to decrease diarrhea. Other complications of tube feeding include aspiration of tube feedings into the lung; mechanical problems with nasally placed feeding tubes, including discomfort, sinusitis, pharyngeal or esophageal mucosal erosion due to local tube trauma; and, with percutaneous feeding tubes, entrance site leakage, skin breakdown, cellulitis, and pain. Metabolic complications of tube feeding include fluid imbalances, hyperglycemia, electrolyte abnormalities, azotemia, and, occasionally, refeeding syndrome (discussed later). In general, if tube feedings are deemed to be required for more than 4 to 6 weeks, a percutaneous feeding tube should be placed.

In tube-fed patients who are receiving either subcutaneous or intravenous insulin to control hyperglycemia, significant hypoglycemia due to the continued actions of insulin may occur if tube feedings are discontinued inadvertently or for diagnostic or therapeutic tests. Hospitalized patients receiving tube feedings should have their blood glucose concentration monitored on a daily basis (or several times per day as indicated) and their blood electrolytes (including magnesium, potassium, and phosphorus) and renal function monitored several times each week (or daily in the ICU setting). Other blood chemistries should be determined at least weekly. This should be accompanied by close

monitoring of intake and output records (including urine, stool, and drainage outputs) and gastrointestinal tolerance. When patients are able to consume oral food, tube feeding should be decreased and then discontinued (e.g., with daily calorie counts by a registered dietitian). For patients requiring home tube feeding, it is important to consult social service professionals to ensure appropriate care and follow-up.

Administration of Parenteral Nutrition

The basic principle in considering PN therapy is that the patient must be unable to achieve adequate nutrient intake via the enteral route. PN support includes administration of standard complete nutrient mixtures that contain dextrose, L-amino acids, lipid emulsion, electrolytes, vitamins, and minerals (in addition to certain medications as indicated, such as insulin or octreotide), given via a peripheral or central vein. Administration of complete PN therapy to patients with gastrointestinal tract dysfunction has become a standard of care in most hospitals and ICUs throughout the world, although use in individual institutions varies widely. PN is life-saving in patients with intestinal failure (e.g., short bowel syndrome). Existing data indicate that PN benefits patients with preexisting moderate to severe malnutrition or critical illness by decreasing overall morbidity, and possibly mortality, compared with patients receiving inadequate EN or hydration (intravenous dextrose) therapy alone. A consensus is emerging, based on recent rigorous studies in critical illness, that PN should probably not be initiated until days 3 to 4 after ICU admission in patients who are unable to tolerate adequate EN.

Compared with PN, EN is less expensive, probably maintains intestinal mucosal structure and function to a greater extent, is safer in terms of mechanical and metabolic complications (see later discussion), and is associated with reduced rates of nosocomial infection. Therefore, the enteral route of feeding should be used and advanced whenever possible, and the amount of administered PN should be correspondingly reduced.

Generally recognized indications for PN include the following situations:

1. Patients with short bowel syndrome or other conditions causing intestinal failure (e.g., motility disorders, obstruction, severe ileus, severe inflammatory bowel disease), especially those with preexisting malnutrition.
2. Clinically stable patients in whom adequate enteral feeding (e.g., >50% of needs) is unlikely for 7 to 10 days because of an underlying illness.
3. Patients with severe catabolic stress requiring ICU care in whom adequate enteral nutrient intake is unlikely for more than 3 to 5 days.

There is no reason to withhold PN in hospitalized patients for any period of time if they exhibit preexisting moderate to severe malnutrition and are deemed to be unlikely to meet their needs by the oral or enteral route.

Generally accepted contraindications for PN include the following conditions:

1. If the GI tract is functional and access for enteral feeding is available.

- If PN is thought to be required for 5 days or less.
- If the patient cannot tolerate the extra intravenous fluid required for PN or has severe hyperglycemia or electrolyte abnormalities on the planned day of PN initiation
- If the patient has an uncontrolled bloodstream infection or severe hemodynamic instability.
- If new placement of an intravenous line solely for PN poses undue risks based on clinical judgment
- On an individualized basis, if aggressive nutritional support is not desired by the competent patient or legally authorized representative, such as in preterminal patients or those with terminal illness.

PN can be delivered either as peripheral vein solutions or as central vein solutions through a percutaneous subclavian vein or internal jugular vein catheter for infusion into the superior vena cava (nontunneled in the hospital setting), through a subcutaneously tunneled central venous catheter (e.g., Hickman catheter) or central venous port (for chronic home PN therapy), or through a peripherally inserted central venous catheter (PICC). Although data are limited, it is clearly preferable to manage long-term central venous PN to be managed at home with the use of a tunneled central venous catheter rather than a PICC line because of the higher rate of local complications (e.g., phlebitis, catheter breakage) and possibly catheter-associated infections with PICC lines.

A comparison of typical fluid, macronutrient, and micronutrient content of peripheral and central vein PN solutions is shown in Table 68-3. Intravenous lipid emulsions (typically added to PN as a 20% soybean oil–based solution in the United States) provide both essential linoleic and α -linolenic fatty acids and energy (10 kcal/g); these are typically infused over a 24-hour period in the complete PN administration bag. The maximal recommended rate of fat emulsion infusion is approximately 1.0 g/kg/day. Most patients are well able to clear triglyceride from plasma after intravenous administration of fat emulsion. Recently, an intravenous lipid emulsion of 80% olive oil/20% soybean oil was approved for use in adult PN in the United States. It is important to monitor blood triglyceride levels at baseline and then approximately weekly and as indicated to assess clearance of intravenous fat; triglyceride levels should be maintained lower than 400 mg/dL to decrease the risk of pancreatitis or diminished pulmonary diffusion capacity in patients with severe chronic obstructive lung disease.

Central venous administration of PN allows higher concentrations of dextrose (3.4 kcal/g) and amino acids (4 kcal/g) to be delivered as hypertonic solutions; thus, lower amounts of fat emulsion are needed to reach caloric goals (see Table 68-3). Requirements for potassium, magnesium, and phosphorus are typically higher with central vein PN compared to peripheral vein PN. The higher concentrations of dextrose and amino acids allow most patients to achieve caloric and amino acid goals with only 1 to 1.5 L of PN per day. In central vein PN, initial orders typically provide 60% to 70% of non–amino acid calories as dextrose and 30% to 40% of non–amino acid calories as fat emulsion. These percentages are adjusted as indicated based on levels of blood glucose and triglyceride, respectively. Based on comprehensive data associating hyperglycemia with hospital morbidity and

TABLE 68-3 COMPOSITION OF TYPICAL PARENTERAL NUTRITION SOLUTIONS

COMPONENT*	PERIPHERAL PN	CENTRAL PN
Volume (L/day)	2-3	1-1.5
Dextrose (%)	5	10-25
Amino acids (%) [†]	2.5-3.5	3-8
Lipid (%) [‡]	3.5-5.0	2.5-5.0
Sodium (mEq/L)	50-150	50-150
Potassium (mEq/L)	20-35	30-50
Phosphorus (mmol/L)	5-10	10-30
Magnesium (mEq/L)	8-10	10-20
Calcium (mEq/L)	2.5-5	2.5-5
Trace elements [§]		
Vitamins		

*Electrolytes in parenteral nutrition (PN) are adjusted as indicated to maintain serially measured serum levels within the normal range. The percentage of sodium and potassium salts as chloride is increased to correct metabolic alkalosis, and the percentage of salts as acetate is increased to correct metabolic acidosis. Regular insulin is added to PN as needed to achieve blood glucose goals (separate intravenous insulin infusions are commonly required with hyperglycemia in intensive care unit settings).

[†]Provides all essential amino acids and several nonessential amino acids. The dose of amino acids is adjusted downward or upward to goal as a function of the degree of azotemia or hyperbilirubinemia in patients with renal or hepatic failure, respectively.

[‡]Lipid is given as soybean oil– or olive oil/soybean oil–based fat emulsion in the United States. In Europe and other non-U.S. countries, intravenous fish oil, olive oil, medium-chain triglycerides, and combinations of these are available for use in PN. Lipid is typically mixed with dextrose and amino acids in the same PN infusion bag (“all-in-one” solution).

[§]Trace elements added on a daily basis to peripheral vein and central vein PN are mixtures of chromium, copper, manganese, selenium, and zinc. (These elements can also be supplemented individually.)

^{||}Vitamins added on a daily basis to peripheral vein and central vein PN are mixtures of vitamins A, B₁ (thiamine), B₂ (riboflavin), B₃ (niacinamide), B₆ (pyridoxine), B₁₂, C, D, and E, biotin, folate, and pantothenic acid. Vitamin K is added on an individual basis (e.g., for patients with cirrhosis). Specific vitamins can also be supplemented individually.

mortality, expert panels now recommend tight blood glucose control in ICU settings (between 80 and 130 to 150 mg/dL) and close blood glucose monitoring. Separate intravenous insulin infusions should usually be administered in the ICU when patients receiving central vein PN develop hyperglycemia.

Specific requirements for intravenous trace elements and vitamins have not been rigorously defined for patient subgroups, and in most stable patients, therapy is directed at meeting published recommended doses using standardized intravenous preparations to maintain blood levels in the normal range (see Table 68-3). Several studies have shown that a significant proportion of ICU patients have low levels of zinc, selenium, vitamin C, vitamin E, and vitamin D despite receiving specialized PN (or EN). Depletion of these essential nutrients may impair antioxidant capacity, immunity, wound healing, and other important body functions, and supplementation is recommended if serum concentrations are low. For example, zinc (and other micronutrients such as copper) should probably be increased in the PN of patients with burns, large wounds, significant gastrointestinal fluid losses, and other conditions if serum concentrations indicate low levels. Recent data suggest that thiamine depletion is not uncommon in patients receiving chronic diuretic therapy or in those with severe malabsorption.

The most common complication of peripheral vein PN is local phlebitis resulting from use of the catheter. In such cases, a small dose of hydrocortisone and heparin is typically added to the solution. Alterations in blood electrolytes can be treated with adjustment of concentrations in the peripheral PN prescription. Hypertriglyceridemia typically responds well to lowering of the total PN lipid dose. Central vein PN is associated with a much

higher rate of mechanical, metabolic, and infectious complications than peripheral vein PN. Mechanical complications include those related to insertion of the central venous catheter (e.g., pneumothorax, hemothorax, malposition of the catheter, thrombosis). Infectious complications include catheter-related bloodstream infections and non-catheter-related infections. The risk for these infections appears to be increased with use of non-subclavian vein central venous access (e.g., jugular vein, femoral vein) and multiple-use catheters with non-dedicated PN infusion ports used for additional purposes such as blood drawing or medication administration. Poorly controlled blood glucose levels (>140 to 180 mg/dL) are not uncommon in patients requiring central vein PN and are associated with an increased risk of nosocomial infection. Risk factors for hyperglycemia include poorly controlled blood glucose at PN initiation; use of high dextrose concentrations (>10%) in the initial few days of PN administration or too rapid an increase in total dextrose load; insufficient exogenous insulin administration; inadequate monitoring of blood glucose responses to central vein PN administration; and administration of corticosteroids and vasopressor agents such as norepinephrine (which stimulate gluconeogenesis and cause insulin resistance).

Recent data also suggest that inadequate or no provision of the amino acid glutamine may increase infection risk in patients requiring PN. This amino acid appears to be conditionally essential in catabolic states and serves as an important fuel for immune cells and cells of the gut mucosa. Several expert panels now recommend that glutamine be routinely added to the PN in ICU patients, but this practice remains controversial because some studies show no benefit (or even harm) in certain patient subgroups and an improvement in hospital mortality has not been documented.

Studies on nutrient utilization efficiency and metabolic complications in severely catabolic patients suggest that lower amounts of total energy and protein/amino acids should be administered than were routinely given in the past, particularly in unstable and ICU patients. High calorie, carbohydrate, amino acid, and fat loads (“hyperalimentation”) are easily administered via central vein PN but can induce severe metabolic complications, including carbon dioxide overproduction, azotemia, hyperglycemia, electrolyte alterations, and hepatic steatosis and injury (E-Table 68-5). Dextrose and lipid doses in PN should be advanced over several days after initiation, with close monitoring of the blood glucose concentration, electrolytes, triglycerides, organ function tests, intake and output measurements, and the clinical course.

Refeeding syndrome with central vein PN administration is relatively common in patients at risk, including those with preexisting malnutrition, electrolyte depletion, alcoholism, or prolonged periods of intravenous hydration therapy (e.g., 5% dextrose) without nutritional support, all of which are common in hospital patients. Refeeding syndrome is mediated by administration of excessive intravenous dextrose (>150 to 250 g, for example in 1 L of PN containing 15% to 25% dextrose). This, in turn, markedly stimulates insulin release, which rapidly lowers blood concentrations of potassium, magnesium, and especially phosphorus as a result of intracellular shifts and utilization in

carbohydrate metabolic pathways. Administration of high doses of carbohydrate also consumes thiamine, which is required as a cofactor for carbohydrate metabolism and can precipitate symptoms of thiamine deficiency (see E-Table 68-2), especially in patients with poor thiamine nutriture at baseline. Hyperinsulinemia also tends to cause sodium and fluid retention at the level of the kidney. Together, fluid and sodium retention, the drop in electrolytes (which can cause arrhythmias), and hypermetabolism due to excessive calorie provision can result in heart failure, especially in patients with preexisting heart disease and cardiac muscle atrophy due to prolonged protein-energy malnutrition. Prevention of refeeding syndrome requires vigilance to identify patients at risk; use of initially low PN dextrose concentrations; empiric provision of higher doses of potassium, magnesium, and phosphorus based on current blood levels and renal function; and supplemental thiamine (100 mg/day for 3 to 5 days).

If home PN is indicated, the primary physician should consult with social service professionals to identify appropriate home care companies and nutrition support professionals to assess intravenous line access, metabolic status, and the home PN order and to arrange for follow-up care and monitoring of PN. It is important not to arrange for rapid discharge of hospitalized patients newly started on PN. Obtaining appropriate venous access and monitoring of fluid and electrolyte status over a 2- to 3-day period is an important aspect of care for most patients started on PN, and it is imperative for those with severe malnutrition and those at risk for refeeding syndrome.

 For a deeper discussion on this topic, please see Chapters 214, “Nutritional Assessment,” and 215, “Protein-Energy Malnutrition” in Goldman-Cecil Medicine, 25th Edition.

E-TABLE 68-5 SOME COMMON METABOLIC COMPLICATIONS OF PARENTERAL NUTRITION

PN ORDER PROBLEM	METABOLIC OR CLINICAL CONSEQUENCE
Excess kcal, CHO, fat	Abnormal liver function tests
Excess kcal, CHO, fat	Hepatic steatosis
Excess CHO	Hypercapnia
Excess fluid, kcal, CHO, fat	Respiratory insufficiency
Excess amino acids	Azotemia
Excess sodium and fluid	Sodium and fluid retention
Excess CHO, inadequate insulin	Hyperglycemia-mediated immune cell dysfunction, infection
Inadequate or excessive electrolytes	Abnormal blood electrolyte levels
Excess fluid, kcal, sodium, CHO, inadequate electrolytes	Cardiac failure, arrhythmias
Excess CHO, inadequate electrolytes, thiamine	Refeeding syndrome

CHO, Carbohydrate; kcal, calories; PN, parenteral nutrition.

Disorders of Lipid Metabolism

Geetha Gopalakrishnan and Robert J. Smith

DEFINITION AND EPIDEMIOLOGY

Lipids such as free fatty acids (FFA), cholesterol, and triglycerides are hydrophobic molecules that bind proteins for transport. Nonesterified FFA travel as anions complexed to albumin. Esterified complex lipids are transported in lipoprotein particles. Lipoproteins have a hydrophobic core (cholesteryl esters and triglycerides) and an amphiphilic surface monolayer (phospholipids, unesterified cholesterol, and apolipoproteins). Ultracentrifugation separates lipoproteins into five classes based on their density (Table 69-1).

Proteins on the surface of lipoproteins (i.e., apolipoproteins) activate enzymes and receptors that guide lipid metabolism. Defects in the synthesis and catabolism of lipoproteins result in dyslipidemia. Prevalence of dyslipidemia in the United States is approximately 20% and varies with the population studied. An estimated 70% of individuals with premature coronary heart disease (CHD) have dyslipidemia. In clinical trials, treatment of dyslipidemia improved both CHD and all-cause mortality rates. Two classes of lipids, triglyceride and cholesterol, play a significant, yet modifiable, role in the pathogenesis of atherosclerosis and therefore are the focus of this chapter.

PATHOLOGY

In the intestinal lumen, dietary triglycerides and cholesterol esters are hydrolyzed by pancreatic lipase to produce glycerol, FFA, and free cholesterol. Formation of micelles enables the absorption of glycerol and FFA into the intestinal cell. The transport of free cholesterol is mediated by a cholesterol gradient that exists between the lumen and the intestinal cell. Within the cell, glycerol combines with three fatty acid chains to form triglycerides, and cholesterol is esterified to form cholesterol esters. Chylomicrons are formed from triglycerides (85% of chylomicron mass) and cholesterol esters assembled with surface lipoproteins. Chylomicrons enter into the circulation and acquire more surface apolipoproteins such as apo C-II and apo E from high-density lipoprotein (HDL) particles (Fig. 69-1). Apo C-II

activates lipoprotein lipase (LPL), which is located on the capillary endothelium. LPL hydrolyzes the core chylomicron triglycerides to release FFA, which function as an energy source. Excess fatty acids are stored in adipose tissue or utilized in hepatic lipoprotein synthesis. The triglyceride-poor chylomicron remnant is then cleared from the circulation by hepatic LDL receptors. These receptors are activated by apo E, which is located on the surface of chylomicrons.

Very-low-density lipoproteins (VLDL) are synthesized by the liver (see Fig. 69-1). FFA and cholesterol obtained from the circulation or synthesized by the liver are incorporated into VLDL particles. Any condition that increases the flux of FFA to the liver, such as poorly controlled diabetes, will increase VLDL production. The liver assembles triglycerides (55% of VLDL mass), cholesterol (20%), and surface apolipoproteins to form VLDL particles. Apo C-II, the cofactor for LPL, hydrolyzes the triglyceride core of VLDL particles to generate VLDL remnant or intermediate-density lipoprotein (IDL). The IDL, depleted of triglycerides (25%), can be cleared from the circulation by apo E-mediated LDL receptors, or it can be hydrolyzed further to form low-density lipoproteins (LDL). LDL particles are triglyceride poor (5% of LDL mass) and consist mostly of cholesterol esters (60%) and apolipoproteins. Apo B100 on the surface of LDL binds LDL receptors and facilitates LDL clearance from the circulation. Internalized LDL-cholesterol is used to synthesize hormones, produce cell membranes, and store energy.

In the liver, LDL-cholesterol is used to synthesize bile acids (see Fig. 69-1), which are secreted into the intestinal lumen along with free cholesterol. Bile acids help transport fat. Approximately 50% of the cholesterol and 97% of the bile acid entering the lumen is reabsorbed back into the circulation. The reabsorbed cholesterol regulates cholesterol and LDL receptor synthesis.

Many cells in the body, including liver parenchymal cells, synthesize cholesterol (Fig. 69-2). Acetate is converted to 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA). HMG-CoA reductase converts HMG-CoA to mevalonic acid, which is then

TABLE 69-1 PROPERTIES OF LIPOPROTEINS

LIPOPROTEIN CLASS	DENSITY (g/mL)	ORIGIN	APOLIPOPROTEINS	LIPID
Chylomicrons	<0.95	Intestine	C-II, E	TG (85%), cholesterol (10%)
VLDL	<1.006	Liver	B100, C-II, E	TG (55%), cholesterol (20%)
IDL	1.006-1.019	VLDL catabolism	B100, E	TG (25%), cholesterol (35%)
LDL	1.019-1.063	IDL catabolism	B100	TG (5%), cholesterol (60%)
HDL	1.063-1.25	Liver, intestine	A-I, E	TG (5%), cholesterol (20%)

LDL Cholesterol Uptake from Circulation

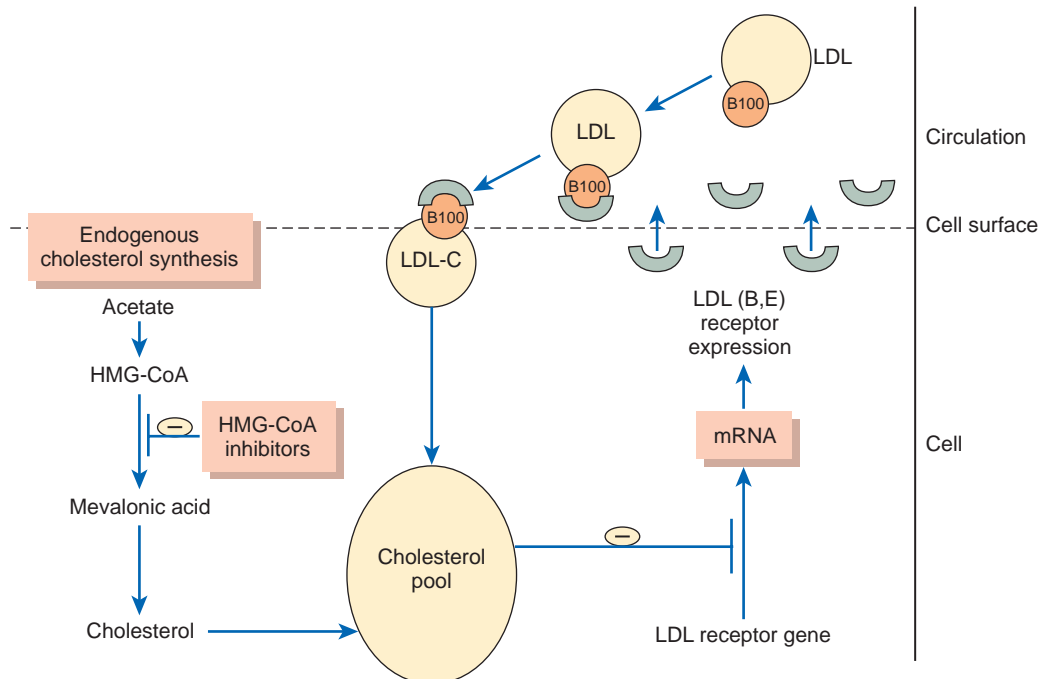

FIGURE 69-2 Regulation of low-density lipoprotein (LDL) receptor expression (see text for details). B100, Apolipoprotein B100; B,E, membrane receptor for lipoproteins containing apo B and apo E (synonymous with the LDL receptor); HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; LDL-C, LDL-cholesterol; mRNA, messenger RNA.

converted to cholesterol through a series of steps. HMG-CoA reductase is the rate-limiting step in the cholesterol synthesis pathway. Drugs that inhibit this enzyme decrease cholesterol biosynthesis and cellular cholesterol pools. Internalization of LDL particles into cells is regulated by negative feedback (see Fig. 69-2). A negative cholesterol balance increases the expression of

LDL receptors and subsequent uptake of cholesterol from the circulation. A positive cell cholesterol balance suppresses LDL receptor expression and decreases uptake of LDL-cholesterol into cells. Circulating LDL then enter macrophages and other tissues via scavenger receptors. Because the scavenger receptors are not regulated, these cells accumulate excess intracellular

cholesterol, resulting in the formation of foam cells and atherosclerotic plaques.

The anti-atherogenic effect of HDL is attributed to the removal of excess cholesterol from tissue sites and other lipoproteins. HDL is synthesized in the liver and intestine (see Fig. 69-1). Excess phospholipids, cholesterol, and apolipoproteins on remnant chylomicrons, VLDL, IDL, and LDL, are transferred to HDL particles and thus increase HDL mass. Apo A-I, a surface lipoprotein on HDL particles, mobilizes cholesterol from intracellular pools and accepts cholesterol released during lipolysis of triglyceride-rich lipoproteins. It also activates lecithin-cholesterol acyltransferase (LCAT), an enzyme that esterifies cholesterol. These cholesterol esters move the hydrophilic HDL surface to the hydrophobic HDL core. Cholesterol ester transfer protein (CETP) transfers core HDL cholesterol esters to other lipoproteins such as VLDL. These lipoproteins deliver cholesterol to peripheral sites for hormone and cell membrane synthesis.

Defects in the production or removal of lipoproteins results in dyslipidemia. Both genetic and acquired conditions have been implicated in the pathogenesis of lipid disorders (Tables 69-2 and 61-3). These are discussed later in the chapter.

CLINICAL PRESENTATION

Dyslipidemia plays a significant role in the development of atherosclerosis. Increased incidence of CHD with high LDL- and low HDL-cholesterol is well documented. Excess LDL results in the formation of cholesterol plaques that deposit in arteries (atheroma), skin and tendon (xanthomas), eyelids (xanthelasma),

and iris (corneal arcus). The impact of triglycerides on vascular disease is less clear. Metabolic disorders such as diabetes and obesity are often associated with vascular disease and hypertriglyceridemia, and the atherogenic impact of other elements in these disorders is difficult to separate from the effect of hypertriglyceridemia. However, in several population-based studies, abnormal triglyceride levels correlated with increased risk for CHD. Marked hypertriglyceridemia (>1000 mg/dL) is associated with the chylomicronemia syndrome, characterized by pancreatitis and xanthomas.

DIAGNOSIS

Dyslipidemia is defined by a total cholesterol, triglyceride, or LDL level greater than the 90th percentile or an HDL level lower than the 10th percentile for the general population. Because chylomicrons are present in plasma for up to 10 hours after a meal, fasting total cholesterol, triglyceride, and lipoprotein assessments are required for diagnosis. It is advisable to confirm dyslipidemia with two separate determinations.

Total cholesterol, triglyceride, and HDL levels can be measured directly; VLDL and LDL levels usually are calculated. If the triglyceride concentration is lower than 400 mg/dL, then VLDL is calculated by dividing the triglyceride level by 5. LDL-cholesterol is estimated by subtracting VLDL and HDL from the total cholesterol. VLDL and LDL cannot be determined if triglyceride levels are greater than 400 mg/dL. In that case, the lipoprotein abnormality can be identified by inspecting the serum. When the triglyceride level exceeds 350 mg/dL, the

TABLE 69-2 GENETIC DISORDERS OF LIPID METABOLISM

DISORDER	GENETIC DEFECT	DYSLIPIDEMIA
Familial hypercholesterolemia	Mutation in the gene that encodes LDL receptor	Elevated TC and LDL
Familial defective apolipoprotein B100	Impaired binding of LDL to LDL receptor due to a defect in apo B100 protein	Elevated TC and LDL
Elevated plasma Lp(a)	Increased binding of LDL to apolipoprotein(a)	Elevated Lp(a)
Polygenic hypercholesterolemia	Increased binding of apo E4-containing lipoprotein to LDL receptor resulting in downregulation of the LDL receptor	Elevated TC and LDL
Familial combined hyperlipoproteinemia	Polygenic disorder associated with increased hepatic VLDL production, resulting in increased LDL and decreased HDL production; some individuals have a mutation in the LPL gene that affects expression and function of LPL	Elevated TC, LDL, and TG Low HDL
Familial dysbetalipoproteinemia	Lower affinity of apo E2 for LDL receptor	Elevated TG, TC, and LDL
Lipoprotein lipase deficiency	Mutation in the LPL gene	Elevated TG
Apolipoprotein C-II deficiency	Decrease in activation of LPL due to a deficiency of apo CII	Elevated TG
Familial hypertriglyceridemia	Overproduction of hepatic VLDL and increased catabolism of HDL	Elevated TG Low HDL

HDL, High-density lipoprotein; LDL, low-density lipoprotein; TC, total cholesterol; TG, triglyceride; VLDL, very low-density lipoprotein.

TABLE 69-3 MECHANISMS OF SECONDARY HYPERLIPIDEMIA

CLINICAL	ELEVATED LIPOPROTEIN	MECHANISM
Diabetes	Chylomicron, VLDL, LDL	Increase in VLDL production and decrease in VLDL/LDL clearance
Obesity	Chylomicron, VLDL, LDL	Increase in VLDL production and decrease in VLDL/LDL clearance
Lipodystrophy	VLDL	Increase in VLDL production
Hypothyroidism	LDL, VLDL	Decrease in LDL/LDL clearance
Estrogen	VLDL	Increase in VLDL production
Glucocorticoids	VLDL, LDL	Increase in VLDL production and conversion to LDL
Alcohol	VLDL	Increase in VLDL production
Nephrotic syndrome	VLDL, LDL	Increase in VLDL production and conversion to LDL

LDL, Low-density lipoprotein; VLDL, very-low-density lipoprotein.

serum is cloudy. After refrigeration, a white surface layer depicts excess chylomicrons, whereas a dispersed, opaque infranatant reflects a VLDL dysfunction.

Current guidelines recommend selective screening of children who have a family history of lipoprotein abnormality or premature vascular disease and adults who have an increased risk for CHD. The U.S. Preventive Services task force recommended universal screening starting at 35 years of age for men and at 45 years of age for women; there is a paucity of data supporting long-term benefits from screening of younger individuals. Either a fasting or a nonfasting total cholesterol and HDL measurement can be the initial screen. If the total cholesterol value is greater than 200 mg/dL or the HDL value is less than 40 mg/dL, then a repeat fasting lipid panel is required. If the total cholesterol value is less than 200 mg/dL and the HDL value is greater than 40 mg/dL, then retesting is recommended every 5 years. Individuals with CHD, risk factors for CHD, or CHD equivalents (i.e., symptomatic carotid artery disease, peripheral arterial disease, abdominal aortic aneurysm, or diabetes) should be screened more frequently based on risk assessment, as shown in Table 69-4. CHD risk factors include age (men >45 years, women >55 years), family history of premature CHD (affected male first-degree relative <55 years or female first-degree relative <65 years of age), smoking, hypertension, and low HDL (<40 mg/dL). HDL concentrations higher than 60 mg/dL are cardioprotective. Overall, the level of evidence to support screening is fair (level B) but increases with age, male gender, and CHD (level A).

TREATMENT

Treatment is initiated after two abnormal lipid findings. Treatment of elevated total cholesterol and LDL-cholesterol can slow the development and progression of CHD. Meta-analysis of primary and secondary prevention trials indicates that CHD mortality decreases by approximately 15% for every 10% reduction in serum cholesterol. LDL-cholesterol treatment strategies are based on risk indicators (Table 69-5). There is strong evidence that dietary modifications can reduce LDL-cholesterol and triglyceride levels (Table 69-6). However, evidence that lifestyle-induced lipid modifications improve cardiovascular outcomes is limited (level C). If target goals are not achieved, then pharmacologic therapy is considered (Table 69-7). Ample

evidence supports statin use in primary and secondary prevention of CHD (level A). Treatment effects of statin can be assessed after 1 to 2 months. Additional agents can be considered if target goals are not achieved with maximal drug dosing.

A fasting lipid panel is required to diagnose hypertriglyceridemia. Triglyceride levels higher than 200 mg/dL are classified as abnormal. Borderline triglyceride levels range from 150 to 200 mg/dL, and normal values are lower than 150 mg/dL. A diet and exercise program is recommended for all individuals with abnormal triglyceride levels (level C). However, pharmacologic treatments to reduce triglyceride levels may be considered if fasting levels are higher than 200 mg/dL, especially if the individual is at risk for CHD or pancreatitis (see Table 69-7). Fibrates, fish oil, and nicotinic acid should be considered if the triglyceride level is higher than 500 mg/dL (level C). However, for levels lower than 500 mg/dL, statins are first-line therapy (level B).

Low HDL concentrations (<40 mg/dL) can also increase the risk for CHD. In the Framingham Heart Study, every decrease in HDL of 5 mg/dL increased the risk for myocardial infarction. Both lifestyle modifications (e.g., diet low in saturated fat, exercise) and pharmacologic therapy (e.g., nicotinic acid, fibrate) can improve HDL levels. However, target goals and treatment recommendations have not been established due to a lack of evidence.

TABLE 69-5 THERAPEUTIC APPROACH TO REDUCE LEVELS OF LOW-DENSITY LIPOPROTEIN-CHOLESTEROL*

RISK CATEGORY	TREATMENT GOAL: LDL (mg/dL)	LIFESTYLE CHANGES: LDL (mg/dL)	DRUG THERAPY: LDL (mg/dL)
≤One risk factor	<160	≥160	≥160-190
≥Two risk factors	<130	≥130	≥130-160
CHD or CHD risk equivalent	<100 (optional <70)	≥100	≥100-130

CHD, Coronary heart disease; HDL, high-density lipoprotein-cholesterol; LDL, low-density lipoprotein-cholesterol.

*Recommendations of the Adult Treatment Panel III, National Cholesterol Education Program (NCEP), as modified in 2004. CHD risk factors include age (men >45 yr, women >55 yr), family history of premature CHD (male first-degree relative <55 yr, female first-degree relative <65 yr), smoking, hypertension, diabetes mellitus, and HDL <40 mg/dL. Subtract a risk factor if HDL >60 mg/dL. CHD risk equivalents include symptomatic carotid artery disease, peripheral arterial disease, abdominal aortic aneurysm, and diabetes mellitus.

TABLE 69-4 RECOMMENDATIONS FOR SCREENING FOR DYSLIPIDEMIA*

1. A fasting lipid profile is recommended at age 20 yr
2. Rescreen every 5 yr if
 - LDL <160 mg/dL in patients with 0-1 risk factor
 - LDL <130 mg/dL in patients with ≥2 risk factors
3. Rescreen every year if
 - LDL 130-159 mg/dL in patients with ≥2 risk factors
 - LDL <100 mg/dL in patients with CHD or CHD risk equivalent

CHD, Coronary heart disease; HDL, high-density lipoprotein-cholesterol; LDL, low-density lipoprotein-cholesterol.

*Recommendations of the Adult Treatment Panel III, National Cholesterol Education Program (NCEP), as modified in 2004. CHD risk factors include age (men >45 yr, women >55 yr), family history of premature CHD (male first-degree relative <55 yr, female first-degree relative <65 yr), smoking, hypertension, and HDL <40 mg/dL. Subtract a risk factor if HDL >60 mg/dL. CHD risk equivalents include symptomatic carotid artery disease, peripheral arterial disease, abdominal aortic aneurysm, and diabetes mellitus.

TABLE 69-6 RECOMMENDATIONS FOR NUTRITIONAL INTAKE*

NUTRIENT	RECOMMENDED INTAKE
Total Fat	25-35% of total calories
Saturated	<7%
Polyunsaturated	<10%
Monounsaturated	<20%
Carbohydrates	50-60% of total calories
Protein	15% of total calories
Cholesterol	<200 mg/day
Fiber	20-30 g/day

*Recommendations of the Adult Treatment Panel III, National Cholesterol Education Program (NCEP), as modified in 2004.

TABLE 69-7 DRUGS COMMONLY USED FOR THE TREATMENT OF HYPERLIPIDEMIA

DRUG CLASS	LDL (% CHANGE)	HDL (% CHANGE)	TRIGLYCERIDES (% CHANGE)	SIDE EFFECTS
HMG-CoA inhibitors	↓ 20-60	↑ 5-10	↓ 10-30	Liver toxicity, myositis, rhabdomyolysis; enhanced warfarin effect
Cholesterol absorption inhibitors	↓ 17	No effect	↓ 7-8	Abnormal liver enzymes in combination with an HMG-CoA inhibitor, myalgia, hepatitis, rhabdomyolysis, pancreatitis, potential increase in cancer risk and cancer death
Bile acid sequestrants	↓ 15-30	Slight increase	No effect	Nausea, bloating, cramping, abnormal liver function; interferes with absorption of other drugs such as warfarin and thyroxine
Fibric acid	↓ 5-20	↑ 5-20	↓ 35-50	Nausea, cramping, myalgias, liver toxicity, enhanced warfarin effect
Nicotinic acid	↓ 10-25	↑ 15-35	↓ 25-30	Hepatotoxicity, hyperuricemia, hyperglycemia, flushing, pruritus, nausea, vomiting, diarrhea
Omega-3 fatty acids	↑ 4-49	↑ 5-9	↓ 23-45	Eructation, taste perversion, dyspepsia

HMG-CoA, Hydroxymethylglutaryl-coenzyme A reductase.

Lifestyle Modification

Lifestyle modification should be the initial step in the management of hyperlipidemia (see Table 69-6). Restricting the dietary intake of fat lowers total cholesterol by approximately 15% and LDL cholesterol by 25%. Low-fat diets that limit saturated fat content promote LDL receptor expression and increase the uptake of LDL-cholesterol from the circulation. By contrast, saturated fat downregulates hepatic LDL receptors and increases circulating LDL. Because unsaturated fats (polyunsaturated and monounsaturated) generally do not have this effect, they are the preferred form of fat intake. However, polyunsaturated fats containing fatty acids with a *trans* rather than *cis* double bond configuration (*trans*-fatty acids) increase plasma cholesterol levels similarly to saturated fat.

Limiting the intake of saturated and *trans*-unsaturated fatty acids requires appropriate calorie substitutions. Increasing carbohydrate content to achieve this goal can increase the hepatic synthesis of triglyceride. Dietary substitution with soluble fibers (e.g., oat bran) has been recommended, because these fibers have a limited effect on triglyceride levels. They also bind bile acids in the gut and thereby decrease cholesterol levels. Other polyunsaturated fats, such as omega-3 fatty acids, are cardioprotective. They are abundant in fatty fish, flaxseed oil, canola oil, and nuts. They reduce VLDL production, inhibit platelet aggregation, and decrease CHD. Even two servings per week of fatty fish such as salmon can be beneficial.

Dietary restriction of fat (<10%) is essential for the treatment of marked hypertriglyceridemia. Other factors such as carbohydrate and alcohol intake can also increase the synthesis of triglyceride. Restriction of alcohol intake to 1 or 2 servings per week and adherence to a low-fat, high-fiber diet will improve hypertriglyceridemia.

Exercise has been shown to increase LPL activity. Even a single exercise session can reduce triglycerides and increase HDL. The impact of exercise on LDL is less clear. With low- to moderate-intensity exercise regimens, clearance of VLDL particles increases LDL production. However, this effect is not seen with high-intensity exercise programs. A decrease in LDL-cholesterol occurs with high-intensity exercise, and this effect is independent of weight loss.

Pharmacotherapy

If diet and exercise modifications do not sustain a normal lipid profile, then drug therapy is appropriate (see Table 69-7). Likely

benefit needs to be balanced against potential adverse effects when determining drug therapy. Many patients require two or three agents to achieve adequate control.

HMG-CoA reductase is the rate-limiting enzyme involved in cholesterol biosynthesis. Inhibition of this enzyme decreases intracellular cholesterol pools and subsequently increases uptake of LDL cholesterol from the circulation. HMG-CoA reductase inhibitors (e.g., lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, and rosuvastatin) increase cholesterol utilization, decrease VLDL synthesis, and increase HDL synthesis. As a result, lower LDL and triglyceride levels and higher HDL levels are observed with treatment. Meta-analysis of primary and secondary CHD prevention trials found reductions in all-cause and cardiovascular mortality rates with statin therapy. These agents limit progression and may even cause regression of coronary atherosclerosis. Therefore, they represent first-line therapy in the management of abnormal LDL-cholesterol levels. Elevated liver enzymes and muscle toxicity are potential dose-related complications. Myositis can occur with statins alone, but the risk is higher when statins are used in combination with nicotinic acid or fibric acid derivatives. Some of these agents can also potentiate the effect of warfarin.

Cholesterol absorption inhibitors (e.g., ezetimibe) function by interfering with the transport of cholesterol at the intestinal brush border. They increase cholesterol utilization and decrease LDL-cholesterol levels. Despite reductions in LDL-cholesterol, improvements in cardiovascular events and mortality have not been reported with treatment. Ezetimibe may be used as a single agent or in combination with an HMG-CoA reductase inhibitor to lower LDL-cholesterol levels. In combination, this agent can increase serum transaminase levels and potentially increase the risk of cancer and cancer death.

Drugs that interfere with the absorption of cholesterol from the intestinal lumen increase cholesterol utilization and decrease circulating levels of cholesterol. Bile acid sequestrants (e.g., cholestyramine, colestipol, and colestevlam) bind bile acids in the intestinal lumen and increase fecal excretion. Subsequently, more LDL-cholesterol is used by the liver to synthesis bile acids. The decrease in cellular cholesterol pools upregulates LDL receptors and decreases the amount of LDL-cholesterol in the circulation. Mild increases in HDL-cholesterol are also seen with this agent as a result of increased intestinal HDL formation. Treatment is associated with a reduction in the incidence of CHD. Bile acid sequestrants may be used alone for mild lipid dysfunction or in

combination with another lipid-lowering agent such as an HMG-CoA reductase inhibitor. Abnormal liver function and gastrointestinal symptoms (e.g., nausea, bloating, cramping) are common side effects that limit the use of bile acid sequestrants. They can also interfere with the absorption of other drugs such as warfarin and thyroxine.

Fibric acid derivatives such as gemfibrozil and fenofibrate increase FFA oxidation in muscle and liver. The reduced lipogenesis in the liver decreases VLDL and subsequent LDL production. Fibric acid derivatives also enhance LPL activity and HDL synthesis. As a result, treatment is usually associated with not only lower triglyceride and LDL levels, but also higher HDL levels. Reduced cardiovascular events have been demonstrated in a subset of individuals with high triglyceride (>200 mg/dL) and low HDL (<40 mg/dL) levels, but improvements in cardiovascular or all-cause mortality otherwise have not been confirmed with these agents. Liver toxicity and myositis are potential side effects of fibric acid derivatives, and they also interfere with the metabolism of warfarin, leading to a need for its dose adjustment.

Nicotinic acid has an antilipolytic effect and therefore decreases the influx of FFA to the liver. As a result, hepatic VLDL synthesis and LDL production are reduced. Nicotinic acid also decreases HDL catabolism. Lower triglyceride and LDL levels and higher HDL levels are observed with treatment. In addition, nicotinic acid stimulates tissue plasminogen activator and prevents thrombosis. It is the preferred agent for the reduction of lipoprotein(a) or Lp(a) (discussed later). The cardioprotective effect of nicotinic acid may be linked to its effect on Lp(a) and HDL. Side effects include hepatotoxicity, hyperuricemia, hyperglycemia, and flushing.

Omega-3 fatty acids reduce VLDL production and subsequently lower triglyceride levels (by 35%). They also modestly increase HDL (3%) and LDL (5%). The impact on lipids can occur over months to years and requires treatment doses as high as 3 to 4 g of fish oil per day. However, reductions in death due to sudden cardiac events and CHD are observed within weeks of treatment initiation. This benefit can be seen with lower treatment doses (fish oil <2 g/day) and is most likely related to the impact of omega-3 fatty acid on cardiac electrophysiology. Omega-3 fatty acids constitute 30% to 50% of fish oil supplements and 85% of prescribed pharmacologic preparations (i.e., Lovaza and Vascepa). In clinical trials, both Lovaza and Vascepa 4 g/day lowered triglyceride levels by 45%. Fish oil supplements seem to be a reasonable, cost-effective means to reduce triglyceride levels; side effects include eructation, taste perversion, and dyspepsia.

Other agents to consider are neomycin, lomitapide, and mipomersen. These agents can be considered in the management of patients with refractory LDL elevations. Neomycin complexes with bile acid and lowers LDL levels. It also inhibits production of apolipoprotein(a) in the liver and lowers Lp(a). It is recommended as adjuvant therapy for patients with familial hypercholesterolemia and Lp(a) excess. Important side effects include nephrotoxicity and ototoxicity. Lomitapide inhibits microsomal triglyceride transfer protein in the liver and decreases apo B. Significant reductions in LDL (up to 50%) are seen with treatment. Liver toxicity is a serious adverse event associated with this agent.

Mipomersen is another agent approved for use in homozygous familial hypercholesterolemia. It binds apo B messenger RNA and inhibits apo B production. Apo B is a structural component of VLDL, IDL, and LDL. Treatment reduces LDL by up to 50%. Side effects include flu-like symptoms, injection site reactions, elevations in liver enzymes, and liver toxicity. The side effect profile and expense associated with both lomitapide and mipomersen limit the use of these agents to individuals with homozygous familial hypercholesterolemia.

LIPID DISORDERS

A number of specific disorders of overproduction or impaired removal of lipoproteins result in dyslipidemia (see [Tables 69-2](#) and [69-3](#)). These disorders are often familial, but secondary causes also need to be considered. Comorbid conditions (diabetes, hypothyroidism), medications (estrogen, glucocorticoids, β -blockers), and lifestyle factors (diet, alcohol) can increase the production and clearance of lipoproteins. Addressing these factors can often normalize lipid levels. If abnormalities persist, evaluation of genetic factors and treatment with pharmacologic therapy may need to be considered.

Familial Hypercholesterolemia

Mutations in the gene that encodes the LDL (apo B/E) receptor result in familial hypercholesterolemia. Impairment in LDL receptor synthesis or function decreases the clearance of LDL and increases circulating LDL levels, resulting in cholesterol plaque formation. These plaques deposit in the arteries (atheroma), skin or tendons (xanthoma), eyelids (xanthelasma), and iris (corneal arcus). The homozygous form of this autosomal dominant disorder is rare. Affected individuals present early in life with elevated levels of total cholesterol (600 to 1000 mg/dL) and LDL-cholesterol (550 to 950 mg/dL). Triglyceride and HDL-cholesterol levels are normal. These patients develop CHD, aortic stenosis due to atherosclerosis of the aortic root, and tendon xanthomas (often in the Achilles tendon). If the condition remains untreated, patients with homozygous familial hypercholesterolemia typically die of myocardial infarction before 20 years of age. The heterozygous form of familial hypercholesterolemia affects 1 in every 500 individuals, with the partial receptor defect resulting in cells that display half the normal number of fully functional LDL receptors. These individuals have less strongly elevated concentrations of total cholesterol (>300 to 600 mg/dL) and LDL-cholesterol (250 to 500 mg/dL) than do those with the homozygous form. Premature CHD (before 45 years of age in men and 55 years in women) and tendon xanthomas are characteristic clinical findings.

Although familial hypercholesterolemia can be established by identifying one of the many gene mutations in the LDL receptor or by demonstrating diminished LDL receptor function, the diagnosis of familial hypercholesterolemia usually is made on the basis of clinical features. Elevated total cholesterol (>300 mg/dL) and LDL-cholesterol (>250 mg/dL) in an individual with a personal or family history of premature CHD and tendon xanthomas identifies patients at risk for familial hypercholesterolemia. Treatment requires a low-fat (<20% of total calories), low cholesterol (<100 mg/day) diet in combination with drug

therapy. Usually, patients with familial hypercholesterolemia require multiple agents to lower cholesterol levels to the target range. In patients who do not tolerate the medications or who have limited receptor function, liver transplantation to provide functional receptors, ileal bypass surgery to decrease gastrointestinal absorption of bile acids, or LDL apheresis to remove excess LDL may be considered. Both lomitapide and mipomersen may also be considered as adjuvant therapy.

Familial Defective Apolipoprotein B100

In this autosomal dominant disorder, a defect in the apo B100 protein results in impaired binding of LDL particles to the LDL receptor. The disorder affects as many as 1 in 750 Caucasians with hypercholesterolemia. The clinical presentation is similar to familial hypercholesterolemia, with elevated total cholesterol and LDL-cholesterol levels associated with premature CHD and tendon xanthomas. However, the homozygous and heterozygous clinical forms of familial defective apo B100 are milder than familial hypercholesterolemia, because apo E-mediated clearance of remnant particles is still functional. Total cholesterol concentration ranges from 350 to 550 mg/dL in the homozygous and 200 to 350 mg/dL in the heterozygous disorder. DNA analysis can identify the apo B100 gene mutation and confirm the diagnosis, but genetic diagnosis is not necessary to initiate therapy. A low-cholesterol, low-fat diet in combination with a statin, bile acid resin, and/or niacin is recommended to lower cholesterol levels to target ranges.

Elevated Plasma Lipoprotein(a)

Lp(a) is a specialized form of LDL that is assembled extracellularly from apolipoprotein(a) and LDL. Lp(a), when present at elevated levels, interferes with fibrinolysis by competing with plasminogen. This leads to decreased thrombolysis and increased clot formation. Lp(a) also binds macrophages, promoting foam cell formation and atherosclerotic plaques. Screening should be considered in individuals who have a family or personal history of premature CHD without dyslipidemia and in those for whom cholesterol-lowering therapy has failed. The diagnosis can be made by documenting Lp(a) levels higher than 30 mg/dL in a patient with premature CHD. The primary goal of therapy is to lower LDL levels with agents such as statins. If LDL goals cannot be achieved, then Lp(a)-lowering therapy with niacin and neomycin may be considered.

Polygenic Hypercholesterolemia

Hypercholesterolemia in a population is mostly due to small influences of many different genes. The exact nature of these genetic defects is poorly defined, but apo E may play a role in the pathogenesis. Apo E4 on chylomicrons and VLDL remnants has a high affinity for the LDL receptor. Elevated binding of apo E4-containing lipoproteins to LDL receptors may downregulate LDL receptor synthesis and increase circulating LDL levels. Environmental factors such as diet can influence production of chylomicrons and VLDL, resulting in downregulation of the LDL receptor in conditions with high apo E4. This leads to an increased propensity for CHD, and treatment with LDL-lowering agents is recommended based on risk factors (see [Table 69-7](#)).

Familial Combined Hyperlipoproteinemia

Familial combined hyperlipoproteinemia (FCHL) is an autosomal dominant polygenic disorder that affects 1% to 2% of the population. Factors such as diet, glucose intolerance, and medications can influence the phenotypic presentation. In FCHL, the liver synthesizes excess VLDL. VLDL is hydrolyzed by LPL to produce LDL. Mutations in the *LPL* gene affecting its expression or function can decrease the efficiency of VLDL catabolism. Dysfunction of LPL is observed in one third of patients with FCHL. Diminished LPL activity increases circulating VLDL-triglyceride; furthermore, fewer VLDL remnant particles are available for HDL synthesis. Therefore, FCHL needs to be considered in all patients whose total cholesterol level is greater than 250 mg/dL, triglycerides greater than 175 mg/dL, or HDL-cholesterol less than 35 mg/dL.

There are no definitive diagnostic tests, but family screening can help confirm the diagnosis. The phenotype of FCHL is variable, with individuals displaying high LDL-cholesterol, high VLDL-triglyceride, or both based on the genetic defect and environmental factors. Patients also typically have high apo B (>120 mg/dL) and a low ratio of LDL-cholesterol to apo B100 (<1.2). They accumulate small dense LDL particles, which are thought to be atherogenic and contribute to premature CHD. Xanthomas or xanthelasmas are not a feature of this disorder. Affected individuals require a low-fat, low-cholesterol diet plus multiple lipid-lowering drugs to achieve target goals. Fibric acid derivatives, which hydrolyze the triglyceride core of VLDL particles and increase LDL production, are recommended for treatment of the hypertriglyceridemia. Patients with FCHL often additionally require a statin or niacin to lower their LDL-cholesterol level.

Familial Dysbetalipoproteinemia

Apo E on the surface of lipoprotein particles binds LDL receptors and facilitates clearance of remnant particles from the circulation. The apo E2 allele has a lower affinity for LDL receptors than apo E3 or apo E4. In individuals who are homozygous for apo E2, LPL hydrolyzes the triglyceride core and the resulting cholesterol-rich chylomicrons. VLDL and IDL remnant particles accumulate in the circulation. Expression of this phenotype usually requires a precipitating condition that increases lipoprotein production (e.g., diabetes, alcohol consumption) or decreases clearance (e.g., hypothyroidism). In addition to the more common autosomal recessive mutation of apo E described earlier, several apo E mutations have been described that result in an autosomal dominant phenotype manifesting in childhood. Premature CHD, peripheral vascular disease, and xanthomas involving the palmer crease are characteristic clinical features. Individuals with familial dysbetalipoproteinemia have elevated levels of total cholesterol (300 to 400 mg/dL) and triglycerides (300 to 400 mg/dL). Definitive diagnosis requires genetic testing to identify apo E2 homozygosity or mutation. Treatment of coexisting conditions such as diabetes and hypothyroidism can normalize lipid levels in apo E2 homozygotes. If target levels are not achieved, dietary therapy and lipid-lowering drugs such as fibric acid derivatives and HMG-CoA reductase inhibitors should also be considered.

Lipoprotein Lipase Deficiency

Mutations in the *LPL* gene resulting in deficiency of LPL synthesis or function lead to increased circulating chylomicron and VLDL particles and severe hypertriglyceridemia. Homozygous LPL deficiency is rare. It manifests in childhood with triglyceride levels higher than 1000 mg/dL. Heterozygous LPL deficiency occurs in 2% to 4% of the population and usually requires a precipitating factor, such as uncontrolled diabetes or estrogen therapy, to manifest the phenotype. These individuals have moderate hypertriglyceridemia (250 to 750 mg/dL) that can increase to levels greater than 1000 mg/dL with secondary factors. This can result in the chylomicronemia syndrome, which is characterized by marked hypertriglyceridemia (>1000 to 2000 mg/dL), pancreatitis, eruptive xanthomas, lipemia retinalis, and hepatosplenomegaly. Visual inspection demonstrates lipemic plasma. After refrigeration for 12 hours, a creamy top layer (increased chylomicrons) or turbid plasma infranatant (increased VLDL), or both, can be demonstrated. Documentation of diminished LPL activity confirms the diagnosis. A diet low in fat (<10% of total calories or 20 to 25 g/day) is the primary treatment. Secondary factors such as uncontrolled diabetes and alcohol use should be addressed, and VLDL-lowering agents (e.g., fibric acid derivatives, niacin) may be needed to prevent severe hypertriglyceridemia.

Apolipoprotein C-II Deficiency

Apo C-II is an activating cofactor for LPL. Deficiency of apo C-II is a rare autosomal recessive disorder that leads to increased chylomicrons and VLDL particles in the circulation, resulting in severe hypertriglyceridemia. Clinical manifestations are similar to those of LPL deficiency, including hypertriglyceridemia (>1000 mg/dL) and symptoms of pancreatitis, eruptive xanthomas, lipemia retinalis, and hepatosplenomegaly. Treatment recommendations include appropriate management of secondary factors such as diabetes and hypothyroidism, dietary fat restriction (<10% of calories), and drug therapy (e.g., fibric acid derivatives). For severe hypertriglyceridemia, plasma transfusion (with apo C-II) can be considered.

Familial Hypertriglyceridemia

Familial hypertriglyceridemia is an autosomal dominant disorder that is characterized by overproduction of hepatic VLDL. The exact defect or mutation is unknown. Secondary factors that increase VLDL, such as diabetes, alcohol ingestion, and estrogen therapy, appear to exacerbate this condition. Low HDL

associated with familial hypertriglyceridemia is related to increased catabolism. Individuals with this condition have hypertriglyceridemia (200 to 500 mg/dL) and low HDL-cholesterol (<35 mg/dL) at presentation. This diagnosis is considered in individuals who have a family and personal history of hypertriglyceridemia, CHD, and normal LDL levels. Cloudy infranatant after overnight refrigeration of plasma identifies a disorder of VLDL metabolism. Treatment starts with management of secondary factors that may exacerbate the condition. Dietary fat restriction (<10% of calories) and drug therapy with fish oil, niacin, and fibric acid derivatives should be initiated if target goals are not achieved.

 For a deeper discussion on this topic, please see Chapter 206, "Disorders of Lipid Metabolism," in Goldman-Cecil Medicine, 25th Edition.

THE SPECIALTY OF WOMEN'S HEALTH

The specialty of women's health grew out of the recognition that differences in the biology of men and women are responsible for differences in the prevalence, presentation, and management of some diseases. The focus of women's health is on conditions unique to women (e.g., pregnancy), conditions that are more common in women (e.g., breast cancer, osteoporosis, some rheumatologic diseases), and conditions that have different presentations, natural history, risk factors, and prevention or treatment strategies in women and men (e.g., heart disease, sexually transmitted infections, urinary tract infections). Specialists in this area come from all disciplines and include obstetrician-gynecologists, general internists, subspecialty internists, family medicine, radiologists, and surgeons. In this chapter, we focus on medical issues unique to women and highlight what is known about gender differences in common diseases. For more detailed discussions of specific topics, please refer to the appropriate chapters in this edition of *Cecil Essentials of Medicine* and the 25th edition of *Goldman-Cecil Medicine*.

WHAT MAKES WOMEN DIFFERENT FROM MEN?

There are substantial biologic, physiologic, and psychosocial differences between men and women. Although we have an in-depth understanding of some of the differences, others are just beginning to be elucidated, and still others remain undiscovered.

Women tend to be physically smaller than men. Women have less renal mass, and defining normal renal function takes this into account. Women typically have a 15% lower creatinine clearance rate than men with the same level of creatinine. The volume of muscle and fat varies by gender and age, which affects the metabolism of medications and estimates of kidney function. Women have smaller blood vessels than men. Until smaller intravascular catheters were created, this biologic difference made cardiac catheterizations in women technically more challenging.

Gender also influences treatment. A study of more than 700 physicians presented with several hypothetical patient scenarios found that the race and sex of a patient independently influenced how physicians managed chest pain. Women, particularly black women, were significantly less likely to be referred for catheterization than white men.

Differences in physiology affect biologic responses. For example, to increase cardiac output, women increase heart rate, whereas men increase stroke volume, in part by increasing vascular resistance. These physiologic differences may have different pathophysiologic consequences for men and women. Sympathetic tone varies by gender. Women have reduced sympathetic

activity and enhanced parasympathetic activity compared with men. This may be one reason that premenopausal women tend to have lower blood pressure than age-matched men and why women may be more susceptible to orthostatic hypotension and fainting than men.

Hepatic drug clearance varies by gender, ethnicity, and race. Gender-related differences in pharmacokinetics in part determine the clinical effectiveness and potential adverse effects of drug therapy. Physiologic differences include the usually lower body weight and organ size, higher percentage of body fat, lower glomerular filtration rate, and different gastric motility in women compared with men. Molecular differences involve drug transporters and drug-metabolizing enzymes. Clinically important gender differences in pharmacodynamic processes include risk of QT prolongation, which can lead to a potentially fatal ventricular arrhythmia, torsades de pointes. A much higher percentage of women than men develop torsades after taking a variety of drugs, including certain antibiotics, antiarrhythmics, and antipsychotics. In addition to differences in drug transport and metabolism that result in different plasma and intracellular drug levels, the baseline electrocardiographic rate of corrected QT interval (QTc) is naturally longer in women than in men. Because there are gender differences in the rate of cardiac repolarization, drugs that are known to prolong the QTc interval should be carefully prescribed and monitored.

The approach to menstrual disorders is guided by an understanding of the physiology of reproduction. Estrogen levels vary substantially throughout life. With the onset of puberty, the hypothalamus begins releasing gonadotropin-releasing hormone (GnRH), leading to ovarian stimulation. The normal menstrual cycle requires precise regulation and feedback of hormones involving the hypothalamus, pituitary gland, and ovaries, with the uterus acting as an end organ for ovarian steroid effects. The menstrual cycle consists of the follicular or proliferative phase, ovulation, and the luteal or secretory phase. The physiologic changes that define the menstrual cycle, including variations in hormones, the uterine lining, and basal body temperature (taken on awakening), are graphically represented in [Figure 70-1](#).

During the follicular phase, the hypothalamus secretes GnRH, which stimulates the pituitary to release gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). LH and FSH then stimulate ovarian follicular development and estrogen secretion. Estrogen secretion results in proliferation of the endometrium. Eventually, one follicle with its oocyte becomes dominant, and maturation results in ovulation, which occurs soon after an LH surge. With ovulation, the oocyte leaves the dominant follicle and migrates toward the fallopian tube. The

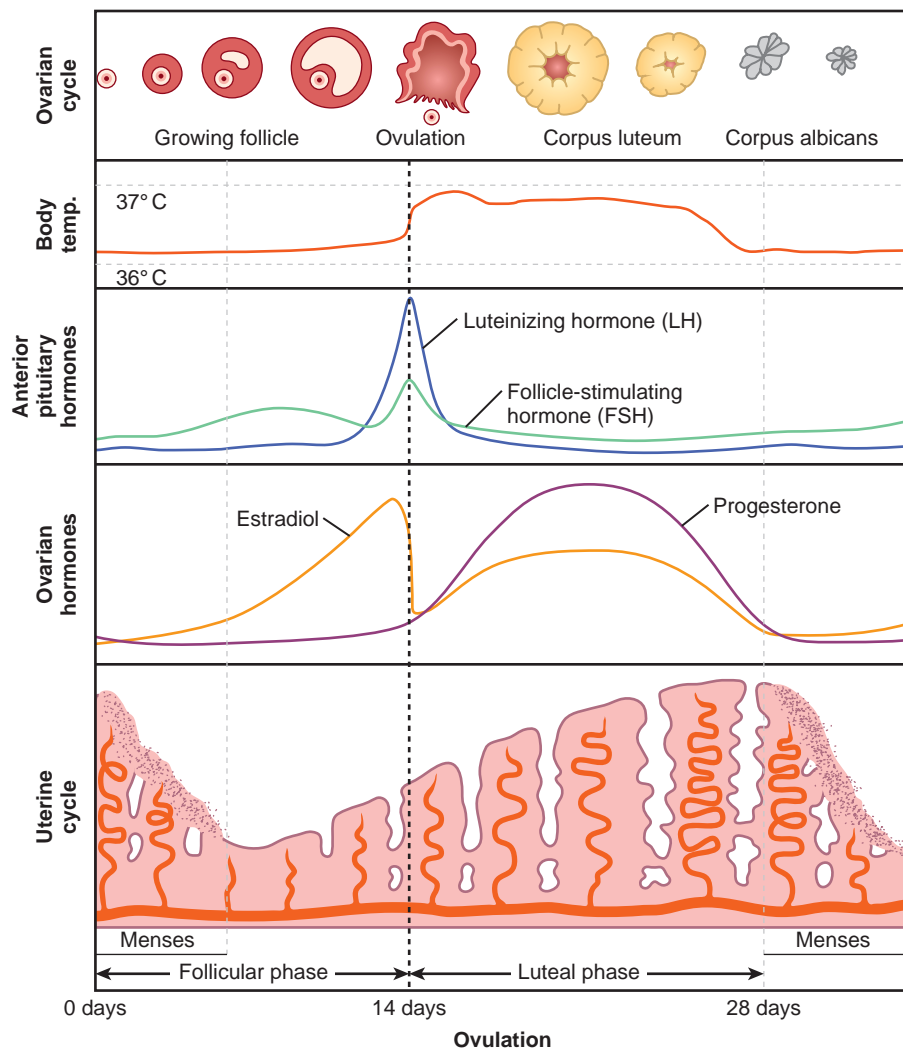

FIGURE 70-1 The physiologic changes that define the menstrual cycle.

remaining cells in the follicle become the corpus luteum, which produces progesterone during the luteal phase. If fertilization does not occur, progesterone is secreted for about 14 days, and the follicle then involutes. This is associated with decreasing levels of estrogen and progesterone. The endometrium is shed in response to the falling estrogen and progesterone levels, and menstruation occurs.

Normal menstrual cycles usually occur monthly from adolescence until the time of menopause, which begins between the ages of 45 and 55 years. Cycle duration tends to become consistent within several years of menarche due to maturation of the hypothalamic-pituitary-ovarian hormonal axis. The median menstrual cycle length is 28 days, with a normal range between 25 and 35 days. The duration of menses typically is between 2 and 7 days. Delays in the expected onset and abnormalities of menstrual cycles often require evaluation for possible disease, including hormonal and structural disorders.

Estrogen receptors have been identified throughout the body, including reproductive organs and nonreproductive organs such as the brain, arteries, bone, smooth muscle, and urethra. Declining levels of estrogen at menopause explain some of the systemic changes that occur in postmenopausal women. The diagnostic

approach to abnormal genital bleeding and menopause is discussed later in this chapter.

Gender Differences in Societal Factors

Complex societal factors, including processes of socialization, expectations about work and home, lifestyle behaviors, and other psychosocial factors, can explain differences in the health of men and women. Research shows that women still occupy different positions in society than men. Women are less likely to be employed and more likely to have lower incomes, live in poverty, and be single parents than men. Men are more likely than women to smoke, consume alcohol, eat an unbalanced diet, and be overweight. Women are more likely than men to be physically inactive. However, both men and women of lower socioeconomic status (SES) have a higher prevalence of risky lifestyle behaviors. Women are more likely to report health problems, in part due to higher social demands and perceived obligations. Gender differences exist in perceived control and self-esteem, with women reporting lower levels of both than men, although women do report higher levels of social support.

Research has documented a relationship between health inequalities and socioeconomic inequalities in income,

education, occupational status, and employment status. Women may have overall lower rates of mortality, but they paradoxically report higher levels of depression, psychiatric disorders, distress, and a variety of chronic illnesses than men. It is important to recognize the impact of these social determinants on the health of all patients and to understand that the pathways through which social position, behavior, and psychosocial forces influence health are different for men and women. Patients must be encouraged to engage in a healthy lifestyle because healthy behaviors help to prevent weight gain, high blood pressure, cardiovascular disease, diabetes, arthritis, and early mortality.

WOMEN'S HEALTH ISSUES OVER THE LIFESPAN

Issues for Adolescents

Adolescence is a period of rapid physical and emotional change, and patients may have both pediatric and adult issues. Adolescents often do not have a good understanding of health issues and are embarrassed or nervous about asking questions. Health care providers must help adolescents navigate this period of change and educate them about healthy behaviors in an open and non-judgmental manner to create a therapeutic relationship.

Gender, Sexual Identity, and Sexual History

Adolescents often struggle with issues of gender, sexuality, and sexual behavior. They often avoid discussing these topics because of embarrassment, fear of being judged, or concerns about confidentiality. Discussing these issues in a safe, nonjudgmental manner can improve adolescents' understanding and promote healthy and responsible choices.

Individuals who identify themselves as lesbian, gay, bisexual, or transgender are at higher risk for substance abuse, intimate partner violence, and mental health issues. Asking about gender identity and sexual orientation is an important part of taking a sexual history. Many adolescents experiment, and their sexual behavior is not always a reflection of their gender identity or sexual orientation. A sexual history should include the number and gender of partners; use of contraception and barrier protection; types of sexual activities, including oral, vaginal, and anal sex; history of sexual abuse and intimate partner violence; history of coerced or forced sexual interactions; and use of alcohol or illicit substances during sex. Adolescents should be encouraged to make healthy choices regarding sexual activity, including abstaining from sex, using contraception and barrier protection, and seeking respectful partners.

Confidentiality

Adolescents often come to medical visits accompanied by a parent, and parental consent should be obtained for treatment of many medical issues. It is also important to interview all adolescents alone for part or all of the visit to discuss social and health history, because they do not feel comfortable discussing many issues in front of parents. Their history should remain confidential unless they divulge something that puts them or another individual at risk or have certain illnesses that are reportable to the department of public health. Regulations on confidentiality vary from state to state.

Adolescents often underestimate their parents' ability to understand their issues. Physicians should encourage adolescents to be open with their parents about health issues and bridge the communication divide.

Eating Disorders

Eating disorders often begin during the adolescent period. They include anorexia, bulimia, binge eating, and other disordered eating behaviors. These illnesses are characterized by distorted body image and dysfunctional behaviors that can lead to long-term physical and psychological issues. Rates of eating disorders are increasing, and white females tend to be disproportionately affected. Eating disorders often start with dieting and progressively develop into dysfunctional behaviors. Physicians who take care of adolescents should monitor weight and body mass index (BMI) and screen for alterations in body image and behaviors that suggest disordered eating. Management of eating disorders often requires a multidisciplinary approach with a primary care physician, psychologist, and nutritionist.

Sexually Transmitted Infections

Sexually transmitted infections (STIs) are common among adolescents. Human papillomavirus (HPV), *Chlamydia trachomatis*, and *Trichomonas* infections account for most cases, although gonorrhea, syphilis, herpesvirus, and human immunodeficiency virus (HIV) infections also occur.

All patients between the ages of 13 and 21 years should be screened for chlamydial and gonorrheal infections annually. Annual opt-out HIV testing is also recommended by the Centers for Disease Control and Prevention (CDC) for all patients between the ages of 13 and 64 years.

The HPV vaccine has been added to the standard pediatric immunization schedule and is recommended for girls and boys 9 to 11 years of age. If the HPV vaccine was not part of the normal schedule, it is approved for patients up to 26 years old. The vaccines have proved to be highly safe and effective, providing another means to prevent cervical cancer.

Primary Amenorrhea

Amenorrhea is defined as the lack of menses in a sexually mature female. It is categorized as primary or secondary amenorrhea. Primary amenorrhea is the lack of menarche by age 16 despite normal sexual development or the lack of menarche by age 14 in the absence of sexual development.

Primary amenorrhea is often caused by genetic or anatomic abnormalities. Breast development, presence of a uterus, and the levels of FSH and LH are important factors in determining the cause of primary amenorrhea. Lack of a uterus despite breast development may suggest androgen insensitivity or müllerian agenesis. If the uterus exists, an outflow tract obstruction such as an imperforate hymen or a transverse vaginal septum may be identified. However, if secondary sexual characteristics are missing, measuring FSH and LH levels can help to determine the difference between hypogonadotropic hypogonadism (i.e., constitutional delay or pituitary or hypothalamic failure) and hypergonadotropic hypogonadism (i.e., premature ovarian failure or Turner syndrome).

Issues for Adult Women

Promoting Wellness and Preventive Health

Comprehensive health care for women includes gender-specific and general services and counseling to promote healthful behaviors and practices to prevent disease. [Table 70-1](#) highlights evidence-based recommendations for preventive care specifically for women at average risk.

Screening for Cervical Cancer

Cervical cancer, the tenth leading cause of cancer death in the United States, occurs most often in women who have never been screened or not screened in the past 5 years. Infections with high-risk strains of HPV (16 and 18) are responsible for approximately 70% of cervical cancer cases. The incidence increases with early onset of intercourse; greater number of lifetime sexual partners; co-infection with other STIs, including HIV; high parity; long-term use of oral contraceptives; and cigarette smoking. Peak incidence of HPV infection occurs among women younger than 25 years of age, but most of these infections are transient. Approximately 10% of women remain HPV positive 5 years after infection. Cervical abnormalities that do transform into cancer are thought to progress over time from less severe to more severe lesions.

The U. S. Preventive Services Task Force (USPSTF) and the American Cancer Society (ACS), American Society of Colposcopy and Cervical Pathology (ASCCP), and American Society for Clinical Pathology (ASCP) published consensus guidelines for screening average-risk women. These recommendations do not apply to women who have had cervical intraepithelial neoplasia with moderately abnormal cells (i.e., CIN 2) or higher-grade cervical lesions, cervical cancer, or in utero diethylstilbestrol (DES) exposure or to women who are immunocompromised or HIV positive ([Table 70-2](#)).

Contraception

Approximately 62% of reproductive-age women in the United States are using some form of contraception, but almost one half of pregnancies are unintended. When helping patients choose a contraceptive method, several important variables should be considered. The first is efficacy and a patient's ability to adhere to the method. The efficacy of contraceptive methods depends on appropriate use ([Table 70-3](#)). Patients' past experiences with different forms of contraception and personal preferences may help to predict how well they will comply with current regimens.

Obtaining a thorough personal and family medical history can help to determine what methods are appropriate. Certain medical issues can make a choice too risky for one patient but provide a health benefit for another. For example, oral contraceptives that increase the risk of thrombosis are contraindicated for a patient with a strong family history of venous thrombosis, but they could correct anemia in a patient with menorrhagia. The patient's sexual history and assessment of the risk for STIs play a role in contraceptive choice and education about the use of barrier methods.

Methods of Contraception

Barrier methods include the male and female condom, diaphragm, and cervical cap. The diaphragm and cervical cap need to be fitted by a medical professional, require a prescription, and need to be left in 6 to 8 hours after intercourse to be effective. The male condom, which can be purchased over the counter, has the added benefit of helping to prevent the transmission of STIs.

Combination hormonal contraceptives are the most common form of hormonal birth control. They typically contain a low dose of estrogen ($\leq 35 \mu\text{g}$) and one of several progestones. Delivery methods include pills, patches, and intravaginal rings. Contraindications to combination hormonal contraception are related to the estrogen component and include a personal history of a thromboembolic event or known thrombogenic mutation, cerebrovascular accident (CVA), coronary artery disease (CAD), uncontrolled hypertension, migraine with aura, smoking after age 35, breast cancer, estrogen-dependent neoplasms, undiagnosed abnormal vaginal bleeding, liver tumors, and pregnancy.

Potential noncontraceptive benefits of combination oral contraceptives include regulation of menstrual flow and improvement in ovarian cyst recurrence, endometriosis, acne, polycystic ovarian syndrome, and mittelschmerz (i.e., midcycle pain). Long-term use of combination oral contraceptives has been associated with a reduced lifetime risk of endometrial and ovarian cancers. The World Health Organization (WHO) medical eligibility criteria for contraceptive use provide excellent guidance for the choice of contraceptive methods based on patients' risk factors (available at http://www.who.int/reproductivehealth/publications/family_planning/9789241563888/en/index.html [accessed August 1, 2014]). Patients should be able to take pills at approximately the same time each day.

The contraceptive patch is a form of combination hormonal contraception that is delivered transdermally. The patch is applied on a weekly basis for 3 weeks and then discontinued for 1 week. The patch delivers a higher average dose of estrogen but has lower peak doses. Another form of combination hormone delivery is the intravaginal ring. A flexible ring is inserted intravaginally for 3 weeks and then removed for 1 week when menses occur. The patch and the ring are reasonable options for patients concerned with medication compliance.

Progesterone-only contraceptives are an option for women intolerant of estrogen or at increased risk for thromboembolic events. Contraindications include active CAD, breast cancer, liver tumor, and phlebitis. They are slightly less efficacious than the combination pills, and women may experience breakthrough bleeding.

Depot medroxyprogesterone acetate (DMPA) is a progesterone-only injection administered every 12 weeks. It is a very reliable form of contraception. Major side effects include irregular bleeding (which resolves over time) and amenorrhea (50% at 1 year). Weight gain, hair changes, and acne are possible side effects. The U.S. Food and Drug Administration (FDA) issued a black box warning that DMPA may decrease bone density, especially in adolescents.

The intrauterine device (IUD) can be a great option for women who do not desire pregnancy in the next 5 to 10 years. Worldwide, it is the most widely used method of reversible

TABLE 70-1 PREVENTIVE HEALTH RECOMMENDATIONS FOR WOMEN

SCREENING	RECOMMENDATION	AGE AND INTERVAL
Alcohol	All women should be screened for alcohol misuse. Hazardous drinking defined as >7 drinks/week or >3/occasion. Drinking results in physical, social, and psychological harms, and women engaged in hazardous drinking should be provided with behavioral counseling interventions.	Beginning at age 18 and at contact with health care provider
Cardiovascular disease	All women should be assessed for their CV disease risk (hypertension, tobacco use, diabetes, family history, physical inactivity, unhealthy dietary lipids, overweight and obesity) and counseled on risk reduction strategies. The 10-yr CV risk can be calculated with risk assessment tool calculator. Lipid disorders screening includes total cholesterol, HDL, LDL, and triglycerides after a 12-hr fast	At contact with health care provider Women age ≥45 and women 20-44 yr if other risk factors present; interval not clear, but every 5 yr if low risk
Cancer		
Breast cancer	Mammography	ACS suggests annually at age 40 for as long as in good health; yearly for women of any age with greater than 20% lifetime risk USPSTF suggests biennial screening for women age 50-74. Biennial screening before age 50 should be addressed on an individual basis. Women in poor health are unlikely to benefit from screening. Current evidence insufficient to assess the additional benefits and harms of screening in women >75 yr.
	MRI	Based on breast cancer risk calculated using NCI's breast cancer risk assessment tool
Cervical cancer	See Table 70-2	
Ovarian cancer	Routine screening is not recommended by any organization. Women at high risk (strong family history, <i>BRCA1</i> and <i>BRCA2</i> genes) may consider screening.	
Uterine cancer	Routine screening is not recommended by any organization.	Women at high risk for HNPCC can be offered screening with endometrial biopsy at age 35.
Depression	All women should be screened; multiple screening tools available. Brief intervention: (1) "Over the past 2 weeks, have you felt down, depressed, or hopeless?" (2) "Over the past 2 weeks, have you had little interest or pleasure in doing things?"	At contact with health care provider
Infectious diseases		
STIs	Counseling recommended	High-intensity behavioral counseling to prevent STIs for all sexually active adolescents and adults at increased for STIs
Chlamydia	Testing recommended	All sexually active women ages 24 and younger and older women who are at increased risk
Gonorrhea	Testing recommended	All sexually active women if they are at increased risk for infection
Hepatitis C	Testing recommended	Screen women at high risk for infection and offer one-time screening if born between 1945 and 1965
HIV	Testing recommended	Adolescents and adults ages 15-65 yr; younger adolescents and older adults who are at increased risk and all pregnant women
HPV	See Table 70-2	
Obesity	All women should be screened. Women with a BMI >30 kg/m ² should be referred for behavioral interventions.	At contact with health care provider
Osteoporosis	Insufficient evidence to recommend combined calcium and vitamin D supplementation for primary prevention. Women should be counseled about daily calcium and vitamin D requirements and adequate weight-bearing and resistance exercises for prevention. DEXA bone density test; fracture risk can be assessed by FRAX	All women ≥65 yr and women <65 yr whose fracture risk is equal to or greater than that of a 65-yr-old woman with no additional risk factors. Women 50-64 yrs with a 9.3% 10-yr fracture risk determined by FRAX
Stroke	Daily aspirin for prevention of stroke when potential benefit of ischemic stroke reduction outweighs potential harm of increased gastrointestinal hemorrhage	Women 55-79 yr
Thyroid disorders	USPSTF finds insufficient evidence to recommend for or against routine screening for asymptomatic women; testing recommended for symptoms.	
Tobacco use	All women should be screened and provided with smoking cessation interventions.	At contact with health care provider
Violence	Screening and counseling for interpersonal and domestic violence	At contact with health care provider

ACS, American Cancer Society; BMI, body mass index; CV, cardiovascular; DEXA, dual-energy x-ray absorptiometry; FRAX, fracture risk assessment tool; HDL, high-density lipoprotein cholesterol; HIV, human immunodeficiency virus; HNPCC, hereditary nonpolyposis colon cancer; HPV, human papillomavirus; LDL, low-density lipoprotein cholesterol; MRI, magnetic resonance imaging; NCI, National Cancer Institute; STIs, sexually transmitted infections; USPSTF, U.S. Preventive Services Task Force.

TABLE 70-2 SCREENING RECOMMENDATIONS FOR CERVICAL CANCER

AGE	USPSTF	ACS/ASCCP/ASCP	COMMENTS AND RATIONALE
<21	No screening before the age of 21 despite time of sexual activity	No screening before the age of 21 despite time of sexual activity	HPV positivity and cytologic abnormalities are likely to regress in young women.
21-29	Screening with liquid-based or conventional cytology alone every 3 yr; HPV testing should not be performed.	Screening with liquid-based or conventional cytology alone every 3 yr; HPV testing should not be performed.	HPV co-testing should not be used for women <30 yr of age because incidence of HPV is high and cytologic abnormalities are often transient, leading to unnecessary and sometimes harmful interventions
30-65	Cytology alone every 3 yr or cytology with co-testing every 5 yr	Co-testing with cytology and HPV every 5 yr (preferred method) or cytology alone every 3 yr if HPV testing is not available	
>65	No further testing if adequately screened in the past and not otherwise at increased risk for cervical cancer	No further testing if adequately screened in the past	Adequate screening defined as two negative results in the past 10 yr with one in the past 5 yr and no history of CIN2 or greater grade neoplasia. Because cancer risk decreases with age and prior normal Pap tests, overtesting may lead to false-positive test results.
After hysterectomy	No further screening if no CIN2 or higher grade neoplasia	No further screening if no CIN2 or higher grade neoplasia	Clinicians should confirm that total hysterectomy was performed.
HPV vaccinated	Continue recommended screening	Continue recommended screening	

ACS, American Cancer Society; ASCCP, American Society of Colposcopy and Cervical Pathology; ASCP, American Society for Clinical Pathology; CIN 2, cervical intraepithelial neoplasia with moderately abnormal cells; HPV, human papillomavirus; Pap, Papanicolaou smear; USPSTF, U.S. Preventive Services Task Force.

contraception. Two types of IUDs are available in the US, and both are almost as effective as sterilization. The copper IUD can be left in 10 years, and the progesterone IUD can be left in for 5 years. The copper IUD can be associated with heavier menstrual bleeding and cramps. The progesterone IUD may initially have breakthrough bleeding, but almost one half of users become amenorrheic. Implanon is a progesterone rod that is implanted under the skin and is highly effective for 3 years. It can be placed in outpatient offices and is helpful in limiting dysmenorrhea, but it is associated with irregular menses.

Postcoital emergency contraception can be achieved with one or several hormonal options or with placement of a copper IUD. Hormonal options are available over the counter in the United States, and recommended use is up to 72 hours after intercourse. After contraception is discontinued, the time of return to fertility depends on the type of contraceptive used. The average time for return to fertility with combination hormonal contraceptives is 3 months. With DMPA, fertility can be delayed by 12 to 22 months.

Pregnancy

Preconception Counseling and Pregnancy Planning

Preconception counseling begins by obtaining a thorough medical history to assess potential risks to the mother and fetus. Women with a personal or family history of genetic disorders may benefit from formal genetic counseling. For the woman with no significant medical problems and no serious family medical history, education about maintaining a healthy lifestyle, nutritional supplementation, and avoidance of toxicities to the fetus are important.

In 2009, the Institute of Medicine published guidelines for weight gain during pregnancy and recommended that women planning pregnancy achieve their normal BMI before conception. Advising and assisting the overweight or obese patient in weight loss efforts before pregnancy can prevent gestational diabetes, adverse fetal outcomes, and pathologic musculoskeletal

conditions. Avoidance of tobacco, alcohol, and illicit drugs is critical because they are harmful to both mother and fetus. All women planning pregnancy or capable of becoming pregnant should be advised to take a daily multivitamin with folic acid (400 to 800 µg) to reduce the risks of neural tube defects and other congenital anomalies, including cardiovascular defects, urinary defects, and cleft lip.

Routine laboratory evaluation includes rubella titer, varicella titer (in women with a negative history of varicella), hepatitis B surface antigen, and a complete blood count (CBC), assessing for hemoglobinopathy. Women should receive HIV testing and counseling.

An important goal is to ensure that women are immune to measles, mumps, rubella, tetanus, diphtheria, poliomyelitis, and varicella. Women should receive influenza vaccine in pregnancy due to the increased risk of complications from influenza infection. Ideally, women should receive all indicated vaccinations at least 1 month before conception. Live vaccines (e.g., rubella) should not be given during pregnancy.

The patient's medications, including prescribed, over-the-counter, and herbal medications, should be reviewed to identify potential teratogens. Medications not considered absolutely necessary for the well-being of the mother or fetus should be stopped. This is not always possible or indicated for women being treated for chronic medical conditions.

Medical conditions known to increase the risk of adverse pregnancy outcomes for women and their offspring include diabetes, thyroid disease, seizure disorders, hypertension, rheumatoid arthritis, chronic renal disease, thrombophilias, asthma, and cardiovascular disease. Preconception care of these conditions can improve pregnancy outcomes. Patients usually are referred to high-risk pregnancy care for evaluation. Approximately 1% of pregnancies in the United States are complicated by pregestational diabetes. Gestational diabetes (GDM) occurs in approximately 7% of pregnancies. GDM has a high recurrence rate (30% to 80%) in subsequent pregnancies and a significantly increased

TABLE 70-3 COMPARISON OF LONG-ACTING, REVERSIBLE CONTRACEPTION METHODS

METHOD	PERCENTAGE OF WOMEN WITH AN UNINTENDED PREGNANCY DURING FIRST YEAR OF USE		PERCENTAGE OF WOMEN CONTINUING USE AT 1 YEAR [‡]
	Typical Use [*]	Perfect Use [†]

Emergency contraceptive pills	Use within 72 hr after unprotected intercourse reduces risk of pregnancy $\geq 75\%$. ^{††}		
Lactational amenorrhea method	Highly effective, temporary method of contraception ^{††}		

Modified from Trussell J, Wynn LL: Reducing unintended pregnancy in the United States, *Contraception* 77:1–5, 2008.

^{*}Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides, withdrawal, fertility awareness–based methods, the diaphragm, the male condom, the pill, and Depo-Provera are taken from the 1995 National Survey of Family Growth (NSFG), corrected for underreporting of abortion; see the reference above for the derivation of estimates for other methods.

[†]Among couples who initiate use of a method (not necessarily for the first time) and who use it perfectly (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Trussell and Wynn (2008) provide the derivation of the estimate for each method.

[‡]Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

[§]The percentages for becoming pregnant in columns 2 and 3 are based on data from populations in which contraception is not used and from women who cease using contraception to become pregnant. Among these populations, about 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentage who would become pregnant within 1 year among women now relying on reversible methods of contraception if they abandoned contraception altogether.

^{||}Foams, creams, gels, vaginal suppositories, and vaginal film.

[†]The ovulation and 2-day methods are based on evaluation of cervical mucus. The standard days method avoids intercourse on cycle days 8 to 19.

^{**}With spermicidal cream or jelly.

^{**}Without spermicides.

^{††}The treatment schedule is one dose within 120 hr after unprotected intercourse and a second dose 12 hr after the first dose. Both doses of plan B can be taken at the same time. Plan B (one dose is one white pill) is the only dedicated product specifically marketed for emergency contraception. The U.S. Food and Drug Administration also has declared the following 22 brands of oral contraceptives to be safe and effective for emergency contraception: Ogestrel or Ovral (one dose is two white pills); Leven or Nordetto (one dose is four light orange pills), Crystelle, Levore, Low Ogestrel, Lo/Ovral, or Quasense (one dose is four white pills), Tri Leven or Triphasil (one dose is four yellow pills), Jolesse, Portia, Seasonale, or Trivora (one dose is four pink pills), Seasonique (one dose is four light blue-green pills), Empresse (one dose is four orange pills), Alesse, Lessira, or Levlite (one dose is five pink pills), Aviane (one dose is five orange pills), and Lultera (one dose is five white pills).

^{††}To maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breast-feeding is reduced, bottle feedings are introduced, or the baby reaches 6 months of age. The best estimates of failure rate of all types of tubal sterilization is 1.31 after 5 years and 1.85 per 100 women after 10 years; it is highest for tubal fulguration and lowest for segmental resection in the 10 years after the procedure.

risk for future development of type 2 diabetes. In women with pregestational diabetes and GDM, adequate control of diabetes reduces the risk of congenital malformations.

Thyroid disease is the second most common endocrine disease that affects reproductive-age women. Hyperthyroidism and overt hypothyroidism occur in approximately 0.2% and 2.5% of all pregnancies, respectively. Adequate treatment of thyroid illness improves pregnancy outcomes. Approximately 70% to 80% of women with rheumatoid arthritis experience remission of disease during pregnancy, although the remaining women have active or worsening disease in pregnancy. Women with systemic lupus erythematosus (SLE) often experience exacerbations in pregnancy.

SLE increases the risk of adverse fetal outcomes, including spontaneous abortion, fetal growth restriction, and preterm birth.

A few conditions confer significant mortality risks to the mother and fetus. Pulmonary hypertension (especially Eisenmenger's syndrome), congenital heart disease with hypoxia, poor functional class, and arrhythmias are associated with adverse maternal outcomes.

Medications in Pregnancy

Pregnant women should avoid the use of most medications (Table 70-4). However, the benefits of medications may outweigh the risks, particularly for women with chronic medical

TABLE 70-4 FOOD AND DRUG ADMINISTRATION CATEGORIES OF DRUG SAFETY DURING PREGNANCY

CATEGORY	INTERPRETATION
A	Adequate, well-controlled studies in pregnant women have not shown an increased risk to the fetus in any trimester of pregnancy.
B	Animal studies have revealed no evidence of harm to the fetus; however, there are no adequate and well-controlled studies in pregnant women. Or Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester.
C	Animal studies have shown an adverse effect, and there are no adequate and well-controlled studies in pregnant women. Or No animal studies have been conducted, and there are no adequate and well-controlled studies in pregnant women.
D	Adequate, well-controlled, or observational studies in pregnant women have demonstrated a risk to the fetus. However, the benefits of therapy may outweigh the potential risk.
X	Adequate, well-controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities or risks, and the use of the product is contraindicated in women who are or may become pregnant.

conditions. Few medications are absolutely contraindicated in pregnancy. Decisions about continuing or stopping medications require a discussion about the risks and benefits and an informed decision on the part of the woman.

Pregnancy Complications and Risk of Future Diseases

Women with a history of gestational diabetes are at increased risk for diabetes later in life. Women whose pregnancies were complicated by a gestational hypertensive disorder, such as preeclampsia or gestational hypertension, are at increased risk for subsequent essential hypertension. Women who have a history of a child with a neural tube defect should take 4 g of folic acid daily. Women with a prior problem pregnancy may benefit from close follow-up with an obstetric provider such as a high-risk pregnancy specialist to reduce subsequent problems.

Two important conditions to recognize are postpartum depression and postpartum thyroiditis. Postpartum depression may complicate 10% to 15% of pregnancies. The symptoms are the same as those of clinical depression in a nonpregnant woman. Risk factors for postpartum depression include a history of depression before pregnancy and depression during the current pregnancy. Postpartum thyroiditis may be seen in 7% to 8% of women. Only about one third of women have the classic hyperthyroid phase followed by hypothyroidism and recovery. Another 30% exhibit only hyperthyroidism, and the remaining 40% to 50% have only hypothyroidism. Unexpected symptoms after delivery should prompt an evaluation of thyroid function.

Lesbian Health

Being lesbian is not a homogeneous experience. The racial, ethnic, and socioeconomic diversity of the United States is mirrored in the lesbian community. The Institute of Medicine

TABLE 70-5 CAUSES OF SECONDARY AMENORRHEA

CAUSE	EXAMPLES
Physiologic changes Ovarian changes	Pregnancy, lactation, menopause Radiation- or chemotherapy-induced ovarian failure, chromosomal abnormalities, autoimmune or idiopathic
Anovulation	Hyperandrogenism (polycystic ovary syndrome, congenital adrenal hyperplasia), hyperprolactinemia (prolactinoma, phenothiazines, narcotics, and other medications), hyperthyroidism, hypothyroidism, hypopituitarism, pituitary adenoma, Cushing's syndrome, hypothalamic hypogonadism (eating disorder, athletic triad, stress)
Medications Uterine outflow abnormalities	Hormonal, cytotoxic, others Surgery, Asherman's syndrome

released a report acknowledging that lesbian, gay, bisexual, and transgender (LGBT) individuals experience unique health care disparities and encouraged health care providers to increase cultural competence to care for these populations. Lesbians are significantly more likely than heterosexual women to experience discrimination during health care visits. Many providers do not take a sexual history or inquire about sexual orientation. Health care providers may inadvertently assume heterosexuality and communicate heterosexist attitudes, making it more difficult for patients to disclose their sexual orientation. Physicians can create a safe and welcome environment for their lesbian patients by consistently adopting gender-neutral language. For example, "Do you have a significant other?" rather than "Are you married?" It is also important that confidentiality is ensured and that staff are aware of and comfortable with lesbian patients and their families.

Between 50% and 80% of lesbians report heterosexual sexual activity (which confers the highest risk for HPV acquisition) at some point in their lives, and screening for cervical cancer should follow the same guidelines as for heterosexual women. Although many STIs occur less frequently in lesbians, screening should be considered when appropriate. Counseling about lifestyle issues and screening when appropriate are the same for lesbians as for heterosexual women.

Gynecologic Issues

Menstrual disorders are common and usually categorized as *amenorrhea* and *abnormal uterine bleeding*. Abnormalities may indicate problems related to the reproductive system or may be an early sign of an important underlying systemic illness.

Amenorrhea

Amenorrhea occurs in 5% of women each year. It is the absence of menses for at least 3 to 6 months outside of the setting of pregnancy or lactation. Women with a previously established menstrual pattern have *secondary amenorrhea* (Table 70-5). *Oligomenorrhea* occurs when menses are irregular or infrequent, with a cycle length usually greater than 35 to 40 days, and it is often associated with *chronic anovulation* or oligo-ovulation. The most common cause of secondary amenorrhea is pregnancy. Lactation causes amenorrhea for up to 6 months in a woman who is exclusively breast-feeding her infant. Prolonged amenorrhea can follow cessation of some hormonal contraceptives, especially

DMPA. Menopause should be suspected in a woman older than 45 years.

Amenorrhea and oligomenorrhea may be caused by pathologic changes at any point in the endometrial-ovarian-pituitary-hypothalamic axis. The differential diagnosis for secondary amenorrhea is broad and is categorized by the primary organ failure or dysfunction: ovarian, hypothalamic, pituitary, and uterine (in descending order of frequency).

Evaluation should begin with a history, physical examination to assess comorbidities and anatomy, and urine test for human chorionic gonadotropin (HCG). If not pregnant, further evaluation should include serum levels of TSH, prolactin, and FSH. For women who have evidence of hyperandrogenism, the serum levels of total testosterone, 17-hydroxyprogesterone, and dehydroepiandrosterone sulfate (DHEAS) should be measured. Additional testing and evaluation should be pursued based on these findings.

For women with elevated prolactin levels, normal or low FSH levels with no clear reason (e.g., weight loss, exercise, recent illness, stress) or with visual symptoms or headaches, magnetic resonance imaging (MRI) of the brain should be performed to look for pituitary abnormalities. A high serum FSH level indicates premature ovarian failure, and women should be counseled regarding management, fertility concerns, and estrogen replacement. If a woman has a normal FSH level and a history of uterine manipulation, she should have a progestin challenge to rule out outflow tract abnormalities. Women with low or normal FSH levels and a history consistent with functional hypothalamic amenorrhea due to weight loss or exercise should be counseled about healthy weight and physical activity.

Abnormal Bleeding

Abnormal bleeding can be caused by many abnormalities, including anovulation, endometrial pathology, and coagulopathies. Women with *polymenorrhea* have a cycle less than 21 days long; women with *oligomenorrhea* have an interval greater than 40 days. Women with excessive bleeding in duration or quantity have *menorrhagia*. *Menometrorrhagia* is excessive bleeding at irregular intervals.

Women should be asked about their bleeding, including the onset, duration, pattern, and quantity of bleeding. A classification system (Fig. 70-2) for abnormal uterine bleeding (AUB) is organized by cause (i.e., structural or nonstructural). It has eliminated the terms *menorrhagia* and *menometrorrhagia* and replaced them with *heavy menstrual bleeding* and *intermenstrual bleeding*,

respectively. In the PALM-COEIN classification, the four main structural causes for AUB are *polyp*, *adenomyosis*, *leiomyoma*, and *malignancy* or hyperplasia, and the five nonstructural causes are *coagulopathy*, *ovulatory dysfunction*, *endometrial*, *iatrogenic*, and *not yet classified*.

Evaluation of AUB assesses for evidence of ovulatory cycles by inquiring about symptoms such as breast tenderness, cramping, and fluid retention before the onset of bleeding. Absence of these symptoms suggests anovulatory bleeding and focuses the differential diagnosis on hormonal causes. Anovulatory bleeding is the result of failed ovulation and the absence of a luteal phase. The ovary secretes estrogen unopposed by progesterone and leads to continued proliferation of the endometrium. This endometrium is unstable, which results in periodic, irregular, and often heavy bleeding. Bleeding due to coagulopathy follows a typically ovulatory pattern and produces heavy, regular bleeding. A personal or family history of bleeding disorders should be sought, because a significant fraction (5% to 32%) of women with heavy menstrual bleeding have an underlying bleeding disorder.

A general physical examination seeks evidence of anemia and a systemic cause of AUB such as thyroid disease or polycystic ovary syndrome. Genitourinary examination should verify the source of bleeding and may identify a cervical polyp, which typically is associated with postcoital bleeding, or an enlarged uterus, suggesting uterine fibroids. Pregnancy must always be excluded with a urine pregnancy test; a Pap smear and cervical cultures should be obtained to assess for cervical disease or infection. Laboratory testing should include a CBC, thyroid studies, and coagulation studies. Endometrial sampling should be performed for women age 45 or older and for women younger than 45 years of age who are at risk for endometrial hyperplasia or endometrial cancer (i.e., women with obesity or a history of chronic anovulation, failed medical therapy or persistent symptoms). For women with suspected structural abnormalities, a transvaginal ultrasound study should be pursued initially.

Management of abnormal bleeding depends on the underlying pathology identified and the degree of anemia caused by the bleeding. Hemodynamically unstable women may require uterine curettage or intravenous estrogen. For hemodynamically stable women, control of bleeding is usually achieved through the use of a combination of estrogen and progestin preparations such as oral contraceptive pills. Levonorgestrel-releasing IUDs can be used for women who have contraindications to estrogen therapy or for women who require long-term therapy. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used by women who do

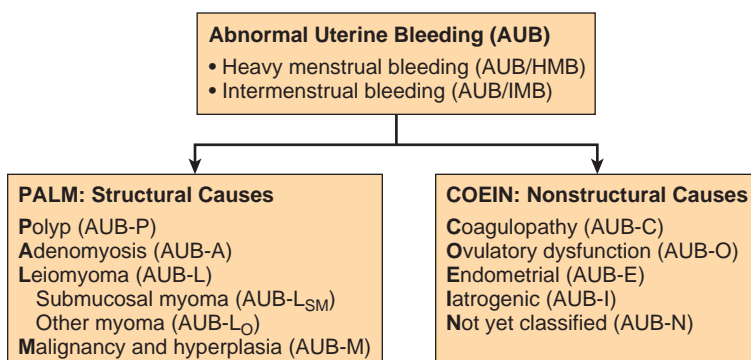

FIGURE 70-2 The PALM-COEIN classification of abnormal uterine bleeding. (From Munro MG, Critchley HO, Broder MS, Fraser IS; FIGO Working Group on Menstrual Disorders: FIGO classification system (PALM-COEIN) for causes of abnormal bleeding in nongravid women of reproductive age, *Int J Gynaecol Obstet* 113:3–13, 2011.)

not require contraception and who have dysmenorrhea. Surgical options, including endometrial ablation and hysterectomy, are usually reserved for women who have failed other treatments and do not desire future pregnancy.

Infertility

According to the CDC, 11% of U.S. women have trouble conceiving or carrying a pregnancy to term. Infertility is a failure to conceive after 1 year of regular intercourse without contraception. Infertility is more common with increasing age and is becoming more prevalent as women are deferring pregnancy and attempting to conceive at older ages.

Infertility may be caused by female factors or male factors. The most common female cause is an ovulatory factor (20% to 35%), which is often related to metabolic abnormalities, followed by tubal disease (20% to 25%) and uterine factors (5% to 15%). Approximately 20% to 30% of couples experience unexplained infertility. Evaluation should include a complete reproductive, medical, and gynecologic history and a physical examination to help identify metabolic or structural gynecologic abnormalities. Testing may include TSH, FSH, and prolactin levels in women with irregular menses or oligomenorrhea luteal phase serum progesterone levels or basal body temperature charting to confirm ovulation, and day 3 FSH testing in women 35 years of age or older to evaluate ovarian reserve. Further evaluation and treatment are usually performed by reproductive specialists.

Menopause

Menopause occurs when a woman has not had a menstrual cycle for 12 consecutive months or when her ovaries have been removed. The average age at menopause in western countries is 51.4 years, with a range of 40 to 58 years. Women who smoke experience an earlier menopause in a dose-dependent fashion, with an average of 1.5 years sooner than nonsmokers. Because the life expectancy of women is almost 80 years, many women spend at least one third of their lifetime in the postmenopausal period.

Although symptoms such as hot flashes and vaginal dryness may develop during menopause, the process itself is a normal part of the life cycle. This transition offers clinicians the opportunity to help women focus on important preventive health measures and define their risk for major chronic diseases, such as osteoporosis and CAD, as early as possible.

Transition from Perimenopause to Menopause

Much of our information about the menopausal transition is from the Study of Women's Health Across the Nation (SWAN). This multisite, multiethnic cohort study of women was designed to better understand the health of women during their middle years.

The transition to menopause can be erratic and prolonged over a 5- to 10-year period. It is characterized by ovarian and endocrine changes that ultimately result in the depletion of primordial oocyte stores and the cessation of ovarian estrogen production. An accelerated loss of follicles begins at about 37 years of age and is correlated with a small increase in FSH and decrease in inhibin levels. As the FSH concentration increases, the follicular phase of the cycle decreases, and one of the earliest clinical signs of the

menopausal transition is shortening of the menstrual cycle from a mean length of 30 days in the early reproductive years to 25 days in the early menopausal transition.

Later in the menopausal transition, the few remaining follicles respond poorly to FSH, and anovulation may occur. Menstrual cycles may become erratic with prolonged periods of oligomenorrhea. Ovulation may still occur, and women in this time period are advised to continue effective contraception until 12 months of amenorrhea have occurred. Ultimately, when ovarian follicles are depleted, the ovary no longer secretes estradiol but continues to secrete androgens due to continued stimulation by LH.

Perimenopausal Symptoms

Menstrual irregularities (experienced by almost 75% of women) are usually the first change noticed by women entering the menopausal transition. Although changes in the menstrual flow are expected and most women can be reassured, clinicians need to be aware of bleeding patterns that may represent underlying pathology and require evaluation (Table 70-6).

Sleep disturbances in perimenopausal women are a well-documented phenomenon. Hot flashes or sweats can disturb sleep patterns and interfere with sleep quality, resulting in fatigue, irritability, and difficulty concentrating. Vaginal dryness and dyspareunia are common symptoms that can interfere with sexual function.

Changes in mood and cognition are common complaints during the menopausal transition, but a causative link between hormonal fluctuations and mood disturbances and cognitive changes has not been established. Women who do experience significant depression at this time are more likely to have experienced depression earlier in their lives, particularly at times of hormonal change (e.g., postpartum depression, premenstrual dysphoric disorder [PMDD]). Mood issues during the perimenopausal transition should be approached in the same manner as at other ages. In addition to mood, many women in perimenopause complain of difficulties with concentration and memory. In the SWAN cohort, women had a small, transient decline in cognitive abilities during perimenopause, but anxiety and depression also had independent negative effects on cognition. Most epidemiologic studies do not demonstrate an increased risk of depression or a decline in cognitive skills during the menopausal transition.

The hot flash is the hallmark symptom of menopause. In the United States, up to 75% of women who experience a natural menopause and 90% of women who experience a surgical menopause have these vasomotor symptoms. Hot flashes may occur a few times per year or several times each day; 10% to 15% of

TABLE 70-6 ABNORMAL UTERINE BLEEDING PATTERNS IN POSTMENOPAUSAL WOMEN

Heavy menstrual bleeding (>80 mL), especially with clots
Menstrual bleeding lasting >7 days or ≥ 2 days longer than usual
Intervals of <21 days from the onset of one menstrual period to the onset of the next period
Spotting or bleeding between periods
Uterine bleeding after sexual intercourse

women have hot flashes that are very frequent or severe. For most women, vasomotor symptoms are self-limited, lasting on average 1 to 2 years; however, up to 25% of women may have symptoms for longer than 5 years.

The exact cause of a hot flash is not understood, although it is related to a disturbance of hypothalamic thermoregulation. Women experience a sudden onset of warmth, ranging from noticeable to markedly uncomfortable, especially over the face and upper body. This may be accompanied by significant perspiration. There are racial and ethnic differences in reported hot flashes, with African American women experiencing increased rates compared with white women and Hispanic and Asian women experiencing lower rates.

In the 1950s, it was discovered that estrogen could relieve hot flashes, and its use became widespread. In 1975, a study published in the *New England Journal of Medicine* showed that women who used estrogen for more than 7 years had a 14-fold increase in uterine cancer. Subsequent research determined that endometrial hyperplasia and cancer is reduced to essentially zero when low-dose progestin is continued for 12 to 13 days per month. Women on estrogen with an intact uterus must use progestin therapy to prevent endometrial hyperplasia and cancer.

Hormone treatment (i.e., estrogen or combined estrogen and progestin for women with an intact uterus) remains the most effective treatment of menopausal vasomotor symptoms (level A evidence). It is also FDA approved for the treatment of urogenital atrophy and the prevention of osteoporosis. In the 1990s, the results of the Heart and Estrogen/Progestin Replacement Study (HERS) found that women with preexisting heart disease had increased numbers of cardiac events when placed on estrogen.

The Women's Health Initiative (WHI) was designed to look at various hormone regimens and their effects on disease prevention, particularly cardiovascular disease, in postmenopausal women. More than 16,000 women participated in the trials, which ran for 5.6 years in the combined estrogen-progestin arm and 6.8 years in the estrogen-only arm. In the combined-therapy group, there was an increased risk for coronary heart disease (CHD) (hazard ratio [HR] = 1.29), an increased risk for stroke (HR = 1.41), an increased risk for pulmonary embolism (HR = 2.13), and increased risk for breast cancer (HR = 1.26). The combined-therapy trial was discontinued because of this excess risk.

The conclusion from the combined-therapy trial was that combination estrogen-progestin therapy should not be initiated or continued for the prevention of CHD. The estrogen-only trial did not find a significant increase in CHD or breast cancer but did show an increased risk of stroke (HR = 1.39). The conclusion was that estrogen alone should not be recommended for the prevention of chronic disease in postmenopausal women and hormone therapy should not be prescribed for disease prevention.

Postmenopausal Therapy

Hormone Therapy

Several medical societies have published guidelines for the use of postmenopausal hormone therapy, including the American College of Obstetricians and Gynecologists (ACOG) and the North American Menopause Society (NAMS). Most guidelines agree that estrogen and estrogen-progestin therapy are

appropriate for the treatment of moderate to severe vasomotor symptoms and for urogenital atrophy in women who have been appropriately counseled on the risks and benefits (level B evidence). If hormone therapy is initiated, the lowest dose needed to treat the symptoms should be used and usually for a short term (i.e., 2 to 3 years and not more than 5 years). For women who have only vaginal dryness, vaginal estrogen can be used instead of oral estrogen. It may be acceptable under some circumstances, provided the woman is aware of the potential benefits and risks, to extend low-dose therapy if the benefits of treatment outweigh the risks, and a woman has failed attempts to stop (level C evidence).

Alternative Therapies

Interest in nonhormonal and "natural" alternatives in the treatment of menopausal symptoms is extremely high. As many as 75% of menopausal women have used some form of alternative or complementary treatment to relieve menopausal symptoms. Behavioral options such as dressing in layers, regular exercise, stress reduction techniques, and avoidance of known triggers are safe and may be helpful for a number of women. Some of the more common herbal remedies for menopausal symptoms include isoflavones (e.g., soy, red clover) and black cohosh. None of these therapies has consistently been shown to decrease hot flashes beyond placebo in rigorous randomized, controlled trials.

There are effective nonhormonal medication options for treatment of hot flashes, although hormone therapy is superior to these alternatives. Although paroxetine is the only other FDA-approved medical treatment for hot flashes, paroxetine and venlafaxine have been shown to decrease hot flash frequency, but they may cause sexual side effects. Gabapentin and clonidine have been shown to reduce hot flash frequency beyond placebo.

Sexual Dysfunction

According to the largest study of prevalence of female sexual dysfunction in the United States (PRESIDE study), more than 40% of women report some form of sexual problems. Women between 45 and 65 years of age are disproportionately affected, just before and after the menopausal transition. Female sexual dysfunction diagnoses in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* include disorders of desire, arousal, and orgasm; dyspareunia; and vaginismus. Disorders of desire and arousal are the most common. Risk factors for dysfunction include depression and anxiety, relationship conflict, stress and fatigue, and a history of abuse. Medical and physical issues, such as pelvic floor disorders, endometriosis, and psychiatric and neurologic disease, can negatively affect sexuality.

Symptomatic vaginal atrophy occurs in up to 40% of postmenopausal women. As women age and enter menopause, the decline in estrogen levels causes thinning of the vaginal epithelium, decreased vaginal elasticity, and decreased vaginal lubrication, resulting in painful intercourse. Evaluation should include a thorough medical and sexual history and a pelvic examination, including vaginal cultures for STIs if there is pain or vaginal discharge.

Management of sexual dysfunction should be based on the underlying cause, such as evaluation of selective serotonin reuptake inhibitors (SSRIs), antihistamines, β -blockers, and

antipsychotics that may affect sexual function. Nonpharmacologic therapies include counseling, lifestyle changes to decrease stress and anxiety, physical therapy for vaginismus and pelvic floor dysfunction, and lubricants and vaginal moisturizers for dyspareunia caused by vaginal dryness. For some women, vaginal lubricants and moisturizers may be sufficient and are the first-line therapy.

Pharmacologic therapy for sexual dysfunction has primarily focused on hormonal therapy. In the WHI, hormone therapy did not have a beneficial effect on sexual dysfunction, but a Cochrane review examined hormone therapy for sexual function and found a small to moderate benefit in perimenopausal or early postmenopausal women. Topical vaginal estrogen results in little systemic absorption and is very effective in relieving the symptoms of vaginal atrophy.

Genitourinary Symptoms

Urinary incontinence rates increase with age. Urinary incontinence is common after menopause, with about 25% of women affected. The cause is often multifactorial. The endothelium of the urethra and bladder becomes more fragile and less elastic with menopause. Urethral tone also decreases with age. Uterine prolapse, cystoceles, and rectoceles increase the risk of incontinence. Risk also increases as body weight increases due to increased pressure on the bladder. Urinary incontinence and its behavioral and pharmacologic treatment options are discussed in Chapter 26, "Incontinence," in *Goldman-Cecil Medicine*, 25th Edition.

MEDICAL PROBLEMS WITH UNIQUE CONSIDERATIONS FOR WOMEN

Obesity, Metabolic Syndrome, Polycystic Ovary Syndrome, and Diabetes

Rates of obesity have increased steadily in recent decades, and more than one third of U.S. adults are obese (BMI >30). Overall, obesity appears to affect men and women equally, although women of lower SES are disproportionately affected. Obesity increases the risk for many diseases, including CAD, which is the leading cause of death for men and women. In women, central obesity (waist-hip ratio >0.9) predicts the risk of CAD. The risk of many cancers (e.g., endometrial cancer) is increased for obese individuals. Obesity has specific implications for women during pregnancy. It increases the risk of numerous pregnancy-related complications, including gestational diabetes mellitus, fetal macrosomia, hypertension, shoulder dystocia, and cesarean delivery, and contributes to postpartum complications such as thrombosis and infection. Obesity is also associated with irregular menses and higher rates of anovulation.

Metabolic effects related to obesity have been elucidated. The risk of cardiovascular disease related to the metabolic syndrome appears to have a stronger correlation in women. The National Cholesterol Education Program/Adult Treatment Panel III defines metabolic syndrome as the presence of three or more of five risk factors that increase the chance of developing heart disease or stroke: central obesity, elevated triglyceride levels, low levels of high-density lipoprotein (HDL) cholesterol, hypertension, and impaired fasting glucose values. Metabolic syndrome significantly increases the risk of type 2 diabetes and

cardiovascular disease, and these patients should be targeted for aggressive lifestyle modification to reduce contributory risk factors.

Polycystic ovary syndrome (PCOS) is an endocrine disorder primarily of androgen excess that affects approximately 5% to 10% of women worldwide. Reproductive and metabolic effects include anovulation, infertility, acne, hirsutism, obesity, and metabolic syndrome. Increased insulin resistance is a significant consequence of the syndrome, increasing the risk of type 2 diabetes, particularly in obese women. Women with PCOS are at increased risk for endometrial and ovarian cancers.

The risk of type 2 diabetes mellitus increases with obesity, and like obesity, the incidence of diabetes has been on the rise in the United States. More than 10% of adult Americans carry the diagnosis of diabetes, and many remain undiagnosed. Rates of diabetes are highest in black, Hispanic, and Native American groups. The increased cardiovascular disease risk conferred by diabetes is greater for women than for men, and women with diabetes have lower survival rates and quality of life after a cardiovascular event than their male counterparts. Women also have higher rates of blindness associated with diabetes. Identifying women with impaired fasting glucose values (i.e., prediabetes) can help to identify women likely to develop diabetes in the future. In addition to reviewing traditional risk factors for diabetes, a history of gestational diabetes and infant birth weight greater than 9 pounds should be considered when evaluating female patients for the risk of diabetes.

Breast Pain, Discharge, and Masses

Breast symptoms are common in practice and cause significant anxiety to patients. Although most breast complaints are about benign conditions, it is important to evaluate breast symptoms thoroughly to ensure that breast cancers are not being missed. Initial evaluation starts with obtaining a history and asking when symptoms began and how they evolved. For instance, a mass that is prominent premenstrually and then decreases in size in the follicular phase of menses is likely a benign cyst.

Breast pain is a common, nonspecific symptom that is usually benign. Localized breast pain is the only symptom in 10% to 15% of women with newly diagnosed breast cancer. Breast pain has cyclical and noncyclical patterns. Approximately two thirds of breast pain is cyclical in nature and related to the normal hormonal variations in the menstrual cycle. Noncyclical breast pain does not follow the usual menstrual pattern and is usually unilateral. Causes of noncyclical breast pain include large breasts, diet and lifestyle factors (e.g., caffeine, nicotine), inflammatory breast cancer, and various medications, including oral contraceptives, antidepressants, and antibiotics. In women older than 35 years of age, diagnostic mammography should be completed. If mammography and the physical examination are normal, reassurance can be provided. In women younger than 35 years of age, normal examination results can obviate the need for further testing.

Breast discharge is an uncommon sign of malignancy. About 5% of women with breast cancer have discharge as a symptom. Concern for malignancy is increased if the discharge occurs without provocation, is persistent, and is unilateral; if the discharge is serous, serosanguineous, or bloody; if it occurs in an older patient; or if it is associated with a mass or lump. The most

common malignancy causing discharge is ductal carcinoma in situ. However, a benign intraductal papilloma is the most common cause of bloody nipple discharge.

Most bilateral discharge that occurs only with manipulation is a normal physiologic response. Galactorrhea, bilateral milk production occurring in a nonlactating woman, can be seen in many conditions, including prolactinomas, thyroid dysfunction, and chronic renal failure. It can be a response to many drugs, including antipsychotics, oral contraceptives, and marijuana.

Initial evaluation for breast discharge includes a pregnancy test, prolactin level determination, and thyroid tests. If there is concern about malignancy, a breast specialist performs cytology, immunology, and occult blood testing on the discharge and obtains mammography and ultrasound studies.

There are four categories of breast masses: abscesses, benign masses, benign tumors, and cancer. Benign masses include cysts, galactoceles, papillomas, and fibroadenomas. Cancerous masses are typically painless, dominant masses that persist. Although breast cancers have characteristically been described as hard and immobile with irregular borders, no examination finding reliably distinguishes between a benign and cancerous mass.

Persistent masses require evaluation, which may include ultrasound, mammography, and biopsy, depending on the findings from the history, physical examination, and patient's age. Women younger than 30 years of age are at lower risk for malignancy. Ultrasound is the first imaging modality indicated for young women. If the mass is a cyst, it can be aspirated if symptomatic. If the mass is solid and is not characteristic of a fibroadenoma (which can be observed or biopsied), a biopsy is indicated to rule out malignancy. In women older than 30 years of age, mammography is the first diagnostic test that should be ordered, even if the woman had a recent negative screening mammogram. Ultrasound is often done simultaneously to further evaluate the mass or an area of abnormality detected on the mammogram. Negative imaging results should not preclude further work-up of a clinically suspicious mass. Mammography misses 10% to 20% of clinically palpable breast cancers.

Pelvic Pain

Pelvic pain is characterized as acute or chronic, and both types are commonly encountered in primary care practice. Acute pelvic pain usually manifests over hours to days and may be gynecologic, gastrointestinal, or urologic in origin. Life-threatening conditions, including ruptured ectopic pregnancy and appendicitis, need to be ruled out. Gynecologic causes include complications of pregnancy, acute pelvic infection, and ovarian pathology, including cyst and torsion.

Chronic pelvic pain (CPP) is lower abdominal pain of at least 6 months' duration, and it is severe enough to cause functional impairment or require treatment. Approximately 10% of ambulatory gynecologic referrals are for CPP. The history obtained for evaluation of CPP should include characteristics of the pain; a thorough review of systems; prior medical, surgical, gynecologic, and obstetric history; and a thorough psychiatric and social history, including episodes of domestic violence as a child or an adult and periods of substance abuse.

The most common conditions associated with CPP include endometriosis, chronic pelvic inflammatory disease, interstitial cystitis, irritable bowel syndrome, pelvic floor myalgia,

myofascial pain, and neuralgia. Interstitial cystitis or painful bladder syndrome is a clinical diagnosis consisting of pain, pressure, or discomfort related to the bladder and associated with lower urinary tract symptoms lasting more than 6 weeks and occurring in the absence of infection or other identifiable causes. Mental health issues, including substance abuse, somatization, depression, and physical or sexual abuse, can also cause CPP and are important to identify so that women need not undergo unnecessary testing and interventions.

Physical examination should assess for focal areas of pain, scars, hernias, or masses in the abdomen, and a pelvic examination should be performed. After the most likely diagnosis has been identified, an empirical, targeted treatment may be instituted and followed for efficacy. Further work-up should be considered if the patient does not respond or symptoms change. If empirical therapy and a thorough investigation do not yield a diagnosis, laparoscopy may be considered to identify pelvic pathology.

Depending on the underlying cause, management strategies may include heat therapy (for musculoskeletal pain), counseling and psychiatric referral, gastrointestinal referral, medications (e.g., gabapentin for neuropathic pain, NSAIDs, hormonal contraceptives), hysterectomy, and nerve transection procedures. Multidisciplinary approaches, including medications and interventions that address dietary and psychosocial factors, may be superior to medical treatment alone.

Intimate Partner Violence

Intimate partner violence (IPV) is a serious, preventable public health problem. In 2013, the USPSTF revised their guidelines to recommend that clinicians screen women of childbearing age (14 to 46 years old) for IPV and provide or refer women to intervention services when appropriate. Several screening instruments detect IPV effectively, and most experts think the benefits of detection outweigh the potential harm. Providers can choose among many tools for screening, including Hurt-Insult-Threaten-Scream (HITS), Ongoing Abuse Screen/Ongoing Violence Assessment Tool (OAS/OVAT), and Abuse Assessment Screen (AAS).

A short but effective survey may be more practical. The STaT (i.e., slapped, threatened, and thrown things) screening tool is relatively easy to implement by asking three questions: Have you ever been in a relationship in which your partner has pushed or slapped you? Have you ever been in a relationship in which your partner threatened you with violence? Have you ever been in a relationship in which your partner has thrown, broken, or punched things?

A self-administered questionnaire may be even more effective than face-to-face questioning. When screening for and discussing IPV, the provider must be nonjudgmental and compassionate and must ensure confidentiality.

Even when historical or physical examination clues are evident, IPV often remains undiagnosed by providers. Patients often conceal abusive relationships. They may blame themselves for the abuse, or they may not be emotionally ready to acknowledge the abuse. Although there are risk factors for IPV, victims are found among people of all ages, races, ethnicities, and gender and sexual identities.

Identified risk factors for IPV include younger age, female sex, lower SES, and a family history or personal history of violence.

Clues in the history include frequent emergency room visits, delay in seeking treatment, an inconsistent explanation of injuries, missed appointments, repeated abortions, late initiation of prenatal care, medication noncompliance, inappropriate affect, overly attentive or verbally abusive partner, apparent social isolation, and reluctance to undress or difficulty with examination of genitals or rectum. Common presenting complaints include somatic symptoms (e.g., chronic pain, headaches, irritable bowel symptoms), psychological symptoms (e.g., depression, anxiety, panic disorder, posttraumatic stress disorder, substance use), and gynecologic symptoms (e.g., STIs, chronic pelvic pain, unintended pregnancy). After identification, a woman may be referred to a mental health provider or social worker.

Psychiatric Issues

Fewer than one half of people who meet the diagnostic criteria for psychological disorders are identified. Patients are also reluctant to seek professional help. Only two of every five people with a mood, anxiety, or substance use disorder seek assistance within a year of onset of the disorder. Overall rates of psychiatric disorders are almost identical for men and women. However, substantial gender differences exist in the rates of common mental disorders, including depression, anxiety, and somatic complaints. In the United States, the estimated lifetime prevalence is 21% for women and 13% for men. Depression is the most common women's mental health problem, and it may have a worse prognosis for women because it is often more persistent than in men.

Advances have been made in understanding mood disturbances during specific phases of women's reproductive lives, specifically during the postpartum period, the premenstrual phase (i.e., premenstrual syndrome and PMDD), and the menopausal transition. Depression occurring at these times may represent a specific biologic response to the effects of hormonal fluctuations in the brain and may require different treatments from depression unrelated to these periods. For treating PMDD, SSRIs, oral contraceptives, alprazolam (a benzodiazepine), and GnRH agonists are effective in some women.

The disability associated with mental illness is worse for individuals with three or more comorbid disorders. Women are more likely than men to have comorbid conditions, including anxiety disorders, eating disorders, and somatization. Gender-specific risk factors for common mental disorders that disproportionately affect women include gender-based violence, low income and income inequality, low or subordinate social status, and the responsibility as caretaker of others. The high prevalence of sexual violence against women correlates with the higher prevalence of post-traumatic stress disorder (PTSD) among women than men. Somatization disorders are diagnosed almost exclusively in women. Lifetime prevalence is 0.2% to 2% if strict criteria are used. Somatoform disorders are associated with significant disability and a significantly greater number of clinic and emergency room visits than for other psychiatric diagnoses. There seem to be genetic and environmental contributions to risk.

Generalized anxiety disorder and panic disorder are about twice as prevalent among women than men, with lifetime prevalences of 5% and 3.5%, respectively. Although there is a higher prevalence of social anxiety disorder among women than men, more men may seek treatment for the disorder. Social expectations and gender roles may play a role in this difference.

More than 90% of eating disorders, anorexia nervosa, and bulimia occur in women. Approximately 0.5% to 1% of women between the ages of 15 and 30 years have anorexia, and about 1% to 3% of women have bulimia. There is a strong association between eating disorders and mood disorders, particularly depression. There are no marked gender differences in the rates of severe mental disorders such as schizophrenia and bipolar disorder, which affect less than 2% of the population.

Accessing mental health care is different for men and women. Women are more likely to seek help from and disclose mental health problems to their primary health care physician, whereas men are more likely to seek specialist mental health care and are the principal users of inpatient care. Evidence exists for possible gender bias in the treatment of psychological disorders. Physicians are more likely to diagnose depression in women than men, even when they have similar scores on standardized measures of depression or have identical symptoms at presentation. Women are more likely to be prescribed mood-altering psychotropic drugs.

Coronary Artery Disease

There are significant gender differences in the epidemiology and clinical manifestations of CAD. CAD remains the leading cause of death for men and women, but since the mid-1980s, more women than men die each year of this disease. Women with CAD tend to be diagnosed at a later age (approximately 10 years later) than men. Most CAD in women occurs postmenopausally, when estrogen levels decline. Estrogen increases levels of protective HDL cholesterol, which may affect atherosclerotic plaque progression and regression. Estrogen may also be beneficial due to its vasodilatory, antiinflammatory, and antioxidative properties.

Women with CAD are more likely than men to experience atypical symptoms, such as fatigue, abdominal pain, indigestion, nausea and vomiting, and shortness of breath. These nonclassic symptoms may partially explain why women tend to seek health care later than men. Even when women seek health care, they have a longer time to diagnosis and a longer time to medical intervention than men. Women are also more likely than men to have sudden cardiac death at presentation. They are less likely to receive proven effective therapies, such as β -blockers, aspirin, thrombolytics, and statins, and they are less often referred for invasive testing and coronary artery bypass grafting (CABG). Women are also more likely to die after a myocardial infarction and CABG compared with men.

Black and Hispanic women have a higher prevalence of cardiovascular disease risk factors than white women, including hypertension, cigarette smoking, sedentary lifestyle, hypercholesterolemia, diabetes, and obesity. Although some of these differences may be genetically based, others are likely influenced by behavioral, cultural, and psychological factors. Women of lower SES, regardless of race, have a higher prevalence of cardiovascular risk factors than women of higher SES.

Racial differences exist in the management of myocardial infarction. Black women are offered reperfusion therapy and coronary angiography at lower rates, and in-hospital mortality rates are higher compared with those of white women.

Patient factors and physician factors may contribute to the observed clinical differences in CAD between men and women. Women may delay their own care because they are caretakers.

Many women are unaware of the prevalence of CAD. In a 2006 survey, only 55% of women identified cardiovascular disease as the leading cause of death among women. Studies have shown that physicians also underestimate the magnitude of cardiovascular disease in women and that they tend to place women in lower risk categories compared with men despite equivalent risk profiles. Much of the evidence used to guide the treatment of coronary disease in women is based on trials predominantly enrolling men. Treatments and interventions found to benefit men might not provide the same benefit to women.

Osteoporosis

More than 10 million Americans have osteoporosis; 8 million are women. It is a disease that disproportionately affects women, particularly as they age. The lifetime risk of fracture of a patient with osteoporosis is as high as 40%. Most osteoporosis trials have involved mostly white women, limiting generalizability to all races and ethnicities. Racial minorities are diagnosed and treated less often.

Human Immunodeficiency Virus Infection

Since the beginning of the HIV epidemic in the 1980s, the percentage of women affected has grown considerably, with women now accounting for 25% of those living with HIV in the United States, compared with 7% when the epidemic began. African American women and Latinas are disproportionately affected. In 2010, the rate of new infections among black women was 20 times that of white women and almost 5 times that of Hispanic women (38.1 versus 1.9 and 8.0 per 100,000, respectively). Mortality rates are higher among racial minorities than among white women.

Many factors affect racial disparities. Communities in which there is a higher HIV prevalence (many African American and Latino communities) pose a greater risk of acquisition of HIV with every sexual encounter. Other factors include economic barriers, lack of insurance, stigma, and higher levels of STIs, which increase the likelihood of acquiring and transmitting HIV.

There are unique barriers to prevention of HIV in women. Women may be unaware of the partner's risk factors for HIV, such as injection drug use, multiple partners, or unprotected sex with men. Unprotected vaginal sex is a much higher risk for women than for men, and unprotected anal sex is riskier than unprotected vaginal sex. Women who have experienced sexual abuse are more likely to engage in high-risk sexual behaviors, such as exchanging sex for drugs, having multiple partners, or having sex with a partner who is physically abusive.

Although many of the clinical manifestations of HIV infection and acquired immunodeficiency syndrome (HIV/AIDS) in women are similar to those in men, significant gender-based differences exist. Women may not prioritize their own care. Women are also disproportionately affected by poverty, IPV, unstable housing, substance abuse, lack of transportation, lack of insurance, and the necessity of finding child care, all of which pose barriers to care.

Biologic differences also exist. Although women typically have lower viral loads than men despite the same level of CD4 counts,

the rates of disease progression are similar. Rates of opportunistic infections are similar for men and women. Women may have gynecologic complaints as their initial manifestation of HIV/AIDS, including *Candida* vaginitis, pelvic inflammatory disease, abnormal Papanicolaou smear results, and STIs such as herpes simplex virus, chancroid, and syphilis.

Risk for cervical abnormalities and cervical cancer is related to the degree of immunosuppression, age, and co-infection with high-risk HPV genotypes (16, 18, 52, and 58). Women with preserved CD4 counts and negative HPV test results are at relatively low risk for cervical cytologic abnormalities. Women with HIV infection are more likely to progress more rapidly to cervical cancer. The CDC recommends two cervical cytology screens at 6-month intervals in the first year after an HIV diagnosis. Those with normal results and deemed low risk (i.e., no prior abnormal Pap smear, HPV infection, or AIDS) may have the Pap smear performed annually, with more frequent examinations performed for those deemed high risk. Vulvar and perianal intraepithelial neoplasias are more common in women with HIV than HIV-seronegative women, and the lesions should be evaluated.

Antiretroviral therapy and follow-up monitoring are similar for men and women with HIV/AIDS. Women should be counseled to also use a barrier contraceptive (i.e., male or female condom), because this has proven efficacy in reducing the transmission of HIV and other STIs, although it is less effective for pregnancy prevention.

 For a deeper discussion on this topic, please see Section XIX, "Women's Health," in Goldman-Cecil Medicine, 25th Edition.

INTRODUCTION

This chapter addresses disorders that are unique to men because they involve the male genitalia and reproductive system. It

incorporates commonly encountered and clinically important aspects of voiding, oncology, reproductive function, and endocrinology.

A. Androgen Deficiency in Adult Men

DEFINITION AND EPIDEMIOLOGY

Several clinical guidelines address the syndrome of symptomatic low testosterone levels in men. The two most referenced are from the Endocrine Society and from a collaboration of five societies, including the International Society for the Study of the Aging Male (ISSAM), International Society of Andrology (ISA), European Association of Urology (EAU), European Academy of Andrology (EAA), and American Society of Andrology (ASA). One guideline uses the term “androgen deficiency in adult men” and the other uses the term “late-onset hypogonadism” to refer to a disease process characterized by low serum testosterone levels and clinical symptoms.

The syndrome of androgen deficiency in adult men (late-onset hypogonadism) can be defined as a low level of serum testosterone (total or free) combined with three symptoms of low testosterone such as erectile dysfunction (ED), decreased libido, and lethargy or sleep disturbance. Using this general definition, the incidence of androgen deficiency ranges from 2.1% to 6% in the literature. On the other hand, the incidence of low serum testosterone (so-called low T) in men older than 40 years of age is much higher, between 17% and 38.7% in multiple studies. The clinical guidelines require only one symptom for the diagnosis of androgen deficiency, so the true incidence of androgen deficiency is probably closer to that of low T.

Over the last 10 years, there has been increased coverage of low T in the mainstream press and media. In addition, clinics specializing in testosterone replacement have proliferated. As a result, androgen use among men has increased threefold, from 0.8% in 2001 to 2.91% in 2011. This increase in the prescribing of testosterone is probably the result of both a heightened awareness about the problem and overutilization in men who have been improperly diagnosed. The diagnosis and treatment of androgen deficiency is challenging and full of potential pitfalls. Therefore, it is imperative for physicians to have a thorough understanding of this disease process, particularly in these times when information in the media and on the Internet creates an eager and motivated patient population.

PATHOPHYSIOLOGY

Normal aging sometimes results in malfunctions of the hypothalamic-pituitary-gonadal axis that lead to decreased serum testosterone levels. One of these errors is termed *primary hypogonadism* (testicular failure). In this disease process, the testicles produce an inadequate amount of testosterone (and sperm) even though there is adequate stimulation from the anterior pituitary gland in the form of elevated or normal release of luteinizing hormone (LH). Low serum testosterone also can result from failure of the pituitary gland to secrete an adequate amount of LH. When this occurs, the Leydig cells of the testicle that produce testosterone are not adequately stimulated and hence do not make a normal amount of testosterone. This form of testosterone deficiency is termed *secondary hypogonadism*. It can result from disease processes such as pituitary tumors, hemochromatosis, and obstructive sleep apnea.

Measurements of total testosterone (TT) include the concentrations of both unbound (free) and bound testosterone in the serum. Only 2% of testosterone is unbound; the other 98% is bound to proteins such as albumin or sex hormone binding globulin (SHBG). Because it is not bound to another substance, free testosterone (FT) is the more biochemically active form of testosterone. If a man has a low normal TT level but a low FT level and has clinical manifestations of this hormone deficiency, he is considered to have androgen deficiency syndrome.

Increased levels of SHBG in the serum can decrease the level of FT. The level of SHBG increases with smoking, coffee consumption, age, and disease processes such as hepatitis and hyperthyroidism. Therefore, increased levels of SHBG can contribute to androgen deficiency. Obesity decreases levels of SHBG, but it can cause androgen deficiency through the peripheral conversion of testosterone into estrogen in adipose cells. Conditions such as extreme exercise, recreational drug use, nutritional deficiency, stress, use of certain medications, and acute illness can transiently lower serum testosterone.

CLINICAL PRESENTATION

Low testosterone levels can affect a patient's general, sexual, physical, and psychological health. In [Table 71-1](#), these symptoms are grouped according to their specific relation to androgen deficiency. Various studies have categorized and used the symptoms of androgen deficiency in different ways. For example, one clinical trial looking at the incidence of androgen deficiency defined the syndrome as the presence of 3 of 12 clinical symptoms combined with a low serum FT or TT level, whereas, in a similar trial, patients were considered to be androgen deficient if they had a low testosterone and exhibited three specific sexual symptoms. The guidelines simply state that clinicians should use the different symptoms as means to decide whether to check a patient's serum testosterone level. According to the guidelines, a patient with treatable androgen deficiency must have at least one symptom. The symptom most closely associated with androgen deficiency is decreased libido.

DIAGNOSIS

For several reasons, the diagnosis of androgen deficiency is not straightforward. By the very simplest of definitions, it requires a low serum testosterone level in conjunction with at least one clinical symptom. Most clinical guidelines suggest measuring a TT in any adult man who has symptoms associated with androgen deficiency. In general, recognizing that laboratory standards may differ, if the TT level is greater than 350 ng/dL (12.1 nmol/L), the patient does not have androgen deficiency; if the TT is lower than 200 ng/dL (6.9 nmol/L), then a symptomatic patient is considered to have androgen deficiency. If the TT level falls between those two values, FT should be assessed, and low values (typically 5 to 9 ng/dL) indicate androgen deficiency. FT tests are not recommended initially because of their greater cost. In addition, screening of asymptomatic men for low testosterone is not medically necessary.

In men with borderline testosterone levels, repeat measurement of a morning testosterone level is warranted because there is significant day-to-day variability and testosterone levels vary on a circadian rhythm. Ideally, levels should be checked within 4 hours of waking (usually between 7 and 11 A.M.), when testosterone levels are highest. It is not necessary to fast before a testosterone laboratory test; however, in a study from 2013, there

was a 25% reduction in TT levels in healthy men 60 minutes after an oral glucose tolerance test. Strength training also transiently decreases serum testosterone levels in healthy men (but typically not outside the normal range).

Testosterone levels should not be checked during acute or subacute illness. However, physicians should have a lower threshold to check the testosterone level in patients with chronic illnesses that are known to cause a symptomatically lower testosterone concentration, such as diabetes mellitus, chronic obstructive lung disease, inflammatory arthritic disease, renal disease, human immunodeficiency virus (HIV)-related disease, obesity, metabolic syndrome, and hemochromatosis. In fact, one guideline states that all patients who have a pituitary mass, HIV-associated weight loss, or a low-trauma fracture should have their testosterone level checked regardless of symptoms.

In addition, one guideline recommends checking LH levels to rule out secondary hypogonadism in all patients, whereas another recommends that LH and prolactin should be measured only in patients with TT lower than 150 ng/dL (5.2 nmol/L). In patients with disease processes (e.g., obesity, hepatitis and hyperthyroidism) that are known to alter the level of SHBG, it may be prudent to initially check FT rather than TT.

Men being considered for testosterone replacement should have their prostate-specific antigen (PSA) level measured and a digital rectal examination (DRE) performed to assess the prostate. If either is abnormal, referral to a urologist should be considered. [Table 71-2](#) provides helpful guidelines for evaluating possible androgen deficiency.

TREATMENT

Testosterone therapy is recommended for men with androgen deficiency, and the goal of therapy should be to maintain secondary sex characteristics and improve sexual function, sense of well-being, and bone mineral density. In addition, metabolic and cardiovascular benefits are suggested by available data. Before starting treatment, clinicians should obtain baseline hematocrit and PSA levels.

There are at least nine different types of testosterone replacement formulations. In the United States, the most commonly used forms are testosterone enanthate or cypionate by intramuscular (IM) injection, transdermal testosterone patches, testosterone gels, and implantable timed-release pellets. Because of the

TABLE 71-1 SIGNS AND SYMPTOMS OF ANDROGEN DEFICIENCY

SPECIFIC SIGNS AND SYMPTOMS	LESS SPECIFIC SIGNS AND SYMPTOMS
Reduced sexual desire (libido) and activity	Decreased energy and self-confidence
Decreased spontaneous erections	Feeling sad, depressed mood
Breast discomfort, gynecomastia	Poor concentration and memory
Less axillary and pubic hair and less shaving	Sleep disturbance and sleepiness
Very small or shrinking testes	Mild anemia (normochromic, normocytic)
Infertility and low sperm count	Reduced muscle bulk and strength
Height loss and low bone mineral density	Increased body fat and body mass index
Hot flashes and sweats	Diminished physical or work performance

TABLE 71-2 ANDROGEN DEFICIENCY DIAGNOSIS DO'S AND DON'TS

- Do check total testosterone (TT) in every symptomatic adult male >40 yr
- Do confirm borderline tests with a repeat measurement
- Do check in the morning
- Do have a lower threshold to check testosterone in patients with certain chronic illnesses
- Do consider measuring prolactin and LH level in patients with very low testosterone
- Do consider checking hematocrit and PSA levels with the testosterone level to decrease blood draws
- Don't check the testosterone level during acute or subacute illness
- Don't start with measurement of free testosterone in most cases (\$\$\$)
- Don't monitor testosterone treatment with measurements of free testosterone (\$\$\$)
- Don't consider testosterone replacement in a patient trying to father a child

LH, Luteinizing hormone; PSA, prostate-specific antigen.

frequency of significant skin irritation with the testosterone patch, many practitioners prefer one of the other modes, usually based on patient preference. For dosage and administration of gel testosterone formulations, the clinician should refer to the package insert. For IM testosterone, a good starting dosage is 100 mg every 2 weeks. Pellet implantation is an office procedure, but adequate testosterone levels are typically maintained for 3 to 4 months.

Side Effects of Testosterone Therapy

Testosterone therapy causes decreased sperm production and usually decreased testicular volume, and it may cause acne, oily skin, and breast tenderness. In addition, testosterone can increase hematocrit and cause life-threatening erythrocytosis. If the hematocrit becomes elevated, then testosterone replacement should be suspended. Occasionally, a patient requires phlebotomy to avoid or treat dangerous erythrocytosis. Testosterone replacement is not a treatment for infertility and has in fact been investigated as method of male contraception. Patients who are interested in fathering children should not take testosterone. If necessary, human chorionic gonadotropin (HCG) may be administered for men wishing to preserve fertility.

Only oral testosterone has negative effects on the liver, so it is not necessary to monitor liver function during treatment. Testosterone therapy may worsen obstructive sleep apnea and congestive heart failure; therefore, patients in whom these conditions are untreated should not be started on testosterone therapy. Present data suggest that testosterone therapy does not worsen levels of high-density lipoproteins. Patients should be aware that testosterone therapy suppresses endogenous testosterone and sperm production. Depending on the duration of treatment, it

may take 1 to 2 months or longer after treatment discontinuation for testosterone and sperm production to return to baseline levels.

Testosterone Therapy and the Prostate

In general, testosterone therapy should be avoided in patients with a history of prostate or breast cancer. However, this is a controversial issue. Some urologists may decide that replacement is acceptable under specific circumstances because there are data to suggest that testosterone replacement may not pose an undue risk of prostate cancer recurrence or progression. In addition, there is no conclusive evidence that testosterone replacement has any effect on benign prostatic hypertrophy (BPH).

Monitoring Testosterone Treatment

TT should be measured 5 to 12 weeks after initiation of testosterone treatment. If IM testosterone is being administered every 2 weeks, morning TT levels should be checked 1 week after an injection. If a testosterone gel is used, morning TT should be checked at least 1 month after initiation of treatment. Hematocrit values should be assessed at 3 months and 6 months and then annually. If the hematocrit level is greater than 54%, the treatment should be stopped. If testosterone therapy was started to help with osteoporosis or osteopenia, a bone mineral density test should be done after 1 to 2 years. If there is an abnormality in the PSA level or it increases by 0.75 ng/mL in 1 year, referral to a urologist should be considered. If the TT level is low, the clinician should increase the dosage and reassess after 5 to 12 weeks. The goal of therapy should be a level between 400 and 600 ng/dL. Finally, therapy should be discontinued if the patient does not have clinical improvement.

B. Erectile Dysfunction

ED is defined as the inability to maintain an erection for satisfactory sexual function in the absence of premature ejaculation. Premature ejaculation is not technically a form of ED. Impotence is the most common cause of ED in the United States and is defined by an inability to attain or maintain adequate penile rigidity sufficient for intercourse. Other important, although less common, causes of ED are Peyronie's disease and trauma.

ED affects millions of American men. According to the Massachusetts Male Aging Study, 52% of men older than 40 years of age are afflicted with some form of impotence. The prevalence of impotence triples between age 40 and 70 years. By age 70 years, 15% of men experience complete ED. Age and physical health are the most important predictors of the onset of ED. Smoking is the most important lifestyle variable.

Recently, many clinics that specifically treat ED and premature ejaculation have opened across America to meet a growing need for treatment of these conditions. However, these clinics often charge money for treatments and medications that primary care physicians can provide and are covered by insurance. Therefore, it is more important than ever for primary care physicians to have a thorough understanding of this disease process.

MECHANISM OF ERECTION

Psychogenic or tactile sexual stimulation is usually the initial step in the pathway leading to penile erection. Nerve signals are carried through the pelvic plexus into the cavernous nerves of the penis. The pelvic plexus receives input from both the sympathetic and the parasympathetic nervous system. Sympathetic fibers originate in the thoracolumbar spinal cord, and parasympathetic fibers originate in the second through fourth sacral spinal cord segments (S2 through S4). Afferent somatic sensory signals are carried from the penis through the pudendal nerve to S2 through S4. This information is routed both to the brain and to spinal cord autonomic centers. Adrenergic innervation appears to play a role in the process of detumescence. High concentrations of norepinephrine have been demonstrated in the tissue of the corpora cavernosa and tributary arterioles. Afferent signals capable of initiating erection can originate within the brain, as with psychogenic stimulation, or they can result from tactile stimulation. There is no discrete center for psychogenic erections; however, the temporal lobe appears to be important.

Sexual stimulation causes the release of nitric oxide (NO) by the cavernous nerves into the neuromuscular junction

(Fig. 71-1). NO activates guanylyl cyclase, which converts guanosine triphosphate (GTP) into cyclic guanosine monophosphate (cGMP). Protein kinase G is activated by cGMP and in turn activates several proteins that decrease the intracellular concentration of calcium ions (Ca^{2+}). Decreased Ca^{2+} concentration in the smooth muscle causes muscular relaxation, cavernosal artery dilation, increased blood flow, and subsequent penile erection. The control of blood flow on the venous outflow side is less well understood.

CAUSES OF ERECTILE DYSFUNCTION

Psychogenic ED was once thought to be the most common type of ED. However, advances in understanding of the mechanics and neurophysiology of erectile function have identified other more common causes. Psychogenic ED is now thought to account for fewer than 15% of patients seen by ED specialists. The anatomic site now believed to be the most common cause of ED is the neuromuscular junction. This is the place where the cavernosal nerves meet the smooth muscle and endothelium of the deep cavernous penile arteries. The decreased release of NO by cavernosal nerves and the impaired response by smooth muscle cells that occurs at the neuromuscular junction is termed *endothelial dysfunction*. Other common causes of ED include certain endocrine disorders, vascular diseases, central and peripheral nerve disorders, and medications.

Cardiovascular Disease

In the United States, atherosclerotic vascular disease, hyperlipidemia, smoking, and hypertension are frequent causes of ED. These relationships are expected because erection is achieved by a combination of relaxation of arteriolar smooth muscle and increased venous resistance of channels penetrating the wall of

the corpora cavernosa. Cardiovascular disease may decrease erectile ability by decreasing blood flow to the penile arteries, by mechanical obstruction of the vascular lumen, or, more commonly, by endothelial dysfunction. Endothelial dysfunction is the most common cause of ED. It results from interruption of the neural control mechanism of vascular smooth muscle function and leads to decreased blood flow and pressure in the corpora cavernosa.

The principal blood vessels supplying the corpora cavernosa are the cavernosal arteries, which are terminal branches of the internal pudendal artery. Diseases of large and small arteries may decrease corporal blood pressure and lead to decreased penile lengthening and rigidity. Veno-occlusive disease in the penis is also a significant cause of ED. These patients often experience normal initial rigidity, but quickly lose their erection before ejaculation occurs.

Neurogenic Erectile Dysfunction

Because the nervous system plays an integral part in the physiology of an erection, any disease process that affects the brain, the spinal cord, or the peripheral nerves can cause ED. For example, dementia, Parkinson's disease, and stroke are diseases of the brain associated with ED. Patients with spinal cord injury commonly have ED. Because of an intact reflex pathway, most patients with spinal cord injury respond to tactile sensation, but they usually require medical therapy to maintain the erection through intercourse. Iatrogenic injury to nerves during surgery (e.g., prostatectomy, rectal surgery) is also a common cause of neurogenic ED. Neurogenic ED due to decreases in penile tactile sensation can occur with increasing age.

Endocrine Disorders

Testosterone plays a permissive role in erectile function, and many endocrine disorders can directly or indirectly decrease plasma free or bound testosterone. However, androgen deficiency is an uncommon primary cause of ED because erectile ability is only partially androgen dependent. Patients with androgen deficiency typically have decreased or absent libido in addition to loss of erectile rigidity. Androgen replacement may induce return of erectile function in patients with very low or undetectable serum testosterone concentrations. More commonly, however, the impotent patient has normal or mildly decreased levels of circulating androgens. Testosterone replacement rarely restores erectile function in men with mildly decreased serum testosterone. Testosterone supplementation is never indicated for patients with normal circulating androgen levels.

The most common endocrine disorder affecting erectile ability is diabetes mellitus. In addition to causing atherosclerotic and microvascular disease, diabetes affects both the autonomic and the somatic nervous system, including loss of function of long autonomic nerves. The loss of long cholinergic neurons results in interruption of the efferent side of the erectile reflex arc. Diabetes also appears to produce dysfunction of the neuromuscular junction at the level of arterial smooth muscle in the penile corpora cavernosa. Studies have indicated markedly decreased acetylcholine and NO concentrations in the trabeculae of the corpora cavernosa in diabetic patients. These findings probably represent a combination of neural loss and

FIGURE 71-1 Sexual stimulation causes the release of nitric oxide (NO) by the cavernous nerve into the neuromuscular junction. ATP, Adenosine triphosphate; cGMP, cyclic guanosine monophosphate; GMP, guanosine monophosphate; GTP, guanosine triphosphate; PDE5, phosphodiesterase type 5.

neuromuscular junction dysfunction. Other endocrine disorders, such as hypothyroidism, hyperthyroidism, and adrenal dysfunction, can also cause ED. Because of the uncommon occurrence of thyroid and adrenal disorders in patients presenting for treatment of ED, testing of those axes is not a part of the routine work-up of ED.

Medication-Induced Erectile Dysfunction

Many commonly prescribed medications can cause or contribute to decreased erectile function. Table 71-3 lists the major classes of medications implicated in ED and suggests how commonly these medications interfere with erectile function. Changing medications may restore erectile function in some patients. However, proceeding directly to treatment of ED is usually the preferred option in all but the most straightforward cases.

Medical and Surgical Therapies

Since the introduction of sildenafil in 1998, the Process of Care Model for the evaluation and treatment of ED has been adopted. It targets the primary care provider as the initial source of care for patients with ED. Currently available therapies for ED include oral phosphodiesterase type 5 (PDE5) inhibitors, intraurethral alprostadil, intracavernous vasoactive injection therapy, vacuum constriction devices, and penile prosthesis implantation. A stepwise treatment approach starting with oral agents and progressing to more invasive therapeutic interventions should be used (Fig. 71-2). Informed patient decision making is critical to successful progression through the Process of Care pathway. Patient referral is primarily based on the need or desire for specialized diagnostic testing and management.

Oral Phosphodiesterase Type 5 Inhibitors

Current medical therapy is based on inhibition of PDE5, which degrades cGMP to inactive 5'-GMP, as shown in Figure 71-1. Sildenafil, vardenafil, avanafil, and tadalafil competitively inhibit PDE5 breakdown of cGMP. Use of a PDE5 inhibitor results in improved erectile rigidity even in patients with decreased NO or cGMP synthesis. However, not all patients respond to PDE5 inhibition. Adequate sexual stimulation and intact neural and

vascular pathways are necessary to produce an adequate amount of NO and cGMP to increase deep penile artery blood flow. PDE5 inhibitors are effective in men with organic, psychogenic, neurogenic, and mixed cases of ED. The overall response rate to PDE5 inhibitors is 70%.

Unless contraindicated, PDE5 inhibition should be considered first-line therapy for most men. The combination of PDE5 inhibitors and α -adrenergic receptor blockers can result in transient hypotension. This interaction is complex and depends on the specific medication in each category. In general, it is safe to use selective α -blockers such as tamsulosin and alfuzosin with any PDE5 inhibitor. However, PDE5 inhibitors should not be used concurrently with nitrate medications because a large (>25 mm Hg) synergistic drop in blood pressure occurs in many patients. Periodic follow-up is necessary to determine therapeutic efficacy, side effects related to PDE5 inhibition, and changes in health status. Overall, 30% of men do not respond to this class of medication.

Alprostadil Intraurethral Drug Therapy

If PDE5 inhibition is not successful, an acceptable second-line medical treatment is intraurethral administration of prostaglandin E₁ (alprostadil [Muse]), which can be inserted into the urethra with the use of a pellet applicator. This method of delivery assumes substantial venous communications between the corpus spongiosum surrounding the urethra and the corpus cavernosum, and it is effective in many patients who fail oral PDE5 inhibitor medications. It is not as effective as intracavernous injection (described later). Some patients experience difficulty initiating this type of treatment, so it may be beneficial to administer the first dose in an office setting. To lubricate the urethra, patients should void before insertion of the pellet.

Up to one third of patients have normal, transient burning penile pain, and this should be discussed with the patient before treatment. Dizziness and presyncope are uncommon complications. This medication has rapid onset and minimal risk of priapism. It can be used with increased efficacy in combination with PDE5 inhibitors. Transient burning pain in the sexual partner can occur and is caused by leakage of the medication from the urethra into the vagina. This can be managed by wearing a condom.

TABLE 71-3 FREQUENCY OF DECREASED ERECTILE RIGIDITY AND EJACULATORY DYSFUNCTION BY MEDICATION CLASS

MEDICATION CLASS	DECREASED ERECTILE RIGIDITY	EJACULATORY DYSFUNCTION
β -Adrenergic antagonists	Common	Less common
Sympatholytics	Expected	Common

Diuretics	Less common	Uncommon
Antidepressants	Common†	Uncommon‡
Antipsychotics	Common	Common
Anticholinergics	Less common	Uncommon

*Patients are able to ejaculate, but retrograde ejaculation is seen in 5% to 30%.

†Uncommon with serotonin reuptake inhibitors.

‡Delayed or inhibited ejaculation with serotonin reuptake inhibitors.

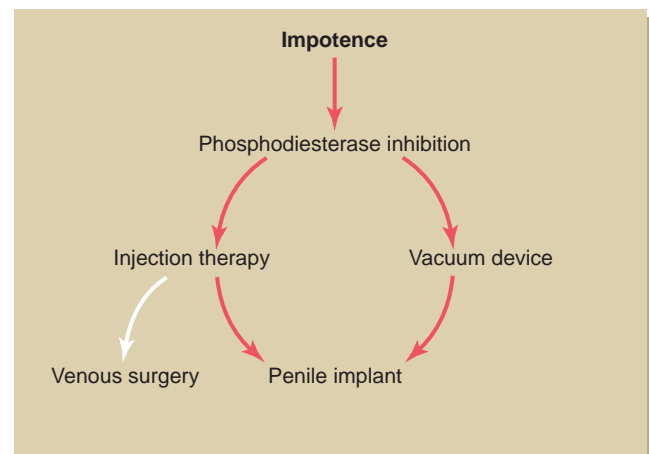

FIGURE 71-2 A logical treatment algorithm for impotence.

Intracavernosal Injection Therapy

Pharmacologic injection therapy involves the injection of vasodilator agents into the corpora cavernosa to produce erection by dilating the corporal artery smooth muscle. More than 90% of patients with ED respond to this type of therapy. Commonly used agents include alprostadil, papaverine, and phentolamine (Regitine). These medications can be used alone or in combination. As monotherapy, alprostadil is most commonly used. Of the three, only alprostadil has been evaluated in rigorous clinical trials and has specific marketing approval from the U.S. Food and Drug Administration for the treatment of ED. Phentolamine is used to potentiate the action of papaverine and can be used in combination with both alprostadil and papaverine. These vasoactive drugs can be formulated with different combinations of medications and concentrations to achieve increased efficacy and decreased side effects. *Bimix* and *trimix* are terms used to refer to a combination of two or three of these medications, respectively.

The common side effects of this type of treatment are bruising and penile pain (50%). Penile pain is more common in young patients and is usually worse with alprostadil. Therefore, a combination using lower-dose alprostadil or just papaverine and phentolamine might be beneficial in younger patients. Other, more serious risks of injection therapy include priapism and corporal scarring (Peyronie's disease). Priapism has been reported to occur in 1% to 4% of patients. Prolonged erections occur more commonly in patients with neurogenic ED, especially young men with spinal cord injury. Significant acquired penile curvature (Peyronie's disease) is seen uncommonly and usually follows several years of injection therapy. Penile curvature appears to be less common with use of alprostadil than with papaverine. The most common problem with pharmacologic injection therapy is not complications from therapy but rather the fact that 50% to 60% of patients stop using the technique within 1 year.

As with intraurethral alprostadil, initial treatment should be performed under the supervision of a physician. The medication can be injected using a self-contained medication-syringe kit or a 29-gauge (5/8-inch) insulin syringe with medication drawn from a refrigerated vial. It is advisable to start with a small test dose and slowly titrate the dosage for desired effect over several weeks. The patient should not use the medication more than

once in 24 hours and should be instructed to seek medical care promptly for prolonged painful erections lasting longer than 4 hours. Typically, administration of the test dose should be carried out in the morning, and the patient should be expected to stay in close proximity to the medical office to monitor for priapism. If a patient experiences priapism after a test dose, he should seek prompt medical attention within 4 hours of injection. Priapism usually resolve without sequelae after intracavernosal injection of 0.5 to 1 mL of a 250 µg/mL solution (0.5 mg diluted in 2 mL of normal saline) of phenylephrine in a setting where blood pressure and heart rate are monitored. Formal guidelines for the treatment of priapism are available on the website of the American Urologic Association (AUA).

Vacuum Constriction Devices

Vacuum constriction devices enclose the penis in a plastic tube with an airtight seal at the penile base. Air is pumped out of the cylinder, creating a vacuum. Blood flows into the corporal bodies, leading to penile erection. A constriction band slid from the cylinder to the base of the penis maintains the erection. Simultaneous use of a vacuum device and a PDE5 inhibitor is safe and may improve outcomes. Some of the common side effects that affect patient satisfaction with these devices are coldness, numbness, and bruising of the penis.

Penile Prosthesis

A penile prosthesis, either semirigid or inflatable, is implanted in the operating room. Most patients prefer the inflatable devices because they provide a more natural erection when inflated and a flaccid penis when deflated. Although implantation of a penile prosthesis is more invasive than the other techniques, this device is the most effective long-term option for impotence treatment. Ninety percent of patients and partners are satisfied with the result.

Important interval improvements have been made in the design of implantable penile prostheses to make them more durable and resistant to infection. Improvements in the connection between tubing and corporal cylinders have cut the mechanical failure rate to less than 5% in 5 years. Components also have special coatings that either contain antibiotics or absorb antibiotics applied topically at the time of implantation. These improvements have cut the rate of postoperative infection in half.

C. Benign Prostatic Hyperplasia

BPH, a nonmalignant enlargement of the prostate gland, is a common condition in the aging male patient. It is estimated that more than 90% of all men will develop histologic evidence of BPH during the course of their lifetime; of those, at least 50% will develop lower urinary tract symptoms (LUTS) that prompt them to seek medical care. Broadly speaking, LUTS can be divided into two groups: obstructive voiding symptoms and overactive bladder symptoms (Table 71-4).

Although most patients who seek medical care for BPH do so because of the associated LUTS, these same symptoms can also result from other illnesses such as diabetes mellitus, spine disease, Parkinson's disease, multiple sclerosis, and

cerebrovascular disease (Fig. 71-3). It is important to evaluate all patients for these non-BPH-related conditions to ensure optimal management. It is also important to pay close attention to medication use because a number of medications used in the elderly population can result in various urologic symptoms, including both obstructive and overactive bladder voiding symptoms.

PATHOPHYSIOLOGY

Prostate growth and the subsequent development of BPH occur under the influence of testosterone and the more metabolically active dihydrotestosterone (DHT). Testosterone produced by the testes is converted to DHT by the action of the enzyme

5 α -reductase. DHT is the major intracellular androgen and is believed to be responsible for the development and maintenance of the hyperplastic cell growth characteristics of BPH.

BPH develops predominantly in the periurethral prostatic tissue, referred to as the *transition zone* (Fig. 71-4). Tissue growth in this area leads to the phenomenon of bladder outlet obstruction (BOO), which leads to LUTS. BOO occurs as a result of two mechanisms: mechanical obstruction from increased tissue volume in the periurethral zone of the prostate and dynamic obstruction, which is caused by decreased bladder neck relaxation during voiding and increased smooth muscle tone in the bladder neck and prostate gland. Also important, but less well

characterized, is the response of the bladder muscle to the increase in outlet resistance provided by those two mechanisms. As bladder outlet resistance increases, the bladder responds by increasing the force of contraction. This added work results in physical and mechanical changes in bladder function.

Early in the course of BOO, the bladder is able to compensate; however, with persistent obstruction, the patient typically develops LUTS, particularly overactive bladder symptoms such as nocturia, frequency, and urgency. These symptoms frequently drive patients to seek medical care. Later during the course of the obstructive process, the bladder wall becomes thickened and loses compliance. The subsequent loss of compliance results in a decreased functional capacity of the bladder, which exacerbates the patient's overactive bladder symptoms.

TABLE 71-4 SYMPTOMS OF LOWER URINARY TRACT SYNDROME

OVERACTIVE BLADDER	OBSTRUCTIVE VOIDING
Frequency	Hesitancy
Nocturia	Slow stream
Urgency	Stop-and-start voiding
Urge incontinence	Sensation of incomplete emptying

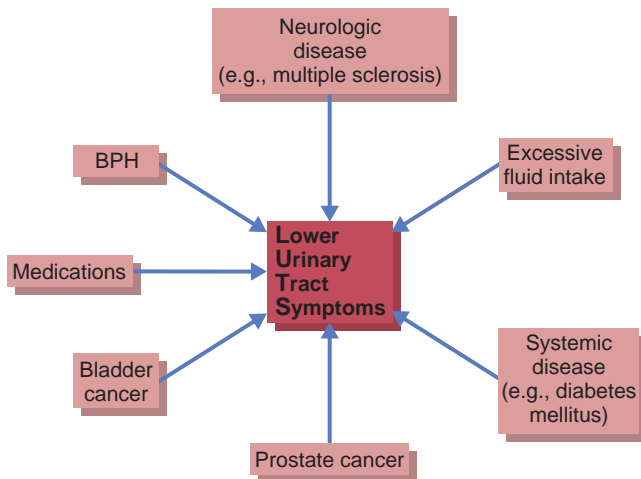

FIGURE 71-3 Causes of lower urinary tract symptoms (LUTS). BPH, Benign prostatic hyperplasia.

DIAGNOSIS

The initial evaluation of a patient with LUTS suggestive of BPH should include a detailed medical history that focuses on the patient's urinary symptoms as well as the past medical history, including comorbid conditions and any previous surgical procedures, general health conditions, and history of alcohol and tobacco use. The assessment of symptoms can be facilitated with the use of the AUA Symptom Index (also known as the *International Prostate Symptom Score*, or IPSS). This is a self-administered, validated questionnaire consisting of seven questions related to the symptoms of BPH and BOO. The AUA Symptom Index classifies symptoms as mild (0 to 7), moderate (8 to 19), or severe (20 to 35). Validated instruments such as the AUA Symptom Index are useful during the initial evaluation as an overall assessment of symptom severity and during follow-up visits to assess the effectiveness of any medical or surgical interventions.

A general physical examination should be performed that includes a DRE and a focused neurologic examination. Urinalysis, either by dipstick or by microscopic examination of urine sediment, is also mandatory to rule out hematuria and evidence of urinary tract infection. Glycosuria can be a significant finding, particularly if not previously identified. The initial clinical practice guidelines for the diagnosis of BPH recommended a serum creatinine measurement to assess renal function in all patients

FIGURE 71-4 Zonal anatomy of the prostate gland.

with signs or symptoms suggestive of BPH. However, this recommendation came under scrutiny because of its low yield for the detection of renal insufficiency secondary to obstructive uropathy. Serum creatinine measurement is no longer a routine part of the BPH work-up. According to the same clinical practice guidelines, PSA measurement is optional during the initial evaluation. PSA can function as a surrogate for prostate volume measurement in addition to being a screening test for prostate cancer. The Medical Therapy of Prostatic Symptoms (MTOPS) study, sponsored by the National Institutes of Health, demonstrated that PSA increases linearly with prostate volume and that a PSA level greater than 4 ng/mL conveys a 9% risk of requiring surgical therapy for benign disease over a 4.5-year period.

The following additional diagnostic tests are also considered optional; however, they may be useful, particularly in patients with moderate to severe AUA symptom scores, in determining whether the patient's symptoms are compatible with obstruction from BPH. Uroflowmetry is a noninvasive method of measuring urinary flow rate. The maximal urinary flow rate, Q_{max} , is considered the most useful measurement for identifying patients with BOO. However, patients with diminished flow rates may also have impaired bladder contraction. Typical values range from 25 mL/second in a young man without BOO to 10 mL/second or slower in a man with significant BOO. Of note, patients with a flow rate of less than 15 mL/second have better outcomes after transurethral resection of the prostate (TURP, discussed later). Measurement of postvoid residual (PVR) urine may be accomplished by urethral catheterization or, preferably, by ultrasonography. Elevated PVR volumes indicate an increased risk for acute urinary retention and eventual need for surgical intervention. The MTOPS study demonstrated that 7% of men with PVR greater than 39 mL required surgical intervention over a 4.5-year period. Elevation of PVR to greater than 200 mL raises the question of functional impairment of the bladder and warrants further evaluation with urodynamic testing.

Routine evaluation of the upper urinary tracts (kidneys and ureters) with excretory urography or ultrasonography is not recommended for the average BPH patient unless there is concomitant urinary pathology (i.e., hematuria, urinary tract infection, renal insufficiency, a history of prior urologic surgery, or a history of nephrolithiasis). Likewise, transrectal ultrasonography (TRUS) is not routinely recommended unless it is used for preoperative assessment of prostate gland size while planning surgical intervention.

DIFFERENTIAL DIAGNOSIS

Many conditions can cause LUTS in the aging male. A DRE and PSA testing are helpful in distinguishing between BPH and prostate cancer. Early-stage prostate cancer is typically asymptomatic, and patients can have both conditions concurrently. Although PSA testing is not sufficiently sensitive or specific to reliably differentiate BPH from prostate cancer, it is a useful tool to stratify a patient's risk for the presence of prostate cancer.

In response to ongoing controversy about PSA screening, the AUA released a new guideline in 2013 pertaining to the early detection (screening) of prostate cancer. According to this guideline, the purpose of early detection is to decrease prostate cancer mortality. Overall, the guideline recommends against routine

prostate cancer screening (PSA and DRE) in men younger than 55 years of age. However, prostate cancer screening should be considered between the ages of 40 and 55 years in men who have higher risk of prostate cancer (i.e., family history or African American race). For men ages 55 to 69 years, the guideline recommends an individualized approach with discussion about the benefits of prostate cancer screening versus the known risks of screening and treatment. The guideline did not recommend screening in any man older than 70 years of age or in any man with less than 10 to 15 years of life expectancy.

Both the DRE and serum PSA determination have a role in the early diagnosis of prostate cancer. Prostate cancer typically arises from the peripheral portion of the prostate, which can be palpated on DRE. Induration or nodularity of the prostate on DRE should be considered suspicious for prostate cancer. PSA is a protein produced by both benign and malignant prostate cells. Serum PSA levels may be elevated in the face of prostate enlargement, inflammation, or cancer. Although an elevated PSA level is not diagnostic of prostate cancer, it can lead to a prostate biopsy to exclude cancer. Probably because of progressive enlargement in prostate size, serum PSA values increase as men age. The historical view that a PSA value lower than 4 ng/mL is "normal" has been abandoned since the recognition that PSA represents a continuum of risk based on age with no lower threshold. The comparative rate of change for PSA over time, sometimes termed *PSA velocity*, can be informative. In general, a change in PSA of more than 0.75 ng/mL is considered worrisome and may prompt a prostate biopsy.

Prostatitis is another condition that can cause LUTS. It may result from bacterial infection or from a nonbacterial inflammatory process, and the symptoms may substantially overlap those of BPH, particularly in older men. Diabetes mellitus, neurologic diseases such as Parkinson's disease or cerebrovascular disease, and other conditions of the urinary tract, such as urethral strictures, may result in LUTS in patients with BPH. Finally, many medications, particularly those with significant anticholinergic side effects, can cause symptoms mimicking those associated with BPH.

MEDICAL MANAGEMENT

Medical management is the preferred first-line treatment option for patients diagnosed with LUTS due to BPH. Most cases can be managed effectively with a minimum of side effects. The MTOPS study demonstrated that combination therapy with a long-acting α -blocker and a 5 α -reductase inhibitor was more effective than single-agent therapy alone. In general, medical management is initiated for patients with moderate to severe AUA symptom scores. However, in the absence of indications for surgery (refractory urinary retention, hydronephrosis with or without renal impairment, recurrent urinary tract infections, recurrent gross hematuria, or bladder calculi), the decision to embark on any course of therapy, medical or otherwise, is principally driven by the bothersomeness of the patient's symptoms. Every patient has a different perception of his symptoms: Nocturia twice nightly may be a minor nuisance for some but may represent a significant problem for others. There is no absolute AUA symptom score or other objective measure that dictates the need for initiation of therapy for symptomatic BPH. Each patient

must be evaluated individually, and the treatment course must be tailored to the patient's individual situation.

α -Adrenergic Antagonists

α -Blockers are the most commonly prescribed medications for the treatment of LUTS associated with BPH. The bladder neck and prostate are richly innervated with α -adrenergic receptors, specifically α_{1a} -receptors, which constitute about 70% to 80% of the total number of α -receptors in these areas. α_{1b} -Receptors modulate vascular smooth muscle contraction and are located in the bladder neck and prostate to a lesser degree.

Doxazosin, terazosin, tamsulosin, and extended-release alfuzosin are long-acting α -receptor antagonists. They are typically administered once daily, usually at bedtime to minimize the potential for orthostatic hypotension. These medications act through α_1 -receptors and can cause vasodilation resulting in transient hypotension and lightheadedness. Blood pressure reduction is greater in patients with hypertension (average reduction, 10 to 15 mm Hg) relative to normotensive patients (average reduction, 1 to 4 mm Hg). Overall, 10% to 20% of patients experience some (often transient) side effects from these medications, including dizziness, asthenia, headaches, peripheral edema, and nasal congestion. Dose titration is recommended for doxazosin and terazosin to minimize occurrence of these adverse effects and optimize the therapeutic response. Doxazosin and terazosin require at least 4 or 5 mg, respectively, to achieve a therapeutic effect. Maximal response is usually seen within 1 to 2 weeks with doxazosin and within 3 to 6 weeks with terazosin. Overall, these drugs reduce symptom scores by 40% to 50% and improve urinary flow rates by 40% to 50% in about 60% to 65% of patients treated.

Tamsulosin is a selective α_{1a} -receptor antagonist with a long half-life. It has a significantly lower degree of nonspecific α -receptor binding compared with other α -receptor antagonists. Therefore, side effects such as postural hypotension and dizziness are less common. This drug does not appreciably affect blood pressure in hypertensive or normotensive patients. Maximal response is usually seen within 1 to 2 weeks after the initiation of therapy.

5 α -Reductase Inhibitors (Finasteride and Dutasteride)

Finasteride and dutasteride block the intracellular conversion of testosterone to DHT by inhibiting the action of the enzyme 5 α -reductase. This results in an approximate 18% to 25% reduction in prostate gland size over 6 to 12 months. It is most effective in reducing symptoms and preventing disease progression in patients with large prostate glands (>40 mL [Prostate measurement for clinical purposes is usually described in mL, but 1 mL = 1 g = 1 cc]), although recent evidence suggests that symptomatic improvement and stabilization of disease progression may occur in treated men with prostates as small as 30 mL. 5 α -Reductase inhibition has also been shown to decrease the risk for urinary retention and subsequent surgical intervention, again predominantly in those patients with larger glands. Initial response is seen within 6 months, and maximal effect occurs 12 to 18 months after the initiation of therapy.

Finasteride and dutasteride reduce serum PSA by about 50%. This must be taken into consideration when interpreting PSA

values in men taking these agents. After 6 months of therapy, the effective PSA level in a patient taking finasteride or dutasteride may be calculated by doubling the measured PSA value. Free PSA (the percentage of non-protein-bound PSA) is also reduced by about 50%. Use of finasteride or dutasteride may result in sexual dysfunction, including decreased erectile rigidity, decreased libido, and decreased ejaculate volume. ED caused by 5 α -reductase inhibitor therapy is reversible and returns to baseline within 2 to 6 months after discontinuation of therapy.

Phosphodiesterase Type 5 Inhibitors

Although they are more often thought of as medications for the treatment of ED, sildenafil, vardenafil, and tadalafil have been shown to be efficacious in the treatment of the symptoms of BPH. As previously discussed, these medications work by preventing the degradation of cGMP by PDE5. This results in lower intracellular calcium levels and, consequently, smooth muscle relaxation. This process works in the vasculature of the penis as well as the smooth muscle cells of the prostate, urethra, and bladder neck. A number of randomized, double-blind, placebo-controlled trials have shown improvements in LUTS in men treated with a once-daily regimen of one of these medications. Although it has not been conclusively shown that PDE5 inhibitors are more efficacious than α -blockers, it does appear that the combination of the two medications works better than either one of them alone. The common side effects of these medications are headache, nasal stuffiness, and facial flushing.

Anticholinergic Medications

For most men, symptoms of overactive bladder make up a large component of LUTS associated with BPH. Most men with bladder outlet obstruction have symptoms of urgency, frequency, and nocturia. As in female patients, one of the best ways to treat these symptoms of overactive bladder is with daily use of anticholinergic medications such as oxybutynin, tolterodine, or solifenacin. When these medications are used in combination with an α -blocker, there can be significant improvement in LUTS in men with symptoms of overactive bladder. Except in patients with small prostates (<29 mL), it does not appear that anticholinergic monotherapy is better than combination therapy or α -blocker monotherapy. The typical side effects of this class of medications include dry mouth, constipation, nausea, and impaired cognition. The risk of urinary retention related to the use of these medications in men appears to be minimal.

SURGICAL MANAGEMENT

Minimally Invasive Therapy

Although TURP remains the standard for surgical treatment of BPH, substantial effort has been devoted to the development of less invasive and less morbid methods of treating patients with symptomatic BPH. This has led to a number of minimally invasive therapies, primarily using different methods of generating heat within the prostate gland to cause tissue destruction. These office-based heat techniques transiently increase bladder outlet obstruction for 1 to 2 weeks due to postprocedure swelling. Maximal tissue reduction and treatment effect occur within 12 weeks.

Transurethral microwave thermotherapy (TUMT) is one of the most widely studied minimally invasive methods of treating symptomatic BPH. Catheter-mounted transducers use microwave energy (30 to 300 Hz) to heat prostatic tissue, resulting in coagulative necrosis and shrinkage of the prostate gland. The subsequent reduction in prostate transition zone volume results in an improvement in flow rates and symptom scores. Transurethral needle ablation (TUNA) uses low-level radio frequency energy to effect similar changes within the prostate gland. Other therapies currently available or in development include interstitial lasers and high-intensity focused ultrasound. All of these therapies are designed to deliver sufficient energy to the prostate to cause tissue destruction, resulting in a smaller prostate gland consequent improvement in the patient's symptoms.

The most common side effects of these treatments are temporary increases in overactive bladder symptoms, transient urinary retention, hematuria, and ejaculatory dysfunction (primarily retrograde ejaculation). Late complications such as urethral strictures and ED have been reported but are significantly less common than with traditional surgical approaches. The major benefits of these less invasive therapies are the reduction in traditional surgical morbidities (e.g., bleeding) and risks associated with general or spinal anesthesia and decreased rates of long-term complications such as incontinence, ED, bladder neck contractures, and urethral strictures. Additionally, most of these procedures can be accomplished safely on an outpatient basis, either in the office or in an ambulatory surgical setting.

Success rates for the heat-based minimally invasive therapies are intermediate between those achieved with medical management and those of traditional surgical therapy, with 65% to 75% of patients experiencing symptomatic improvement and improved flow rates. The long-term durability of these therapies appears to be good but is presently being evaluated.

Traditional Surgical Management

TURP remains the "gold standard" for the surgical management of symptomatic BPH. A TURP procedure involves removal of the transition zone of the prostate through the penis using a cutting electrocautery loop. The goals of the surgery are to reduce the transition zone prostate tissue to the level of the prostatic capsule and to create a smooth, open appearance of the prostatic urethra and bladder neck. Improvements in the conventional technique have included bipolar electrosurgical cutting, which allows saline irrigation and eliminates the chance of transient urinary retention syndrome.

Newer operating room-based therapies have evolved that produce end results similar to those of TURP. Holmium laser enucleation (HoLEP) is a surgical technique performed by specially trained urologists, generally indicated for large size prostates. Other procedures include various forms of

vaporization of the transition zone tissue of the prostate. In contrast to the TURP, no pieces of prostate are removed with these procedures. The various vaporization procedures include potassium titanyl phosphate (KTP or GreenLight) laser therapy, also called photovaporization of the prostate, and bipolar plasma vaporization of the prostate (button TURP). With the exception of HoLEP, all of these procedures are useful for all but the largest prostate glands (>100 mL), which are typically best managed with open surgical enucleation. Rates of urinary incontinence, retrograde ejaculation, and urethral stricture are all higher after operating room procedures than after office-based therapies. Perioperative morbidity, including the need for blood transfusion, although substantially decreased by technical improvements, is likewise higher after TURP and similar procedures. However, standard electrosurgical resection of the prostate (TURP) is the most effective surgical treatment for symptomatic BPH short of enucleation. Success rates, as measured by improved symptom scores and increased urinary flow rates, are 80% to 90% after TURP.

Transurethral incision of the prostate (TUIP) is a more limited surgical procedure consisting of incision of the bladder neck and proximal prostatic urethra. Although it is more invasive than the heat-based therapies, success rates approach those of TURP in properly selected patients (i.e., those with prostate glands <30 mL). Morbidity after TUIP is significantly less than after TURP, but long-term durability of symptom relief is less than that seen with TURP.

Open surgical enucleation (open or simple prostatectomy) is reserved for patients with very large glands. This is an invasive surgery that typically involves a 5- to 10-cm incision in the midline of the lower abdomen and an incision in the bladder neck or the capsule of the prostate. After the incision has been made, the transition zone of the prostate (prostatic adenoma) is bluntly removed. Success rates are high, but the rate of complications is higher than with any of the other traditional surgical approaches (Table 71-5). This surgery is uncommonly performed in the United States, having been replaced by HoLEP in many centers.

CONCLUSION

The management of LUTS resulting from BPH has undergone a dramatic shift from principally a surgical approach to a medical approach. This evolution of care, coupled with the aging of the U.S. population, has resulted in a shift of care for these patients from the urologist to the primary care physician. In the absence of severe LUTS or indications for early surgical intervention, the primary care physician can now successfully manage most cases of mild to moderate BPH. If there is no response to medical therapy, the patient can be offered office-based minimally invasive surgical therapy.

TABLE 71-5 SUCCESS IN MEDICAL VERSUS SURGICAL MANAGEMENT OF BENIGN PROSTATIC HYPERPLASIA

DEGREE OF IMPROVEMENT	α_1 -BLOCKERS	FINASTERIDE	TURP	TUIP	OPEN SURGERY
Symptoms (%)	48	31	82	73	79
Flow rate (%)	40-50	17	120	100	185
Mean probability (%) of achieving the stated improvements	74	67	88	80	98

TUIP, Transurethral incision of the prostate; TURP, transurethral resection of the prostate.

D. Testis Cancer

Testicular tumors are the most common solid malignancies in men aged 15 to 34 years, and the incidence of testis cancer appears to have increased over the last 25 years. The advent of platinum-based chemotherapy in the 1970s and a more recent systematic multidisciplinary approach have greatly improved the survival of patients with testicular cancer over the last 40 years. Survival now approaches 99% for low-risk disease and 80% for high-risk disease.

Cryptorchidism (undescended testicle) is a well-accepted risk factor for subsequent development of testicular cancer. Abnormalities in spermatogenesis are well documented and are thought to be a primary effect of testicular tumors; up to 15% of patients are diagnosed with testicular cancer during a work-up for male factor infertility. Also, it appears that patients with an atrophic testicle have an increased risk of testicular cancer. Testicular microlithiasis does not appear to connote an increased risk of testicular cancer, although this conclusion is somewhat controversial; patients with this incidental finding on testicular ultrasonography do not require additional surveillance beyond monthly testicular examinations. Between 2% and 3% of patients have bilateral tumors at presentation, and 5% to 10% of those with involvement of only one testicle will go on to develop cancer in the normal contralateral testicle. Despite impairments in spermatogenesis, most men with testicular cancer are capable of fathering children; discussion of fertility issues is extremely important, especially in patients who may require adjuvant therapies such as external-beam radiation and systemic chemotherapy.

The most common presenting sign or symptom of testis cancer is a firm, painless mass arising from the testis. However, patients may also have an acute scrotum at presentation as a result of tumor hemorrhage, and up to 33% of patients are treated for presumed epididymitis. Scrotal ultrasonography is diagnostic; testis cancer is usually distinguishable from benign scrotal disease because of the clear involvement of the testicular parenchyma rather than the paratesticular tissues. Signs and symptoms of advanced disease include cough, gastrointestinal symptoms (mass), back pain (retroperitoneal metastasis), neurologic symptoms (brain metastasis), lower-extremity swelling (iliac or inferior vena cava thrombus), and supraclavicular lymphadenopathy.

DIAGNOSIS AND STAGING

Initial management of the primary tumor is inguinal orchiectomy with high ligation of the spermatic cord. Histopathology distinguishes germ cell tumors (GCTs) from stromal tumors. Seminoma is the most common GCT occurring in pure form. Teratoma, yolk sac tumor, embryonal carcinoma, and choriocarcinoma are classified as nonseminomatous GCT and frequently occur as mixed GCT (more than one histologic pattern within the primary tumor). Testicular cancer is unique in that serum tumor markers (STMs) play an important role in tumor staging. STMs include HCG, α -fetoprotein (AFP), and serum lactate dehydrogenase. Elevations of serum HCG may be seen in choriocarcinomas, in embryonal carcinomas, and in 15% of seminomas. Elevated AFP can be seen in yolk sac tumors and embryonal carcinomas, and this finding excludes a diagnosis of

seminoma. These STMs may be secreted either by the primary tumor or by metastatic foci (Table 71-6).

The retroperitoneal lymph nodes are the most common initial site of metastasis. Therefore, staging of the retroperitoneum with an abdominal CT scan is important in evaluating the extent of disease. However, accurate staging of the retroperitoneum remains problematic, with the literature quoting false-negative and false-positive rates of 20% to 30% with CT scanning. Common landing zones for lymph node metastasis include the precaval, interaortocaval, and preaortic lymph nodes below the renal hilum and above the aortic bifurcation. Chest radiography or thoracic CT scanning completes the clinical staging because the lungs and posterior mediastinum are the most common sites of distant metastatic disease.

TREATMENT

Histopathology, pathologic stage, and STM status are used to determine subsequent treatment after inguinal orchiectomy. All patients with elevated STMs after orchiectomy receive cisplatin-based chemotherapy, regardless of histology. Radiation therapy and retroperitoneal lymph node dissection (RPLND) have a high likelihood of failure in the face of elevated STMs.

Seminoma manifests as clinical stage I in 70% of cases, stage II in 20%, and stage III in 10%. In the past, most experts recommended radiation therapy to the retroperitoneum for patients with stage I or II disease because of the radiosensitivity of seminomas. However, patients with stage I seminoma are now more likely to undergo surveillance because of the recognition that new retroperitoneal metastases found during surveillance are sensitive to either chemotherapy or radiation. Patients with bulky stage II disease (lymph node >5 cm) and those with stage III disease should receive combination chemotherapy.

Nonseminomatous GCTs manifest more frequently at an advanced stage (stage I, in 30%, stage II in 40%, and stage III in 30%). RPLND is frequently recommended in patients with clinical stage I or low-volume stage II disease. Reasons for recommending RPLND include accurate pathologic staging of the retroperitoneum, low relapse rate (<2%) after properly performed RPLND, curative potential in the face of viable GCT, and the potential for retroperitoneal teratoma, which is resistant to chemotherapy. Side effects associated with RPLND include lymphocele, chylous ascites (0.4%), and small bowel obstruction (1% to 2%). Nerve-sparing RPLND is able to preserve antegrade ejaculation in more than 80% of patients.

TABLE 71-6 TESTIS CANCER STAGING STUDIES

Tumor markers
AFP—elevated only with nonseminomatous tumors
HCG—may be increased with either seminoma or nonseminomatous tumors
Abdominal CT scan—retroperitoneal nodes are most common site of regional nodal metastasis
Chest radiograph or CT scan—lung is most frequent site of distant metastasis

AFP, α -Fetoprotein; HCG, β -human chorionic gonadotropin; CT, computed tomography.

Primary chemotherapy is sometimes recommended to patients with stage I or II nonseminomatous testis cancers. Also, some men may choose surveillance alone for a stage I tumor, which implies normal serum marker status and a normal abdominal CT scan. Up to 25% may be expected to develop recurrence, usually within 2 years, and chemotherapy is used after evidence of recurrence.

E. Male Infertility

Approximately 90% of all couples are able to conceive a child in the first year. For this reason, a male patient should not be evaluated for infertility unless he has tried to have a child for at least 1 year. Although it is difficult to localize the cause of infertility to one gender, the prevalence of male factor infertility in infertile couples is probably 25% to 50%. From a very basic perspective, male infertility is caused by problems delivering sperm, from either a decreased amount of sperm or a deficiency in the quality of the sperm. These problems can result from ED, retrograde ejaculation, ejaculatory duct obstruction, obstruction of the vas deferens, endocrine dysfunction, varicoceles, or genetic abnormalities.

HISTORY AND PHYSICAL EXAMINATION

The evaluation of a patient with infertility should begin with a thorough history and physical examination. During the history, the clinician should include questions about how long and how frequently the couple has been trying to conceive, prior pregnancies with current or previous partners, erectile function, and use of lubricants. A detailed past medical, surgical, social, and family history is also very important.

The physical examination should commence with an overall assessment of the patient's general health. Next, the clinician should focus on examination of the genitalia. The surface of the testicle should be closely examined because studies have shown an increased incidence of testicular cancer in patients with infertility. Testicular size and consistency should also be assessed. The normal testicle has a volume of approximately 20 mL and does not feel soft or spongy. In addition, the spermatic cord should be carefully examined to confirm the presence of a vas deferens on each side. The scrotum should be examined for the presence of a varicocele, with and without performance of the Valsalva maneuver. Finally, a rectal examination should be performed to palpate for abnormalities of the prostate and seminal vesicles.

SEMEN ANALYSIS

Semen analysis is probably the most important part of the evaluation of an infertile male patient. The patient should abstain from ejaculation for 2 to 7 days before the test, and clinical decision making should be based on at least two tests performed 7 days apart. Sperm concentration increases with days of abstinence. In a study from 2004 looking at the effect of frequency of ejaculation on sperm concentration, the concentration continued to increase after 10 days of abstinence. After the specimen has been collected by the patient, it should be delivered to the laboratory at body temperature as soon as possible. Motility significantly decreases after 2 hours.

Platinum-based chemotherapy is the standard for patients with advanced disease. Cure rates of 70% to 80% are achieved even in patients who have relatively bulky metastatic disease at presentation. Side effects of chemotherapy include renal dysfunction, neuropathy, Raynaud's phenomenon, hematologic toxicity, pulmonary toxicity, cardiovascular toxicity, and a 0.5% risk for secondary leukemia.

The most important parts of the microscopic examination of the semen sample are sperm concentration, morphology, and motility. The normal sperm concentration is greater than 20 million sperm per milliliter, and a value lower than 20 million per milliliter is termed *oligospermia*. The absence of sperm is termed *azoospermia*. Depending on the laboratory, sperm morphology is usually reported as a percentage. Typically, normal morphology in more than 50% of sperm examined is considered acceptable. Morphologic studies primarily assess the size and shape of the head and tail. Motility is also expressed as a percentage and refers to the percentage of sperm that are moving in a coordinated and progressive manner. Mortality values higher than 50% are considered to be normal. Abnormal sperm motility is termed *asthenospermia*, and abnormal morphology is *teratospermia*.

Other factors checked during a semen analysis include semen volume, pH, and fructose positivity. A semen volume between 2 and 4 mL is considered normal. A volume of less than 2 mL may be a sign of ejaculatory duct obstruction (absent fluid from vas deferens and seminal vesicle) or retrograde ejaculation. Because the testicles contribute only a small portion of the fluid released during ejaculation, a vasectomy should not affect ejaculate volume. The normal range of semen pH is 7.2 to 8.0. An acidic pH may be a sign of congenital absence of the vas deferens or seminal vesicle hypoplasia. Depending on the laboratory, the fructose test result should be positive or in the normal range. Fructose is made by the seminal vesicles and provides nutrition for the sperm. Low or absent fructose may also be a sign of ejaculatory duct obstruction or seminal vesicle hypoplasia.

OTHER DIAGNOSTIC TESTS

If a patient has an abnormal semen analysis, an endocrine evaluation should be performed. The complete initial endocrine evaluation includes measurements of LH, follicle-stimulating hormone (FSH), prolactin, and testosterone. These hormone levels should be checked in the morning (before 11 A.M.). In general, an elevated FSH is a bad prognostic sign indicating that the patient will not be found to have a correctable form of infertility. From a simplistic point of view, this is because the hypothalamic-pituitary axis is trying to stimulate sperm production but the testicle is not responding. Genetic testing in the form of a chromosome analysis (karyotype and Y-linked microdeletion assessment) should be considered in patients with severe oligospermia or azoospermia to rule out disorders such as Klinefelter's syndrome and abnormalities of the Y chromosome.

As long as a normal physical examination can be performed, there is no need to do a scrotal ultrasound study on patients with infertility. If the patient has a body habitus that makes physical

examination difficult, a scrotal ultrasonography may aid in the diagnosis of a clinical varicocele. In general, patients in need of further diagnostic evaluation of infertility should be referred to a specialist.

TREATMENT OF MALE INFERTILITY IN PRIMARY CARE

There are several options for the treatment of male infertility, and the choice of treatment depends on the results of the history, physical examination, and diagnostic evaluation. First, fertility is a reflection of a patient's overall general health. Decreasing the patient's stress level, improving sleep habits, and fostering a healthy diet may all have beneficial effects on fertility. There is conflicting evidence as to whether antioxidants in the form of vitamins or diet modification improve the viability of sperm. Patients can purchase antioxidant multivitamins at most supermarkets and health food stores. Because the evidence for benefit is mixed, it is important to tell the patient not to overspend on this treatment.

Other lifestyle modifications may also improve fertility. For example, avoiding hot baths and whirlpools may provide more optimal conditions for sperm production. In addition, tobacco, alcohol, and marijuana use have all been shown to negatively affect fertility in males. Certain medications also can have a negative impact on infertility. α -Blockers used to treat BPH can cause retrograde ejaculation. Exogenous testosterone replacement decreases sperm production, and at least 2 months are required for sperm production to recover once testosterone therapy is stopped.

The timing and frequency of intercourse can affect the ability to conceive. Ovulation predictor kits are readily available to patients without a prescription and may improve fertility. Because sperm can survive at least 2 days in the female genital tract, having intercourse every 2 days may maximize male sperm concentration and delivery. In addition, patients should make sure that they are not using a lubricant that has spermicidal activity.

F. Benign Scrotal Diseases

VARICOCELE

A varicocele is classically described as an abnormal dilation of the veins of the pampiniform plexus that can be palpated as a "bag of worms" with or without having the patient performing the Valsalva maneuver while standing. When examining a patient for any scrotal pathology, it is important to have the patient stand. A clinical varicocele is one that can be palpated on physical examination. Because the occurrence of varicoceles increases with age, the prevalence in the literature is highly variable. The prevalence of a unilateral palpable left-sided varicocele is between 6.5% and 22%, and that of bilateral palpable varicoceles ranges from 10% to 20%. The prevalence of an isolated right-sided palpable varicocele is less than 1%; because of their very rare association with retroperitoneal malignancy, many clinicians perform axial imaging on patients with a unilateral right-sided varicocele. In general,

Patients who have a palpable varicocele and oligospermia with or without defects in sperm morphology or motility may benefit from a varicocelectomy and should be referred to a urologist for further evaluation (see later discussion). The most common methods of surgical correction are varicocelectomy and gonadal vein embolization.

Patients with oligospermia and a normal or low FSH level may benefit from treatment with clomiphene citrate (Clomid). The typical dosage is 25 mg daily or 50 mg every other day for at least 2 months (it takes 64 days for new sperm to be made). Most studies of this drug have shown a significant increase in sperm production but little impact on fertility. However, it may be beneficial for selected patients with the above-mentioned laboratory values.

If a varicocele is present in an infertility patient or severe oligospermia or azoospermia does not respond to the treatments already mentioned, referral to a urologist for additional testing is warranted. Oligospermia or azoospermia with a low semen volume and a negative fructose result may suggest ejaculatory duct obstruction. If azoospermia is present with no sonographic evidence of ejaculatory duct obstruction, a testicular biopsy might be the prudent next step. If retrograde ejaculation is suspected (oligospermia, normal fructose, and low semen volume), the urologist may elect to examine a postejaculation, centrifuged urine specimen for the presence of sperm.

Once the evaluation by the urologist has been completed, he or she may recommend that the patient proceed with assisted reproductive technology (ART). The simplest form of ART is intrauterine insemination, for which patients with oligospermia and normal motility are excellent candidates. In vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) are more costly but often successful. Even patients with azoospermia due to Klinefelter's syndrome have had frequent success (46% rate of pregnancy) with ICSI.

A left-sided varicocele does not have clinical significance unless it can be palpated on physical examination. A left-sided varicocele that is incidentally found during ultrasonography of the scrotum and is not palpable on examination is considered a subclinical varicocele and is typically not the source of any pathology.

Palpable and nonpalpable varicoceles are most commonly found incidentally and in most cases have no clinical significance. However, palpable varicoceles can cause ipsilateral testicular atrophy. Therefore, it is important for the clinician to compare the size of the testicles in patients who desire future fertility. If the physical examination is unclear, scrotal ultrasonography can be used to accurately measure the size of both testicles. Any patient who desires future children and has a size discrepancy greater than 20% should be monitored closely and possibly referred to a urologist. Although varicoceles are most commonly found incidentally, they may also be found during a work-up for

male factor infertility, scrotal pain, or asymptomatic testicular atrophy.

The pathophysiology of varicoceles is poorly understood but involves dilation of the internal spermatic vein and transmission of increased hydrostatic pressure across dysfunctional venous valves. Stasis of blood in the venous system disturbs the counter-current heat exchange that is responsible for maintaining testicular temperature and may result in testicular parenchymal damage and impaired spermatogenesis.

Varicoceles are the most common cause of both primary infertility (patient has fathered no children) and secondary infertility (patient has fathered at least one child), accounting for 33% of cases. However, most men with palpable varicoceles are able to father children without difficulty. In a man with infertility and a palpable varicocele, semen analysis commonly reveals a low sperm count and abnormal sperm morphology and motility. After surgical correction of a varicocele in a patient with infertility, semen parameters improve in 60% to 80% and subsequent pregnancy rates range from 20% to 60%.

It is prudent to perform scrotal ultrasonography on any patient with chronic testicular pain. Varicoceles are commonly found during this evaluation, but usually only palpable (clinical) varicoceles are considered as a source of pain. If a nonpalpable varicocele is found on an ultrasound examination, the patient should not be told that it is the cause of his pain. More than 80% of men with chronic pain from a palpable varicocele have improvement in their pain after surgical correction.

Common operative techniques for treatment of a varicocele include high retroperitoneal ligation of the internal spermatic vein, microsurgical inguinal and subinguinal varicocelectomy, laparoscopic varicocelectomy, and gonadal vein embolization. The inguinal approach using microscopic magnification has the highest success and lowest complication and recurrence rates. The most common complication is hydrocele formation, whereas a rare complication is inadvertent ligation of the testicular artery resulting in testicular atrophy and loss. Surgical intervention for subclinical (nonpalpable) varicoceles is not indicated.

SPERMATOCELE (EPIDIDYMAL CYST)

Spermatoceles and epididymal cysts are dilations of the tubes that connect the testicle to the epididymis (ductuli efferentes). Although they are technically the same thing, many clinicians refer to small lesions as epididymal cysts and larger ones as spermatoceles. These cystic lesions are very common and are found in 29% of asymptomatic men on ultrasonography. After a vasectomy, 35% of men develop a new small spermatocele; therefore, distal obstruction likely contributes to their development.

On physical examination, spermatoceles are somewhat mobile, firm masses that are separate and distinguishable from the smooth border of the testicle. It may be possible to transilluminate larger lesions. They are filled with a clear fluid that usually contains abundant amounts of sperm. If the lesion cannot be transilluminated, it is advisable to perform an ultrasound study of the scrotum to distinguish a spermatocele from a solid mass. Of note, the vast majority of solid masses of the epididymis are benign. Small spermatoceles and epididymal cysts normally have no clinical significance and are typically

not the source of a patient's chronic testicular pain. They can be surgically removed if they are large or are causing discomfort for the patient.

ACUTE EPIDIDYMITIS

Acute epididymitis is a clinical syndrome that may manifest with fever, acute scrotal pain, and impressive swelling and induration of the epididymis. Pathophysiologically, epididymitis is most often caused by retrograde bacterial spread from the bladder or urethra. In men younger than 35 years of age, the most common causative agents are those organisms associated with urethritis—namely, *Neisseria gonococcus* and *Chlamydia trachomatis*. In older men, acute epididymitis is usually caused by a coliform bacteria such as *Escherichia coli* and often occurs in association with another lower urinary tract infection or bladder outlet obstruction.

The most important consideration in diagnosing acute epididymitis is differentiating this disease from acute testicular torsion. Physical examination can be nonspecific, although focal epididymal swelling and tenderness are suggestive, and the presence of white cells and bacteria in the urine is indicative of an infectious etiology. Scrotal sonography with Doppler flow can be extremely helpful in differentiating acute epididymitis from torsion in difficult cases.

Patients with acute epididymitis have significant inflammation that can also involve the testicle (epididymo-orchitis). Patients with severe epididymitis involving the testicle are often systemically ill. In most instances, initial treatment should consist of antibiotics, nonsteroidal anti-inflammatory medications, and possibly oral narcotics. In some cases, broad-spectrum antibiotics or even hospital admission may be necessary. In general, patients younger than 35 years of age should be treated with ceftriaxone and doxycycline or a single dose of azithromycin. Older patients are usually empirically treated with a fluoroquinolone or trimethoprim sulfamethoxazole for 2 to 4 weeks. Complications associated with acute epididymitis include abscess formation, testicular infarction, infertility, and chronic epididymitis or orchalgia.

HYDROCELE

A hydrocele is a serous fluid collection located between the parietal and visceral layers of the tunica vaginalis of the scrotum. Noncommunicating hydroceles usually surround the testicle and spermatic cord. Communicating hydroceles are actually indirect inguinal hernias; they contain only fluid and not bowel or fat because the opening into the peritoneal cavity is small. Communicating hydroceles can be distinguished from noncommunicating hydroceles on physical examination by gently pushing the fluid out of the scrotum and into the peritoneum. Communicating hydroceles are more commonly identified in the pediatric age group.

Patients with a noncommunicating hydrocele usually have complaints of heaviness in the scrotum, scrotal pain, or an enlarging scrotal mass. Usually the diagnosis is easily made based on the physical examination and transillumination of the scrotum. If the testis is not palpable, an ultrasound study should be performed to rule out a testicular tumor associated with a secondary or reactive hydrocele. Noncommunicating hydroceles are caused

by increased secretion or decreased reabsorption of serous fluid by the tunica vaginalis. Infection, trauma, surgery, neoplastic disease, and lymphatic disease are causative in many adults, whereas the remainder of cases are idiopathic.

Treatment of symptomatic noncommunicating hydroceles is surgical. Although the recurrence rate is significantly higher with aspiration and sclerotherapy, this approach can be a good option in patients who are considered poor surgical candidates. Hydrocelectomy procedures involve either excision of the redundant tunica vaginalis or a plication of the sac without excision. After surgery, the rates of hydrocele recurrence and chronic pain are 9% and 1%, respectively.

TESTICULAR TORSION

Testicular torsion is considered a true urologic emergency. The testicle receives its blood supply from the testicular artery (aorta), the vasal artery (inferior vesicle artery), and the cremasteric artery (inferior epigastric artery). All three vessels are transmitted to the testicle through the spermatic cord. Torsion of the spermatic cord impairs arterial inflow as well as venous outflow. If detorsion is not performed within 6 to 8 hours, testicular infarction and hemorrhagic necrosis are likely to occur. Typically, patients are younger than 21 years of age, although testicular torsion can occur later. Delay in presentation and diagnosis is more common in the adult patient population and is related to patient and physician factors.

The characteristic signs and symptoms of acute testicular torsion are the acute onset of scrotal pain, swelling, nausea, vomiting, loss of normal rugae of the scrotal skin, absent cremasteric reflex, and a high-riding, rotated, tender testicle. The diagnosis of testicular torsion remains a clinical one, however; if ultrasound equipment is readily available, all patients should have a scrotal ultrasound study before surgery. In rare cases, surgical exploration is undertaken when the index of suspicion is high but imaging is not available. Doppler ultrasonography is extremely useful in differentiating testicular torsion from other causes of acute scrotum, such as acute epididymitis, torsion of the appendix testis, and trauma.

It is possible to untwist testicular torsion by manipulating the testicle through the scrotum in the emergency room or in a physician's office. After giving the patient parenteral narcotics, the testicle can be untwisted by gently pulling down on it and, usually, rotating it laterally (like opening a book). If this is successful, the testicle will uncoil like a spring and fall into its normal position, with immediate relief of the patient's pain. Even if the procedure is successful, patients should still be taken to the operating room for bilateral orchiopexy. Of note, testicular torsion is the result of medial twisting of the testicle only 68% of the time.

Important surgical principles include surgical detorsion and assessment of testicular viability in the operating room. If the testis is determined to be viable, bilateral orchiopexy is performed using the technique of three-point fixation (sutures placed medially, laterally, and inferiorly). In the presence of infarction, orchiectomy is recommended. Orchiopexy of the contralateral testicle is always performed simultaneously. When diagnosis and surgery occur in a timely fashion, testicular salvage rates approach 70%. Delayed surgical therapy results in dropoff of the salvage rate to 40%.

Normal Physiology of Bone and Mineral Homeostasis

Andrew F. Stewart

● CALCIUM HOMEOSTASIS

The maintenance of normal calcium homeostasis is critical to survival for at least three reasons. First, the serum calcium concentration regulates the degree of membrane excitability in muscle and nervous tissue. Increases in serum calcium levels produce refractoriness to stimulation of neurons and muscle cells, which translates clinically into coma and muscular weakness. Conversely, reductions in serum calcium levels lead to increases in neuromuscular excitability that translate clinically into convulsions and spontaneous muscle cramps and contractions referred to as *carpopedal spasm* or *tetany*. Second, terrestrial life requires the existence of a skeleton, and calcium is the major structural cation in the skeleton. The mineral phase of the skeleton is composed of a calcium salt called *hydroxyapatite*, and reductions in bone mineral content lead to spontaneous fractures. Third, intracellular calcium has a major intracellular signaling role, and control of intracellular calcium is essential to the survival of all cells. This mechanism is used to advantage pharmacologically through the widespread clinical use of drugs that regulate intracellular calcium concentrations and calcium-channel activity for the treatment of a wide variety of human diseases. Physicians, regardless of their specialty, encounter disorders of calcium homeostasis on a regular basis.

The serum total calcium concentration is normally maintained at about 9.5 mg/dL. Of this total amount, about 4.5 mg/dL is bound to serum proteins, principally albumin, and about 0.5 mg/dL circulates as insoluble complexes such as calcium sulfate, phosphate, and citrate. The remaining 4.5 mg/dL circulates as free or unbound or ionized calcium. This free, ionized serum calcium is important clinically and physiologically. This calcium is available to be filtered at the glomerulus, to interact with cell membranes to regulate their electrical potential or excitability, and to enter and exit the skeletal hydroxyapatite crystal lattice.

It is important to maintain normal levels of ionized serum calcium, although total serum calcium is customarily measured in most clinical laboratories. In some instances, total serum calcium can change without a change in the ionized calcium level. For example, if the serum albumin level declines as a result of hepatic cirrhosis or the nephrotic syndrome, the total serum calcium also declines, but the ionized serum calcium concentration remains normal. Measuring the ionized serum calcium level directly is sometimes important.

A complex group of regulatory processes have evolved to protect the integrity of this system. When a physician encounters

patients in whom hypercalcemia, hypocalcemia, or disorders of skeletal mineralization have occurred, multiple safety control points have been breached (discussed later).

To maintain homeostatic control, the calcium ion interfaces with three important compartments, as shown in the calcium physiologic black box in [Figure 72-1](#). Although intracellular calcium is important in intracellular signaling, it is quantitatively unimportant in overall systemic calcium homeostasis. The three critical regulatory fluxes that maintain normal serum calcium concentration are those of the intestine, kidney, and skeleton.

Calcium Fluxes into and out of Extracellular Fluid

Intestinal Calcium Absorption

The normal dietary calcium intake for an adult is about 1000 mg per day. About 300 mg of the total is absorbed (i.e., unidirectional absorption is about 30%), and this absorption occurs in the duodenum and proximal jejunum. About 150 mg of calcium per day is secreted by the liver (in bile), the pancreas (in pancreatic secretions), and the intestinal glands such that net absorption (called *fractional absorption*) of calcium is about 15% of intake.

The efficiency of calcium absorption is regulated at the level of the small intestinal epithelial cell, the enterocyte, by the active form of vitamin D, 1,25-dihydroxyvitamin D ($1,25[\text{OH}]_2\text{D}$),

FIGURE 72-1 The calcium physiologic black box. The central box represents extracellular fluid (ECF), which contains a total of about 1000 mg of calcium. It has three regulatory interfaces with the gastrointestinal (GI) tract, skeleton, and kidney. The fluxes into and out of the ECF are measured in milligrams per day.

also called *calcitriol*. Increases in $1,25(\text{OH})_2\text{D}$ enhance calcium absorption, and decreases in $1,25(\text{OH})_2\text{D}$ reduce absorption of dietary calcium. Dietary calcium absorption can be increased over the short term by increasing calcium intake or increasing plasma $1,25(\text{OH})_2\text{D}$ concentrations, or both. Pathologic increases in serum calcium (i.e., hypercalcemia) can be caused by increases in circulating $1,25(\text{OH})_2\text{D}$ (e.g., in sarcoidosis) or by excessive calcium intake (i.e., milk-alkali syndrome). Conversely, hypocalcemia can result from a decline in $1,25(\text{OH})_2\text{D}$ (e.g., chronic renal failure, hypoparathyroidism). If a normal individual consumes 1000 mg of calcium per day and the net absorption from the gastrointestinal (GI) tract is 150 mg per day, 850 mg of calcium will be excreted in the feces each day.

Renal Calcium Handling

The filtered load of calcium by the kidneys is about 10,000 mg per day. In terms of overall regulation of calcium homeostasis, this number is very large, making the point that the kidney is the most important moment-to-moment regulator of the serum calcium concentration. The amount also emphasizes that disorders of renal calcium handling (e.g., thiazide diuretic use, hypoparathyroidism) can be expected to produce significant abnormalities in serum calcium homeostasis.

Of the 10,000 mg filtered at the glomerulus each day, about 9000 mg (90%) is reabsorbed *proximally* by the proximal convoluted tubule, the pars recta, and the thick ascending limb of Henle loop. This 90% is absorbed in conjunction with sodium and chloride reabsorption and is not subject to regulation by parathyroid hormone (PTH). The remaining 10% (1000 mg) that arrives at the distal tubule on a daily basis is subject to regulation by PTH, which stimulates renal calcium reabsorption. The anticalciuric effect of PTH can be extremely efficient, and elevated PTH concentrations can essentially eliminate calcium excretion into the urine. This action is a potent mechanism for retaining calcium under conditions of calcium deprivation (e.g., a low-calcium diet, vitamin D deficiency, intestinal malabsorption) and can contribute to hypercalcemia under pathologic conditions, as in primary hyperparathyroidism.

About 150 mg of calcium is excreted by the kidney in the final urine on a daily basis in a healthy individual. If the kidney filters 10,000 mg of calcium each day, and if 150 mg is excreted in the final urine, 9850 mg (98.5%) is reabsorbed at proximal and distal sites. A healthy person is in zero calcium balance with respect to the outside world: intake (1000 mg/day) – output [(850 mg/day in feces) + (150 mg/day in urine)] = 0.

Skeletal Biology and Calcium Homeostasis

The skeletal compartment contains about 1.2 kg of calcium in a male adult and 1.0 kg in a female adult. Most of this calcium is in the form of crystal hydroxyapatite, a calcium phosphate salt. Although calcium contributes in an important way to the structural integrity of the skeleton, the skeleton also serves as a quantitatively large reservoir (i.e., a sink) for adding and removing calcium to and from the extracellular fluid (ECF) compartment at appropriate times.

The adult skeleton is composed of two types of bone: cortical (or lamellar) bone and trabecular (or cancellous) bone (Fig. 72-2). Cortical bone predominates in the skull and the shafts of

FIGURE 72-2 The structure of human bone. A human proximal femur examined using a gross pathologic specimen (*left panel*) and a radiograph of the same section (*right panel*). Notice that two types of bone are represented. One type is cortical bone (i.e., lamellar bone), and the other is cancellous bone (i.e., trabecular bone). The proportion of trabecular and cortical bone differs by location. For example, the shaft of the femur contains mostly cortical bone, whereas the proximal end of the femoral neck and the greater trochanter contain little cortical bone and almost exclusively contain trabecular bone. This distinction is important, because most osteoporotic fractures occur at sites in which trabecular bone predominates, including the greater trochanter, the femoral neck, the vertebrae, and the distal radius. (Courtesy Webster S.S. Jee, MD, University of Utah, Salt Lake City, Utah.)

long bones, and trabecular bone predominates at other sites, such as the distal radius, the vertebral bodies, and the trochanters of the hip.

Bone is not an inert tissue, as might be imagined from visiting the dinosaur room at a natural history museum; instead, bone is a vital tissue that is continually turning over. The adult skeleton is completely remodeled every 3 to 10 years. Remodeling is perhaps best appreciated by recalling that orthopedic surgeons routinely and intentionally set fractures imperfectly, knowing that the normal processes of bone remodeling will restore the bone's original shape with the passage of time.

The cells that regulate bone turnover can be divided into those that remove old bone, those that provide new bone (Fig. 72-3) (see Chapter 74), and those that regulate these two processes. Cells that remove, or *resorb*, old bone are *osteoclasts*. These cells are large, metabolically active, multinucleated cells derived from the fusion of circulating macrophages. They deposit themselves on the surface of bone and form a *sealing zone* over the bone surface into which they secrete protons (i.e., acid), proteases (e.g., collagenase), and proteoglycan-digesting enzymes (e.g., hyaluronidase). The acid solubilizes hydroxyapatite crystals, releasing calcium, and the enzymes digest bone proteins and proteoglycans (e.g., collagen, osteocalcin, osteopontin), which constitute the nonmineral, or *osteoid*, component of bone. Osteoclasts move along the surface of trabecular bone plates and drill tunnels in cortical bone, periodically releasing the digested contents within their sealed zones into the bone marrow space and thereby creating resorption lacunae, called *Howship's lacunae*, on the trabecular bone surface. The released calcium contributes to the ECF calcium pool, and the released proteolytic products, such as

FIGURE 72-3 Cellular components of bone remodeling. Bone remodeling is a continuous process that involves the activation of osteoclast precursors in the macrophage lineage (i.e., colony-forming units of granulocyte-macrophage progenitors [CFU-GM]) that become actively resorbing osteoclasts, which tunnel into the bone surface to dig resorption lacunae. Osteoblast precursors in the fibroblast–bone marrow stromal cell lineage (CFU-F) then appear and become active at the sites of prior resorption, and they secrete new osteoid, which later mineralizes to fill the lacunae created by osteoclastic bone resorption. (From Manolagas SC, Jilka RL: Bone marrow, cytokines, and bone remodeling: emerging insights into the pathophysiology of osteoporosis, *N Engl J Med* 332:305–311, 1995.)

deoxypyridinoline cross-links (i.e., collagen fragments and hydroxyproline), can be used clinically as indices of bone resorption.

New bone formation is accomplished by *osteoblasts*, which are derived from marrow stromal cells or bone surface lining cells. Osteoblasts synthesize and secrete the components of the non-mineral phase of bone, called *osteoid*. The components are mostly proteins and include collagen, osteopontin, osteonectin, osteocalcin, proteoglycans, and a plethora of growth factors, including transforming growth factor- β and insulin-like growth factor-I. This complex provides the scaffolding on which the mineral crystal hydroxyapatite forms lattices.

In the past decade, attention has focused on a third, previously underappreciated bone cell type, the *osteocyte*. These cells are descendants of osteoblasts and are embedded into the mineralized phase of bone. Osteocytes physically connect with one another and to cells at the mineral surface through long dendritic processes. The dendritic processes extensively permeate the mineralized phase of bone through an elaborate canalicular network. Osteocytes serve a critical role in sensing biomechanical strain within bone, and through their cellular extensions to the cell surface, they communicate signals that attract, activate, or repress osteoclasts and osteoblasts. In this way, they determine which areas of the skeleton require new bone formation and which need to be targets of osteoclastic bone remodeling.

Through the process of bone turnover, or bone remodeling, osteoclasts continually remove old bone, and osteoblasts

continually produce new osteoid that mineralizes, eventually replacing the old bone removed by osteoclasts with new bone. This process replaces old bone—and by implication, defective or damaged bone with microfractures and reduced mechanical strength—with new, mechanically strong bone, although the evidence for this action is limited. The principal therapy for osteoporosis is with the use of antiresorptives such as estrogens, estrogen-like drugs, and bisphosphonates, which dramatically reduce bone turnover while improving bone mass and bone mechanical properties.

Bone remodeling is important for systemic calcium homeostasis. Osteoclasts can be used to access calcium from the skeleton in times of need to maintain a normal serum calcium concentration. Conversely, unmineralized osteoid produced by osteoblasts can be used at appropriate times as a sink into which excess serum calcium can be deposited. Under normal circumstances, osteoclasts resorb bone at a rate such that about 500 mg of calcium is removed per day from the skeleton and delivered to the ECF compartment. At the same time, osteoblasts produce osteoid that mineralizes at a rate such that about 500 mg of calcium leaves the ECF and enters the skeleton at new sites. From the perspective of the black box shown in [Figure 72-1](#), the skeleton is in zero calcium balance with the ECF, and the whole organism is in zero calcium balance with the external environment.

Considering the complexity of this calcium homeostatic system and the importance of maintaining tight control of serum calcium levels, an obvious need exists for systemic regulation and

integration of the calcium fluxes across the GI, skeletal, and renal compartments. The two key metabolic regulatory hormones that coordinate these activities are PTH and the active form of vitamin D, $1,25(\text{OH})_2\text{D}$.

Regulatory Hormones

Parathyroid Hormone

PTH is a peptide hormone produced by the four parathyroid glands (Fig. 72-4). These glands are located behind the normal thyroid lobes, with two on the right and two on the left. Through the calcium sensor—a G protein–coupled receptor for calcium that is located on the surface of the parathyroid cell—the serum ionized calcium concentration is continuously monitored. In this exquisitely sensitive system, minor (e.g., 0.1 mg/dL) reductions in serum ionized calcium lead to PTH secretion, and minor increments in serum calcium lead to suppression of PTH secretion.

PTH is secreted as an 84-amino-acid peptide hormone that is rapidly (half-life of about 3 to 5 minutes) cleaved by the Kupffer cells in the liver into an active amino-terminal form; the carboxyl-terminal form is inactive. Continuous monitoring of the serum calcium concentration by the parathyroid glands, the immediate secretion of PTH in response to hypocalcemia, and the rapid clearance of PTH after secretion enable the parathyroid gland and PTH to regulate serum calcium with remarkable precision.

PTH targets three organs, two directly and one indirectly. The first directly targeted organ is the kidney, in which renal calcium excretion is inhibited by PTH. PTH also inhibits phosphate and bicarbonate reabsorption, which produces phosphaturia and hypophosphatemia and proximal renal tubular acidosis, respectively. The renal actions of PTH occur immediately. PTH also stimulates the production of the active form of vitamin D, $1,25(\text{OH})_2\text{D}$.

PTH also directly targets the skeleton. PTH can mobilize calcium immediately from the skeleton through activation of

osteoclastic bone resorption. Over days to weeks, PTH stimulates the activity of osteoblasts to produce new bone and thereby remove calcium from the circulation. The ability to stimulate osteoclasts acutely without activating bone formation is important for the rapid delivery of calcium to the ECF.

PTH has the indirect effect of increasing intestinal calcium absorption by increasing renal synthesis of $1,25(\text{OH})_2\text{D}$. Seen in concert, PTH is secreted in response to hypocalcemia, and the actions of PTH combine to restore a low serum calcium concentration to normal by preventing renal calcium losses, by adding calcium to the ECF from the skeleton, and by indirectly stimulating (through $1,25(\text{OH})_2\text{D}$) increases in intestinal calcium absorption.

Vitamin D Metabolism

Vitamin D is two compounds: ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) (Fig. 72-5). Both substances are inactive precursors. One (D_3) is derived principally from skin exposed to sunlight, and the other (D_2) is derived from plant sterols. Both D_2 and D_3 are found in multivitamins and commercial dietary supplements.

Both precursors are converted constitutively by the enzyme vitamin D 25-hydroxylase (CYP2R1) in the liver to their respective 25-hydroxyvitamin D ($25[\text{OH}]\text{D}$) derivatives. The derivatives also are inactive precursors, but they have two types of clinical significance. First, severe liver disease such as cirrhosis prevents this essential step and leads to vitamin D–deficient syndromes collectively called *hepatic osteodystrophy*. Second, $25(\text{OH})\text{D}$ is the standard clinical laboratory measure of the vitamin D status (i.e., repletion or deficiency) of patients with hypocalcemia, osteomalacia or rickets, osteoporosis and intestinal malabsorption, and other similar conditions.

$25(\text{OH})\text{D}$ is converted, or activated, in the renal proximal tubule by the enzyme 25-hydroxyvitamin D_3 1α -hydroxylase (CYP27B1) to the active form of the vitamin, $1,25(\text{OH})_2\text{D}$. This substance, which is also called *calcitriol*, is regulated by PTH. Increases in PTH stimulate $1,25(\text{OH})_2\text{D}$ production, and decreases in PTH diminish $1,25(\text{OH})_2\text{D}$ synthesis. The primary

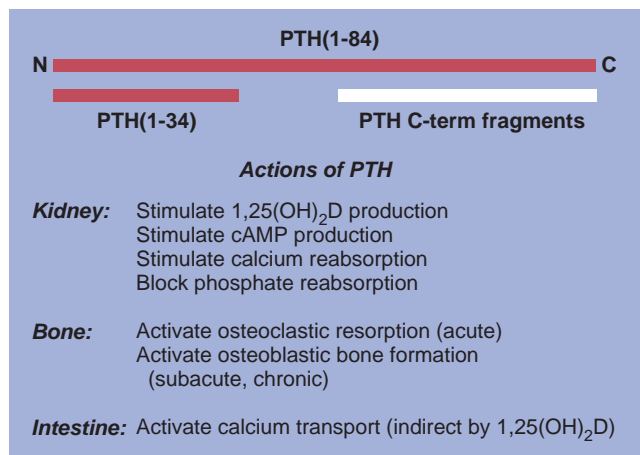

FIGURE 72-4 Structure and actions of parathyroid hormone (PTH). PTH is secreted as an 84-amino-acid protein, which is cleaved in the liver to derivative amino-terminal and carboxyl-terminal (C-term) forms. Actions of the amino-terminally intact forms of PTH are listed. cAMP, Cyclic adenosine monophosphate; $1,25(\text{OH})_2\text{D}$, 1,25-dihydroxycholecalciferol.

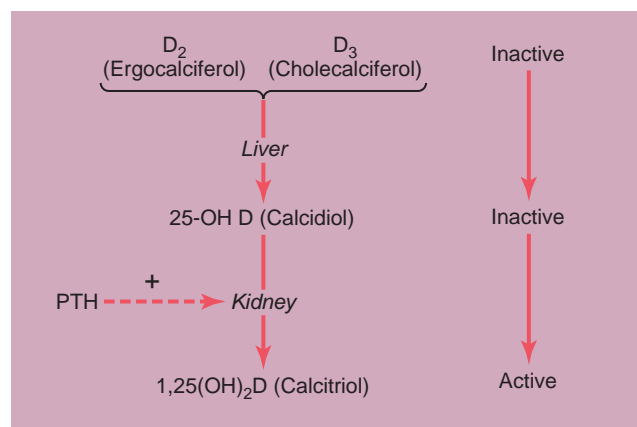

FIGURE 72-5 The vitamin D metabolic pathway. Biologically inactive vitamin D exists in two forms, D_2 and D_3 , which are hydroxylated in the liver and kidney to yield the biologically active form of vitamin D: 1,25-dihydroxycholecalciferol ($1,25[\text{OH}]\text{D}$), also called *calcitriol*. PTH, Parathyroid hormone.

action of $1,25(\text{OH})_2\text{D}$ is to regulate intestinal calcium absorption. PTH, through $1,25(\text{OH})_2\text{D}$, indirectly regulates calcium absorption from the diet by the intestine. The hypocalcemia of hypoparathyroidism is a result, in part, of inadequate intestinal calcium absorption. Conversely, hyperparathyroidism is associated with hypercalciuria and nephrolithiasis, both of which directly result from increases in circulating $1,25(\text{OH})_2\text{D}$ levels. Measurement of $1,25(\text{OH})_2\text{D}$ can be used as an index of parathyroid function and intestinal calcium absorption.

Calcitonin

Calcitonin is produced by the parafollicular or C cells of the thyroid gland in response to hypercalcemia. It was once viewed as an essential calcium-regulating hormone. Pharmacologic doses of calcitonin may reduce serum calcium levels, but little evidence exists that calcitonin has homeostatic relevance in humans.

Integration of Calcium Homeostasis

Ingestion of a greater than normal dietary calcium load (Fig. 72-6A) leads to a mild rise in the serum calcium level, followed by immediate suppression of PTH. This action immediately permits marked increases in renal calcium excretion by the distal tubule. It also immediately decreases osteoclastic activity, which prevents continued bone resorption but allows continued calcium entry from the ECF into an unmineralized osteoid sink. These two effects produce a rapid, short-term reduction in serum calcium to normal levels. However, if the high-calcium diet is maintained over the long term, these adaptations are insufficient. Continued renal calcium wasting leads to hypercalciuria (with nephrolithiasis and nephrocalcinosis), and unopposed osteoblastic bone formation leads to excessive skeletal mineralization (i.e., osteopetrosis).

Two additional responses (see Fig. 72-6B) are required to prevent the long-term adverse effects of a high-calcium diet. First, subacute or chronic suppression of PTH reduces circulating $1,25(\text{OH})_2\text{D}$. This reduces the efficiency of calcium absorption from the intestine, calcium entry into the ECF, and urinary

calcium excretion. Second, a chronic decrement in PTH leads to a chronic decline in osteoblastic activity. No osteoid is formed, and the ability to deposit calcium into the skeletal sink is lost.

Conversely, during brief periods of dietary calcium deficiency (Fig. 72-7A), as occurs between meals, the serum calcium level declines almost imperceptibly and the PTH rises, which immediately prevents renal calcium losses from continuing. At the same time, an acute activation of osteoclasts occurs, delivering calcium into the ECF. The acute response to low calcium intake is the appropriate elimination of renal calcium losses and development of a new source of calcium entry into the ECF.

Over the longer term, the initial response is inadequate and leads to skeletal demineralization. A longer-term solution is required, and the adaptation is twofold (see Fig. 72-7B). First, a chronic low calcium intake, as may occur in a person with lactose intolerance, leads to a chronic elevation in PTH, and over a matter of days to weeks, this leads to an increase in the $1,25(\text{OH})_2\text{D}$ level, which increases the efficiency of calcium absorption from the intestine (i.e., increase in the fractional absorption of calcium) to compensate for the reduction in dietary intake. Second, chronically elevated PTH leads to an increase in osteoblast activity and osteoid synthesis, with resultant increases in skeletal calcium deposition. In this steady-state adaptation to a low-calcium diet, PTH levels are elevated, and coupled increases in osteoclastic and osteoblastic activities take place (i.e., increased bone turnover), but net skeletal calcium losses are negligible or normal.

From an evolutionary standpoint, as life moved from a calcium-rich marine environment to a terrestrial setting in which calcium availability was unpredictable, a complex, elegant regulatory mechanism evolved that permitted survival without requiring intentional behavioral adaptations to the vagaries of calcium supply. As discussed in Chapter 73, disorders that cause hypercalcemia or hypocalcemia are always caused by abnormalities at the interfaces of the ECF with the intestine, kidney, and skeleton. The physician need only recall these homeostatic premises to dissect the pathophysiologic process with precision and treat the underlying disorder effectively.

From Lentz RD, Brown DM, Kjellstrand CM: Treatment of severe hypophosphatemia, *Ann Intern Med* 89:941-944, 1978.

H₂O, Water; K₂HPO₄, dipotassium hydrogen phosphate; KH₂PO₄, potassium dihydrogen phosphate; Na₂HPO₄, disodium hydrogen phosphate; NaH₂PO₄, sodium dihydrogen phosphate.

*Hydration states are important. For example, 268 mg Na₂HPO₄ • 7H₂O (molecular weight 268) equals 1.00 mmol, whereas 268 mg Na₂HPO₄ (molecular weight 142) equals 1.89 mmol.

[†]Commercial preparations: Neutra-Phos, Willen Drug Company, Baltimore, Md. (Neutra-Phos K has twice as much potassium and no sodium); Phospho-Soda, C.B. Fleet Company, Lynchburg, Va. (enema is one-third the strength of Phospho-Soda and can be used orally); sodium phosphate, Abbott Laboratories, North Chicago, Ill.; potassium phosphate, Invenex Pharmaceuticals, Grand Island, N.Y., or Abbott Laboratories. Because Neutra-Phos was not readily dissolved and its specific composition is unknown, data shown are those provided by the manufacturer.

PHOSPHATE HOMEOSTASIS

Phosphorus is an inorganic element, abbreviated as *P* in physical chemistry literature and as *Pi* in physiologic use. The biologically relevant molecule is the negatively charged, trivalent phosphate ion (PO₄). Phosphorus is the form that most clinical laboratories measure rather than the more biologically relevant phosphate ion.

Phosphate is an important physiologic buffer, and at neutral pH in blood, phosphate is apportioned between HPO₄ (divalent) and H₂PO₄ (monovalent). Physicians need to be aware that phosphorus measurements in blood are reported in milligrams per deciliter (mg/dL), whereas pharmaceutical preparations list phosphorus in millimoles (mmol). A chart converting milligrams to millimoles for some common phosphate-containing preparations is

provided in [Table 72-1](#). These values and total doses should be reviewed for the specific phosphorus preparation being prescribed in consultation with the pharmacist and hospital formulary if necessary.

Phosphate regulates or participates in the regulation of an enormous number of biologic processes fundamental to life. They include being an integral component of the DNA double helix, shuttling oxygen from hemoglobin to cells and vice versa using 2,3-diphosphoglycerate (2,3-DPG), intracellular signaling through kinases that attach phosphate groups to other molecules, facilitating critical intracellular messenger systems such as cyclic monophosphate (cAMP) and inositol phosphates, maintaining basic intracellular redox status through the nicotinamide adenine dinucleotide phosphate (NADP-NADPH) system, and serving

as the gateway to the glucose metabolic pathway through glucose 6-phosphate.

Phosphorus is primarily an intracellular ion. In addition to its critical intracellular roles, phosphate has a key extracellular role. The anion pairs with calcium in the hydroxyapatite crystal lattice that provides structural integrity to the skeleton (discussed earlier). As with calcium, phosphate is critical to skeletal strength, and disorders of phosphorus homeostasis, such as hypophosphatemic rickets, lead to pathologic skeletal fractures. The skeleton also serves as a major storage site for phosphate that is accessed in times of severe phosphate deficiency.

The broad intracellular roles for phosphate have two corollaries. First, clinically significant intracellular phosphate deficiency may exist without marked hypophosphatemia. Second, life-threatening phosphate deficiency is often unrecognized because its manifestations (i.e., reduced levels of consciousness, hypotension, respirator dependence, and muscular weakness) are non-specific but common in intensive care unit settings. Astute clinicians learn to recognize general debility as a potential sign of phosphorus deficiency. Phosphate repletion in this setting may produce dramatic results.

In contrast to regulation of the serum calcium concentration, which is very tight, the regulation of serum phosphate concentrations is relatively lax. The serum phosphorus level is maintained in a broad range between about 3.0 and 4.5 mg/dL. In contrast to extracellular calcium concentrations, extracellular phosphate concentrations are not critically important. Because phosphate is abundant in most diets, a tight systemic regulatory mechanism for serum phosphate is unnecessary.

A physiologic black box can be developed for phosphate metabolism (Fig. 72-8). The box represents the ECF, and as with calcium, it has interfaces with the GI tract, kidney, and skeleton. Because most phosphate is contained within cells, the phosphate black box has a quantitatively significant interface with the intracellular compartment.

Intestinal Phosphate Absorption

A normal diet contains about 1200 to 1600 mg of phosphorus, and about two thirds of this amount, or 800 to 1200 mg, is

FIGURE 72-8 The phosphate physiologic black box. See Figure 72-1 for nomenclature and the text for details. GI, Gastrointestinal; ICF, intracellular fluid.

absorbed each day. This fixed fractional absorption of about 67% occurs in the duodenum and jejunum. In the normal world of phosphate abundance, this intake is more than ample. Under conditions of dietary phosphorus deficiency, as occurs in chronic alcoholism, intensive care units, intestinal malabsorption, or phosphate-binding antacid use, failure of adequate phosphorus absorption presents a physiologic challenge for which no physiologic remedy exists.

Skeletal Phosphate Fluxes

As with calcium, osteoclastic bone resorption and osteoblastic new bone formation (see Figs. 72-1 and 72-3) lead to skeletal phosphate exit or entry, respectively. Although the skeleton can be used as a source of phosphorus, phosphorus can be viewed as a passive passenger with calcium in the calcium regulatory process. Under pathophysiologic conditions, skeletal calcium fluxes may become important. For example, skeletal destruction in multiple myeloma or severe immobilization syndromes leads to hypercalcemia and hyperphosphatemia, which with the concomitant hypercalcemia leads to nephrocalcinosis and renal failure. Conversely, osteoblastic metastases in prostate and breast cancers and the hungry bone syndrome after parathyroidectomy lead to clinically significant hypophosphatemia.

Intracellular-Extracellular Phosphate Fluxes

Phosphate shuttles from extracellular to intracellular compartments. This issue becomes important in certain clinical settings. For example, in the setting of metabolic acidosis, phosphate leaves the intracellular compartment and may lead to hyperphosphatemia, whereas under conditions of alkalosis, serum phosphate concentrations decline, and hypophosphatemia develops as phosphate enters the intracellular compartment.

The intracellular phosphate level has important clinical implications, in part, in the settings of crush injury (i.e., rhabdomyolysis) and tumor lysis syndrome. In both conditions, large intracellular loads of phosphate are delivered into the ECF and result in hypocalcemia, seizures, nephrocalcinosis, and renal failure. Conversely, glucose shifts phosphate into cells as glucose 6-phosphate, and overzealous intravenous or oral caloric restitution in the undernourished patient can result in severe hypophosphatemia and sudden death.

Renal Phosphate Handling

The most important mechanism for maintaining a normal serum phosphorus concentration is renal phosphorus regulation. As with calcium, phosphate is filtered by the glomerulus, and 90% is reabsorbed (i.e., tubular reabsorption of filtered phosphate [TRP]). The remaining 10% is excreted (i.e., fractional excretion of phosphorus [FE_{Pi}]). The FE_{Pi} can be calculated in a spot urine sample as follows:

$$FE_{Pi} = \left(\frac{\text{urine Pi [mg/dL]}}{\text{urine creatinine [mg/dL]}} \right) \left(\frac{\text{serum creatinine [mg/dL]}}{\text{serum phosphorus [mg/dL]}} \right)$$

The TRP is simple to calculate:

$$TRP = 1 - FE_{Pi}$$

The renal handling of phosphorus is best considered as a tubular maximum (T_m)-regulated process. The T_mP is normally

identical to a normal serum phosphorus concentration in blood, about 3.3 mg/dL. If the serum phosphate concentration rises above this level, phosphaturia occurs, and the serum phosphorus declines to 3.3 mg/dL. If the serum phosphate concentration declines below 3.3 mg/dL, filtered phosphate is entirely reabsorbed, and urinary phosphate excretion declines to zero.

The TmP can be considered as a dam in the phosphate reservoir, over which excess phosphate spills and whose level controls the concentration of serum phosphorus. The TmP is not fixed but can be moved upward or downward, depending on metabolic needs and prevailing metabolic conditions (described later).

The TRP or FE_{P_i} can be readily calculated, and the TmP can be derived from the nomogram of Bijvoet, which is shown in Figure 72-9. This process proves enormously useful in clinical practice because it is the central starting point for determining whether hypophosphatemia is principally renal or nonrenal in origin.

Parathyroid Hormone and Phosphatonins

PTH has long been appreciated to be phosphaturic; it lowers the TmP or, more accurately, inhibits proximal renal tubular phosphate reabsorption. This characteristic explains the hypophosphatemia associated with primary and secondary hyperparathyroidism and the hyperphosphatemia associated with hypoparathyroid states. Excessive PTH lowers the TmP, whereas low PTH values allow the TmP to rise to supranormal levels.

FIGURE 72-9 Nomogram shows the tubular maximum for the phosphorus glomerular filtration rate (TmP-GFR). It allows conversion of the fractional excretion of phosphorus (or its inverse, the tubular reabsorption of filtered phosphate [TRP]) into the TmP-GFR. The TRP is calculated, and a line is drawn extending from the serum phosphorus level (left vertical line), through the TRP (middle diagonal line), to the right vertical line, which represents the TmP/GFR. TmP values are provided in millimolar and milligram per deciliter units. TmP values below 1.0 mmol or 2.5 mg/dL are abnormal and indicate phosphaturia. C_{creat} , Creatinine concentration; C_{PO_4} , phosphate concentration. (From Walton RJ, Bijvoet OL: Nomogram for derivation of renal threshold phosphate concentration, *Lancet* 2:309–310, 1975.)

The TmP level is regulated by other factors. For example, experimental dietary phosphorus deprivation in laboratory animals and humans leads to a PTH-independent increase in the TmP, and high-phosphate feeding results in a PTH-independent decline in the TmP. For decades, investigators in this area have postulated the existence of a phosphaturic hormones called *phosphatonins*, one of which is fibroblast growth factor-23 (FGF-23). This field has progressed rapidly over the past decade, but much remains to be worked out. The main physiologic points are that a hormonal system independent of PTH also regulates renal phosphorus handling and that the kidney is the prime regulatory organ for phosphate homeostasis.

REGULATION OF SERUM MAGNESIUM

Magnesium is a divalent cation. Magnesium homeostasis parallels phosphorus homeostasis. Magnesium and phosphate are principally intracellular, with concentrations inside the cell that far exceed those outside the cell. Both substances govern key intracellular regulatory processes. In the case of magnesium, these processes include fundamental events such as DNA replication and transcription, translation of RNA, the use of adenosine triphosphate as an energy source, and regulated peptide hormone secretion.

Both substances are abundant inside all kinds of cells. Because they are well supplied in vegetarian and carnivorous diets, little evolutionary pressure exists to develop a complex regulatory network, and as with phosphate, serum magnesium concentrations are not tightly regulated. Because magnesium is principally intracellular, measurement of serum levels may provide false estimates of actual total body and intracellular magnesium status. Because magnesium is essential for fundamental processes such as gene transcription and cellular energy use, life-threatening magnesium deficiency is often unrecognized because its symptoms are frustratingly nonspecific: weakness, respirator dependence, diffuse neurologic syndromes (including seizures), and cardiovascular collapse.

Magnesium has a molecular weight of 24 (1 mole = 24 g), and because it is divalent, one equivalent is 12 g. Blood magnesium measurements are often provided in milligrams per deciliter (mg/dL) or milliequivalents per liter (mEq/L); oral magnesium supplements are expressed in milligrams per tablet or milliequivalents per vial; and urinary magnesium excretion values are given in milliequivalents or milligrams per 24 hours. Constructing a black box for magnesium is helpful (Fig. 72-10), and the magnesium values are provided in milligram and milliequivalent units.

As with phosphorus, magnesium has quantitatively important interfaces with the intestine, skeleton, intracellular supplies, and kidney. At the level of the intestine, magnesium is widely available in normal diets, and regulation is limited; the body absorbs about one third of what is ingested. In normal circumstances, dietary magnesium is abundant, absorption is ample, and magnesium deficiency does not occur. However, deficiency may occur with alcoholism, in intensive care unit settings in which adequate nutrition often is not provided, or with intestinal malabsorption.

At the level of the skeleton, magnesium is incorporated into the hydroxyapatite crystal as mineralization of osteoid occurs, and it is released by osteoclastic bone resorption (see Figs. 72-1 and 72-3). In quantitative terms, these fluxes are small.

FIGURE 72-10 The magnesium physiologic black box. See [Figure 72-1](#) for nomenclature and the text for details. Magnesium values are provided in milligrams (mg) and milliequivalents (mEq). GI, Gastrointestinal; ICF, intracellular fluid.

Many instances of magnesium deficiency are caused by excessive renal losses. Examples include the magnesuria that accompanies saline infusions, diuretic use, alcohol use, and secondary hyperaldosteronism states such as cirrhosis and ascites. As with calcium and phosphorus, the fractional excretion of magnesium (FE_{Mg}) can be calculated, and it should be used as an index of whether the kidney is appropriately conserving magnesium in states of hypomagnesaemia or whether renal magnesium wasting is the cause of the hypomagnesaemia. The normal FE_{Mg} is 2% to 4%. Hypomagnesemic individuals have FE_{Mg} values below 1% to 2%.

With regard to homeostatic regulation, magnesium homeostasis can best be viewed as a renal T_m -regulated process (see Renal Phosphate Handling), with the renal T_m for magnesium set at a fixed level of about 2.2 mg/dL. In this scenario, abundant dietary magnesium exists, and excessive magnesium intake is managed by spillage of excess magnesium over the T_m set at 2.2 mg/dL and into the urine. Conversely, in settings of dietary magnesium deficiency, which equate evolutionarily with caloric deficiency, short-term deficiency is prevented when serum levels fall below the renal T_m of 2.0 mg/dL. No known independent hormonal regulatory system for magnesium exists.

PROSPECTUS FOR THE FUTURE

Although it may seem that calcium, PTH, vitamin D, magnesium, and phosphorus homeostasis and skeletal biology are well understood, it should be clear that many of the physiologic details described in this chapter have been elucidated only during the past 10 to 15 years, and new regulatory proteins (e.g., fibroblast growth factor 23) and diseases continue to be identified. This area of research is dynamic, with many unanswered questions remaining.

Disorders of Serum Minerals

Steven P. Hodak and Andrew F. Stewart

INTRODUCTION

In this chapter, we consider disorders that lead to increases or decreases in the circulating concentrations of calcium, phosphorus, and magnesium. [Chapter 72](#) describes normal calcium, phosphorus, and magnesium metabolism.

The optimal approach to diagnosing and treating these disorders is to understand their underlying physiology and pathophysiology. Coherent diagnostic and successful therapeutic plans can then be developed. Years of experience suggest a persistent propensity to jump to the common items on the differential diagnosis list without fully considering the other options. In so doing, the correct and often easily treatable diagnosis is overlooked. For example, hypercalcemia in the setting of a pulmonary nodule may indicate the humoral hypercalcemia of malignancy, and many physicians jump to this diagnosis with its grim prognosis. However, this complex may represent hypercalcemia in a patient with treatable tuberculosis or primary hyperparathyroidism (HPT) in a person with a long-standing and inactive pulmonary scar. Complete differential diagnoses are provided in the tables that follow.

HYPERCALCEMIA

Symptoms and Signs

Hypercalcemia causes hyperpolarization of neuromuscular cell membranes and therefore refractoriness to stimulation (see [Chapter 72](#)). This condition manifests clinically as skeletal muscular weakness, smooth muscle hypoactivity with constipation and ileus, and the full spectrum of neurologic dysfunction, progressing from lassitude to mild confusion to deep coma. Hypercalcemia also leads to renal failure. It reduces the glomerular filtration rate (GFR) through afferent arteriolar vasoconstriction and activation of the calcium receptor in the distal nephron. It causes a form of nephrogenic diabetes insipidus that is associated with polydipsia and polyuria. These events lower the extracellular fluid (ECF) volume and lower the GFR.

Hypercalcemia may lead to interstitial calcium phosphate crystal deposition in the kidney (i.e., nephrocalcinosis or interstitial nephritis) and nephrolithiasis with obstructive uropathy. Hypercalcemia may also lead to shortening of the QTc interval on the electrocardiogram. Frequently, however, asymptomatic hypercalcemia is discovered on routine laboratory testing.

Whether a person develops symptoms depends on several factors. One is the degree of hypercalcemia. People with serum calcium values above 13 mg/dL usually are symptomatic. The

duration of hypercalcemia is also important. A gradual increase in serum calcium, even into the severe 15- to 17-mg/dL range, may cause few symptoms if it occurs slowly enough. The overall health status and age of the person with hypercalcemia influence the severity of symptoms. For example, a child with severe immobilization-induced hypercalcemia in the 15-mg/dL range may be completely alert, whereas an elderly person with underlying Alzheimer's disease and narcotic use may become comatose with a serum calcium level of 11.5 mg/dL.

Pathophysiology

The physiologic black box described in [Chapter 72](#) should be considered when attempting to diagnose or treat hypercalcemia. These disorders can be grouped into factitious disorders (e.g., abnormalities in serum proteins), renal disorders (e.g., thiazide diuretics, lithium use), gastrointestinal disorders (e.g., sarcoid, milk-alkali syndrome), skeletal disorders (e.g., hypercalcemia of malignancy, immobilization hypercalcemia), and combined disorders. Primary HPT is a good example of the latter, with important gastrointestinal (GI) and renal components. The diagnoses in [Table 73-1](#) should be considered with regard to the underlying pathophysiologic mechanism and the clinical setting.

Differential Diagnosis

Malignancy-Associated Hypercalcemia

The most common cause of hypercalcemia among hospitalized patients is cancer. Hypercalcemia occurs late in the course of cancer and usually progresses rapidly, followed by death. About 50% of patients with cancer survive 30 days after the development of hypercalcemia.

Hypercalcemia usually is encountered only in patients with large tumor burdens. Conversely, small, occult cancers rarely cause hypercalcemia. The exceptions to this rule are small neuroendocrine tumors, such as islet cell tumors and bronchial carcinoids. Certain tumors are common causes of hypercalcemia, including breast, renal, squamous, and ovarian carcinomas and multiple myeloma and lymphoma. Other common cancers, such as colon, prostate, and gastric carcinomas, are not commonly associated with hypercalcemia.

Cancer may lead to hypercalcemia through several mechanisms, the most common of which is humoral hypercalcemia of malignancy (HHM). HHM accounts for about 80% of patients with malignancy-associated hypercalcemia (MAHC) and is the result of excessive secretion by tumors of parathyroid hormone-related protein (PTHrP). PTHrP mimics the actions of parathyroid hormone (PTH) on the kidney to prevent calcium excretion

TABLE 73-1 DISORDERS ASSOCIATED WITH HYPERCALCEMIA

Malignancy-associated hypercalcemia	Vitamin D and derivatives (calcitriol, dihydroxycholesterol)
Humoral hypercalcemia of malignancy	Vitamin A (including retinoic acid derivatives)
Hypercalcemia caused by 1,25-dihydroxyvitamin D ₃ (1,25[OH] ₂ D ₃)-secreting lymphomas	Foscarnet
Hypercalcemia caused by direct skeletal invasion	Milk-alkali syndrome
True ectopic hyperparathyroidism	Immobilization plus high bone turnover
Primary and tertiary hyperparathyroidism	Juvenile skeleton
Familial hypocalciuric hypercalcemia or familial benign hypercalcemia	Paget's disease
Granulomatous disorders	Myeloma and breast cancer with bone metastases
Sarcoid	Prehumoral hypercalcemia of malignancy
Berylliosis	Mild primary hyperparathyroidism
Foreign body	Secondary hyperparathyroidism (e.g., from continuous ambulatory peritoneal dialysis)
Tuberculosis	Chronic and acute renal failure
Coccidioidomycosis	Recovery phase of rhabdomyolysis-induced acute renal failure
Blastomycosis	Chronic hemodialysis
Histoplasmosis	Calcitriol
Granulomatous leprosy	Immobilization
Eosinophilic granuloma	Decreased calcium clearance
Histiocytosis	Calcium carbonate
Inflammatory bowel disease	Total parenteral nutrition (TPN)
Endocrine disorders other than hyperparathyroidism	Calcium-containing TPN in patients with decreased glomerular filtration rate
Hyperthyroidism	Chronic TPN in patients with short bowel syndrome
Pheochromocytoma	Hyperproteinemia
Addisonian crisis	Volume contraction with hyperalbuminemia
Vasoactive intestinal peptide-producing tumor (VIPoma); watery diarrhea, hypokalemia, and achlorhydria (WDHA) syndrome	Myeloma with calcium-binding immunoglobulin
Medications	End-stage liver disease
Thiazides	Manganese intoxication
Aminophylline	
Lithium	
Estrogen/antiestrogen in breast cancer with bone metastases (estrogen flare)	

and on the skeleton to activate osteoclasts and induce bone resorption. PTHrP is the product of many normal cell types and, in health, is typically produced at low levels.

Tumors classically associated with the HHM mechanism are squamous carcinomas of any site (i.e., larynx, lung, cervix, and esophagus), renal carcinomas, ovarian carcinomas, and breast cancer. Hypercalcemia in HHM occurs in the absence of skeletal metastases or in the setting of a few skeletal metastases. If tumor resection or ablation is possible, hypercalcemia reverses. In addition to hypercalcemia, these patients have elevations in PTHrP concentrations and reductions in the levels of PTH, 1,25-dihydroxyvitamin D₃ (1,25[OH]₂D), and serum phosphorus and the tubular maximum for phosphorus (TmP) (see [Chapter 72](#)).

A second form of MAHC is caused by local tumor invasion of the skeleton, a process called *local osteolytic hypercalcemia* (LOH). LOH accounts for about 20% of patients with MAHC. In these patients, unlike those with HHM, the skeletal metastatic or primary tumor burden is large, and the offending tumor is most

often a breast cancer or a hematologic neoplasm such as multiple myeloma, leukemia, or lymphoma. Local factors are secreted by tumors in the bone marrow that induce osteoclastic bone resorption. They include PTHrP, macrophage inflammatory protein 1 α (MIP-1 α), receptor-activating nuclear factor- κ B ligand (RANKL), interleukin-6, and interleukin-1. These patients have reductions in PTH, PTHrP, and 1,25(OH)₂D levels, and have normal to elevated serum phosphorus values.

A third form of MAHC is secretion of 1,25(OH)₂D by lymphomas and dysgerminomas. This form is unusual, and the mechanism is interesting. Although direct bone involvement may occur and may contribute to hypercalcemia, the increase in 1,25(OH)₂D leads to intestinal calcium hyperabsorption and to systemically driven bone resorption. This condition is essentially a malignant version of the hypercalcemia that occurs in sarcoidosis (see [Granulomatous Disorders](#)).

Primary and Tertiary Hyperparathyroidism

Although MAHC is the most common cause of hypercalcemia among inpatients, primary HPT is by far the most common cause among healthy outpatients. Together, MAHC and HPT account for about 90% of cases of hypercalcemia. Most often, the hypercalcemia of HPT is mild, with serum calcium values in the range of 10.6 to 11.5 mg/dL. However, HPT occasionally produces spectacular hypercalcemia in the 20-mg/dL range. In about 85% of patients, hypercalcemia results from a single parathyroid adenoma that overproduces PTH, and in about 15% of patients, it results from multiple-gland hyperplasia. In less than 1% of patients, HPT may result from parathyroid carcinoma. For all these etiologies, the diagnosis is made by the discovery of an elevated serum PTH level in a patient with hypercalcemia. Hypophosphatemia, a reduction in the TmP, increased plasma 1,25(OH)₂D and serum chloride levels, and a reduction in the serum bicarbonate concentration are typical features.

Primary HPT often is asymptomatic. However, some patients develop hypercalciuria and calcium nephrolithiasis, most often as a result of calcium oxalate and, less commonly, calcium phosphate stones. Some patients with HPT, especially those with a more severe form, have a reduction in bone mineral density characterized histologically as hyperparathyroid bone disease, also called *osteitis fibrosa cystica* (see [Chapter 74](#)). Other patients may develop mild to severe renal failure as a result of the mechanisms described earlier. Each of the previously described conditions—significant osteopenia, kidney stones, reduced renal function, and a serum calcium concentration greater than 1 mg/dL above normal—is an indication for parathyroidectomy. Other patients may be monitored conservatively. In patients who refuse or are unable to undergo surgery, medical management of hypercalcemia may be attempted using bisphosphonates or the calcium receptor mimetic cinacalcet.

HPT can occur as part of one of the multiple endocrine neoplasia (MEN) syndromes. It is associated with pituitary and islet tumors (MEN 1) and with pheochromocytomas and medullary carcinoma of the thyroid (MEN 2).

Secondary HPT is an appropriate increase in circulating PTH associated with eucalcemia or hypocalcemia. It occurs in an attempt to correct hypocalcemia resulting, for example, from vitamin D deficiency or chronic renal failure

Tertiary HPT refers to HPT associated with hypercalcemia that occurs in the setting of prolonged stimulation of the parathyroid glands, such as chronic renal failure with hypocalcemia or chronic vitamin D deficiency resulting from malabsorption. Chronic parathyroid stimulation leads to parathyroid hyperplasia and sometimes adenomas, and these conditions may fail to suppress normally and cause hypercalcemia. The classic example is development of PTH-dependent hypercalcemia after successful renal transplantation.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia, also called *familial benign hypercalcemia*, is an autosomal dominant inherited disorder that results from heterozygous inactivating mutations in the calcium receptor. Parathyroid glands that bear such a defective receptor on their surface inappropriately perceive circulating calcium concentrations to be low. They therefore behave as though the patient is hypocalcemic and appropriately secrete additional PTH. This action causes the serum calcium concentration to rise, and the PTH equilibrates at a high-normal to elevated level. The hypercalcemia is usually mild, in the 11- to 12-mg/dL range, but it may be higher. Because the partially inactivated calcium receptors are expressed in the kidney, the kidney inappropriately conserves calcium, leading to hypocalciuria and contributing to hypercalcemia. Because these same calcium receptors are also expressed in the central nervous system, the hypercalcemia is not perceived, and affected individuals are therefore asymptomatic. The two names of this syndrome describe it accurately.

With the exception of the hypocalciuria and the autosomal dominant pattern of inheritance, these individuals are similar biochemically to patients with primary HPT. Because affected individuals are asymptomatic and do not develop adverse sequelae from the syndrome, its primary importance is that affected individuals be properly identified and protected from unnecessary and ineffective parathyroidectomy. Homozygous individuals, usually infants, develop severe hypercalcemia requiring urgent total parathyroidectomy.

Granulomatous Disorders

Most granulomatous disorders can lead to hypercalcemia (see [Table 73-1](#)). The prototypes are sarcoidosis, tuberculosis, and the fungal diseases listed. As with the kidney, granulomas have the ability to convert inactive 25-hydroxyvitamin D to the active metabolite, 1,25(OH)₂D. When exposed to sunlight, ultraviolet radiation, or relatively trivial quantities of dietary vitamin D, individuals with these disorders may develop mild to severe hypercalcemia.

Hypercalcemia results from intestinal calcium hyperabsorption and 1,25(OH)₂D-induced bone resorption; the former is the important component in most cases. Because of the hypercalcemia, PTH is suppressed, and the serum phosphorus level is elevated. The combination of hypercalcemia and hyperphosphatemia may lead to nephrocalcinosis and renal failure. Treatment focuses on correcting the underlying disorder. Measures include a low dietary calcium intake, a low vitamin D intake, limiting sun exposure, and hydration. Loop diuretics are administered to accelerate calcium clearance, and if the hypercalcemia is severe, glucocorticoids are used.

Endocrine Disorders Other Than Hyperparathyroidism

In addition to HPT, four other endocrine disorders have been associated with the development of hypercalcemia. As many as 50% of people with *hyperthyroidism* have at least mild hypercalcemia. The hypercalcemia is rarely greater than 11 mg/dL. The mechanism is thought to be an increase in osteoclast activation by thyroid hormone.

A second disorder is *pheochromocytoma*. Some of these individuals are hypercalcemic as a result of primary HPT occurring in the MEN 2 syndrome, but others become hypercalcemic as a result of PTHrP secretion by a pheochromocytoma. Hypercalcemia has also been reported in patients with hypoadrenalism and those with islet cell tumors called VIPomas.

Medications

Drugs that may cause hypercalcemia include thiazide diuretics, lithium, aminophylline, theophylline, vitamins D and A, foscarnet, and estrogens and tamoxifen in the setting of breast cancer with extensive skeletal metastases.

Milk-Alkali Syndrome

The normal intake of calcium is in the range of 600 to 1200 mg/day for most people. As reviewed in [Chapter 72](#), absorption of calcium from the diet is tightly controlled. However, ingestion of very large quantities of calcium may overwhelm this system and lead to hypercalcemia. This condition was originally described in the 1940s in patients ingesting enormous quantities of milk, cream, and antacids. It is still encountered with some regularity in patients ingesting large quantities of calcium carbonate or other calcium-containing antacids for peptic ulcer disease. For hypercalcemia to occur, calcium intake must exceed 4 g/day, and it is often in the 10- to 20-g/day range. Severe hypercalcemia is common and may lead to renal failure.

Immobilization

Hypercalcemia due to immobilization requires two conditions: *complete immobilization* (e.g., quadriplegia) for a period of weeks, occurring on a background of *high bone turnover*, as occurs in young adults or children, HPT, Paget's disease, and malignant skeletal disease such as breast cancer with bone metastases or multiple myeloma. Immobilization activates osteoclastic bone resorption and inhibits osteoblastic activity, producing a severe uncoupling of bone resorption from formation, with rapid and enormous net losses of calcium from the skeleton into the ECF. Left untreated, the condition results in severe demineralization. The syndrome is associated with hypercalciuria, which with chronic urinary catheterization leads to urinary tract infection and severe calcium nephrolithiasis.

The most effective treatment for hypercalcemia is active weight bearing. Hydration and antiresorptive drugs such as the bisphosphonates may be used.

Chronic and Acute Renal Failure

Chronic and acute renal failure has been associated with hypercalcemia. The more common initial abnormality is hypocalcemia induced by a reduction in kidney-derived 1,25(OH)₂D and an

increase in serum phosphate as a result of diminished glomerular filtration. However, hypercalcemia may occur in patients with chronic renal failure as a result of calcium antacid use or as a result of $1,25(\text{OH})_2\text{D}$ or paracalcitol treatment to prevent renal osteodystrophy.

Parenteral Nutrition

Enteric and parenteral forms of nutrition have been associated with hypercalcemia. Large doses of oral calcium provided in hypercaloric enteric feeding regimens, particularly in the setting of reduced renal function, may lead to a form of the milk-alkali syndrome. More mysterious is the well-described hypercalcemic syndrome occurring in patients treated with total parenteral nutrition (TPN). These patients typically have short-bowel syndrome and are on long-term TPN. In some patients, the hypercalcemia can be traced to large amounts of calcium, vitamin D, or aluminum in the TPN solution.

Hyperproteinemia

About 50% of circulating calcium is bound to serum albumin and other proteins. Increases in serum proteins naturally lead to an artifactual increase in total, but not ionized, serum calcium concentrations. This increase is commonly observed in settings of volume depletion and dehydration. Patients with this syndrome do not display features typical of authentic hypercalcemia: reduced mental status, prolonged QTc interval on the electrocardiogram, and hypercalciuria. Treatment of the “hypercalcemia” should be avoided, because it may lead to hypocalcemic symptoms and signs such as paresthesia, tetany, and seizures.

Treatment of Hypercalcemia

A point worth emphasizing is that not everyone requires treatment for hypercalcemia. Patients with mild HPT with borderline serum calcium values and without other complications may be observed. Patients with end-stage refractory cancer with severe hypercalcemia arguably may be best served by withholding therapy. Familial hypocalciuric hypercalcemia is best left untreated.

Therapy for hypercalcemia is optimally directed at reversing the underlying pathophysiologic abnormality. Disorders associated with increased intestinal calcium absorption (e.g., sarcoid, milk-alkali syndrome, $1,25[\text{OH}]_2\text{D}_3$ -secreting lymphomas) are best treated by consuming a low-calcium diet and avoiding vitamin D. Hypercalcemia in the setting of volume depletion and diminished renal function is managed by expanding the ECF volume and GFR with saline and encouraging diuresis with loop diuretics.

Medications that induce hypercalcemia should be discontinued. Disorders associated with increased osteoclastic bone resorption, such as MAHC and immobilization hypercalcemia, are best treated using inhibitors of bone resorption such as the bisphosphonates pamidronate or zoledronate. Disorders with multiple abnormalities require combinations of these measures. Resection of parathyroid tissue in patients with parathyroid disease is effective, and cinacalcet or bisphosphonates may be used if parathyroid surgery cannot be performed.

HYPOCALCEMIA

Symptoms and Signs

Hypocalcemia leads to a reduction in the potential difference across cell membranes, producing hyperexcitability, particularly of cells of the neuromuscular class (see [Chapter 72](#)). Neuromuscular cells spontaneously fire and produce spontaneous seizures, paresthesias, and skeletal muscle contractions (i.e., carpal spasm, pedal spasm, or tetany).

Two physical signs are observed on examination: Trousseau sign, which is spontaneous contraction of the forearm muscles in response to application of a blood pressure cuff around the upper arm and inflation to above systolic pressure, and Chvostek sign, which is twitching of the facial muscles with gentle tapping of the facial nerve as it exits the parotid gland. An electrocardiographic sign is a prolonged QTc interval. Prolonged hypoparathyroidism may be associated with basal ganglia calcification, which is asymptomatic but impressive on computed tomography scans and plain x-ray films of the skull.

Pathophysiology

Hypocalcemia may result from five mechanisms: a reduction in serum binding proteins (e.g., albumin), an increase in serum phosphate with a resultant increase in the calcium-phosphate solubility product, an increase in renal calcium excretion, a reduction in intestinal calcium absorption, or a loss of calcium from the ECF into the skeleton. In practice, several of these factors are operative in several disorders. For example, in hypoparathyroidism, a reduction in intestinal calcium absorption combines with an inability to reabsorb calcium from the distal tubule to cause hypocalcemia, or in breast cancer with extensive osteoblastic metastases, increases in osteoblast activity remove calcium from the ECF, and anorexia leads to a reduction in intestinal calcium intake. This knowledge is important because effective therapy requires the underlying disorder to be appropriately managed. Giving oral vitamin D supplements to a patient with sprue may not be effective unless the underlying malabsorption is treated; parenteral vitamin D may be more effective.

Differential Diagnosis

Disorders that may lead to hypocalcemia are summarized in the following sections and [Table 73-2](#).

Hypoparathyroidism

Hypoparathyroidism causes hypocalcemia as a result of a decrease in intestinal calcium absorption combined with reduced renal calcium reabsorption in the distal tubule. Hypoparathyroidism may be idiopathic or autoimmune, occurring in isolation or as part of the polyglandular failure syndrome in association with Graves' hyperthyroidism, Hashimoto's thyroiditis, Addison's disease, type 1 diabetes, vitiligo, mucocutaneous candidiasis, and other autoimmune disorders. Hypoparathyroidism may commonly be encountered as surgical hypoparathyroidism in patients who have undergone thyroid, parathyroid, or laryngeal surgery. Surgical and autoimmune hypoparathyroidism together account for most patients with hypoparathyroidism. Less common causes include congenital hypoparathyroidism caused by DiGeorge syndrome, isolated parathyroid failure, or genetic mutations. Rarely,

TABLE 73-2 DIFFERENTIAL DIAGNOSIS OF HYPOCALCEMIA

Hypoparathyroidism	Vitamin D–dependent rickets, renal 1 α -hydroxylase deficiency, 1,25-dihydroxyvitamin D–receptor defects
Surgical	Chronic renal failure
Idiopathic and autoimmune infiltrative diseases	Hepatic failure
Wilson's disease (copper)	Hypoalbuminemia
Hemochromatosis	Sepsis
Sarcoidosis	Hypermagnesemia and hypomagnesemia
Metastatic (breast) cancer	Rapid bone formation
Congenital	Hungry bone syndrome after parathyroidectomy or thyroidectomy
Isolated, sporadic	Osteoblastic metastases
DiGeorge syndrome	Vitamin D therapy of osteomalacia, rickets
Infant of mother with hyperparathyroidism	Hyperphosphatemia
Hereditary	Crush injury, rhabdomyolysis
X-linked	Renal failure
Parathyroid gland calcium receptor (G α 11 subunit)–activating mutations	Tumor lysis
Parathyroid hormone (PTH) signal peptide mutation	Excessive phosphate (PO $_4$) administration (PO, IV, PR)
GCM2 (formerly GCMB) mutation	Medications
Pseudohypoparathyroidism	Mithramycin, plicamycin
Type Ia: multiple hormone resistance, Albright's hereditary osteodystrophy	Bisphosphonates
Type Ib: PTH resistance without other abnormalities	Calcitonin
Type Ic: specific PTH resistance, resulting from defect in catalytic subunit of PTH-receptor complex	Fluoride
Type II: specific PTH resistance, postreceptor defect of adenyl cyclase, undefined	Ethylene diaminetetraacetic acid (EDTA)
Vitamin D disorders	Citrate
Absent ultraviolet exposure	Intravenous contrast
Vitamin D deficiency	Foscarnet
Fat malabsorption	Pancreatitis
	Hypoalbuminemia
	Hypomagnesemia
	Calcium soap formation

tissue infiltrative diseases such as breast cancer, hemochromatosis (i.e., iron deposition), or sarcoidosis may destroy or replace normal parathyroid tissue.

The diagnosis is made by finding a low serum ionized calcium level in a patient with an inappropriately reduced serum PTH concentration. The phosphorus concentration usually is high normal or frankly elevated, and plasma 1,25(OH) $_2$ D concentrations are reduced (see [Chapter 72](#)).

Treatment is normally directed at increasing intestinal calcium absorption through the use of large doses of calcium (up to 6–8 g of elemental calcium per day) and, when necessary, the addition of the active form of vitamin D (1,25[OH] $_2$ D), in replacement amounts of 0.25 to 1.0 μ g/day. The goal is to induce sufficient intestinal calcium hyperabsorption to overwhelm the ability of the kidney to excrete it. It carries the risk of inducing significant hypercalciuria and therefore nephrocalcinosis and nephrolithiasis. Accordingly, 24-hour urinary calcium levels must be measured regularly to identify dangerously high hypercalciuria. The serum calcium concentration is maintained in the low-normal range, about 8.5 to 9.0 mg/dL. In some instances, addition of a thiazide diuretic such as hydrochlorothiazide, which stimulates renal calcium reabsorption, may be effective in preventing hypercalciuria while raising the serum calcium level.

Pseudohypoparathyroidism

Pseudohypoparathyroidism refers to a group of disorders that have in common resistance to the actions of PTH. In most cases, resistance results from different inactivating mutations in the signal-transducing protein G $_{sc}$. The most common form of the syndrome, type Ia, is associated with multiple hormone resistance and a phenotype referred to as *Albright's hereditary osteodystrophy*, which includes short stature, shortened fourth and fifth metacarpals and metatarsals, obesity, mental retardation, subcutaneous calcifications, and cafe au lait spots.

Patients resemble those with hypoparathyroidism; they are hypocalcemic and have hyperphosphatemia. The diagnosis is made by the finding of an elevated circulating PTH level in a patient with hypocalcemia and hyperphosphatemia for whom other causes of hypocalcemia and secondary hypoparathyroidism have been excluded. The treatment is similar to that of hypoparathyroidism.

Vitamin D Disorders

Active vitamin D, 1,25(OH) $_2$ D, is required to absorb calcium from the intestine. Activation of vitamin D requires adequate amounts of vitamin D from the diet or sunlight exposure, an intact intestine through which to absorb calcium and vitamin D, an intact liver with which to convert vitamin D to 25-hydroxyvitamin D, and an intact kidney to convert 25-hydroxyvitamin D to 1,25(OH) $_2$ D (see [Chapter 72](#)).

Developing hypocalcemia and osteomalacia or rickets (see [Chapter 74](#)) in settings in which one or more of the conversion steps is disrupted is common. Malabsorption syndromes, such as short-bowel syndrome and celiac sprue, lead to hypocalcemia as a result of calcium and vitamin D malabsorption. Chronic liver diseases, particularly primary biliary cirrhosis, lead to hypocalcemia and osteomalacia. Chronic renal insufficiency leads to failure to produce 1,25(OH) $_2$ D, with reductions in serum calcium levels and inefficient absorption of intestinal calcium.

Although Western diets are supplemented with vitamin D in milk and multivitamins, diets composed of no milk, human milk, or unsupplemented bovine milk are vitamin D deficient. Relatively trivial exposure to sunlight can provide ample vitamin D and replace dietary needs for vitamin D. However, vitamin D deficiency can occur in settings in which both sun exposure and dietary intake of vitamin D are poor (i.e., cloudy climates, excessive clothing or body covering, prolonged nursing by infants, and the standard tea and toast diet of older adults), vitamin D deficiency is the rule rather than the exception.

Certain genetic syndromes affecting vitamin D conversion can result in severe hypocalcemia. Long-term, high-dose treatment with anticonvulsants such as phenytoin or phenobarbital or their derivatives may lead to hypocalcemia and osteomalacia.

Hypoalbuminemia

Reductions in serum albumin, as occur in burn patients, the nephrotic syndrome, malnutrition, and cirrhosis, lead to reductions in serum total calcium without a reduction in the ionized total serum calcium level. Several formulas exist for correcting total serum calcium for albumin, but none is entirely accurate.

Measuring ionized calcium directly is important if the authentic ionized serum calcium concentration is needed.

Sepsis

Gram-positive and gram-negative sepsis have been associated with hypocalcemia that usually is mild. The mechanisms are poorly understood. Hypocalcemia occurring in the setting of sepsis appears to confer a particularly adverse prognosis.

Hypermagnesemia

Magnesium is a divalent cation, as is calcium, and in very high concentrations, it may mimic the actions of calcium to suppress PTH. In so doing, it leads to a functional type of hypoparathyroidism and hypocalcemia. In practice, this condition is uncommon.

Hypomagnesemia

Hypomagnesemia is one of the most common causes of hypocalcemia. It is encountered often in patients with alcoholism, malnutrition, cisplatin therapy for cancer, and intestinal malabsorption syndromes. Hypomagnesemia inhibits PTH secretion (i.e. magnesium adenosine triphosphatase is required for PTH secretion) and prevents the calcemic actions of PTH on the kidney and skeleton. Magnesium deficiency causes a functional form of hypoparathyroidism and resistance to PTH. The treatment is straightforward: magnesium replacement, which corrects the syndrome in minutes to hours. Intravenous calcium or vitamin D is ineffective.

Rapid Bone Formation

Increased rates of bone mineralization that are out of proportion to the rate of bone resorption lead to net calcium entry into the skeleton and, if these rates are large, to hypocalcemia. This state occurs in several clinical settings. One condition is the hungry bone syndrome that may follow parathyroidectomy, usually performed for HPT. Preoperatively, the rates of bone turnover (i.e., resorption and formation) are very high but are approximately coupled. Postoperatively, the rate of osteoclastic bone resorption abruptly declines with the decline in PTH, but the elevated rate of mineralization continues for days. Because of this acute postoperative imbalance, the skeleton becomes a sink for calcium, and hypocalcemia ensues.

Rapid bone formation also may occur in patients with vitamin D deficiency who have severe osteomalacia or rickets and large amounts of unmineralized osteoid. When these patients are treated with vitamin D, rapid mineralization of unmineralized osteoid occurs, the skeleton becomes a sink for calcium, and hypocalcemia ensues. Another example of this phenomenon occurs in the setting of extensive osteoblastic bone metastases, such as in prostate or breast cancer and occasionally in other malignancies.

Hyperphosphatemia

Disorders that lead to hyperphosphatemia may cause hypocalcemia as a result of exceeding the calcium-phosphate solubility product in serum. Examples of disorders that may cause the kind of severe hyperphosphatemia required include rhabdomyolysis (e.g., crush injuries), renal failure, and the tumor lysis syndrome.

Severe hyperphosphatemia may be seen after ingestion of large amounts of phosphate-containing purgatives in preparation for colonoscopy, inadvertent perforation of the rectum during the administration of phosphate enemas, and overzealous administration of intravenous phosphate. In these examples, the onset of hyperphosphatemia is relatively abrupt, and the hypocalcemia is immediate and severe. Commonly, the first sign of this sequence of events is a seizure.

Treatment involves reducing the serum phosphorus level by whatever means necessary. Giving intravenous calcium should be avoided because it is precipitated into soft tissues.

Medications

Certain medications may cause hypocalcemia, including those used to treat hypercalcemia. Fluoride compounds (e.g., anesthetic gas), chelating agents such as ethylenediaminetetraacetic acid (EDTA) and citrate (i.e., in stored blood), radiographic intravenous contrast agents, and the antiviral drug foscarnet may cause hypocalcemia.

Pancreatitis

When pancreatitis causes hypocalcemia, it is a poor prognostic sign. The classic mechanism involves the formation of calcium-free fatty acid soaps by lipases that are released from the inflamed pancreas. The free lipases then autodigest omental and retroperitoneal fat into negatively charged ions that tightly bind calcium in the ECF, causing hypocalcemia. The hypocalcemia is reversible by calcium infusion, and it self-terminates when the pancreatitis improves.

● HYPERPHOSPHATEMIA

Symptoms and Signs

Hyperphosphatemia produces no specific signs. It is usually identified incidentally on routine chemical screens or as a result of the induction of hypocalcemia.

Pathophysiology

Hyperphosphatemia develops as a result of two mechanisms. One is a large load of phosphate delivered into the ECF through the GI tract, intravenous medications, or endogenous sources such as muscle or tumor. The second mechanism is the inability to excrete phosphate, as occurs in acute or chronic renal failure. Essentially all natural foods contain phosphate, and therefore almost any diet contains substantial quantities of phosphate (see [Chapter 72](#)). Normally, phosphate is easily cleared by the healthy kidney, but this ability is lost as the GFR declines below 20 to 30 mg/dL.

Differential Diagnosis

The differential diagnoses of hyperphosphatemia are listed in the following sections and in [Table 73-3](#).

Artifactual Occurrence

Hyperphosphatemia may occur artifactually as a result of hemolysis in blood collection tubes. One clue is that the same phenomenon occurs with potassium. The occurrence of unexplained hyperkalemia and hyperphosphatemia should trigger the

TABLE 73-3 CAUSES OF HYPERPHOSPHATEMIA

Artificial Hemolysis	Endogenous phosphate loads
Increased gastrointestinal intake	Tumor lysis syndrome
Rectal enemas	Rhabdomyolysis (crush injury)
Oral Phospho-Soda purgatives	Hemolysis
Gastrointestinal bleeding	Reduced renal clearance
Intravenous phosphate loads	Chronic or acute renal failure
K-Phos	Hypoparathyroidism
Blood transfusions	Acromegaly
	Tumoral calcinosis

collection of a fresh sample and immediate repeat determination of the serum phosphate level.

Increased Gastrointestinal Intake

Hyperphosphatemia may occur in patients receiving large oral phosphate loads. In a literature review, most cases of phosphate-induced hypocalcemia were caused by the administration of phosphate-containing purgatives as preparation for colonoscopy. Another underappreciated cause of this phenomenon is inadvertent perforation of the rectum during the administration of a rectal Phospho-Soda enema, with delivery of large amounts of phosphate directly into the peritoneal cavity, from which it is rapidly absorbed. Upper GI tract bleeding from ulcers of gastritis provides a large GI phosphate load and may be associated with hyperphosphatemia.

Intravenous Phosphate Loads

Large amounts of phosphate may be administered during treatment to replete potassium using potassium phosphate preparations. What appear to be trivial quantities of potassium preparation (e.g., 20 to 40 mEq of K-Phos) actually contain large amounts of phosphate and may lead to severe hyperphosphatemia and hypocalcemia (see [Chapter 72](#)). A second vehicle for delivering phosphate intravenously is transfusions of red blood cells, which ultimately hemolyze and release their copious phosphate stores.

Endogenous Phosphate Loads

Hyperphosphatemia may result from the destruction of large amounts of tissue in three situations. One is the tumor lysis syndrome, typified by a large Burkitt lymphoma responding promptly to chemotherapy with massive cell death. A second phenomenon is acute rhabdomyolysis releasing phosphate from skeletal muscle, and a third is severe hemolysis. In each case, a large phosphate load is delivered into the ECF. Combined with renal impairment common in these situations, this results in renal failure, severe hypocalcemia, seizures, and sometimes death.

Reduced Renal Clearance

Renal clearance of phosphate is the main mechanism for maintaining phosphate homeostasis. Acute and chronic disorders of the kidney lead to hyperphosphatemia. Because PTH prevents phosphate reabsorption in the proximal nephron, hypoparathyroidism is typically associated with high-normal to frankly elevated serum phosphorus values. A condition called *tumoral calcinosis*, in which the ability of the kidney to clear

TABLE 73-4 CAUSES OF HYPOPHOSPHATEMIA

Inadequate phosphate (PO_4) intake	Oncogenic osteomalacia
Starvation	Fanconi's syndrome
Malabsorption	Alcoholism
PO_4 -binding antacid use	Excessive skeletal mineralization
Alcoholism	Hungry bone syndrome after parathyroidectomy
Renal PO_4 losses	Osteoblastic metastases
Primary, secondary, or tertiary hyperparathyroidism	Healing osteomalacia, rickets
Humoral hypercalcemia of malignancy (parathyroid hormone–related protein)	PO_4 shift into extracellular fluid
Diuretics, calcitonin	Recovery from metabolic acidosis
X-linked hypophosphatemic rickets	Respiratory alkalosis
Autosomal dominant hypophosphatemic rickets	Starvation refeeding, intravenous glucose

phosphate is specifically defective, leads to chronic hyperphosphatemia and accumulation of calcium-phosphate salts around large joints of the appendicular skeleton. Children, particularly adolescents, have higher serum phosphate concentrations than adults.

HYPOPHOSPHATEMIA

Symptoms and Signs

Phosphate participates in a vast array of key cellular processes, including DNA synthesis and replication, energy generation and use, oxygen uptake and delivery by erythrocytes, and maintenance of the redox state of every cell in the body (see [Chapter 72](#)). The signs of phosphate depletion are nonspecific, diffuse, and often life-threatening. These signs may include respirator dependence, congestive heart failure, coma, hypotension, and generalized weakness and malaise. Because the signs and symptoms are nonspecific, they are frequently attributed to other causes and are left untreated. They typically occur in intensive care units (ICUs). In these settings, oral nutrition is nonexistent, intravenous phosphate repletion is inadequate, and diuretics and saline infusions accelerate renal phosphate losses. Appropriate therapy can produce startling results, with patients suddenly returning from being moribund to being ambulatory, extubated, and conversant.

Chronic hypophosphatemia leads to defects in skeletal mineralization, a phenomenon called *rickets* in children or *osteomalacia* in adults. These syndromes produce weakness, bone pain, bowing of the long bones, and fractures or pseudofractures (see [Chapter 74](#)).

Differential Diagnosis

Disorders can be divided into hypophosphatemia resulting from inadequate intake, from excessive renal losses, from excessive skeletal uptake, or from shifts of phosphate from the ECF into cells ([Table 73-4](#)). From a diagnostic standpoint, measuring the TmP (see [Chapter 72](#)) is important because it provides rapid determination of which type of hypophosphatemia the patient is confronting.

Inadequate Phosphate Intake

Disorders that involve inadequate phosphate intake are associated with a high TmP. Because essentially all foods are rich in

phosphate, becoming phosphate depleted based on inadequate dietary intake is difficult. However, in settings of severe caloric deprivation, inadequacies can occur. Examples include anorexia nervosa, prisoner-of-war camps, prolonged ICU care, malabsorption syndromes, and chronic alcoholism. In the first three disorders, caloric intake is scant, and little phosphate is consumed. In alcoholism, caloric intake may be high, but alcohol is devoid of phosphate. The use of phosphate-binding antacids such as aluminum hydroxide gels may lead to severe phosphate deficiency, hypophosphatemia, and osteomalacia.

Excessive Renal Phosphate Losses

Disorders involving excessive losses are associated with a low TmP. PTH is phosphaturic, and all types of HPT are associated with hypophosphatemia as long as renal function is normal. This situation is widely appreciated for primary HPT but is less well appreciated for secondary HPT, particularly in the setting of vitamin D and calcium malabsorption. A low serum phosphate level may be the first and only noticeable clue to severe vitamin D deficiency. This fact has led to the diagnosis of celiac sprue in unsuspected cases on many occasions.

PTHrP (see [Malignancy-Associated Hypercalcemia](#)) is phosphaturic, as is PTH, and patients with humoral hypercalcemia of malignancy are commonly hypophosphatemic for this reason as long as their renal function is intact. Thiazide and loop diuretics are potent phosphaturic agents, and their use without phosphate replacement therapy leads to hypophosphatemia. Ethanol is also in this category.

Certain genetic disorders may lead to severe renal phosphate wasting (see [Chapter 74](#)). These disorders include X-linked hypophosphatemia (XLH), also called *vitamin D-resistant rickets*, and autosomal dominant hypophosphatemic rickets (ADHR). Another renal phosphate-wasting syndrome is oncogenic osteomalacia, also called *tumor-induced osteomalacia* (see [Chapter 74](#)). Acquired or inherited diffuse renal proximal tubular disorders, such as Fanconi's syndrome, may lead to hypophosphatemia as a result of renal phosphate wasting.

Excessive Skeletal Mineralization

Increased bone mineralization with respect to bone resorption results in large amounts of phosphate entering the skeleton, leading to hypophosphatemia. One example is the hungry bone syndrome that occurs after parathyroidectomy (see [Hypocalcemia](#)). Other examples are osteoblastic metastases and the treatment of vitamin D-deficient rickets or osteomalacia with vitamin D.

Phosphate Shift into Extracellular Fluid

Phosphate can be shifted from serum into the intracellular compartment by a rise in ECF pH. Recovery from a metabolic acidosis (e.g., diabetic ketoacidosis) and development of a respiratory alkalosis lead to hypophosphatemia. One of the most stunning examples of this phenomenon is the shift of phosphate into cells after administration of oral carbohydrate or parenteral glucose to victims of starvation or anorexia nervosa. Insulin increases the rate of glucose uptake into cells and its subsequent phosphorylation to glucose-6-phosphate. In the setting of significantly depleted phosphate reserve, rapid consumption of oral carbohydrate or parenteral glucose may lead to profound

hypophosphatemia and sudden death due to respiratory or circulatory failure. Refeeding of starvation victims should be accomplished slowly and with attention to phosphate repletion.

Treatment

Phosphorus replacement is best accomplished through the oral route and usually is given in two to four divided doses that deliver 2000 to 4000 g/day. Doses greater than 1000 to 2000 mg/day often cause diarrhea initially (phosphate is used as a purgative), but with gradual increments, larger doses may be well tolerated. Intravenous phosphate should be given only with a clear understanding of the quantities involved (see [Chapter 72](#)) and to patients for whom oral administration is not an option. Frequent monitoring of serum phosphorus, calcium, and creatinine levels is required. Intravenous dosages up to 500 to 800 mg/day may be required.

HYPERMAGNESEMIA

Symptoms and Signs

Clinically significant hypermagnesemia is uncommon. The symptom is drowsiness, and the signs are hyporeflexia and eventual neuromuscular, respiratory, and cardiovascular collapse. It may also lead to hypocalcemia (see [Hypocalcemia](#)). Hypermagnesemia is seen in two settings: severe renal failure accompanied by the administration of magnesium-containing antacids and after the intravenous administration of large doses of magnesium sulfate for eclampsia or preeclampsia.

Differential Diagnosis

The differential diagnosis of hypermagnesemia is brief and is limited to the two disorders previously described ([Table 73-5](#)). Mild hypermagnesemia is common in patients on dialysis, but severe hypermagnesemia occurs only in the settings of renal failure accompanied by parenteral or oral magnesium salt administration, such as the use of magnesium-containing antacids or phosphate binders. Hypermagnesemia occurs commonly but in a controlled fashion in the treatment of eclampsia.

HYPOMAGNESEMIA

Symptoms and Signs

Hypomagnesemia is common, particularly in the ICU setting, but as with hypophosphatemia, it is often overlooked or ignored. Magnesium is essential for a broad range of biologic processes,

TABLE 73-5 CAUSES OF HYPERMAGNESEMIA AND HYPOMAGNESEMIA

Hypermagnesemia	Diuretics
Renal failure accompanied by magnesium antacid use	Saline infusion
Parenteral magnesium sulfate administration for eclampsia	Secondary aldosteronism
Hypomagnesemia	Cirrhosis
Inadequate intake	Congestive heart failure
Starvation	Osmotic diuresis, hyperglycemia
Malabsorption	Cisplatin, aminoglycoside antibiotics, amphotericin
Alcoholism	Hypokalemia
Vomiting, nasogastric suction	Hypercalcemia, hypercalciuria
Excessive renal losses	Proximal tubular diseases
	Genetic defects

and hypomagnesemia may cause hypocalcemia, seizures, and paresthesias independent of hypocalcemia and cause a broad array of neuromuscular, cardiovascular, and respiratory symptoms.

Differential Diagnosis

Differential diagnoses are listed in the following sections and in [Table 73-5](#).

Inadequate Intake

Inadequate intake of magnesium is common among alcoholics and the generally undernourished. It may occur as part of an intestinal malabsorption syndrome and may result from continuous vomiting or nasogastric suctioning. These situations are common in ICU settings and are often overlooked.

Excessive Renal Losses

Excessive renal losses of magnesium are common in clinical practice. Thiazide and loop diuretics cause renal magnesium losses, and saline infusion has a similar effect. Magnesium is lost by the kidney in response to aldosterone in primary hyperaldosteronism but more commonly in the secondary hyperaldosteronism associated with cirrhosis, volume depletion, congestive heart failure, and other common disorders. Osmotic diuresis, as occurs with poorly controlled diabetes mellitus, causes renal magnesium loss. Certain nephrotoxic drugs such as cisplatin, aminoglycoside antibiotics, and amphotericin induce proximal tubular injury and a severe form of renal magnesium wasting. Hypokalemia, hypercalcemia, and hypercalciuria also lead to renal magnesium excretion. Many diseases that lead to proximal tubular injury, such as

Fanconi's syndrome and interstitial nephritis, may lead to magnesium wasting.

Treatment

Magnesium can be replaced intramuscularly or intravenously. Usually, 24 to 48 mEq per 24 hours as magnesium sulfate is provided (see [Chapter 72](#)). Oral magnesium salts such as magnesium oxide are also available, but administering large doses of magnesium orally is difficult because of the cathartic effects of magnesium.

Metabolic Bone Diseases

Mara J. Horwitz and Andrew F. Stewart

INTRODUCTION

Metabolic bone disease is a general term used to describe a host of diffuse skeletal disorders. Many are associated with low bone mass, and some are not metabolic but have genetic, infectious, or other causes. However, metabolic bone disease remains a useful umbrella term. In its broadest sense, it includes common diseases such as osteoporosis (see [Chapter 75](#)), rare osteosclerotic disorders such as fluoride intoxication, genetic disorders, and focal skeletal diseases such as polyostotic fibrous dysplasia.

In this chapter, the focus is on the more common members of this family ([Table 74-1](#)) that may be encountered by an internist. Many additional rare metabolic bone diseases exist and, depending on the context, should be sought. Normal skeletal homeostasis and histopathology are reviewed in [Chapter 72](#) and [Figure 74-1](#).

Osteoclast and osteoblast activity and osteoid mineralization can be assessed by undecalcified bone biopsy of the anterior iliac crest, which is the standard for assessing bone histology. Undecalcified sections are essential because the acid-mediated decalcification performed on routine pathology specimens removes calcium and therefore cannot distinguish between mineralized mature bone and unmineralized osteoid that may be normal or pathologic. The examples shown in [Figure 74-1](#) employ histologic sections of undecalcified bone and highlight osteoclasts, osteoblasts, and osteoid. Because tetracycline is fluorescent and incorporated into the hydroxyapatite crystals as osteoid mineralizes, administering tetracycline to patients before a bone biopsy

allows assessment of the rates and efficacy of skeletal mineralization (see [Fig. 74-1B](#) and [F](#)).

DIFFERENTIAL DIAGNOSIS

Paget's Disease of Bone

Paget's disease, also called *otitis deformans*, is the second most common bone disease after osteoporosis. It affects approximately 2% of the population older than 45 years of age in the United States, but the incidence varies geographically. It is most common in those of European descent and rare in those of African or Asian descent.

In contrast to most metabolic bone diseases, which are diffuse and involve the entire skeleton, Paget's disease is a focal bone disorder. It can be *monostotic* (involving a single bone) or *polyostotic* (involving multiple bones). Paget's disease may affect any skeletal site, but it most commonly involves the pelvis, vertebrae, skull, tibia, and femur. Although Paget's disease is a chronic condition and original lesions may expand, new lesions rarely develop.

The primary cellular abnormality of Paget's disease is increased osteoclastic bone resorption, which is followed by exuberant formation of new bone that is of poor quality (see [Fig. 74-1C](#)). This marked increase in osteoblast activity accounts for the typical sclerotic lesions seen on radiographic examination ([Fig. 74-2A-C](#)), for the increased uptake of radionuclide seen on a bone scan (see [Fig. 74-2D](#)), and for increases in serum levels of alkaline phosphatase, which is the biochemical hallmark of Paget's disease.

Most patients with Paget's disease are asymptomatic, and the disorder is most often detected unexpectedly by an increased serum alkaline phosphatase level on routine testing or on a routine radiograph obtained for other reasons. At clinical presentation, patients may have bone pain, skeletal deformities, fractures, related complications such as osteoarthritis, and nerve compression syndromes (e.g., deafness, spinal stenosis). Rare complications include hypercalcemia in immobilized patients and high-output cardiac failure. Because pagetic lesions tend to be highly vascular, the skin over affected bones may be warmer than in other areas. The most dreaded complication of Paget's disease is the rare (<1%) development of osteosarcoma in a pagetic lesion.

The cause of Paget's disease is unknown but may include a viral origin and a genetic predisposition. Paget's disease is most often diagnosed using a combination of biochemical markers for bone turnover and radiologic studies. For most

TABLE 74-1 CONDITIONS, DISEASES, AND MEDICATIONS THAT CAUSE OR CONTRIBUTE TO METABOLIC BONE DISEASE

Osteoporosis (see Chapter 75)	Osteoporosis-pseudoglioma syndrome
Paget disease of bone	X-linked osteoporosis
Hyperparathyroid bone disease (i.e., osteitis fibrosa cystica)	Miscellaneous factors
Osteomalacia and rickets	Infiltrative diseases
Hypophosphatemic syndromes	Multiple myeloma
Vitamin D syndromes	Lymphoma, leukemia
Anticonvulsants	Sarcoid
Aluminum	Malignant histiocytosis
Metabolic acidosis	Mastocytosis
Renal osteodystrophy	Gaucher' disease
Genetic diseases	Hemolytic diseases (e.g., thalassemia, sickle cell anemia)
Osteogenesis imperfecta	Transplantation osteodystrophy
Hypophosphatasia	

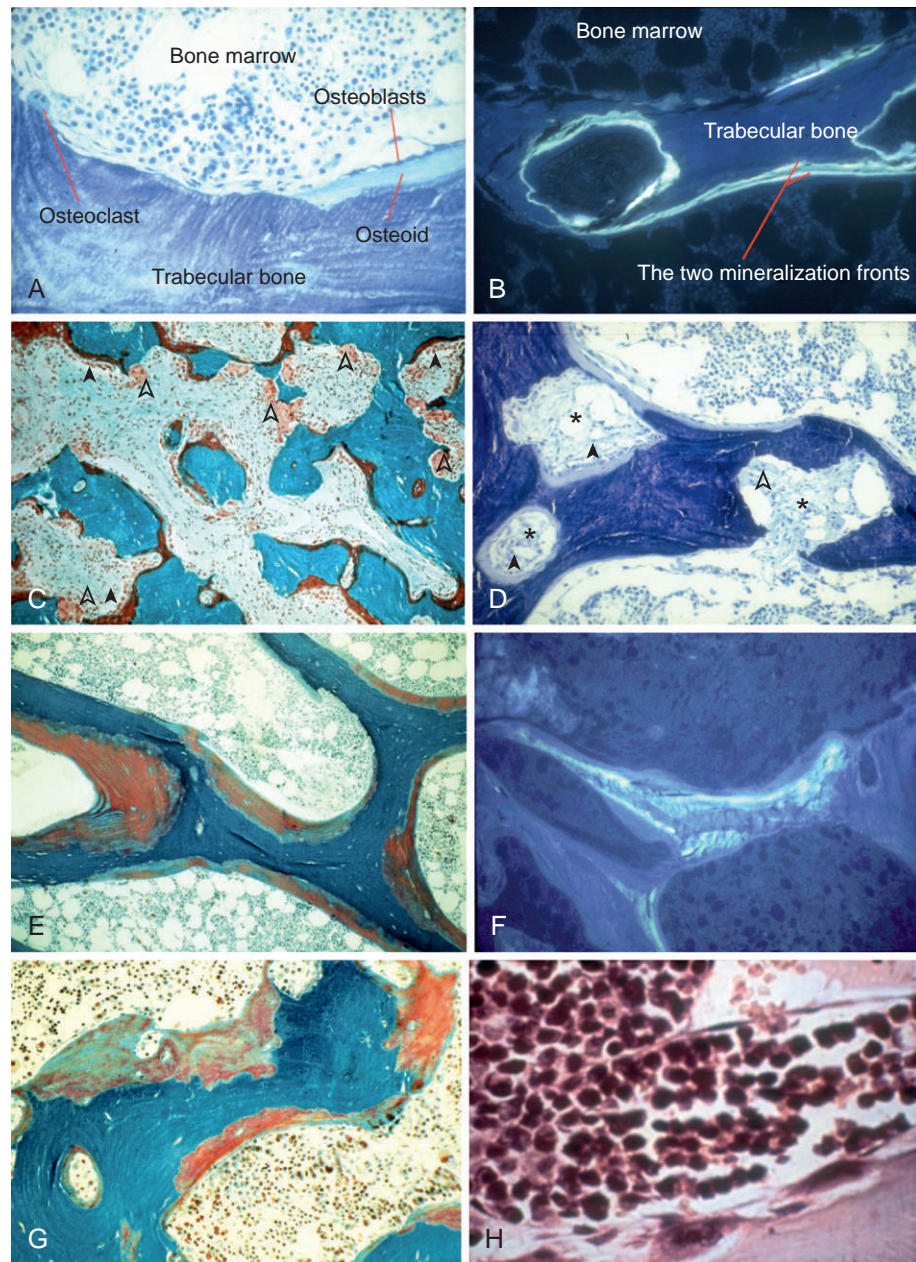

FIGURE 74-1 **A**, Normal bone histology, showing a normal bone-remodeling unit as seen in an undecalcified human anterior iliac crest biopsy. On the left, a multinucleated osteoclast has moved across the mineralized trabecular bone surface over the previous week or two, resorbing (removing) old bone. On the extreme right, the bone surface is covered by osteoid secreted by the overlying osteoblasts. In between the osteoclast- and osteoblast-covered surfaces of the trabecular bone are a large number of flat, fibroblastoid cells referred to as *lining cells*. No osteocytes are visible in this section. **B**, Tetracycline labeling of a bone biopsy from a patient with hyperparathyroid bone disease. Notice the bright yellow parallel lines on the trabecular bone surface. These lines represent the two sets of tetracycline labeling, which occurred 14 days apart. From these sets, the mineralization rate can be described in micrometers (microns) per day, the so-called *mineral apposition rate*, and it is increased dramatically in this example, as is typical of hyperparathyroid bone disease. Contrast with example **F**, which has no tetracycline labeling. **C**, Paget's disease. Enormous and abundant highly multinucleated osteoclasts (*open arrowheads*) are resorbing trabecular bone, and a comparably enormous number of osteoblasts (*closed arrowheads*) are making new but disorganized bone. The marrow space is replaced by fibrous cells. **D**, Primary hyperparathyroidism has the classic features of osteitis fibrosa cystica. Far more osteoid and osteoblasts (*closed arrowheads*) and osteoclasts (*open arrowhead*) exist than in the normal example (**A**). Three large microcysts (*asterisks*) have been created by aggressive osteoclastic bone resorption. These microcysts account for the *cystica* component of osteitis fibrosa cystica. The marrow space, particularly within the microcysts, is filled with fibroblasts, which make up the *fibrosa* component of osteitis fibrosa cystica. **E**, Osteomalacia or rickets. Notice the abundant quantities of partially and chaotically mineralized osteoid (*orange*). These seams are the thick osteoid seams and represent osteoid that has been produced by osteoblasts but that cannot mineralize, which is the signature defect in osteomalacia and rickets. **F**, Tetracycline labeling reveals a complete absence of mineralization, diagnostic of osteomalacia or rickets. Compare with example **B**. **G**, Renal osteodystrophy. This photomicrograph of a biopsy from a patient on dialysis demonstrates many of the classic features of renal osteodystrophy, including evidence of aggressive osteoclastic bone resorption (i.e., numerous osteoclastic lacunae on the bone surface compared with the smooth surfaces in example **A**) and abundant, partially and chaotically mineralized areas of osteoid (*orange*). **H**, Infiltrative bone disease as exemplified by multiple myeloma. The bone marrow is replaced by plasma cells, and two large osteoclasts in lacunae are actively resorbing the trabecular bone surface.

FIGURE 74-2 Typical radiologic abnormalities Paget's disease. **A**, Compare the normal skull (*top*) with the skull (*bottom*) with the classic cotton-wool appearance, an enormously expanded calvarium, and osteosclerosis of the petrous bones. **B**, Classic asymmetrical involvement of the pelvis with a mixture of lytic and blastic lesions. **C**, Bowing deformity of the femur with a markedly thickened cortex. **D**, A whole body radionuclide scan demonstrates polyostotic Paget's disease.

patients, elevated concentrations of total serum alkaline phosphatase is an adequate and sensitive indicator of disease activity. However, the serum level of bone-specific alkaline phosphatase may be a more sensitive marker than serum total alkaline phosphatase for assessing disease in patients with low levels of disease activity. A bone scan at the time of diagnosis can define the location and extent of lesions (see Fig. 74-2D). Radiographs of the affected areas confirm Paget's disease, and they are useful for evaluating complications and local disease progression (Fig. 74-2A-C).

The two major goals of therapy are to relieve symptoms and prevent complications. Indications for treatment include alleviating symptoms (e.g., bone pain, headache, neurologic complications), decreasing blood flow preoperatively to minimize bleeding during elective surgery on a pagetic site, managing hypercalcemia in an immobilized patient with severe Paget's disease, and preventing future complications of progressive local

disease, such as bowing deformities of the long bones, hearing loss as a result of temporal bone involvement, and neurologic complications resulting from foramen magnum or vertebral involvement. Treatment of Paget's disease usually involves a combination of nonpharmacologic therapy (i.e., physical therapy) and pharmacologic therapy, including antiresorptive agents and analgesics for pain management.

The mainstay of therapy is bisphosphonates, including potent aminobisphosphonates such as zoledronate, which decrease bone resorption at pagetic sites by inhibiting osteoclasts. Calcium and vitamin D supplementation is recommended for patients taking the more potent bisphosphonates to prevent hypocalcemia or secondary hyperparathyroidism.

Orthopedic surgery may be indicated when a complete fracture occurs through pagetic bone. Surgery also is indicated for realignment of a severely arthritic knee and for total joint arthroplasty in a severely affected hip or knee.

Hyperparathyroid Bone Disease

Hyperparathyroid bone disease, also called *osteitis fibrosa cystica* (OFC), results from chronically elevated concentrations of parathyroid hormone (PTH). Elevated PTH concentrations may result from primary hyperparathyroidism, in which elevated PTH levels most often result from a parathyroid adenoma or rarely from hyperplasia or carcinoma.

Secondary hyperparathyroidism is an appropriate increase in PTH levels caused by malabsorption, vitamin D deficiency, or chronic renal failure. Calcium levels are normal or subnormal.

Tertiary hyperparathyroidism refers to elevated PTH resulting from long-standing stimulation of the parathyroid glands along with hypercalcemia, as in the setting of renal failure (see [Chapter 73](#)). Chronic stimulation results in hyperplasia or adenomas.

Primary and tertiary forms of hyperparathyroidism are characterized by hypercalcemia. Patients with secondary hyperparathyroidism are eucalcemic or hypocalcemic and have elevated PTH levels.

The skeletal disease in hyperparathyroidism is typified by *high turnover*, which is characterized by coupled increases in osteoclastic bone resorption and osteoblastic synthesis of osteoid, accelerated rates of bone mineralization accompanied by microcysts in the cortex and trabeculae (the *cystica* of OFC), and increased numbers of fibroblasts and marrow stroma (the *fibrosa* of OFC) (see [Fig. 74-1B and D](#)). Levels of both serum markers of bone formation (i.e., alkaline phosphatase and osteocalcin) and markers of bone resorption (i.e., N-terminal and C-terminal telopeptides) are usually increased, reflecting the

bone histology. Patients may complain of bone pain or diffuse aches and pains.

Bone density, assessed by dual-energy x-ray absorptiometry (DEXA), may be normal or low. The pathognomonic radiologic signs of severe hyperparathyroid bone disease are a salt-and-pepper appearance of the calvarium, resorption of the tufts of the terminal phalanges and distal clavicles, subperiosteal resorption of the radial aspect of the cortex of the second phalanges ([Fig 74-3](#)), and Brown tumors (i.e., collections of osteoclasts that produce gross lytic lesions) of the pelvis and long bones. These radiologic signs disappear with parathyroidectomy, and bone mass, as assessed by DEXA, typically increases rapidly and markedly after parathyroidectomy.

The treatment of hyperparathyroid bone disease involves remediation of the chronically elevated PTH concentrations by parathyroidectomy in primary or tertiary hyperparathyroidism or correction of the underlying cause of secondary hyperparathyroidism (see [Chapter 73](#)). If the hypercalcemia is mild and the bone mass is normal, no treatment may be required.

Serum calcium levels can be reduced by using a parathyroid calcium receptor mimetic. Cinacalcet is indicated for patients with chronic renal failure with secondary hyperparathyroidism, patients with parathyroid carcinoma who have failed surgical resection, and patients with severe primary hyperparathyroidism.

Moderate to severe hypocalcemia may be seen after parathyroidectomy. This condition is referred to as the *hungry bone syndrome* (see [Chapter 73](#)). Hyperparathyroid bone disease may be *pure*, occurring in patients with severe primary

FIGURE 74-3 Skeletal radiographic changes of hyperparathyroidism. **A**, A hand film from a patient with primary hyperparathyroidism. The *arrow* indicates a typical giant cell tumor (brown tumor), which is a collection of osteoclasts that lead to macrocystic changes in bone. The *arrowhead* indicates the irregular radial surface of a phalanx resulting from subperiosteal bone resorption, which is typical of hyperparathyroidism. The brown tumor and the subperiosteal resorption refill and disappear when the offending parathyroid tumor or hyperplasia is resected. **B**, Radiograph of a normal hand for comparison. No brown tumors are seen, and the phalangeal periosteal surfaces are smooth. **C**, The classic salt-and-pepper appearance of the skull in hyperparathyroidism. The periosteal surfaces of the inner and outer cortices or tables of the calvarium are indistinct as a result of subperiosteal bone resorption. The lateral view of the calvarium is hazy and indistinct, showing micropunctations. (Courtesy J. Towers, MD, and D. Armfield, MD, University of Pittsburgh, Pittsburgh, Penn.)

hyperparathyroidism caused by a parathyroid adenoma, or it may be *mixed*, occurring in patients with vitamin D–deficient osteomalacia, immunosuppressant-induced transplant bone disease, or renal osteodystrophy.

Osteomalacia and Rickets

Although common in the United States and throughout the world, osteomalacia and rickets are often overlooked. Osteomalacia and rickets are essentially the same disorders, but by definition, rickets occurs in children with open growth plates (i.e., epiphyses), and osteomalacia occurs in adults with closed epiphyses.

The fundamental abnormality in these disorders is an inability to mineralize (i.e., form hydroxylapatite crystals) osteoid seams (see Fig. 74-1). These patients have osteoblasts and can synthesize osteoid, but it is mineralized inefficiently or not at all. This fundamental inability to mineralize osteoid results in accumulation of the characteristic thick osteoid seams seen on bone biopsy (see Fig. 74-1E and F) and a reduction in the mineral content of bone so that it is mechanically deficient. These events lead to bone pain, pseudofractures, fractures, bowing of the long bones, and other skeletal deformities (Fig. 74-4). In children with rickets, the inability to mineralize the growth plate leads to bulbous, knobby deformities of the knees, ankles, and costochondral junctions (i.e., rachitic rosary) and to dental abnormalities. The characteristic radiologic signs of osteomalacia are Looser's zones or Milkman's pseudofractures.

Mineralization disorders result from an inability to form hydroxyapatite (calcium phosphate) crystals in osteoid, the non-mineralized phase of bone. This inability may result from hypophosphatemia (common), calcium deficiency (rare), or vitamin D deficiency (common). Toxins that interfere with mineralization include aluminum, incompletely defined inhibitors of mineralization in uremic plasma, and long-term, high-dose anticonvulsants. Because calcium salts are acid soluble, chronic metabolic acidoses can result in osteomalacia or rickets. Disordered mineralization can be caused by vitamin D deficiency (e.g., malabsorption, liver disease), hypophosphatemic disorders (e.g., X-linked hypophosphatemic rickets, autosomal dominant hypophosphatemia, oncogenic osteomalacia), metabolic acidoses, drug-related disorders, and genetic conditions (e.g., vitamin D–dependent rickets types I and II, hypophosphatasia) (see Chapter 73).

The diagnosis is suggested in the setting of low bone mass, the characteristic radiologic signs described previously, hypocalcemia, elevated PTH and alkaline phosphatase levels, and unexplained bone pain or weakness. However, these are late signs, and the disorder is optimally identified and treated early. The diagnosis is supported by demonstrating reductions of plasma 25-hydroxyvitamin D or its active form, 1,25-dihydroxyvitamin D₃ (1,25[OH]₂D₃); hypophosphatemia; or increased alkaline phosphatase levels in an appropriate clinical setting. Hypocalciuria is typical of vitamin D deficiency. Inappropriate phosphaturia with a low tubular maximum for

FIGURE 74-4 **A**, A typical example of rickets, with bowing of the femurs and tibias. **B**, A skeletal radiograph of a child with rickets. The weight-bearing bones of the lower extremities are bowed, and the epiphyses are open, mottled, and overgrown. **C**, Looser's zones or pseudofractures (arrows) are characteristic of osteomalacia or rickets. The closed epiphyses indicate the patient is an adult. This radiograph is diagnostic of osteomalacia.

phosphorus or glomerular filtration rate (see Chapter 72) typifies renal phosphate wasting disorders. The diagnosis can often be made clinically but can also be confirmed using undecalcified bone biopsy after applying oral double tetracycline labeling techniques, which are used to quantitate the degree of failure of mineralization (Fig 74-1E and F).

Treatment depends on the underlying cause and may include vitamin D formulations, calcium and phosphate supplementation, and removal of the inhibitor of mineralization when possible. These diseases are gratifying to treat because the responses are often dramatic, and patients change rapidly from being chronically ill to feeling robust and healthy.

Renal Osteodystrophy

Renal osteodystrophy is a collection of moderate to severe disorders that produce bone pain, pathologic fractures, and demineralization in the setting of end-stage renal disease or dialysis. Subclinical renal osteodystrophy is common and occurs early as a result of increased levels of phosphorous and fibroblast growth factor 23 (FGF23), which cause defects in skeletal mineralization.
